# Welcome

## Welcome to Seville

Dear Friends,

We are honoured to invite you to celebrate the 27th Annual Congress of the European College of Sport Science (ECSS) with us, and in doing so, we offer you a special gift: Sevilla! A melting pot of more than 3,000 years' history, a city full of art, culture, cuisine, leisure and sports. The city looks forward to welcoming sport scientists from all parts of the world, with open arms, to enjoy this unique ECSS congress.

"Sport Science in the Heart of Arts" is the theme for the 2022 ECSS congress in Sevilla. Make the most of your time before or after the congress and admire the Guadalquivir River, various art forms, diverse cultures, the numerous historic quarters and above all, our people. We suggest that you make your travel arrangements to allow for time to explore this wonderful city and this region of Spain known as Andalucía. With affordable accommodation, summer weather and countless activities and sites to visit, you will have a memorable time.

Added to this, the Sevilla Convention Bureau has kindly offered gift vouchers to all congress delegates that include free give-aways, including public transportation tickets, and discounts at restaurants, museums, flamenco shows, recreational parks, cafés, pubs and various shops. We have also engaged with a local tour operator and asked them to provide discounted trips before and after the congress.

The ECSS congress brings about a new congress model, which will see an enhanced programme built with even higher scientific standards and quality measures, which will all take place in the world-class congress venue, FIBES. We have selected an outstanding, international panel of experts, bringing their specialised knowledge to the plenary, and invited sessions. Prior to the congress, there will be a satellite dedicated to football, where the most reputable researchers in the industry will present their topics and experiences.

We are also working hard on inclusion at the congress and for the first time we will have sessions available with interpretation services which will serve our Latin American colleagues. This will be a unique cooperation that aims to brings new partnerships and friends to the ECSS community. Other unique initiatives for the congress includes a congress mascot which you have the opportunity to design and win some fabulous prizes. We also have planned additional activities that will bring the research community closer to the business community. More information on these in due course.

We cordially invite the sport science community to make a wish and come to ECSS Sevilla 2022!

Nos vemos en Sevilla! / See you in Seville!

Your Congress Co-Presidents,

*África Calvo Lluch, General Director of Sports*
*Eduardo Saez de Villareal Saez, Vice Dean*

### Plenary sessions

#### PL-PS01 Exercise and brain health during growth and aging

**EFFECTS OF EXERCISE ON BRAIN HEALTH IN CHILDREN**

ORTEGA, F.

*UNIVERSITY OF GRANADA*

Pediatric obesity is highly prevalent across the world; and it is related to poorer cognitive and brain development. Exercise is a potential candidate to attenuate these adverse consequences. During this lecture, Dr. Ortega will show results from the ActiveBrains randomized controlled trial. This study aimed to investigate the effects of an exercise program on brain health indicators, including intelligence, executive functions, academic performance and brain outcomes in over 100 children aged 8-11 years with overweight/obesity; as well as to explore potential mediators and moderators of the main exercise effects observed. The main findings show that a 20-week concurrent exercise program (aerobic + resistance training) improves overall and crystallized intelligence, and cognitive flexibility in children with overweight/obesity. Exercise also improves, to a lesser extent, academic performance, which was partially mediated by cognitive flexibility. However, exercise did not influence brain structure (i.e. volume and shapes of hippocampal subregions, global and regional gray and white matter volume, thickness and area of prefrontal cortex subregions, and structural networks) and function (i.e., hippocampal functional connectivity). This intervention increased the performance in a treadmill cardiorespiratory fitness test; and these changes in fitness partially mediated the effects on crystallized intelligence, total academic performance and problem solving. The main results were stratified by sex, chronological and biological age, socioeconomic status and baseline performance, highlighting the larger improvements in intelligence outcomes observed in boys compared to girls. Collectively, exercise can positively affect intelligence and cognitive flexibility, which has important implications. This talk will guide future directions on the field of exercise, brain health and childhood obesity.

**EFFECTS OF EXERCISE ON BRAIN HEALTH DURING AGING**

ERICKSON, K.

*UNIVERSITY OF PITTSBURGH*

Despite the ubiquity of normal age-related cognitive decline there is an absence of effective approaches for improving neurocognitive health. Fortunately, moderate intensity exercise is a promising method for improving brain and cognitive health in late life, but its effectiveness remains a matter of skepticism and debate because of the absence of large and comprehensive clinical trials. In this talk, Dr. Erickson will describe the implementation of the IGNITE randomized clinical trial. This study aimed to examine whether aerobic exercise influences cognitive and brain health in 639 cognitively normal adults between 65 and 80 years of age. Participants are engaging in 3 days/week of supervised exercise and two more days per week of unsupervised exercise for 12 months. All participants have been already randomized to (i) a moderate intensity aerobic exercise condition of 150 min/week, (ii) a moderate intensity aerobic exercise condition at 225 min/week, or (iii) a light intensity stretching-and-toning control condition for 150 min/week. IGNITE is currently ongoing, all baseline assessments are completed, and follow-up assessments are expected to be completed by 2023. Outcome measures includes brain magnetic resonance imaging, positron emission tomography of amyloid deposition, a comprehensive cognitive battery, blood biomarkers, physiological biomarkers, cardiorespiratory fitness, physical function, and a battery of psychosocial questionnaires. While promising findings on the effects of the exercise intervention will come up soon, data on the financial cost associated with a phase III, multi-site exercise intervention trial as well as some baseline findings on the associations between fitness, cognition and brain structure will be presented. Finally, Dr. Erickson will highlight how this trial could transform scientific-based policy and health care recommendations for approaches to improve cognitive function in cognitively normal older adults.

## 10:00 - 11:15

### Invited symposia

#### IS-PN01 Skeletal muscle disuse atrophy: time to 'complicate' uncomplicated disuse?

**UNCOMPLICATED SKELETAL MUSCLE DISUSE ATROPHY: HUMAN IN VIVO INVESTIGATION AND MECHANISTIC BASIS**

DIRKS, M.

*UNIVERSITY OF EXETER*

Skeletal muscle disuse refers to a state of inactivity of one or more muscle groups. This is common during injury, illness or as a characteristic of more sedentary lifestyles. While disuse remains a major contributor to atrophy, its requirement for clinical reasons tends to be accompanied by a multitude of complicating and relevant factors that also influence muscle tissue (e.g. inflammation, cortisolaemia, malnutrition etc.). However, laboratory studies have generally focused on the withdrawal of contractile loading per se in healthy humans, as

controlled means to isolated a single variable; disuse. Such studies have typically utilized bed-rest and/or limb immobilization studies to thoroughly characterize the speed, locality and extent of muscle atrophy, the level of impairment of muscle function and the onset of whole body and local insulin resistance. Moreover, the physiological mechanisms underpinning these aspects of deconditioning have been well-described. This presentation will cover this background, discuss more novel approaches to study disuse (e.g. the arteriovenous-venous forearm balance model) and lay the groundwork for why 'complicating' uncomplicated disuse may be necessary for translation from lab to practice.

**COMPLICATING MUSCLE DISUSE: APPROACHES TO LOOK BEYOND ONLY DISUSE**

WALL, B.

*UNIVERSITY OF EXETER*

Studies isolating muscle disuse (i.e. 'uncomplicated muscle disuse') as a primary variable driving muscle atrophy have yielded important insights into the responsible physiological mechanisms. For instance, a reliable finding is that myofibrillar protein synthesis rates decline rapidly consequent with the onset of disuse, and this decline extends to the response to food intake ('anabolic resistance') and translates to considerably less synthesis of muscle protein over days and weeks explaining the large part of observed atrophy. However, clinical manifestations of muscle disuse typically result in several complicating factors; for example during injury the occurrence of muscle damage (and associated inflammation) or the reduction of energy expenditure and therefore implications for dietary intake. All such aspects also directly affect myofibrillar protein synthesis rates and/or other relevant metabolic processes, and therefore need to be accounted for if we are to properly understand how muscle disuse atrophy may best be understood, and managed, in a variety of clinical situations. This presentation will discuss recent work that has employed strategies to introduce some of these additional variables beyond disuse only, to examine how this can modulate the regulation of muscle mass during disuse.

**NUTRITIONAL REQUIREMENTS AND COUNTERMEASURES DURING MUSCLE DISUSE**

MCGLORY, C.

*QUEENS UNIVERSITY*

Over their lifespan, many individuals experience multiple episodes of skeletal muscle-disuse that arise from illness, injury, or elective surgery requiring bedrest. These periods of muscle-disuse initiate the loss of muscle mass and strength that are associated with several associated negative health effects such as the onset of insulin resistance, a reduction in basal metabolic rate, and the accrual of body fat. In the absence of safe and scalable pharmacological countermeasures, nutrition is considered a primary means by which to combat the negative impact of muscle-disuse. In this regard, there is growing evidence that prophylactic ingestion of amino acids and omega-3 fatty acids may act in concert to attenuate declines in skeletal muscle mass with disuse. However, there is little evidence that such interventions are effective in attenuating declines in muscle strength. Moreover, how amino acid and omega-3 fatty acid ingestion impacts the progression of other clinically relevant processes during muscle-disuse remains largely unknown. The aim of this presentation is to review and critically evaluate the existing literature related to the role of nutrition as a countermeasure to muscle-disuse atrophy with a specific focus on the role of amino acids and omega-3 fatty acids.

## Invited symposia

### IS-BM01 The functional integrity of muscle and connective tissue for locomotor performance

**THE INTERACTION OF ACTIVE AND PASSIVE TISSUE CONTRIBUTIONS TO HUMAN FOOT MECHANICS**

FARRIS, D.

*UNIVERSITY OF EXETER*

Tendons, aponeuroses, and ligaments of the human foot and ankle have long been known to possess spring-like properties that help us recycle bodily energy during walking and running. This provides a metabolically inexpensive contribution to maintaining walking and running mechanics. However, these passive tissues alone cannot support human locomotion, particularly in situations where the external environment and situational demands are constantly changing. In prior work, my colleagues and I have shown that activations of the muscles within the foot (intrinsic foot muscles) are modulated in response to varied mechanical requirements during locomotion [1], and that blocking their activation affects foot and lower limb mechanics [2]. In particular, we have shown that the important push-off phase of walking and running is influenced by intrinsic foot muscles, as is the 'windlass mechanism' that was previously considered to be reliant solely on the plantar aponeurosis [3]. I will begin this presentation by summarising the above work and concluding that contributions from plantar intrinsic foot muscles are important for modulating the mechanics of the human foot in response to external influences.
A highlight of the above work was that running shoes were shown to increase intrinsic foot muscle activation. We proposed that this was due to their midsole functioning as a spring in-series with the foot, and the muscles acting to stiffen the longitudinal arch of the foot. To test this hypothesis we recently conducted a series of experiments where humans hopped on platforms with adjustable stiffness and damping properties. Multi-segment foot mechanics were modelled based on motion capture data, and combined with ground reaction forces to compute joint moments and quasi-stiffness. Fine-wire electromyography techniques were also implemented to record muscle activations from flexor digitorum brevis and abductor hallucis. In response to increased surface compliance, human hoppers adjusted foot and ankle mechanics to maximise the work recycled from the spring-loaded surface, and reduce the active work contribution from foot muscles. Furthermore, the longitudinal arch of the foot was not stiffened in response more compliant surfaces, contradicting our hypothesis from the running-shoe experiment. However, traditional running shoe midsoles are not simply springs, and also dampen impacts. When our platform was set to provide damping of energy, foot muscle activation increased concurrently with foot contributions to mechanical work. Therefore, we suggest that it is the damping of energy by traditional running shoes that results in increased foot muscle activation when wearing them. New generations of highly resilient-elastic running shoes may benefit the wearer by reducing active muscular work within the foot.

**LATCH-BASED MUSCLE-TENDON INTERACTIONS ENABLE RECOVERY FROM RAPID, UNEXPECTED PERTURBATIONS**

DICK, T.

*FACULTY OF MEDICINE*

The ability for humans to stay upright in the face of uneven terrain or unpredictable changes in their environment is remarkable, yet we understand little about the mechanisms that enable this. Much of our knowledge regarding movement performance has come from studies conducted under steady-state conditions. During steady movement, the lower limb muscle-tendons store and return energy, and this elastic behaviour is further exploited during activities where humans must rapidly generate energy (e.g., jumping). To date, we know very little about how humans adjust lower-limb joint biomechanics and muscle-tendon function during movements whereby energy must be rapidly dissipated. The aim of this research is to provide fundamental insights into the mechanisms for movement stability during unexpected perturbations.
To study this, we have developed a perturbation paradigm whereby participants perform steady- state hopping at their preferred frequency. An unexpected perturbation, via manual removal of two custom-built platforms (5, 10, or 20 cm height) from directly under the lower limbs, was elicited at a random time between the 10th and 20th hop. During each trial, motion capture (Vicon, UK) was used to measure the 3D positions of the lower limbs. Ground reaction forces were measured during hopping using a static instrumented split belt treadmill (Bertec, USA). MTU lengths and joint moments were computed using a scaled musculoskeletal model, motion capture and force plate data. Surface electromyography was used to record muscle activations in the medial (MG), lateral gastrocnemius (LG), soleus (SOL), and tibialis anterior (Biometrics, UK). MG and SOL fascicle lengths were determined from B-mode ultrasound images (Telemed, Lithuania).
Our results highlight that humans successfully recover from perturbations via an increase in energy absorption in distal lower-limb joints (i.e. the ankle) at small perturbation heights (5-10cm). However, with increased perturbation height (20cm) humans increase their reliance on the proximal lower-limb joints (i.e. the knee and hip) to absorb mechanical energy and stabilize fall recovery. Our investigations into the muscle–tendon interactions that underpin these joint-level responses shows that an unexpected drop in ground height introduces an automatic phase shift in the timing of plantar flexor muscle activity relative to ground contact and an increase in co-activation of the plantar and dorsi-flexor muscles. Together, this enables a latch-based behaviour whereby the plantar flexor fascicles shorten and stretch the series elastic tendon prior to ground contact. This improves the capacity of the plantar flexors to rapidly absorb energy upon ground contact and may also aid in avoiding potentially damaging strains. These data provide insights to guide design of targeted training programs or lower-limb assistive devices that are capable of improving human locomotor performance during energy-dissipation tasks.

**MUSCLE-SPECIFIC ECONOMY OF FORCE GENERATION AND EFFICIENCY OF WORK PRODUCTION DURING HUMAN RUNNING**

BOHM, S.

*HUMBOLDT-UNIVERSITÄT ZU BERLIN*

During locomotion, muscles generate force and perform work in order to support and accelerate the body and the activity of the lower limb muscles accounts for most of the metabolic energy needed. Running is characterized by a spring-like interaction of the body with the ground, where the bodies energy is stored mainly to elastic tendons as strain energy and recovered during the propulsion phase. In addition, the compliance of tendons together with rotation of muscle fibers (changes of pennation angle) decouples the fiber excursions from the muscle-tendon unit, influencing the muscle operating force-length and force-velocity potential (fraction of maximum force according to the force-length and force-velocity curve). For a given muscle force, the metabolic cost depends on the force-length-velocity potential because it determines the active muscle volume. We showed, that during running the vastus lateralis as the main knee extensor contracts almost isometrically and close to optimal length during the stance phase despite a lengthening-shortening of the muscle-tendon unit [1,2]. This indicates favorable muscle operating conditions due to substantial decoupling by tendon compliance that allows to generate force economically. For the soleus muscle as the main plantar flexor during running, our experiments showed, however, that the muscle fascicles actively shorten throughout the stance phase, i.e. generating work for propulsion [3]. The metabolic cost of muscular work then additionally depends on the velocity of shortening. The enthalpy efficiency (or mechanical efficiency) quantifies the fraction of chemical energy that is converted into muscular work, showing a peak at ~20% of the maximum shortening velocity. We found that the soleus shortens at a velocity in a range of high enthalpy efficiency and around optimal length during stance, providing evidence of efficient work generation during running [2]. Effective decoupling by tendon compliance and marginally fascicle rotation regulated the advantageous operating conditions. We then investigated the soleus enthalpy efficiency as a mechanism that could contribute to improvements in running economy after exercise-induced increases of plantar flexor strength and Achilles tendon stiffness [4]. Using a controlled longitudinal study design featuring a specific muscle-tendon training, increases in muscle strength and tendon stiffness and reduced metabolic cost of running were found. Following training, the soleus fascicles operated at higher enthalpy efficiency during the phase of muscle-tendon unit lengthening and in average over stance. Thus, improvements in metabolic cost of running following increases in plantar flexor strength and tendon stiffness seem attributed to increased enthalpy efficiency of the operating soleus muscle.

## OP-LAG01 Training and testing

### RAPID WEIGHT LOSS, EMOTIONS, AND HEART RATE VARIABILITY IN FEMALE WRESTLERS

CASTOR-PRAGA, C.1, LOPEZ-WALLE, J.1, GARRIDO-ESQUIVEL, A.1, SANCHEZ-LOPEZ, J.2

*1.UNIVERSIDAD AUTÓNOMA DE NUEVO LEÓN, 2. ESCUELA NACIONAL DE ESTUDIOS SUPERIORES*

INTRODUCTION: Rapid Weight Loss (RWL) consists of immediate weight reduction within 10 days of competition, dehydration being one of the most used strategies. Negative effect has been reported at the mood level, but few studies have evaluated the Heart Rate Variability (HRV), which allows us to know the physiological state of the athlete. The aim of this study was to know the hydration status, emotions and HRV prior to the competition, as well as their correlation and differences between athletes who performed the RWL or not.
METHODS: Method: 15 females wrestlers aged 17.13 ± 2.77 participated. They were evaluated prior to the competition through Urine Specific Gravity (USG), PANAS and Elite HRV.
RESULTS: The average number of days in which strategies were used for RWL were 3.33 ± 4.91 and the number of strategies used was 2.73 ± 2.99. Positive correlations were found between: 1) USG and active emotion (r = . 536*; 2) days using strategies and tense (r = . 540*), guilty (r = . 601*), frightened (r = . 573*); and 3) number of strategies used and guilty (r = . 580*), hostile (r = . 544*), and days using them (r = . 947**). Negative correlations between: 1) USG and RR (r = -.460*) and 2) Ratio (SS/SD1) and emotion of motivation (r = -.520*). Older athletes also felt guilty (r = . 825**). Finally, differences were found between athletes who made RWL and those in the hydration state (p < .05*, p < .01**).
CONCLUSION: The athletes who performed the RWL present greater dehydration and their RR intervals are affected, also those athletes who have greater SS (SS/SD1) feel less motivated. And those who perform the RWL, who perform it for more days and more quantity feels tense, guilty, afraid, and hostile. These results provide a preliminary overview of the consequences of RWL.

### DISTRIBUTION OF GENOTYPE AND ALLELE FREQUENCY OF THE I/D POLYMORPHISM OF THE ACE GENE IN ENDURANCE RUNNERS: A SYSTEMATIC REVIEW

VELANDIA, F., BUITRAGO, J., PRIETO, L., RODRÍGUEZ, A., MÉNDEZ, G., CARDONA, C., ORDOÑEZ, N.

*UNIVERSIDAD DE CIENCIAS APLICADAS Y AMBIENTALES U.D.C.A*

INTRODUCTION: The ACE gene determines the physiological functions in the renin-angiotensin-aldosterone system, it has been related to resistance activities (Sarmento et al., 2020). The objective of this study is to analyze the distribution of the genotype and allelic frequency of the I/D polymorphism of the ACE gene in endurance runners and its relationship with sports performance.
METHODS: Systematic review with PRISMA methodology. Studies that identified the allelic and genotypic frequency of the I/D polymorphism in athletic performance athletes were selected.
RESULTS: 21 articles were included and classified into three categories. 1) Genotype II/ID: nine studies in Caucasian runners show that the genotype I/D occurs with higher percentages in athletes and the allele frequency I of athletes increases compared to the control group, presenting a greater correlation with longer distance races. 2) D/D Genotype: Eight studies in Caucasian and Asian runners determine that the D/D genotype is associated primarily in short-duration or power-race athletes. 3)Absence of relationship of the ACE gene with athletic performance: Four studies in African and Caucasian runners determine that other genetic factors influence performance in endurance runners.
CONCLUSION: The Caucasian and Asian population has the ACE gene with polymorphism I or D, but this polymorphism is not identified in African runners of black ethnicity, because sports performance depends on multiple factors associated with morphological and physiological characteristics, conditions environmental and geographic, to the genetics of populations that generate variability of allelic frequencies of this African population (Scott & Pitsiladis, 2006).
Studies highlight the importance of genotype I/I and allelic frequency I of the ACE gene as one of the main factors responsible for athletic performance in endurance athletes (Woods et al., 2000). The I/D genotype shows superior results compared to the other genotypes, with a predominance of allelic frequency I in long-distance runners. When comparing short- and medium-duration runners versus long-term runners, a relationship between the ACE gene and the duration of activity was identified, with a high frequency of allele I in medium- and long-distance athletes.
The genotype can vary according to the distance of the race, the population and the training, although the two genotypes I/I and D/D were presented in Caucasian and Asian populations, it is inescapable to exclude the influence of the sports preparation and the factors epigenetics in modeling athletic performance (Moir et al., 2019). It is concluded that the II/ID/DD genotypes are related to the physical performance of athletes in 17 (81%) of 21 articles studied. It should be noted that in addition to this ACE gene polymorphism relationship, external factors (training, geographical characteristics, diet, psychological factors) have a great influence on physical performance.

# Invited symposia

## IS-AP01 Mental fatigue: Where are we?

### MENTAL FATIGUE: THE CURRENT STATE-OF-THE-ART

ROELANDS, B.

*VRIJE UNIVERSITEIT BRUSSEL*

MF can be defined as a psychobiological state that emerges during prolonged demanding cognitive activity and results in an acute feeling of tiredness, with potential decrements in physical and/or cognitive performance. Over the last years several high quality systematic review papers have been published that identified significant effect of a condition of mental fatigue on subsequent performance capacity. Given

the abundance of papers on the performance aspect, there is significantly less information available about the mechanisms behind this reduced performance capacity. Interestingly, the reduction in physical performance in a mentally fatigued state is not mediated by an exacerbation of peripheral factors normally associated to physical fatigue. The negative effect of mental fatigue on exercise performance is mainly attributed to a higher-than-normal RPE. During the presentation we will focus on recent findings from lab-based studies looking at the effect of mental fatigue on performance. We will further try to identify potential mechanisms from the literature (as an example the accumulation of adenosine in the anterior cingulate cortex). Finally, some studies have already applied behavioral or nutritional countermeasures in an attempt to negate the negative effects of a mentally fatiguing task. We will explore some of these countermeasures in order to pinpoint their potential.

**MENTAL FATIGUE IN ATHLETIC POPULATIONS**

RUSSELL, S.

*THE UNIVERSITY OF QUEENSLAND*

A plethora of laboratory-based research demonstrates the negative impact of mental fatigue on physical, technical, tactical, and psychological aspects of sporting performance. However, studies have largely failed to translate to impact applied elite sporting practice and are commonly lacking in ecological validity. As such, despite its potential impact, mental fatigue and mental recovery is rarely routinely assessed nor managed in athletic populations. Recent research has advanced the way we understand athletes' perceptions and experiences of mental fatigue in training, competition, and camp. The practical implications of this research and comparison to previous laboratory-based findings will be examined including potential indicators, causes, and management or mitigation strategies. Current practice by those working in high-performance sport will be critically discussed with future suggestions for harnessing mental fatigue and enhancing mental recovery to maximize elite sport training and competition performance. Future directions for translatable research and recommendations for protocols will be discussed.

**CONNECTIONS BETWEEN MENTAL FATIGUE ON THE FIELD, IN THE WORKPLACE, AND IN THE CLINIC.**

BAILEY, S.

*ELON UNIVERSITY*

The impact of MF on performance has been explored in athletic settings and in the workplace. Fewer efforts have been made to examine the impact of MF on patients in a clinical setting. During this presentation we will explore the functional and mechanistic connections and differences of MF in athletic settings, the workplace, and in clinical environments. Particular emphasis will be placed on the changes in brain activity (EEG) and corticomotor excitability (motor evoked potential resulting from transcranial magnetic stimulation) subsequent to mental fatigue. We will review various behavioral, nutritional, and environmental strategies that may mitigate the impact of MF on performance in these environments. We will also discuss the impact of bitter and sweet tastants on performance during a MF state and the potential mechanisms that underly these countermeasures. Finally, we will discuss various research settings, methodologies, and designs that could further our understanding of the impact of MF on performance in athletic settings and the workplace, along with function of patients in a clinical environment.

## Oral presentations

### OP-PN03 Skeletal muscle metabolism and quality

**SHORT-TERM LOWERING OF CARBOHYDRATE INTAKE REDUCES SKELETAL MUSCLE GLYCOGEN AND BODY WEIGHT, BUT HAS NO EFFECT ON SHORT-TERM EXERCISE CAPACITY OR MAXIMAL POWER-OUTPUT IN RECREATIONALLY ACTIVE MEN**

INTRODUCTION: In the days preceding competition most endurance athletes consume a diet rich in carbohydrates (CHO) with the aim of storing high amounts of skeletal muscle glycogen. However, glycogen-loading could be associated with increased body weight (glycogen with associated water) and may not be necessary for short-term (1-15 min.) exercise performance. In this study, we investigated the effect of a short-term manipulation of dietary CHO intake on muscle glycogen content, body weight and short-term exercise performance.
METHODS: In a randomized and counterbalanced cross-over design twenty-two recreationally active males (maximal oxygen consumption: 56.5 ± 5.4 mL O2 · min-1 · kg-1) completed two maximal ergometer cycling exercise tests of either 1- or 15-min. (Group 1 and 15, respectively), after different CHO consumption strategies in the preceding days. Muscle glycogen was manipulated after a glycogen depletion training consisting of both arm cranking and cycling exercise where the subjects received a diet consisting of either a moderate (M-CHO: 4 g · kg-1 body weight · day-1) or high (H-CHO: 10 g · kg-1 body weight · day-1) amount of CHO for the remaining of the training day and for the following two days. Muscle biopsies from vastus lateralis were obtained prior to and immediately after each test and glycogen content was determined biochemically. Peak power-output was determined pre and immediately after the post-exercise biopsies. All data were analyzed by validated linear mixed models and presented as mean ± 95 % confidence interval.
RESULTS: The CHO manipulation led to different muscle glycogen contents between conditions (M-CHO: 367 mmol · kg-1 dry weight [DW] (337:396); H-CHO: 525 mmol · kg-1 DW (496:555), P < 0.00001) and caused a higher body weight (M-CHO: 76.6 kg (74.3:78.8); H-CHO: 77.3 (75.1:79.5), P < 0.00001) in H-CHO compared to M-CHO prior to the maximal cycling tests. The average power-output during the 1- and 15-min. of maximal cycling did not differ between conditions (Group 1: H-CHO: 590 W (541:639); M-CHO: 569 W (515:622), P = 0.33) (Group 15: H-CHO: 294 W (269:319); M-CHO: 293 W (267:320), P = 0.99). Peak power-output was reduced by 6.1 % (3.8:8.5) (P < 0.00001) and 5.9 % (3.4:8.5) (P < 0.00001) after 1- and 15-min. of maximal cycling exercise compared to baseline, respectively, and with no difference between conditions (time x diet interaction: P = 0.12 and P = 0.71, respectively).

CONCLUSION: Short-term lowering of the CHO intake from high to moderate in the days preceding competition induced a reduction in both muscle glycogen content and body weight, while short-term performance was unaffected in non-weight-bearing cycling exercise in recreationally active men. The combination of reduced body weight and maintained performance in this non-weight-bearing activity, suggests that a moderate CHO intake prior to competition may have a performance enhancing potential in weight-bearing sports.

### SHORT-TERM MUSCLE DISUSE DOES NOT AFFECT MUSCLE PROTEIN FRACTIONAL BREAKDOWN RATES UNDER FASTED OR FED CONDITIONS.

PAVIS, G.F.1, ABDELRAHMAN, D.R.2, MURTON, A.J.2, WALL, B.T.1, STEPHENS, F.B.1, DIRKS, M.L.1

*1- NUTRITIONAL PHYSIOLOGY GROUP, DEPARTMENT OF SPORT AND HEALTH SCIENCES, UNIVERSITY OF EXETER, UK. 2- DEPARTMENT OF SURGERY & SEALY CENTER OF AGING, UNIVERSITY OF TEXAS MEDICAL BRANCH, USA*

INTRODUCTION: Muscle disuse atrophy is attributed to reduced muscle protein synthesis rates, increased muscle protein breakdown rates, or both. Whilst leg immobilisation reliably decreases fasted and fed fractional synthetic rates (FSR) of muscle protein, static molecular markers indicate a marked rise in muscle protein breakdown within the first few days of immobilisation. The aim of this study was to determine the effect of unilateral knee immobilisation on mixed-muscle protein fractional breakdown rate (FBR) using the tracee-release method, during both fasted and simulated-fed conditions. A secondary aim was to determine the contribution of FBR to net protein balance by simultaneously quantifying FSR.
METHODS: Seventeen healthy, recreationally active male participants were allocated to FAST (n=9; age 21±0 y, BMI 23±1 kg·m-2; mean±SEM) or FED (n=8; age 23±2 y, BMI 23±1 kg·m-2) groups in a randomised, single-blind, parallel group design. Participants underwent 48 h of unilateral knee immobilisation (brace) prior to visiting the laboratory for intravenous L-[15N]-phenylalanine and L-[ring-2H5]-phenylalanine infusions. After 3 h, the L-[15N]-phenylalanine infusion was stopped (t=0 h) and replaced with primed-continuous saline or 10% primene infusion (0.675 ml·kg-1·h-1) for participants in FAST and FED, respectively. At t=0, 1 and 3 h, m. vastus lateralis biopsies were obtained from control (CON) and immobilised (IMM) legs. Arterialised-venous blood samples were collected regularly throughout. An unpaired t-test was used to detect group differences in the area under the insulin vs. time curve (AUC). A two-way ANOVA was used to detect differences in plasma branched chain amino acid (BCAA) and serum insulin concentrations and FBR, FSR and net balances.
RESULTS: Plasma BCAA concentrations were similar between FAST and FED from -2 to 0 h (343±24 and 330±18 µmol·L-1). After t=0, plasma BCAA concentrations were significantly greater in FED vs. FAST (582±21 vs. 356±26 µmol·L-1; interaction P<0.001). Serum insulin concentrations increased in FED but not FAST (interaction P<0.05), with 3h AUC greater in FED vs. FAST (48.1±7.2 vs. 28.7±5.1 mU·L-1·3h; P<0.05). Immobilisation did not influence FBR in either FAST (CON: 0.113±0.016; IMM: 0.128±0.015 %·h-1) or FED (0.146±0.015; IMM: 0.152±0.015) groups (all P>0.05). FSR was significantly lower in IMM vs. CON (P<0.05) in both FAST (0.074±0.004 vs. 0.090±0.006 %·h-1) and FED (0.065±0.024 vs. 0.119±0.016 %·h-1) groups. Net protein balances in CON legs were -0.023±0.016 %·h-1 in FAST and -0.027±0.021 %·h-1 in FED. Immobilisation decreased net protein balance to -0.054±0.015 and -0.087±0.025 %·h-1 in FAST and FED, respectively (P<0.01).
CONCLUSION: In summary, short-term disuse does not affect muscle protein breakdown rates measured under both fasted and simulated-fed conditions. Rather, decreased net muscle protein balance, and therefore muscle disuse atrophy, induced by short-term immobilisation is driven by reduced fasted and fed muscle protein synthesis rates.

### MUSCLE GLYCOGEN UNAVAILABILITY AND FAT OXIDATION RATE DURING EXERCISE: INSIGHTS FROM MCARDLE DISEASE

RODRIGUEZ-LOPEZ, C., SANTALLA, A., VALENZUELA, P.L., RODRIGUEZ-GOMEZ, I., PINOS, T., LUCIA, A., ARA, I.

*1, HGU GREGORIO MARAÑON. 2, UNIV.CASTILLA-LA MANCHA. 3, CIBER FRAILTY AND HEALTHY AGING. 4, UNIV.PABLO DE OLAVIDE. 5, INST. INV. HOSP. 12 DE OCTUBRE. 6, UNIV. EUROPEA*

INTRODUCTION: Carbohydrate availability has been reported to affect fat oxidation capacity during exercise. However, the effects of complete muscle glycogen unavailability on fat oxidation capacity remains unknown. The aim of this study was to examine the maximal fat oxidation (MFO) rate of patients with McArdle disease – a condition caused by inherited, complete blockade of muscle glycogen metabolism that represents a unique human model for the study of fat exercise metabolism – compared to sex- and age-matched healthy individuals.
METHODS: 10 McArdle patients were excluded from the analyses due to intense hyperpnea that clouded substrate oxidation. Nine physically active patients (3 women, 36±12 years) and 12 healthy controls (4 women, 40±13 years) were studied. Cardiorespiratory fitness (peak oxygen uptake, VO2peak), MFO, the exercise intensity eliciting MFO (FATmax), and the MFO-associated workload, respectively, were determined in all participants by indirect calorimetry during an incremental exercise test on a cycle ergometer.
RESULTS: Despite showing a lower VO2peak compared to controls (24.7±4 vs. 42.5±11.4 ml·kg-1·min-1), patients presented considerably higher values of MFO (0.53±0.12 vs. 0.33±0.10 g·min-1), FATmax (94.4±7.2 vs. 41.3±9.1 % of VO2peak) and MFO-associated workload (1.33±0.35 vs.0.81±0.54 w·kg-1) than controls (all p<0.05).
CONCLUSION: McArdle patients show an exceptionally high MFO, which they achieve near their maximal exercise capacity. These findings support the influence of glycogen availability on MFO and suggest that McArdle patients develop a quite unique fat oxidation capacity as an adaptative response to compensate for the inherited blockade in glycogen metabolism, with MFO appearing as a potential limiting factor of exercise tolerance in these patients.

### EFFECTS OF A 3-DAY HIGH-FAT OR HIGH-CARBOHYDRATE DIET ON MAXIMAL FAT OXIDATION AND FATMAX IN MODERATELY TRAINED MEN

TARRY, E.K.1, PETERSEN, E.A.1, VESTERGAARD, S.G.1, OLSEN, M.C.1, HANSEN, M.1, PILEGAARD, H.3, DELA, F.1,2, HELGE, J.W.1

*1. XLAB, CENTER FOR HEALTHY AGING, UNIVERSITY OF COPENHAGEN, DENMARK 2. DEPARTMENT OF GERIATRICS, BISPEBJERG UNIVERSITY HOSPITAL, DENMARK 3. DEPARTMENT OF BIOLOGY, UNIVERSITY OF COPENHAGEN, DENMARK*

INTRODUCTION: Strategies aiming to spare glycogen and promote fat oxidation have shown potential to enhance exercise performance (1) (2). Previous literature has established the relationship between diet manipulation and substrate utilisation but until now, the direct impact of short-term diet interventions on maximal fat oxidation (MFO) and the relative exercise intensity at which MFO occurs (3) (Fatmax) has not been assessed. Therefore, this study aimed to determine the effects of a short term fat-rich or carbohydrate-rich diet on MFO and Fatmax in healthy males.

METHODS: In a randomised, controlled mixed-design; 40 moderately trained men (VO2peak 56.2 ± 1.2 ml/kg/min (mean ± SEM) were allocated to either a 3-4 day isocaloric high-fat (HIFAT: 65 E% fat, 20 E% carbohydrate and 15 E% protein) (n = 20) or high-carbohydrate diet (HICHO: 70 E% carbohydrate, 15 E% fat and 15 E% protein) (n = 20). Six participants completed both intervention diets, with a minimum of 4 weeks washout. Standardised, graded Fatmax and VO2peak tests were carried out in the fasted condition on the first and last day of each dietary intervention to determine MFO and Fatmax, consisting of a 5-minute warm-up at 60W, followed by increases of 35W every 3 minutes thereafter until a respiratory exchange ratio of ≥1.0 was reached (3). Subsequently, VO2peak testing began at 95W and load was increased by 35W each minute until exhaustion.
RESULTS: MFO increased from 0.41 ± 0.05 g/min to 0.59 ± 0.05 g/min (p>0.001) after HIFAT and reduced from 0.36 ± 0.04 g/min to 0.28 ± 0.06 g/min (p>0.001) following HICHO. Fatmax demonstrated a similar trend increasing from 37 ± 2% to 44 ± 2% (p>0.001) in response to HIFAT (p < 0.001), and decreasing from 37 ± 2% to 33 ± 2% (p>0.001) after HICHO. Significant time-by-diet interactions were observed in absolute VO2peak values and when expressed relative to body weight. Post-hoc analysis revealed absolute VO2peak and VO2peak relative to body mass were increased by 1.7% (p=0.036), and 2.7% (p=0.002), respectively after HIFAT. No significant changes in VO2peak were observed following HICHO.
CONCLUSION: A high-fat diet resulted in significantly increased MFO and Fatmax, whilst a high-carbohydrate diet significantly reduced MFO and Fatmax in healthy males. This demonstrates trained individuals can likely achieve metabolic adaptations facilitating greater fat utilisation during exercise following just 3 days of a fat-rich diet.

### OP-BM02 Motor learning and motor control

#### SHORT-TERM BALANCE CONSOLIDATION RELIES ON THE INVOLVEMENT OF THE PRIMARY MOTOR CORTEX (M1): A RTMS STUDY

EGGER, S.1, WÄLCHLI, M.1, RÜEGER, E.1, TAUBE, W.1

*UNIVERSITY OF FRIBOURG, SWITZERLAND*

INTRODUCTION: Structural and functional adaptations occur in the primary motor cortex (M1) after only a few balance learning sessions (1, 2, 3). However, despite the high interest in balance control in general and the role of M1 in particular, the role of M1 in consolidating balance tasks is still not clear. The reason for this is that causal studies are missing and that it is a distinct possibility that adaptations in M1 might be a consequence of improved balance (e.g. less postural sway) rather than the actual driving force for improved balance coordination. One technique to investigate the impact of M1 in learning processes more directly is to impair the consolidation with the application of repetitive TMS (rTMS).
METHODS: Thirty young and healthy participants were randomly allocated into the rTMS or sham-rTMS group without knowing their group affiliation. The experimental design included a balance acquisition phase (6 series (S1 to S6) with 8 trials), followed by either 15 minutes of rTMS (1 Hz at 115 % of rMT to disrupt the involvement of M1) or sham-rTMS. 24 hours later, participants performed a retention test (Ret). RTMS was delivered to M1, more precisely at the hot-spot for the soleus muscle. The rMT was defined in a seated position as the intensity that triggered motor evoked potential peak-to-peak amplitudes greater than 50 µV in at least 5 out of 10 trials.
RESULTS: The two investigated balance parameters (i.e. 'mean deviation' and 'time in +/- 4 degrees') indicate that the postural performance on the rocker-board significantly improved during the acquisition phase ('mean deviation': $F_{1,27} = 81.613$, $p < .001$, $n2p = 0.751$; 'time in +/- 4 degrees': $F_{1,27} = 67.099$, $p < .001$, $n2p = 0.713$) independent of the intervention group (rTMS vs. sham-rTMS 'mean deviation': $F_{1,27} = 0.059$, $p = 0.810$, $n2p = 0.002$; 'time in +/- 4 degrees': $F_{1,27} = 0.147$, $p = 0.704$, $n2p = 0.005$). However, the TIME*GROUP interaction of the ANCOVA with S1 as covariate revealed differences in consolidation (i.e. from S6 to Ret) between the rTMS and sham-rTMS group ('mean deviation': $F_{1,26} = 10.537$, $p = 0.003$, $n2p = 0.288$; 'time in +/- 4 degrees: $F_{1,26} = 10.022$, $p = 0.004$, $n2p = 0.278$).
CONCLUSION: The present results demonstrate for the first time a causal relationship between the involvement of M1 and the early learning and consolidation of a balance task. This can be concluded as the rTMS group demonstrated a worse consolidation (i.e. loss of performance from the end of the acquisition phase to the start of the retention phase) of the balance task in contrast to the sham-rTMS group, which showed a significant increase in performance. The present results confirm and extend previous findings that higher cortical centers (especially M1) adapt in response to balance learning (4, 5).

### CORTICOSPINAL EXCITABILITY DURING RAPID MUSCLE CONTRACTIONS AND ITS ASSOCIATION WITH TORQUE PRODUCTION

CASTELLI, F., MIAN, O., BRUTON, A., CHEMBILA VALAPPIL, A.C., TILLIN, N.A.

*ROEHAMPTON UNIVERSITY*

INTRODUCTION: Rate of force development (RFD) is an important limiting factor of many daily and sporting activities (1). RFD is greatly influenced by neural drive at the start of contraction; specifically motor unit recruitment speed and discharge rate (2). Corticospinal mechanisms affecting neural drive and consequently RFD throughout rapid contractions are unknown. Measuring the amplitude of motor evoked potential (MEPs) and silent period duration (SP) in response to transcranial magnetic stimulation (TMS) during contraction can assess corticospinal excitability and intracortical inhibitions. This study investigated MEP amplitude and SP at different time points during rapid force production and assessed the relationship between these factors and RFD.
METHODS: 14 participants (5 female) completed 1-s isometric rapid voluntary contractions ('fast and hard') and 3-s maximal voluntary contractions (MVCs; 'push hard') of the knee extensors. EMG responses were recorded from the vastus medialis (VM) and lateralis (VL), and rectus femoris (RF). Some contractions were superimposed with TMS at 140% of the active motor threshold. Stimulation was triggered to elicit an MEP and SP responses at approximately 45, 115, and 190 ms after VM EMG onset in the rapid contractions, and at the force plateau in MVCs. MEPs amplitudes were normalised to maximal M-waves, and torque was recorded at the same time points as the MEPs and normalised to MVC torque. 2-way ANOVAs assessed the influence of muscle and time point on the dependent variables and bivariate correlations assessed the relationship between normalised rapid torque and both normalised MEP and SP at match time points.
RESULTS: Normalised MEP was affected by time point ($p=0.021$), being greater at MVC plateau than at 115 ms in rapid contraction ($P=0.031$). SP duration was also affected by time point ($P=0.002$), due to it being longer at MVC plateau than at different time points during the rapid contractions, particularly in the RF. There was no correlation between SP and normalised rapid torque at any time point ($r<0.1$; $P>0.9$). However, normalised rapid torque at 115 ms was correlated with average normalised MEP at 45 and 115ms ($r=0.73$, $p=0.003$).
CONCLUSION: In conclusion, corticospinal excitability (determined via MEP) was constant throughout the rapid contractions but lower, at least at one time point, than at the MVC plateau. The SP lengthened throughout the rapid contractions and was longest at the MVC plateau, suggesting intracortical inhibition increases with torque. The observed correlation between MEP and torque at 115 ms suggests corticospinal excitability determines neural and thus RFD during rapid contractions.

### ACUTE EFFECTS OF ALCOHOL CONSUMPTION ON CORTICOSPINAL PARAMETERS MEASURED BY TRANSCRANIAL MAGNETIC STIMULATION

BUGNON, M., RUFFIEUX, J., TAUBE, W.

*UNIVERSITÉ DE FRIBOURG*

INTRODUCTION: Although alcohol affects many brain functions and induces evident behavioural changes such as locomotor impairments, its short-term effects on the excitability of the corticomotoneuronal pathway are scarcely known. It is widely accepted that alcohol reduces glutamatergic and increases GABAergic neurotransmission. Since GABA-related inhibition is fundamental for motor control and motor learning, this suggests that alcohol might have a strong influence on these brain functions. One non-invasive method to study excitability and GABA-related inhibition parameters is transcranial magnetic stimulation (TMS). Surprisingly, however, and despite the wide use of this method in the field of motor control and motor learning, only few studies have investigated the acute effects of alcohol on corticospinal parameters using TMS (1). Therefore, the aim of this study was to investigate the acute effects of moderate alcohol consumption on excitability and inhibition parameters measured by TMS.
METHODS: 24 participants were allocated to either the alcohol or the placebo group. Before and after the drinks, TMS was applied on the primary motor cortex to elicit motor evoked potentials in the flexor carpi radialis muscle. The following TMS parameters were assessed: (i) corticospinal excitability (CSE), measured at rest, during an isometric contraction and during a precision task; (ii) cortical silent period (CSP), measured during an isometric contraction; (iii) short-interval intracortical inhibition (SICI), assessed using 1 ms (SICI-1) and 3 ms (SICI-3) interstimulus intervals, and measured at rest as well as during a precision task. Data were analyzed using two-way mixed model 2x2 ANOVAs.
RESULTS: Alcohol significantly reduced CSE measured during the precision task (significant interaction effect of TIME x GROUP: $F(1, 22) = 8.645$, $p = 0.008$, $n2p = 0.282$). A trend towards reduced CSE was also observed during the isometric contraction (interaction of TIME x GROUP: $F(1, 22) = 2.119$, $p = 0.160$, $n2p = 0.089$), while no differences were found at rest. Furthermore, we found a trend towards a reduction of SICI-1 by alcohol, both at rest (interaction effect of TIME x GROUP: $F(1, 21) = 2.971$, $p = 0.099$, $n2p = 0.124$) and during the precision task (interaction effect of TIME x GROUP: $F(1, 22) = 2.165$, $p = 0.156$, $n2p = 0.093$). No significant alcohol-related effects were found for SICI-3 and CSP duration.
CONCLUSION: Increases in inhibition due to alcohol intake could be observed in motor cortical circuits. More specifically, a decrease in corticospinal excitability was found during the execution of a precision task as well as a trend towards an increase in SICI-1. However, as not all TMS parameters were affected by alcohol it might be assumed that at moderate concentration levels, alcohol affects motor cortical circuits mainly through the extrasynaptic GABA system (2).

### MODULATION OF CORTICOSPINAL EXCITABILITY BY VIRTUAL REALITY: THE ROLLER COASTER EFFECT

GROSPRETRE, S., MATHIOT, J., EON, P.

*C3S - EA4660*

INTRODUCTION: Virtual Reality (VR) is a training tool that consists of a computer simulation of a three-dimensional environment, displayed in front of an individual by means of a specific electronic equipment such as a headset with integrated screens. The interest, as compared to a classical 2-D display, is based on the interactive and realistic aspect of the simulation. VR is known to consistently stimulate the autonomic nervous system, as evidenced by increases in heart rate and skin conductance, which are two physiological markers of stress and anxiety (1). Significant brain activation in sensori-motor regions is also noted, especially when participants can interact in their virtual

environment (2). However, little is known regarding a possible effect of VR on the modulation of corticospinal excitability, neither the links that could exists between autonomous and voluntary nervous systems modulations during such condition.
METHODS: Ten healthy young participants were enrolled in a single-session experiment. They were seated in a comfortable chair and equipped with a VR headset that displays a simulated roller coaster (RC) ride, known to be particularly efficient to modulate autonomous responses (1). Anxiety was monitored throughout the experiment by recording Galvanic Skin Response (GSR). Corticospinal excitability was quantified by measuring the amplitude of the motor evoked potential (MEP), elicited by transcranial magnetic stimulation on the right First Dorsal Interosseous (FDI) muscle's cortical representation. Several responses were evoked at rest and throughout the whole RC ride, during flat, uphill and downhill sections. MEP amplitudes were normalized to their corresponding maximal M-waves, evoked by stimulation of the ulnar nerve.
RESULTS: First, all MEP/Mmax were significantly higher during RC ride as compared to rest (P=0.02). Then, MEP/Mmax were significantly modulated according to the roller coaster section. The modulation of corticospinal excitability seems to follow an inverse gradient according to the trajectory of the RC cart, being increase during downhill (MEP/Mmax: 0.21±0.07) and decreased during uphill (MEP/Mmax: 0.17±0.05) as compared to flat sections (MEP/Mmax: 0.19±0.08) (main effect of slope: P=0.03). The evolution of MEP/Mmax was concomitant to the evolution of GSR.
CONCLUSION: Popular for its effects on the markers of stress and anxiety, the present study showed that VR can also be an efficient stimulus to modulate motor corticospinal excitability. Moreover, these preliminary data suggest a potential link between voluntary and autonomic nervous systems regulation during VR. Taken together, these promising results highlight the interest of VR in training and rehabilitation as an efficient stressor for both autonomous and motor systems.

**INFLUENCE OF VISUAL AND PROPRIOCEPTIVE INPUTS ON A FORCE REPRODUCTION TASK PERFORMED WITH THE INDEX FINGER IN FEMALES AND MALES**

BAUDRY, S., HENRY, M., ESREFOGLU, A.
*UNIVERSITÉ LIBRE DE BRUXELLES*

INTRODUCTION: Along with the kinaesthetic senses (the senses of position and movement), the sense of force is another aspect of proprioception which represents the ability to correctly perceive and reproduce a given level of force (1). It can be assessed by a force reproduction task consisting of matching a target force with visual feedback of the force produced (TARGET phase) and reproducing the target force without visual feedback (REPRODUCTION phase) after a period of rest. Even though the sense of force contributes to the control of our movements, it has received less attention than kinaesthetic senses. The sensory substrates used to form the estimate of the force during the TARGET phase remains, for example, an open question. Therefore, the objective of the study was to determine the contribution of muscle proprioception (Experiment 1) and vision (Experiment 2) to form the force estimate during the target phase in females and males.
METHODS: Sixty healthy young adults aged from 19 to 27 years [30 females and 30 males] participated in the study. Both experiments consisted of performing a force reproduction task with the index finger in abduction direction at 5% and 20% of the force produced by the participant during a maximal voluntary contraction (MVC). Experiment 1 (n=30) consisted of trials performed with and without local vibration applied on tendon of the first dorsal interosseous during the TARGET phase. Local vibration was used to disrupt the proprioceptive signal. Experiment 2 (n = 30) compared the force reproduction error between trials performed with and without visual feedback during the TARGET phase. Removing the visual feedback during the TARGET phase was used to investigate whether the mismatch in the available sources between the TARGET and the REPRODUCTION phases contributes to the force reproduction error.
RESULTS: The force reproduction error was greater in trial with local vibration than without at 5% ($p = 0.011$) but not 20% MVC ($p = 0.88$). In contrast, the error was lesser in trials without than with visual feedback for the 5% ($p = 0.003$) but not the 20% MVC ($p = 0.19$). No sex difference was observed in the force reproduction error, regardless of the experimental conditions.
CONCLUSION: These results support the contribution of muscle proprioception in the sense of force (2), and further indicate that muscle proprioception contributes to form the force estimate during the TARGET phase. In contrast, providing visual feedback of force during the TARGET phase biases the sense of force assessment for low-force contractions. The greater effect of proprioceptive and visual perturbation at 5% compared with 20% MVC also suggests that contrasting low and moderate force intensities may help to refine the assessment of the sense of force.

### OP-AP05 Strength testing and training

**POST ACTIVATION PERFORMANCE ENHANCEMENT OF PUNCH FORCE AND NEUROMUSCULAR PERFORMANCE OF AMATEUR BOXERS FOLLOWING TWO PUNCH-SPECIFIC UPPER-BODY CONDITIONING ACTIVITIES.**

FINLAY, M., GREIG, M., BRIDGE, C., PAGE, R.
*EDGE HILL UNIVERSITY*

INTRODUCTION: Peak punch force and rate of force development (RFD) are two key performance indicators in boxing. The use of prior voluntary muscle activity may enhance subsequent athletic performance via Post Activation Performance Enhancement (PAPE); however, research has largely comprised conditioning activities (CA) that are impractical to an amateur boxing warm-up environment. This study aimed to assess the efficacy of two punch-specific CA's (isometric [ISO], and elastic resistance [ER]) in enhancing punch force and neuromuscular performance of amateur boxers.
METHODS: Ten male senior elite amateur boxers performed a standardised warm-up, followed by either 3 x 3-second repetitions of the ISO CA, 2 x 5 repetitions of the ER CA, or a control trial, on 3 separate days. Punch force variables and counter-movement jump (CMJ) height were measured via a vertically mounted force plate and a photocell system, respectively. Boxers performed tests at baseline, and at 3, 5, 7, 9, 11, and 13-minutes post CA, with the same time intervals for the control trial. Worthwhile changes in performance were assessed by comparing change scores from baseline at each time interval, to a previously determined smallest worthwhile change (SWC), in addition to

effect sizes (ES) and signal:noise (S:N) ratio. Any mean difference that was greater than the SWC, or where the S:N ratio was > 1, was deemed a worthwhile change.
RESULTS: Punch performance increased above the SWC threshold at several intervals in both the ISO and ER CA, but rarely in the control trial. Peak punch force and RFD was improved following the ISO CA in the cross (+226 N, ES = 0.42, S:N = 1.97; +48472 N.S-1, ES = 0.76, S:N = 3.80), lead hook (+167 N, ES = 0.33, S:N = 1.46; + 28952 N.S-1, ES = 0.34, S:N = 1.61), and rear hook (+231 N, ES = 0.44, S:N = 1.92; + 43560 N.S-1, ES = 0.46, S:N = 2.03). Likewise, the ER CA induced worthwhile increases in the punch force of the cross (+157 N, ES = 0.30, S:N = 1.37) and rear hook (+208 N, ES = 0.36, S:N = 1.73), and in both punch force and RFD of the lead hook (+171 N, ES = 0.35, S:N = 1.50; +20955 N.S-1, ES = 0.27, S:N = 1.17). A single worthwhile increase in jab RFD was found following the ISO CA. No increases in CMJ performance was observed
CONCLUSION: The ISO and ER CA's typically produced worthwhile improvements in punch force and rate of force development (RFD); however, the ISO CA clearly induced greater increases, and across a larger time course overall. The CA's produced a localised effect, as evidenced by a lack of worthwhile improvement in CMJ performance. Peak PAPE was typically observed between 7 to 9-minutes, though this varied between individuals. In conclusion, the ISO and ER CA's appear to elicit worthwhile improvements in punch force and RFD of senior elite amateur boxers, though the punch-specific isometric hold appears to be the superior CA. Future research should apply a more individualised approach to the CA in this study, indeed the current research group are presently exploring this.

### EFFECTS OF DIFFERENT VELOCITY LOSS THRESHOLDS ON SUBSEQUENT MECHANICAL PERFORMANCE IN THE FLYWHEEL SQUAT EXERCISE

MUÑOZ-LÓPEZ, A.1, MÁRMOL, D.1, ÁLVAREZ, P.1, LÓPEZ-LEÓN, I.1, MORENO-LARA, J.1, CASTIZO, M.2, SAÑUDO, B.2, DOMÍNGUEZ, R.1, NUÑEZ, F.J.3

*1 DEPARTAMENTO DE MOTRICIDAD HUMANA Y RENDIMIENTO DEPORTIVO. UNIVERSITY OF SEVILLE, SPAIN. 2 DEPARTAMENTO DE EDUCACIÓN FÍSICA Y DEPORTE. UNI OF SEVILLE, SPAIN. 3 PHYSICAL PERFORMANCE & SPORTS RESEARCH*

INTRODUCTION: INTRODUCTION
In resistance training, the velocity loss in real-time during the set execution is a practical strategy to elicit different acute mechanical responses [1]. When free weights were used, the lower the velocity loss, the lower the mechanical performance detriment. Other modern training equipment is the flywheel resistance training devices [2]. However, it is still unknown how different velocity loss thresholds may affect physical performance. Therefore, this study aimed to analyse the subsequent mechanical performance after executing different velocity loss thresholds in a flywheel device.
METHODS
Ten participants (weight 75.5 ± 17.1 kg, height 1.74 ±0.12 m) with no previous experience using flywheel devices participated in the study. Before the intervention, the participants were familiarized with eight training sessions using the half-squat exercise on a flywheel device (Kbox 3, Exxentric, Sweden). The participants attended the laboratory for four days, where they executed two countermovement jumps and one maximum voluntary isometric force squat test before the intervention and after each set. The intervention consisted of three sets of the half-squat exercise with a moment of inertia of 0.050 kg·m 2 or 0.150 kg·m2 . Each load was executed for two different days. The repetitions were individualized based on three randomised velocity losses (5%, 10%, and 15%). We monitored the velocity losses using a rotary encoder in real-time (SmartCoach lite, Sweden). For jump height and peak force, we
tested the pre vs. post (Time) differences using an ANOVA repeated measures test with three
within-subjects factors (Load (2) x Time (2) x Velocity Loss (3)). In case of a significant interaction, we explored post-hoc differences with Bonferroni adjustment. We set the statistical significance level at p< 0.05.
RESULTS
There was a significant Time x Velocity Loss difference in the jump height (p= 0.010). In addition, there was a significant reduction in the jump height in Time (p< 0.001) and in Velocity Loss as main factors (p< 0.010). Jump height was significantly reduced (p< 0.001) after losing 5% (-19.5%), 10% (-19.8%), and 15% (-27.5%) of speed. Those losses were significantly different between 5 and 15% (p=0.00) and between 10% and 15% (p= 0.004).The peak force only showed a significant reduction in Time as main factor (p<0.001, -15.6%).
CONCLUSION
Higher velocity losses induced higher jump height losses in the flywheel half-squat exercise. Using a velocity loss of 5% or 10% within the set resulted in the same jump performance impairment. However, peak force was not dependent on the velocity loss. Finally, for these two key performance indicators, the load (i.e., moment of inertia) does not influence subsequent impairments. The results of this study are of practical importance for programming basic training variables in flywheel resistance training devices.

### METHODS: RESULTS: CONCLUSION: MATURITY OFFSET, ANTHROPOMETRIC PROFILE, AND THE VERTICAL FORCE-VELOCITY PROFILE IN YOUTH BASKETBALL PLAYERS

JIMÉNEZ-DAZA, P., RAMIREZ-CAPILLO, R., SAEZ DE VILLAREAL, E.

*UNIVERSIDAD PABLO DE OLAVIDE, SEVILLE, SPAIN*

INTRODUCTION: Two of the main current problems in training sports reside in the wide anthropometric differences that exist in the different categories (U-14, U-16 and U-18) (1) and the need to individualize training in order to optimize the present and future performance of basketball players (2, 3). The objective of this work was to analyze the relationships between maturity offset, anthropometric variables and the vertical force-velocity profile in youth (12-18 years old) male and female basketball players. We hypothesized that there will be significant correlations between maturity offset and force-velocity profile.
METHODS: The vertical force-velocity profile was measured in 84 basketball players (44 female players and 40 male players), grouped in competitive-age categories, i.e., under 14, 16 and 18 years of age (U-14, U-16, and U-18, respectively). A bivariate correlational analysis was carried out between maturity offset, anthropometric variables (height, body mass, % fat, muscle mass, bone mass and BMI) and vertical force-velocity profile (Theoretical maximal force, theoretical maximal velocity, theoretical maximal power, force-velocity imbalance and force-velocity profile orientation).
RESULTS: The results showed significant correlations (p <0.05) between force-velocity imbalance (Fvimb) and maturity offset at early ages of training (12-15 years). The anthropometric profile was correlated (p<0.05) with F0 in U-14, V0 in U-16 and Pmax in U-18 basketball players.

CONCLUSION: The vertical force-velocity profile is hypothesized as a useful index to correct vertical force-velocity deficits according to the maturity offset of the female and male basketball players. A novel finding not contemplated in the initial hypotheses is the discovery of the so-called "determinant variable", which could be defined as "the variable of the vertical force-velocity profile that presents the greatest number of significant correlations with the anthropometric data measured and, therefore, is the one that offers us the greatest combined information". that it would be advisable to take into account for the training in youth basketball players variables such as: body mass, height, muscle mass (total and right and left legs), bone mass, F0 (especially in U-14), V0 (especially in U-16) and Pmax (especially in U-18).

**EFFECTS OF PERIPHERAL MUSCLE STRENGTH ASYMMETRIES ON MUSCLE FATIGABILITY IN PROFESSIONAL SOCCER PLAYERS**

FERIOLI, D.1, RAMPININI, E.2, MARTIN, M.2,3, BOSIO, A.2, AZZOLINI, M.2, MAFFIULETTI, N.4

*1, UCAM RESEARCH CENTER FOR HIGH PERFORMANCE SPORT; 2, MAPEI SPORT RESEARCH CENTRE; 3, BANGOR UNIVERSITY; 4, SCHULTHESS CLINIC*

INTRODUCTION: Soccer is a high-intensity intermittent team sport, during which neuromuscular factors are heavily taxed to perform quick accelerations, decelerations, and changes of direction (COD) [1]. Inter-limb strength asymmetries have been reported to negatively affect physical performance including COD tasks across various team sports [2], however little is known about their impact on muscle fatigability during soccer specific exercises such as repeated CODs. Therefore, this study examined the effect of peripheral muscle strength asymmetries across a repeated COD task on muscle fatigability in adult professional soccer players.
METHODS: A total of 249 male professional soccer players (age: 25±5 yrs; stature: 182±6 cm; body mass: 78±7 kg) participated in this study. Each player performed a repeated COD test at least once (range: 1-23; total number of individual test sessions: 1.009). The repeated COD test encompassed four levels of intermittent runs with multiple CODs performed at increasing standardized intensities over an 8-m course. After each level, right and left knee extensors were electrically stimulated in resting isometric conditions to evoke a peak twitch (PT) response (an indicator of peripheral muscle strength). The main outcomes were PT torque after the first (PT1) and fourth (PT4) levels as well as the highest absolute value (PTmax) for both sides. Players were then allocated to specific groups according to their inter-limb asymmetry in PT1, PT4 and PTmax (LOW: ≤10%, MID: 10-20%, HIGH: >20%) and according to the difference in asymmetry between PTmax and PT4 (ΔPT4-PTmax). Muscle fatigability (PTdec) was calculated as the mean percentage decline from PTmax to PT4.
RESULTS: Mixed models were used to determine differences in PTdec between asymmetry groups. No significant differences in PTdec were observed between groups for PT1 and PTmax asymmetries ($p=0.402$ and $p=0.102$, respectively). On the other hand, PTdec was moderately affected by asymmetries observed at PT4 ($p<0.001$; LOW, 17.8%, range: 3.4%-49.5%; MID, 19.1%, range: 3.5%-58.7%; HIGH, 25.7% range: 5.3%-79.6%). In the same way, asymmetries based on ΔPT4-PTmax largely influenced PTdec ($p<0.001$; LOW, 16.2%, range: 3.4%-39.6%; MID, 22.4%, range: 7.2%-52.5%; HIGH, 35.5%, range: 12.0%-79.6%).
CONCLUSION: The current findings suggest that larger peripheral muscle strength asymmetries under fatigue (i.e. at PT4) and larger changes in asymmetries during the COD test (ΔPT4-PTmax) were associated to higher levels of muscle fatigability during repeated CODs in professional soccer players. This study provides novel insights about how peripheral muscle strength asymmetries may impact a soccer-specific task in the presence of muscle fatigability. The present results also highlight the need to evaluate inter-limb strength asymmetries under fatigue and possibly to reduce their extent with the ultimate goal to enhance physical performance.

**HANDGRIP STRENGTH TESTING AND SHOOTING PERFORMANCE IN ICE HOCKEY PLAYERS**

KURZ, E., MAIER, D., SCHENK, P., SCHULZE, S., DELANK, K.S., SCHWESIG, R.

*MARTIN-LUTHER-UNIVERSITY HALLE-WITTENBERG*

INTRODUCTION: Handgrip strength is a valuable indicator of quality of life, performance, and recovery. In ice hockey the stick is held with both arms. More successful ice hockey teams were thus found to have higher combined handgrip strength. This study was designed to determine possible relationships of handgrip strength assessed at different shoulder positions with on-ice shooting performance in professional ice hockey players.
METHODS: Sixteen competitive male ice hockey players (forward/defenseman: 10/6, age: 23-34 years, BMI: 22-29 kg/m²) volunteered to participate in this cross-sectional study. Handgrip strength was measured at both sides during upright standing off-ice in three different shoulder positions using a handheld dynamometer (SH5001, Saehan Corporation, Masan, South Korea). The first position was with the arm adducted and neutrally rotated, elbow flexed at 90° and forearm in neutral (NORM). To involve the shoulder joint, the second and third positions were with the arm abducted at 90° and externally rotated at 90° (ABER), and with the arm elevated and the elbow extended (ELEX). The maximum of two maximal effort trials was used, cumulated from both sides, and normalized to athletes' body mass. After a brief independently executed specific warm-up on-ice, athletes shot three slap shots (SS) and three wrist shots (WS) at an empty goal. The puck speed was recorded by a radar gun system (Stalker Solo 2, Stalker, Plano, TX, USA). The average speed of successful shots only was used. Differences between playing positions were verified by applying Student's unpaired t tests. Possible relationships were explored using Pearson's r statistics.
RESULTS: The playing position did not affect any outcome measured ($p = 0.1$-$0.5$). Athletes' mean combined handgrip strength was 1.37 kg/kg (minimum-maximum: 1.20-1.56), 1.30 (1.13-1.59) and 1.30 (1.17-1.58) at NORM, ABER and ELEX, respectively. The averaged puck speeds of SS and WS were 136 km/h (128-149) and 113 (104-128). There was a relevant and significant association of combined handgrip strength at ABER with SS puck speed ($r = 0.54$, $p < 0.05$), explaining 29% of the variance. However, no relevant associations were found at NORM or ELEX for either shot type ($r < 0.4$, $p > 0.14$).
CONCLUSION: In order to estimate on-ice shooting performance in ice hockey players using general off-ice strength tests, handgrip measurements should be run with the arm abducted, externally rotated and with the elbow flexed at 90°.

### OP-PN30 Relative energy deficiency in sports (RED-S)

#### IMPACT OF EXERCISE IN THE FASTED STATE ON PROSPECTIVE FOOD CONSUMPTION

HÖCHSMANN, C., STEINER, M., KOEHLER, K.

*TECHNICAL UNIVERSITY MUNICH*

INTRODUCTION: Exercise is recommended for weight management, yet weight loss from exercise is often less than expected based on measured energy expenditure. This is primarily due to compensatory energy intake, which occurs in most exercisers and overrides the appetite-suppressing effects of acute exercise. Exercising in a fasted state seems to be a promising way to decrease overall energy intake, as it has been reported that ad libitum 24h energy intake following fasting exercise is significantly lower than after non-fasting exercise. Acute effects of fasted exercise on post-exercise energy intake and particularly on post-exercise decision-making about food remain poorly understood. Therefore, the present study aimed to investigate whether fasting exercise and exercise after a standardized breakfast have different effects on hypothetical post-exercise food intake.
METHODS: In this crossover study, ten healthy participants (29.7 [SD=2.2] years, 22.8 [SD=2.1] kg/m2, 50% women, regular habitual exercise, regular breakfast consumption) completed two identical 30-min exercise sessions on either a treadmill or bike ergometer (as preferred). The exercise sessions occurred following (1) an overnight (12h) fast (FE) or (2) a standardized breakfast (BE; oatmeal, low-fat milk, and apple; ~10-15% of individual daily energy requirements) after an overnight fast. Before (pre), immediately after (post), and 30 minutes after (post30) the exercise session, participants completed electronic questionnaires with visual food cues to determine hypothetical food amount preferences and intertemporal food preferences (immediate vs. delayed consumption after 4 hours).
RESULTS: The preferred food amount for immediate consumption was significantly decreased compared to pre immediately after FE (161 [SD=85] kcal vs 236 [SD=81] kcal, p=0.006) but not after BE (p=0.26). For both exercise conditions, the amount of food selected for immediate consumption at post30 was significantly greater compared to pre (FE: 309 [SD=93] vs 236 [SD=81], p<0.001; BE: 201 [SD=103] vs 124 [SD=67], p=0.009). The preferred food amount for immediate consumption was significantly greater for FE compared to the BE, both for pre (difference: 113 [SD=57] kcal, p<0.001) and post30 (difference: 109 [SD=87] kcal, p=0.004) but not post (p=0.47). There were no significant differences between time points for delayed consumption in either exercise condition.
CONCLUSION: The results of the present study suggest that fasting exercise may contribute to an overall daily energy deficit despite higher post-exercise energy intake (at post30) compared to exercise after a small breakfast. Importantly, hypothetical food intake did not differ between the two conditions immediately after exercise, suggesting that consumption of a meal at that time might maximize the calorie deficit-related benefits of fasting exercise. More (longitudinal) research in larger samples is needed to determine whether fasting exercise is an adequate method for weight loss.

#### CARBOHYDRATE AVAILABILITY IN FEMALE ENDURANCE ATHLETES WITH SYMPTOMS OF RELATIVE ENERGY DEFICIENCY IN SPORT (RED-S)

GRAEFNINGS, M., LYSDAL FAHRENHOLTZ, I., KLUNGLAND TORSTVEIT, M., GARTHE, I., MELIN, A.

*DALARNA UNIVERSITY*

INTRODUCTION: Endurance athletes with high training loads and weight focus have increased risk of low energy and carbohydrate (CHO) availability. Sufficient CHO availability throughout the day is needed to provide substrate to e.g., muscles and hypothalamic-pituitary hormone production. The aim of this study was to investigate the dietary intake with special focus on timing of CHO intake in relation to training load in athletes with symptoms of Relative Energy Deficiency in Sport (RED-S).
METHODS: Female endurance athletes (n=12) [26 ± 4 years, BMI: 21 ± 2 kg/m2, training: 13 ± 4 hours/week], with symptoms of RED-S (Low Energy Availability in Females Questionnaire total score ≥ 8), and without disordered eating behavior were included. Athletes recorded their dietary intake (prospective weighed food records) and training for seven consecutive days. The type of activity and time spent in each intensity (I) zone (1-5) were recorded for each training session. I1 was defined as a workload of 60-72% of max heart rate (HR) (individual performance test), I2 as 72-82% of max HR, I3 as 82-87% of max HR, I4 as 87-92% of max HR and I5 as > 92% of max HR. The nutrient analysis program DietistNet, Sweden was used to assess dietary intake. CHO intake was furthermore analyzed for; key training sessions (high intensity, in the present study starting from I3)/≥120 min) and easy training sessions (all other sessions >30<120 min) as well as for training days; hard training days (≥ 1 key session) and light training days (all other days). Mean difference, 95% confidence intervals (CI) not including 0, and a paired student's t-test were used to determine differences between participants dietary and CHO intake and international sport nutrition recommendations.
RESULTS: The mean daily energy intake was 2821 ± 529 kcal. None of the participants met the recommended daily CHO intake based on individual training load [CI -1.7 (-2.4 to -0.9)], or CHO intake immediate after (1 g/kg) [CI -0.7 (-0.9 to -0.5)] or between (1 g/kg/h) [CI -1.2 (-2.0 to -0.4)] key training sessions. Only 27% fulfilled the CHO intake during (30-60 g/h) key training sessions [CI -15.2 (-29.1 to -1.3)] even though the minimum CHO recommendation of 30 g/h was used in the analyze. The daily CHO recommendations were more difficult to fulfill during hard compared to light training days (p=0.014). All participants met the international sport nutrition recommendations for protein (2.1 ± 0.6 g/kg/day vs. 1.2-2.0 g/kg/day) and fat (36.5 ± 7.2 E% vs. 25-35 E%).
CONCLUSION: In the present study, female endurance athletes with symptoms of RED-S did not match their total or timing of CHO intake in relation to training load according to international sport nutrition recommendations, while protein and fat intake was sufficient. Hence, these results indicate that focus on optimizing CHO intake is needed to prevent and treat RED-S.

**EVALUATION OF THE FUEL INTERVENTION – A RECOVERY PROGRAM FOR FEMALE ENDURANCE ATHLETES WITH RELATIVE ENERGY DEFICIENCY IN SPORT (RED-S)**

FAHRENHOLTZ, I.L., MELIN, A.K., GARTHE, I., HOLLEKIM-STRAND, S.M., WASSERFURTH, P., LOGUE, D., KOEHLER, K., MADIGAN, S., KLUNGLAND TORSTVEIT, M.

*UNIVERSITY OF AGDER*

INTRODUCTION: Relative Energy Deficiency in Sport (RED-S) is a complex syndrome describing health and performance consequences of low energy availability and is commonly reported among female endurance athletes. However, no systematic multicenter intervention study aiming to improve symptoms of RED-S exists. The aim of this study was therefore to develop and test a nutritional intervention study for female athletes with symptoms of RED-S and to investigate their experiences with the program.
METHODS: The Food and nUtrition for Endurance athletes – a Learning (FUEL) program was developed; a practice orientated 16-week sports nutrition intervention for female endurance athletes with risk of RED-S, and with low risk of eating disorders [Low Energy Availability in Females Questionnaire (LEAF-Q) score ≥8 + Eating Disorder Evaluation Questionnaire (EDE-Q) score <2.5]. The program consisted of weekly online sports nutrition lectures and individual consultations with an experienced sports nutritionist every other week. Athletes (n=34) from Norway (n=8), Sweden (n=18), Ireland (n=5), and Germany (n=2) were included, and all but one completed the intervention. One week after the intervention, 29 of the 33 athletes (88%) filled out a questionnaire consisting of 21 questions regarding their experience of participating in the FUEL program.
RESULTS: On a scale from 1 to 10, the overall satisfaction for participating in the FUEL project was 9.3 ± 0.9 and the level of satisfaction for the individual nutrition consultations was 9.4 ± 1.2. Athletes reported having experienced increased surplus energy (69%), improved mood (66%), improved food pleasure (62%), improved self-esteem (59%), improved enjoyment of training (48%), improved ability to cope with everyday stress (45%), and improved body satisfaction (45%) during the intervention. Few negative effects were reported; reduced surplus energy (n=1), decreased ability to cope with everyday stress (n=1), reduced enjoyment of training (n=1), reduced food pleasure (n=1), and reduced body satisfaction (n=1) during the intervention. The negative effects were reported by n=5 in combination with several positive effects and an overall satisfaction level of 10. Among the participating athletes, 73% found the level of the teaching videos appropriate, while 14% found the level too low and 14% found the level too high. Athletes' motivation on a 1-10 scale for participating in the individual consultations was 8.8 ± 1.3 and 7.7 ± 1.9 for online lectures and was unchanged during the intervention period for most (59%) athletes, although motivation for participating in the individual consultations increased during the intervention for 38% of the athletes. All responders replied that they would recommend the program to other female endurance athletes.
CONCLUSION: Based on the positive participant experiences, the FUEL program has potential for a wider range implementation among European female endurance athletes.

**SHORT TERM ENERGY RESTRICTION LOWERS RESTING METABOLIC RATE AND SLOWS POST-OCCLUSIVE FOREARM BLOOD FLOW RECOVERY RATE IN ACTIVE EUMENORRHEIC FEMALES.**

HUTSON, M.J., O'DONNELL, E., BLAGROVE, R.C.

*LOUGHBOROUGH UNIVERSITY*

INTRODUCTION: Amenorrheic exercising females demonstrate lower resting metabolic rate (RMR) and impaired vascular function compared to their regularly menstruating counterparts. While estrogen deficiency due to ovarian disruption has been linked with these perturbations, the independent effects of low energy availability (LEA), the primary cause of menstrual disturbances in female athletes, remain unclear.
METHODS: Healthy, regularly menstruating, active females (n=16, 23.3±4.2 years, BMI=22.5±2.2 kg·m2, VO2peak=46.7±8.6 ml·kg-1·min-1) completed two 3-day conditions of controlled energy availability: 15 (LEA) or 45 kcals·kg fat-free mass-1·day-1 (balanced energy availability, BAL). Each condition was assessed during days 1-9 of the menstrual cycle (low estrogen phase). RMR (indirect calorimetry), augmentation index normalised to 75 bpm heart rate (AIx@HR75, applanation tonometry), resting and peak forearm blood flow (FBF, venous occlusion plethysmography), and other variables of interest were measured at pre- and post-intervention. General estimating equations were used to create statistical models with condition and time as predictors. Interactions were examined and pairwise comparisons were made for pre- to post-intervention in each condition, $p<0.05$ was considered significant. Data are expressed as estimated marginal mean ± SE.
RESULTS: Significant interactions were observed for FFM ($p<0.001$), RMR ($p=0.033$), resting FBF ($p=0.005$), fifth post-peak to resting FBF ratio ($p=0.019$), and peak to fifth post-peak FBF ratio ($p=0.030$). FFM and RMR decreased by 0.9±0.2 kg and 111±33 kcals·day-1 in LEA (both $p<0.001$) and remained stable in BAL (both $p>0.148$), however, change in RMR was not correlated with change in FFM ($r=0.19$, $p=0.311$). Resting FBF decreased in LEA and increased in BAL, but neither change was significant in pairwise comparison (both $p>0.170$). In LEA, the fifth post-peak to resting FBF ratio increased by 0.25±0.10 ($p=0.019$), the peak to fifth post-peak FBF ratio decreased by 4.79±1.94 ($p=0.014$), and both ratios remained stable in BAL (both $p>0.428$). Change in fifth post-peak to resting FBF ratio was not correlated with change in resting FBF ($r=0.07$, $p=0.752$), and change in peak to fifth post-peak FBF ratio was not correlated with change in peak FBF ($r=0.19$, $p=0.345$). There were no significant interactions for heart rate, systolic and diastolic blood pressure, plasma volume, AIx@HR75, or peak FBF (all $p>0.177$).
CONCLUSION: These findings suggest that short term energy deficiency lowers resting metabolism and modulates vascular function in healthy eumenorrheic women, highlighting an independent role for LEA in these perturbations. These observations may have relevance in understanding the effects of LEA on metabolic and vascular health in female athletes presenting with menstrual disturbances.

### OP-AP15 Winter Sports

#### RELIABILITY OF CROSS-COUNTRY SKI SPECIFIC PERFORMANCE TESTS AND PHYSIOLOGICAL MEASUREMENTS IN HIGHLY-TRAINED SWISS CROSS-COUNTRY SKIERS

BUCHER, E., WEHRLIN, J., MILLET, G.P., STEINER, T.

*SWISS FEDERAL INSTITUTE OF SPORT MAGGLINGEN*

INTRODUCTION: Measurements of performance and physiological characteristics in elite athletes need to be reliable and valid, in order to differentiate between meaningful changes, trends and inherent test variability [1]. However, reliability measures for cross-country ski specific test protocols involving various sub-techniques are currently lacking or remain unreported. This study aimed to investigate the test-retest reliability of a comprehensive cross-country ski specific test battery involving endurance, sprint and neuromuscular testing procedures.
METHODS: Twenty-seven highly-trained cross-country skiers (17 male and 10 female, age: 22 ± 4 years, VO2max: 70.1 ± 4.5 and 58.8 ± 4.4 ml/kg/min, respectively) performed a test-retest protocol separated by two days in between. Performance testing consisted of a graded exercise test skating (GXT), a VO2max-test classic (VO2max-test), a 24-min double poling time-trial (24-min DP), a double poling peak velocity test (DP Vpeak), and a 1-min anaerobic capacity test skating (V2 1-min) all using roller skis on a treadmill. In addition, participants also performed a 20-s double poling peak power test on a ski ergometer (SkiErg DP) and explosive strength test for the upper body (UB-ST) on a custom-made device with light, medium and heavy load. Intra-class correlation coefficient (ICC), standard error of measurement (SEM), and coefficient of variation (CV) test statistics were calculated for all variables.
RESULTS: Time to task failure performance in the GXT and VO2max-test, time-trial performance in 24-min DP and V2 1-min, as well as peak velocity in DP Vpeak all demonstrated excellent ICC (0.96 – 0.99) and CV (1.0 – 2.3%). Measured absolute VO2max during the ski specific treadmill test displayed excellent reliability (ICC: 0.99; CV: 1.4%; SEM: 62 mL/min). Relative peak power during the SkiErg DP showed excellent reliability (ICC: 0.99; SEM: 0.18 W/kg; CV: 2.4%), whereas reliability measures for relative upper-body peak power in the UB-ST were acceptable (ICC: 0.89 – 0.95; SEM: 0.59 – 0.91 W/kg; CV: 5.0 – 7.9%) across all loads.
CONCLUSION: In highly-trained cross-country skiers, sport-specific aerobic and anaerobic performance tests on a treadmill using roller skis demonstrated high test-retest reliability, while neuromuscular performance measures for the upper body being somewhat less reliable. The current study provides comprehensive cross-country ski specific test-retest reliability measures for power and endurance based test protocols in various skiing sub-techniques. These findings allow athletes, coaches and scientists to accurately track performance changes between trials, which is a requirement in the elite athlete population with its small inherent performance variation.

#### ANNUAL TRAINING CHARACTERISTICS OF ELITE NORWEGIAN FEMALE CROSS-COUNTRY SKIERS AND BIATHLETES: THE FENDURA PROJECT.

OSBORNE, J.O., ENGSETH, T.P., WELDE, B., SANDBAKK, Ø., MORSETH, B., SOLLI, G.S., THOMASSEN, T.O., TAYLOR, M., ANDERSSON, E.P.

*UIT - THE ARCTIC UNIVERSITY OF NORWAY*

INTRODUCTION: Periodization of training is a systematic regulation of training content through the manipulation of exercise session duration, intensity, frequency, and modality to achieve optimal performance at the appropriate time. Several studies have previously reported the annual training periodization of elite, endurance winter-sport athletes; however, this research has primarily used small samples sizes (e.g., n<20), or not included female athletes. Therefore, the present study aimed to describe the annual training characteristics of elite female Norwegian cross-country skiers and biathletes, and to compare athletes of different performance-levels.
METHODS: A total of 89 elite, female cross-country skiers and biathletes (21 ± 2.8 y; 62.5 ± 4.6 kg, 628 ± 109 training h/year) systematically recorded all day-to-day training session data in an online training diary for the 2020-21 season. Variables collected included duration and frequency of endurance training sessions distributed across three intensity zones (low intensity [LIT]; moderate intensity [MIT]; and high intensity (HIT]), and self-reported session intensity (Borg CR10 scale). Data were grouped into five training phases: general preparatory 1 (GP1; May – July [13 weeks]), general preparatory 2 (GP2; July – October [13 weeks]), specific preparatory (SP; October – December [9 weeks]), competitive period (CP; December – March [14 weeks]), and recovery (April [4 weeks]). Data were analysed with linear or cumulative logit-link mixed models and presented as mean ± standard deviation or [95% confidence intervals].
RESULTS: Over the annual season, athletes trained 634 ± 171 h across 412 ± 89 sessions. The proportion of time spent as LIT was relatively constant (~90%) across all phases and only rose during recovery. In contrast, the proportion of MIT was initially elevated during GP1 (5.2% [4.6-5.8%]) and then decreased in GP2, while HIT started at a lower proportion in GP1 (4.2% [3.6-4.7%]) and increased in subsequent phases (p=.001-.008), peaking during CP (5.6% [5.1-6.2%]). Session intensity was constant across GP1 and GP2 but then decreased for SP and CP (p=.011-.032). National-team athletes performed relatively more MIT than the non-national team athletes during the competitive phase (4.8% [4.2-5.4%] vs 3.6% [2.5,4.6%]; p=.039), although there was no difference between the groups when presented as total MIT duration across the phase (p=.136).
CONCLUSION: This sample of elite female cross-country skiers and biathletes reported a high annual training duration (600+ hours/year). The majority of training was completed as LIT and this proportion was relatively constant throughout the season. Periodization between training phases appeared to be regulated via a shift from MIT to HIT over the season.

#### THERMOREGULATORY RESPONSE TO EXERCISE IN COLD ENVIRONMENT MEASURED AT DIFFERENT BODY PARTS IN ELITE BIATHLETES

BLOKKER, T., BUCHER, E., STEINER, T., WEHRLIN, J.P.

*SWISS FEDERAL INSTITUTE OF SPORT MAGGLINGEN: EIDGENOSSISCHE HOCHSCHULE FUR SPORT*

INTRODUCTION: Extreme cold conditions have a negative impact on endurance exercise performance such as in biathlon, where muscle as well as shooting performance, due to a decrease in manual dexterity, is affected. Hence, it is paramount that biathletes adopt clothing

strategies preventing excessive cooling during downhill sections and on the shooting range, while avoiding excess heat production during the skiing bouts. The purpose of the present study was to measure the thermoregulatory response at different body parts during exercise in a cold environment in biathletes.
METHODS: Thirteen Swiss elite biathletes (6 females, 7 males; age: 27 ± 4 years) performed two skiing exercise bouts (men: 4.12 km; women: 3.49 km) lasting approximately 15 min in the skating technique on two consecutive days at about 78 ± 4 % of maximal heart rate. They were wearing a race suit in accordance to skiing conditions (ambient temperature: -3.7 ± 2.3 °C; relative humidity: 92.9 ± 6.3%). Heat flux, core and skin temperature were measured with a synchronized sensor-system (CORE, greenTEG AG, Rümlang, Switzerland) placed on the thigh, back, anterior and lateral thorax throughout the entire bout. The subjective perceived rate of thermal comfort (SUBJ) was assessed for the torso, arms, hands, legs, feet, head, neck and whole-body via a visual analog 7-point Likert-scale [1] in winter clothing (REF), right before (PRE) and after exercise (POST).
RESULTS: Heat flux measurements during the warm-up demonstrated differences ($p < 0.001$) between sensor locations, with the thigh showing the highest heat loss (344 ± 37 kJ/m2), followed by the back (269 ± 56 kJ/m2), the lateral thorax (220 ± 47 kJ/m2), and the anterior thorax (192 ± 37 kJ/m2). While core temperature slightly increased from 37.0 ± 0.2°C to 37.5 ± 0.2 °C (NS), skin temperature decreased for all measured body parts ($p < 0.001$). However, the thigh skin temperature decreased to a larger extent (-7.5 ± 1.2 °C) compared to the skin temperature on the back (-2.8 ± 1.0 °C), the anterior thorax (-4.4 ± 2.0 °C) and the lateral thorax (-2.5 ± 1.5 °C). From PRE to POST, SUBJ at the hands decreased from 0.51 ± 0.9 a.u. to -0.53 ± 1.8 a.u. ($p < 0.01$). Although SUBJ for other body parts did not change significantly from PRE to POST, a large inter-subject variability was measured, in particular for the hands, head, and whole-body.
CONCLUSION: During moderate intensity cross-country skiing in cold environment, heat flux in the lower extremities appears to be higher compared to the upper body, resulting in a significant drop in skin temperature and potential negative impact on performance.

**AUTOMATIC FRAME RECOGNITION FOR VIDEO TECHNIQUE ANALYSIS IN CROSS-COUNTRY SKIING USING CONVOLUTIONAL NEURAL NETWORKS**

HOLLAUS, B., MIRA, A., FUDEL, R.

*MCI INNSBRUCK*

INTRODUCTION: Professional sports is data-driven. Talent acquisition, optimal training, performance analysis and more rely heavily on data. Technique analysis in Cross-Country Skiing (XCS) is no exception. Papers from [1-3] analyzed the motion and classified techniques of XCS athletes based on inertial measurement unit data. The mandatory sensor nodes make the approach unsuited for everyday XCS training. Therefore, most XCS teams implement technique analysis by filming the athletes. However, extracting the relevant frames manually is inefficient. To make the process more functional, this paper provides a proof of concept that automizes the common video analysis approach employed by XCS teams.
METHODS: A common approach is to extract five key frames from lateral or frontal training videos, according to a reference motion pattern for the respective technique. The five patterns for skating 1-1 would be 1) the initial pose, just before the 2) pole plant followed by the 3) push, 4) pole release and the 5) leg push. To identify these five patterns within the video, a sequence of algorithms have been set up. Each frame of a video is analyzed by Yolov3 [4] to extract the athlete within the respective frame. The result is a bounding box and its coordinates in each frame. After cutting the frame using the bounding box the feature extraction algorithm open pose [5] is applied to extract 25 keypoints of the athletes' pose. Therefore, each frame delivers the bounding box, its coordinates, and key point information. After concatenating the data of a frame into a vector, a trained convolutional neural network is able to predict whether the frame is likely to be of pattern 1, 2, 3, 4, 5, or none of them. Since this is done for all frames within the video, the algorithm is able to pick the five most suitable frames for the five patterns. The network was trained according to videos, which were already labeled by coaches.
RESULTS: The sequence of algorithms performed well on the test dataset of frontal skating 1-1 training video with an accuracy of 87.18% for pose 1, 59.15% for pose 2, 81.43% for pose 3, 85.26% for pose 4, 97.09% for pose 5 and 73.86% for all poses except 1 to 5. The lateral test dataset has led to accuracies of 82.65% for pose 1, 86.21% for pose 2, 77.5% for pose 3, 85.87% for pose 4, 86.42% for pose 5 and 68% for all poses except 1 to 5.
CONCLUSION: Using a neural network approach to classify the poses within frames in XCS leads to highly accurate classifications for frontal and lateral videos. As an exception pose 2 was often mispredicted in frontal videos. This can be explained by the missing information on the pole joint positions. If pole joints were to be included in the feature extraction, a higher accuracy could be expected.

### OP-BM09 Dynamic and static balance

**EVALUATION OF ANKLE DYNAMIC BALANCE AND MOBILITY THROUGH STAR BALANCE TEST AFTER TOTAL ANKLE REPLACEMENT**

SANTILLOZZI, F., ZINNO, R., BARONE, G., DI PAOLO, S., BENEDETTI, M.G., VOCALE, E., CARAVELLI, S., MASSIMI, S., MOSCA, M., BRAGONZONI, L.

*UNIVERSITY OF BOLOGNA*

INTRODUCTION: Ankle osteoarthritis (AO) is a leading cause of chronic disability in a wide range of the world's population. Frequently, AO is secondary to traumas, and it is associated with obesity, metabolic disease, chronic inflammatory joint diseases, septic arthritis, and anatomical pathological variations. In case of no improvement of conservative management, surgical treatment may be necessary. Total ankle replacement (TAR) is a treatment for end-stage AO which aims to reduce pain and restore ankle function i.e. range of motion and mobility. However, the functional improvements of TAR are still debated. The Star Execution Balance Test (SEBT) is proven to be useful for

screening deficits in dynamic postural control among groups with lower extremity conditions. SEBT allows to assess strength, flexibility, neuromuscular control, core stability, range of motion, balance, the interaction between proprioception, and joint stability. The aim of this study is to evaluate dynamic balance and ankle mobility differences between side-to-side pre-and post-TAR. We hypnotize that, after the implantation of the ankle prothesis, patients will improve the outcomes of SEBT.
METHODS: Eighteen patients (mean age = 60.3±10.1) on the waiting list for total ankle arthroplasty were enrolled in this study. All patients were evaluated before and at minimum 9 months after the surgery. Each patient performed the short version of SEBT, which consist of 3 directions to reach with one foot: anterior (A), postero-medial (PM), and postero-lateral (PL). The means of tree trials for each direction were reported. All directions were reached first with the non-operated leg (NoOp) and then with the operated leg (Op). The outcome was normalized upon leg length ((distance cm/leg length cm) x 100). The pre-post surgery and the side-to-side difference in SEBT scores in A, PM, and PL directions were calculated pre- and post-TAR and compared through a paired sample t-test ($p<0.05$).
RESULTS: Considering the pre- and post- surgery evaluation of the replacement ankle, all SEBT have improved (A pre=57.3, post=58.1, $p>0.05$; PM pre=71.9, post=75.3, $p>0.05$; PL pre=53.1, post=60.6, $p<0.05$). Moreover, the outcomes of the healthy leg improved, even though the results were not statistically significant ($p>0.05$). The mean difference between side-to-side pre-and post-TAR were 3.6% [-1.3-8.5], 2.0% [-3.0-5.3], and 5.9% [2.2-9.5] for A, PM, and PL respectively. A significant reduction in side-to-side difference was found for PL direction ($p=0.004$, Cohen's $d=0.79$). No significant differences were found in A and PM directions ($p>0.05$).
CONCLUSION: The results of the study showed that the SEBT outcomes in patients with TAR improved after the implantation of the prosthesis. Indeed, the side-to-side difference between the Op and NoOp leg decreased, showing an improvement in dynamic balance and mobility. The ankle prosthesis allows to partially restore symmetrical levels of dynamic balance between Op and NoOp legs measured through the SEBT.

### THE KINEMATICS OF THE FOOT DURING STATIC BALANCE: A SIX-SEGMENT FOOT MODEL APPROACH

FENNEN, L., DUBBELDAM, R., WAGNER, H.
*WESTFÄLISCHE WILHELMS-UNIVERSITÄT MÜNSTER*

INTRODUCTION: Understanding the foot's motion during different types of exercises is crucial when investigating balancing abilities and processes important for performance and particularly rehabilitation [1,2]. Balancing is a key ability in posture and motion. However, limited previous research investigated the movement of multiple foot segments during static balancing. In order to understand the role of foot segments in stance and locomotion and the implementation of these findings in rehabilitation and treatment, a kinematic analysis of the foot segment's motion during static balancing tasks was performed.
METHODS: 17 subjects (M(age) =24 years, SD = 5) performed three different balancing tasks captured using a 3D kinematic motion capture system from Qualisys AB (Göteborg,
Denmark). The Ghent Foot Model with 21 markers was used, dividing the foot in six kinematic segments [1]. The tasks increased in difficulty level from standing on two feet, to a one foot stance and a one foot stance with eyes closed. The kinematic analysis included joint rotational angles on all three movement planes and cumulative range of motion (cum ROM) defining the amount of motion over time using an individualize MATLAB script (The Math Works Inc., Natick, USA). The Ghent Foot Model divides the foot in the six joints: Rearfoot to tibia (RF_T), midfoot to rearfoot (MF_RF), medial forefoot to midfoot (MFF_MF), lateral forefoot to midfoot (LFF_MF), lateral forefoot to midfoot (LFF_MFF) and hallux to medial forefoot (H_MFF) . The mean CumROM on each anatomical plane was first calculated for each subject and then for each joint. A linear mixed model was used to compare segments motion.
RESULTS: The analysis of the motion of the foot segments over time (CumROM) during the three balancing tasks with increasing difficulty of all joints on all three anatomical planes show significantly different ($F_{20, 1324}= 5.94$, $p < 0.001$). Furthermore, high values for the CumROM are present within the frontal plane of midfoot and both medial and lateral forefoot joints, demonstrate high motion within the forefoot section.
CONCLUSION: The results indicate that during the static balancing anatomical structures represented as the midfoot and medial and lateral forefoot in the Ghent Foot Model have relatively high flexion and extension as well as inversion and eversion CumROM values. Potentially indicating that these structures are of high importance during the execution of static balancing tasks. The current findings indicate special importance of these areas of the feet within therapy concepts after foot and ankle injuries. Further research is needed to support this indication.

### THE RELATIONSHIP BETWEEN BALANCE ABILITY AND RATE OF FORCE DEVELOPMENT OF TOE GRIP FORCE.

DOI, N.
*KYOTO UNIVERSITY*

INTRODUCTION: The foot is the only body part in contact with the ground. Among them, the toes have been suggested to be associated with the stability of the posture during standing and walking. Currently, toe grip force is used as an evaluation of toe muscle strength, that is associated with dynamic and static balance ability. However, the relationship between balance ability and toe grip force is not clear. One of the factors is thought to be related to the type of muscle strength. Most of the previous studies have measured maximum voluntary contraction (MVC) as an outcome for toe grip force. However, as an evaluation of muscle strength, it is recommended to evaluate not only MVC but also Rate of Force Development (RFD), which is an index of instantaneous muscle strength exertion. RFD is a calculation of the gradient of muscle strength change at regular time intervals from muscle exertion. It has been reported that RFD is important for the reaction to unexpected COP sway. Therefore, the purpose of this study was to examine the relationship between balance ability and RFD of toe grip force.
METHODS: This study targeted 25 healthy young men and 25 healthy young women (n=50). Those with orthopedic disease on the feet were excluded. The balance ability was measured by dividing the total trajectory length (mm), rectangular area (mm2) of the center of pressure (COP) when standing on one leg for 40 sec. Toe grip force was measured by dedicated device. The Pearson correlation or Spearman's rank correlation analysis was used to analyze the relationship between balance ability and RFD of toe grip force.
RESULTS: A significant negative correlation was observed between RFD of toe grip force and the rectangular area of COP (0-50ms：$r=-0.43$, $p<0.01$; 0-100ms：$r=-0.36$, $p<0.01$; 0-200ms：$r=-0.34$, $p=0.01$). No significant correlation was observed in the total trajectory length and RFD of toe grip force.

CONCLUSION: This study suggested that there is relationship between RFD of toe grip force and the rectangular area of COP. It is conceivable that the RFD of toe grip force is instantly exerted to control the center of gravity before COP sway significantly when standing on one leg. In addition, the shorter the time from the start point of muscle strength, the stronger the correlation tends to be. It has been reported that RFD is strongly associated with twitching of muscle fibers in the early RFD within 50ms of muscle exertion, and that late RFD after 90ms after muscle exertion is strongly associated with maximum muscle strength. It is considered that the higher the early RFD, the more motor units could be mobilized and the sway of the center of gravity was suppressed. Therefore, it was considered that the subjects with high RFD of toe gripping force had a small rectangular area of the center of gravity sway when standing on one leg.

**RATE OF TORQUE DEVELOPMENT AND CONTRACTILE PERFORMANCE DURING ANKLE PLANTAR FLEXION IN ELITE ATHLETES**

HOLLVILLE, E., NORDEZ, A., GIROUX, C., HEGYI, A., DOREL, S., LACOURPAILLE, L., RABITA, G., GUILHEM, G.

*FRENCH INSTITUTE OF SPORT*

INTRODUCTION: The ability to generate high force levels in limited time (i.e., rate of torque development, RTD) is key factor of performance in sprint running. As an example, a world-class athlete generates horizontal force over 10 N/kg in less than 400ms during sprint start (1). While neural drive has been reported as the key determinant of early RTD (2), muscle-tendon interactions of the medial gastrocnemius (MG) seem to contribute to later phases of RTD (3). However, very little is known about RTD determinants regarding elite athletes. The aim of this study was to investigate elite athletes' ability to rapidly generate high force levels in relation to the contractile characteristics of plantar flexors.
METHODS: 57 French elite athletes (32 track athletes, 22 rugby players, 3 bobsledders; 54% female; 1.75 ± 0.08 m; 70.5 ± 11.3 kg; including Olympic, World and European medallists) were tested. All participants completed 2-3 explosive force production trials "as fast and hard as possible" (3). Rate of torque development (RTD) was calculated over sequential windows (RTD 0–50ms, RTD 50–100ms, RTD 100–150ms and RTD 0-200ms). MG fascicle dynamics was assessed during the first 200ms using an ultrafast ultrasound scanner (sampling rate = 1000 Hz). MG fascicle shortening amplitude as well as mean and maximal fascicle shortening velocity were calculated.
RESULTS: Rate of torque development at each sequential window was 437 ± 159 N.m/s [0-50ms], 1000 ± 323 N.m/s [50-100ms], 682 ± 223 N.m/s [100-150ms], 620 ± 165 N.m/s [0-200ms] (group mean ± SD). MG fascicles shortened throughout the first 200ms of contraction by 1.1 ± 0.4 cm, and maximal shortening velocity was -10.8 ± 3.7 cm/s and peaked at 50ms on average.
CONCLUSION: This study brings novel insights about elite athletes' explosive force ability with exceptionally high rate of torque development, two-fold greater than those reported in healthy individuals using the same method (3). We also found that MG fascicle shortening velocity peaked on average around 50ms in elite athletes in comparison to around 100ms in healthy individuals. This clearly demonstrates the high explosiveness ability of elite athletes. Specifically, not only neural but also mechanical factors determine early RTD and thus sprint propulsion in elite athletes.

### IS-SH01 Creativity, physical education and sport: fostering developmental trajectories

**FREE PLAY AND ALTERNATIVE SPORTS THROUGH PARADOXES AND OPPORTUNITIES**

BONDI, D.

*UNIVERSITY OF CHIETI - PESCARA, ITALY*

Creativity can be conceived as freedom in the limits of rules/constraints. It represents a prominent ability of individuals, dynamically arising from a process, occurring in a context, and resulting into a novel product. In particular, creative motor actions emerge from adaptive movement variability while exploring the environment, eventually optimized by manipulating constraints. Once a child develops fruitfully motor creativity, its retention becomes easier. Considering creative moving and playfulness are interconnected, we should strive for a virtuous loop connecting playful activities and creativity. Play needs to be discussed with an interdisciplinary criticism encompassing pedagogy, kinesiology, neuroscience, psychology, philosophy, anthropology, sociology, medicine, and ethology. This complex approach moves inside the areas of creativity, human behaviour, and development. Into this framework, free play can emerge as an effective tool for favoring creativity, both in physical education and sport. However, aiming to this effect, free play should be fun, voluntary, challenging, relaxed, exaggerated in forms, spontaneous, pleasant, flexible, not stereotyped, led by intrinsic motivation and supported by reward (Bondi & Bondi, 2021). Therefore, we should prioritize to enrich the environment, tutoring, interacting, providing a non-threatening and non-controlling environment, and setting stress-free conditions. Moving over, through unconventional creative expression, the sense of freedom prospers inside the public spaces. Therefore, lifestyle (or alternative) sports, as playful physical activities opportunities, are fruitful resources for open and flexible curricula in physical education and sport. These aesthetic and functional forms of self-exploration, as types of creative free play, contrast to conventional ways of moving and interacting with people and places. As an example, referring to parkour city itself becomes an open-ended toy, and material obstacles become possibilities for developing creative outcomes. Linking the design of urban spaces for physical movements and outdoor sports with imagination and personal skills, these unconventional playful sports may be used as inherently educational disciplines. Building alternative sports-friendly environment could convey social benefits, promote motor competencies, and encourage active lifestyle.

### EMPOWERING CREATIVE EDUCATION AND SPORTS CREATIVITY

LEAL DOS SANTOS, S.

*UNIVERSITY OF TRÁS-OS-MONTES AND ALTO DOURO*

Creativity is one of the essential skill sets for shaping the possibilities of 21st-century and is a key feature of teaching and coaching that is influencing worldwide educational and sports policies. The goal of education should be the nurturing of creative young people who are sufficiently skilled to adjust constantly to new challenges and find innovative and original solutions, that would satisfy the needs of fast changing society. Likewise, sports have emerged as a suitable environment to ignite creativity. In this field, creativity should be understood as the process of perceiving, exploring, and generating novel affordances (opportunities for action) within a given context (training session or formal game) considering the importance of contemplating the experiential process (Rasmussen, et al., 2019). Furthermore, evidence of implementing sports-creativity training programs to cultivate overall creativity is growing. Therefore, this presentation will be centrally focused on the Skills4Genius program tenets (Santos et al., 2017), grounded in the 'Creativity Developmental Framework' assumptions (Santos et al., 2016). The Skills4Genius is a sports creativity-based intervention intended to develop social and emotional skills, such as creative thinking, as well as in-game creativity. Besides, related research supports an interplay between thinking and sports creativity revealing commonalities in the underlying processes responsible for driving creative thinking and children's novel behaviors on the field (Santos et al., 2017; Santos & Monteiro, 2020). The Skills4Genius has been implemented around 2000 Portuguese primary school-aged children and is supported by the Calouste Gulbenkian Foundation, within the Gulbenkian Program for Knowledge, an initiative that establishes one of the most extensive European networks of educational innovation in partnership with OECD. This presentation will be filled with fresh creative thinking strategies and a set of constructivist models to support Physical Education teachers and coaches in order to offer a supportive environment for creativity to thrive. Finally, it will be discussed the potentials and barriers related to the design for creativity.

### A COMPLEX SYSTEMS APPROACH ON CREATIVE BEHAVIOUR IN SPORT AND MOVEMENT-BASED PRACTICES

TORRENTS, C.

*UNIVERSITY OF LLEIDA*

Based on recent research under the complex dynamical systems approach, this presentation aims to explain how constraints can release degrees of freedom in sport and movement-based practices. It also aims to clarify the process of emergence of creative behaviors taking into account the interrelatedness and nesting of constraints acting on the system (Balagué et al. 2019; Torrents et al. 2021a; Torrents et al. 2021b). We base it on the formation of spontaneous multiscale synergies emerging in complex living systems when interacting with cooperative/competitive environments. This is especially important in our domain, as the specificity of motor creativity is conditioned by the time scale where actions emerge, as well as by the interaction with other persons (teammates and opponents).

It will be discussed how constraints form boundaries around the exploration of certain action possibilities, while allowing the emergence of other exploration possibilities. These actions emerge from the nonlinear interaction between the intrinsic dynamics of the creator (individual or team) and environmental constraints. Moreover, self-interaction and co-adaptive loops, as well as the interaction of all constraints acting on the system at different time scales, allow the emergence of creative behaviour. Some team sports and contemporary dance examples related with the manipulation of task constraints from our lab will be presented (Cantón et al. 2021; Lacasa et al. under review; Torrents et al. 2015).

## OP-MH09 Measurement of performance in different populations

### REPEATED MAXIMAL EXERCISE TESTS OF PEAK OXYGEN CONSUMPTION IN PEOPLE WITH MYALGIC ENCEPHALOMYELITIS/CHRONIC FATIGUE SYNDROME: A SYSTEMATIC REVIEW AND META-ANALYSIS

FRANKLIN, J., GRAHAM, M., ATKINSON, G.

*TEESSIDE UNIVERSITY*

INTRODUCTION: We aimed to synthesise studies in which the test-to-retest (24 h) changes in VO2 and work rate have been compared between people with Myalgic Encephalitis/Chronic Fatigue Syndrome (ME/CFS) and controls.
METHODS: Seven databases (CINAHL, PubMed, PsycINFO, Web of Knowledge, Embase, Scopus and Medline) were searched. Included studies were observational studies that assessed adults over the age of 18yrs with a clinical diagnosis of ME/CFS compared to apparently healthy controls. The methodological quality of included studies was assessed using the Systematic Appraisal of Quality for Observational Research critical appraisal framework.
RESULTS: The pooled mean differences in test-to-retest changes in VO2peak and VO2 at the anaerobic threshold were small and not clinically relevant at -1.1 (95%CI -3.3 to 1) ml.kg-1min-1 (Tau = 1.6 ml.kg-1min-1) and -1.83 (95%CI -3.98 to 0.32) ml.kg-1min-1, (Tau = 1.4 ml.kg-1min-1). There was a greater decrease in the pooled mean difference in peak work rate (5 studies), measured at retest, in ME/CFS compared to controls by -8.55 (95% CI -15.38 to –1.72, Tau =4.4) W. The pooled mean difference in work rate at anaerobic threshold (4 studies) measured at retest was greater in ME/CFS compared to controls by -21 (95%CI -38 to -4, tau = 9.8) W. The effect size for this difference was large (d = -0.95) providing evidence that WR at AT effectively discriminates between ME/CFS and controls. The 95% prediction interval was -62.4 to 21.1 W, indicating a high degree of uncertainty. The likelihood that a future study in a similar setting would report a difference in work rate at anaerobic threshold which would exceed a minimal clinically important difference (10 W) is 78% (95%CI 40% to 91%).
CONCLUSION: Synthesised data indicate that test-retest reductions in work rate at peak and at anaerobic threshold may provide a possible objective marker for the presence of ME/CFS.

### CAN SUPRA-MAXIMAL TEST BE USED TO VERIFY MAXIMAL OXYGEN UPTAKE IN ADULT WITH OBESITY? A COMPARISON BETWEEN MAXIMAL EXERCISE TEST ON TREADMILL VS. CYCLE ERGOMETRY

INTRODUCTION: People with obesity often have below average VO2max values compared to normal levels for their age group and sex. Additionally, many do not show the VO2 plateau at exhaustion, which is the primary criterion of attainment of VO2max.
Aims: 1) compare VO2max and the present of plateau using a maximal graded exercise test (GXT) on bike and treadmill ergometers, between obese (OB) and normal weight (NW) individuals. 2) Use a supramaximal exercise test (SMT) to verify that peak O2 uptake in GXT reflects “true” maximal VO2max in the absence of a VO2 plateau.
METHODS: METHODS: 34 sedentary participants volunteered to participate; 17 NW (median BMI 22.1 kg/m2 (20.9-23.3)) and 17 with obesity (median BMI 34.6 kg/m2 (31.4-36.3)). During 2 laboratory sessions, participants completed either a GXT on a cycle ergometer or on a treadmill in random order. 10 minutes post GXT a 2 min SMT to verify O2 consumption values was performed. SMT involves a constant load, one phase higher than the last load reached on the treadmill (Bruce-Ramped Protocol), or 10% higher than the maximum Watt reached on cycle ergometer. VO2max from GXT was considered as verified if peak VO2 in the SMT was <5% higher than that attained in GXT. O2 consumption (VO2), respiratory exchange ratio (RER), maximal heart rate (Max HR) and rate of perceived exertion (RPE) were recorded at the end of the GXT.
RESULTS: Peak VO2 ml /kg /min at GXT was higher in NW compared to OB on treadmill (NW-37.45±7.95 ml/kg /min; OB-29.05±4.82 ml/kg /min p<0.001) and bike (NW-29.26±7.71 ml /kg /min; OB-22.26±3.50 ml /kg/min p<0.001). 56% of participants reached VO2 plateau on the treadmill vs. 17% on the bike, with no significant differences between groups. Max HR and RPE were higher on Treadmill than bike (F=21.86 p<0.0001 and F=14.54; p=.0006 respectively), in both groups with no significant differences between groups.
Of those not reaching a plateau true VO2max was verified by SMT in 38% tested by bike and 63% tested by a treadmill in the NW group, and in the OB group 56% on the bike and 73% on the treadmill, were verified.
CONCLUSION: Obese participants had lower aerobic fitness levels than the NW sedentary group when VO2 was normalized to body weight. However, no significant differences in reaching plateau were observed between the groups. Fewer participants reached plateau on the bike than on the treadmill. In the absence of a plateau phase, the SMT verified VO2max determined by the GXT in 68% and 48% of our cohort tested on treadmill and bike, respectively. These findings suggest that incorporation of a SMT to verify VO2max provides additional data about the maximal aerobic capacity and can be performed using a treadmill or bike.

### LONGITUDINAL DEVELOPMENT IN OXYGEN UPTAKE IN 6–12-YEAR-OLD NORWEGIAN CHILDREN. THE HEALTH-ORIENTED PEDAGOGICAL PROJECT (HOPP).

MAMEN, A.1, BUER, J.2, STEENE-JOHANNESSEN, J.2, FREDRIKSEN, P.M.1

*1 KRISTIANIA UNIVERSITY COLLEGE, 2 NORWEGIAN SCHOOL OF SPORT SCIENCES*

INTRODUCTION: Enhanced aerobic capacity is associated with improved health and reduced mortality in adulthood. Aerobic capacity is best reflected by V̇O2peak, and the level of V̇O2peak is traceable from childhood to adulthood. Mapping of V̇O2peak in childhood is therefore important for detecting deteriorations at an early stage and initiate interventions to prevent disease in adulthood. The purpose of the present study was to evaluate the development in V̇O2peak in 6–12-year-old Norwegian children.
METHODS: Six-year-old students (n=451), included in the Health-Oriented Pedagogical Project, was invited to an annual V̇O2peak test for six years. V̇O2peak was tested using an incremental treadmill test with a maximal speed of 10 km·h-1 and a maximal inclination of 16%. In the first year, the metabolic cart was a K4b2, after that a K5 was used, both from Cosmed sri, Rome, Italy. The K4b2 used the breath-by-

breath method, K5 a (micro) mixing chamber. A mixed linear model split by sex and grades as fixed effects were performed to evaluate the development in V̇O2peak.
RESULTS: The development of aerobic power from 6- to 12-year age differed according to the expression of V̇O2peak used. Absolute V̇O2peak increased from 1.09/1.06 L·min-1 to 1.93/1.84 L·min-1 (boys/girls). The yearly increase tapered off from 11th to 12th year. V̇O2peak relative to body mass increased until age 8: from 47.1/44.3 ml·kg-1·min-1 to 52.9/48.9 ml·kg-1·min-1. At age 12, the results were close to the results at age 6: 46.9/44.0 ml·kg-1·min-1. Allometrically scaled oxygen uptake increased from 132.6/125.4 ml·kg-0.67·min-1 at 6-year age to 169.3/158.6 ml·kg-0.67·min-1 at age 11. The results at age 12 were 157.7/150.2 ml·kg-0.67·min-1. Boys and girls differed significantly on relative and allometrically scaled oxygen uptake from 6 to 11-year age. Absolute oxygen uptake differed significantly for boys and girls only at age 10 and 11 year. When scaling oxygen uptake with fat-free mass, the results at age 12 year was a little higher for girls: 57.3/57.6 ml·FFMkg-1·min-1.
CONCLUSION: When describing the development of cardiometabolic fitness in children, the choice of units has importance. Expressing oxygen uptake in absolute form, as ml (or L) pr. minute will give another impression of the development than relating oxygen uptake to different conditions of body mass. If sex differences are important to document, allometric scaling seems to be appropriate. To describe the bodily growth, oxygen uptake should not be related to body mass in any form. The reason for presenting children's fitness should thus guide the decision of which units to use.

### EFFECT OF SLEEP BEHAVIOR ON VO2MAX CAPACITY IN A SAMPLE OF ACTIVE YOUNG SUBJECTS

CASTELLI, L.1, GALASSO, L.1, CIORCIARI, A.1, MONTARULI, A.1,2, ROVEDA, E.1,2, ZIMMER, P.3

*1: UNIVERSITY OF MILAN: UNIVERSITÀ DEGLI STUDI DI MILANO; 2: IRCCS ISTITUTO ORTOPEDICO GALEAZZI; 3: TU DORTMUND UNIVERSITY*

INTRODUCTION: In addition to being an essential physiological process in humans, sleep is acknowledged as an important factor in influencing physical performance. Sleep deficiency, also linked to higher self-perceived fatigue, could negatively affect physical performance, especially endurance performance [1]. Notwithstanding this background, VO2max has been poorly investigated in relation to sleep quality [2]. The present study aims to shed light on this relationship in a sample of active young subjects.
METHODS: Ninety-six university students (males 54.2%; 21.5 ± 2.9 yrs) were assessed for sleep quality, self-perceived fatigue and motivation by the Pittsburgh Sleep Quality Index (PSQI) and two visual analogue scales (VAS), respectively. Subsequently, they completed an incremental exercise test on a bicycle ergometer. Analyses were performed separately for males and females. Based on PSQI categorization, VO2max, self-perceived fatigue and motivation were compared between good and bad (PSQI score 5 respectively) sleepers and longer and shorter sleepers (sleep duration >/<7.5 hours respectively), while regression analysis defined the predictors of VO2max.
RESULTS: In the male sample, good sleepers and longer sleepers reported higher VO2max (53.9 ± 8.4 vs 49.0 ± 14.1 ml.kg-1.min-1; 54.2 ± 10.9 vs 50.0 ± 8.4 ml.kg-1.min-1) and self-perceived motivation (7.1 ± 1.6 vs 6.3 ± 2.1 a.u.; 7.2 ± 1.5 vs 6.4 ± 2.1 a.u.), but only self-perceived fatigue was significantly lower in good sleepers (2.3 ± 2.1 a.u.) compared to bad sleepers (3.6 ± 1.7 a.u.; p = 0.04). The regression analysis showed sleep (β = - 0.3, p = 0.02) as predictors of VO2max. There were no significant differences between good and bad sleepers and different sleep durations in the female sample. Self-perceived fatigue (β = -0.4, p = 0.03), and not sleep, was a significant predictor of VO2max in females.
CONCLUSION: Sleep seems to affect differently the VO2max the performance between males and females. Even without statistically significance, good and long sleepers tend to perform better and suffer significantly less from fatigue. Furthermore, sleep accounts for 20% of the variance in males, indicating a relevant factor for cardiovascular performance. In females, physical performance seems more affected by fatigue rather than sleep. Probably, taking into account the phase of the menstrual cycle, a different role of sleep on VO2max could have been highlighted [3].

### ASSOCIATION OF EARLY RFD DURING A FUNCTIONAL TASK AND AN ISOMETRIC LEG EXTENSION WITH GAIT SPEED AND BALANCE FROM THE TOLEDO STUDY FOR HEALTHY AGING IN MIDDLE AGE

GUTIÉRREZ REGUERO, H.

*UNIVERSIDAD DE CASTILLA Y LA MANCHA*

INTRODUCTION: The rate of force development (RFD) is positively associated with athletic performance in young people and physical function in older people (1). Furthermore, RFD provides information on the structural and neuromuscular features of skeletal muscle and its functional state (2). RFD is most frequently evaluated using a force plate in traditional exercises such as knee extension, squat or leg press. However, it has been also evaluated during the sit-to-stand (STS) task (3). In this sense, it is currently unknown whether RFD during the STS task (RFD-STS) is more strongly associated to physical performance during other functional tasks as the leg press exercise (RFD-LP) in middle-aged adults.
METHODS: A total of 78 middle-aged adults participating in the Toledo Study for Healthy Aging in Middle Age (TSHA-ma) (32 men and 46 women; 55.3±1.9 years old) took part in this investigation. Early RFD (at 100 ms) was assessed during the first repetition of the 5-rep STS test. On a separate occasion, early RFD was also assessed during a unilateral maximal isometric contraction in the leg press (RFD-LP, knee joint angle: 90°). The best of 2 and 4 trials were selected for RFD-STS and RFD-LP, respectively. Functional performance was assessed by the timed up-and-go test (TUG), maximal 30-m gait speed test and the Y-balance test.
RESULTS: There was an association between RFD-STS and RFD-LP (r=0.42, p<0.001) independently of age and sex, although there were significant differences between both measures (3485±2976 vs 2221±1063 N/s). In addition, RFD-STS was more strongly associated to TUG velocity and 30-m gait speed (r=0.34, p=0.003 and r=0.44, p<0.001) when compared to RFD-LP (r=0.32, p=0.005 and r=0.31, p=0.008). In contrast, balance performance was more associated with RFD-LP (r=0.39, p<0.001) when compared to RFD-STS (r=0.27, p=0.019).
CONCLUSION: Early RFD obtained during the STS task was more strongly associated to gait speed test than early RFD recorded during an isometric unilateral leg extension action, while the latter was more strongly associated to unilateral balance. These findings may help interpret the functional relevance of these distinct RFD measures.

### BETWEEN-GENDER DIFFERENCES IN TRUNK ROTATIONAL POWER IN ATHLETES OF GYMNASTIC AND DANCE SPORTS

ZEMKOVA, E., KYSELOVICOVA, O., JELEN, M.

*FACULTY OF PHYSICAL EDUCATION AND SPORT, COMENIUS UNIVERSITY IN BRATISLAVA*

INTRODUCTION: A previous study revealed sport-specific differences in power-velocity-force profiling during trunk rotations at loads ≥10.5 kg [1]. The highest power is produced by combat sports athletes (boxing, thai boxing, karate, tae kwon do) with a maximum achieved at 10.5 kg, followed by water sports athletes (canoeing, kayaking) with a maximum at 20.0 kg, grappling sports athletes (judo, wrestling) with a maximum at 15.5 kg, and ball sports athletes (golf, hockey, tennis) with a maximum at 10.5 kg [1]. Since body rotations represent one of the essential elements of performance also in gymnasts and dancers, we were interested in whether between-gender differences exist in trunk rotational power at various loads.
METHODS: Groups of female (n=24, age 20.1±1.7 y, height 168.5±6.8 cm, body mass 57.5±5.8 kg) and male (n=15, age 23.1±2.7 y, height 177.9±9.7 cm, body mass 78.3±11.2 kg) competitive gymnasts, aerobic, ballroom and rock & roll dancers completed two trials of standing trunk rotations at each side with a barbell of different weights (increasing from 1 kg up to a weight at which maximal values of power were achieved) placed on their shoulders. The power produced during trunk rotations was evaluated using the FiTRO Torso Premium.
RESULTS: Mean power in the acceleration phase of trunk rotations was significantly higher in male than female athletes at loads of 10.5 kg (206.8±22.0 W and 165.4±17.8 W respectively, p=0.033), 15.5 kg (231.8±27.5 W and 155.6±24.4 W respectively, p=0.001) and 20 kg (196.9±25.3 W and 111.4±20.9 W respectively, p=0.001). Similar significant between-gender differences for angular velocity at weights ≥10.5 kg were observed. Alternatively, power and force were significantly higher at lower velocities in male than female athletes. However, some females were able to produce slightly greater power and force at higher velocities in spite of their lower values at lower velocities when compared to males.
CONCLUSION: While the highest power in males is produced at a higher weight of 15.5 kg (in few of them at 20 kg), females are able to generate the highest power at a lower weight of 10.5 kg (or at higher velocities). This may be ascribed to both the genetic predispositions and the specificity of their acrobatic and dance elements including trunk rotations at various velocities under different load conditions. Male athletes need to exert high forces of upper and lower body in order to lift female counterparts and perform repetitive rotational movements of the trunk.

### SALIVARY DHT CONCENTRATIONS IN WOMEN AFTER TWO DISTINCT RESISTANCE EXERCISE.

LISTA, M., ROMAGNOLI, R., GRECO, F., PIACENTINI, M.F., SGRÒ, P.

*UNIVERSITY OF ROME*

INTRODUCTION: Distinct forms of resistance exercise can stimulate different hormonal response. Hormonal response is associated with the intensity of exercise, time under tension, volume of exercise and muscle masses involved. Different protocols of strength exercise can induce different changes in circulating Dihydrotestosterone - DHT. DHT responsiveness to exercise appeared greater during a heavy volume, and for females. In females DHT is produced from the reduction of free testosterone in peripheral tissues of the body by 5α-reductase. DHT increases in response to acute exercise [Cook, C. J. et al. 2021]. We hypothesized that DHT responses would differ after two distinct protocols and for this reason the aim of this study is to compare the effect of two different strength exercise on salivary DHT release in women.
METHODS: Ten resistance trained women from different sport or fitness activity were recruited to this study. All participants had a minimum strength training history of 2 years with back squat exercise (4 +/- 2,36 Year). They were randomly assigned into 2 groups: Velocity Loss - VL (n = 5) or Failure Training - FT (n = 5). After ten minutes of incremental full squat warm up, both training groups completed one intervention using the back squat exercise. The VL group executed maximum number of repetitions for five sets of back squat at 75% of 1 RM. Every set ended when the barbell losses 10% of velocity recorded in the first repetition of the set. (16,4 +/- 3,5 Reps) All subjects were constantly stimulated to move the barbell at maximum velocity as possible. The FT group executed maximum number of repetitions for five sets of back squat at 75% of 1 RM. Every set ended when the subject failed the last repetition. (85 +/- 27,5 Reps) All subjects were constantly stimulated to complete the maximum number of repetitions as possible. After each set RPE were collected and session RPE were calculated. VL (6,52 +/- 1,07) FT (9,56 +/- 0,49) Saliva samples were collected before warm up (T0), at the end of training (T1) and 30 minutes after the end of training (T2). Salivary DHT concentrations were measured by ELISA Assay Kit.
RESULTS: Our preliminary data suggested that Salivary DHT was not significantly different in the FT protocol than for VL protocol. There were no statistically significant differences in DHT concentration from T0 to T1, from T0 to T2 and form T1 to T2, and no differences were observed among the protocols, on the other hand, we observed a high individual variation. VL (Δ% [DHT] T0-T1 24,39% +/- 50,06%; T0-T2 -17,77% +/- 24,15%; T1-T2 -6,65% +/- 21,34%) FT (Δ% [DHT] T0-T1 11,70% +/- 42,50%; T0-T2 -1,60% +/- 36,94%; T1-T2 -2,38% +/- 14,14%).
CONCLUSION: These variations can be related to training status and the menstrual cycle of the participants. Due to the small number of participants, statistical analysis taken into account the menstrual cycle was not applicable.

### EVOLUTION OF REPETITION VELOCITY THROUGHOUT ONE SET UNTIL FAILURE AGAINST TWO RELATIVE INTENSITIES IN THE SQUAT EXERCISE IN WOMEN

CANO-CASTILLO, C., PAREJA-BLANCO, F., SÁNCHEZ-MORENO, M., BACHERO-MENA, B.

*UNIVERSIDAD PABLO DE OLAVIDE*

INTRODUCTION: Recently, velocity-based training (VBT) has been proposed as a valid method to objectively quantify and adjust training intensity with high precision on a daily
basis (González-Badillo and Sánchez-Medina 2010). Most of the studies using VBT have been carried out in men (Hagstrom et al. 2020). However, there is little information about the acute responses to resistance training in women when controlling and measuring velocity (Rissanen et al. 2022). For this reason, the aim of this study was to analyse the evolution of repetition velocity throughout a set up to failure in the full-squat (SQ) exercise with two different intensities (60% vs. 80% 1RM) in young women.
METHODS: Ten young physically active and resistance-trained women participated in this study (21.2 ± 2.2 years old; 63.5 ± 5.8 kg; 1.66 ± 0.05 m; 72.2 ± 14.6 kg 1RM). The protocols consisted of two training sessions separated by 1-week, performing a single set until failure with two different intensities (60 and 80% 1RM) in SQ exercise. Firstly, an incremental loading test session was carried out in order to establish the individual load-velocity relationship, as well as the 1RM in SQ for each participant. The order of the protocols was randomized. The relationships between the percentage of repetitions performed (%Rep) and the velocity loss (VL%) of two protocols were analysed.
RESULTS: Significant differences ($p \leq 0.001$) were observed in the number of repetitions performed among protocols. Higher number of repetitions were observed for the 60% 1RM protocol (18.1 ± 3.2) compared to the 80% 1RM protocol (6.8 ± 2.1). However, there were no significant differences observed in VL% among the different protocols (52.7 ± 8.1 vs. 47.2 ± 6.8 for 60% and 80% 1RM, respectively). In addition, significant relationships were observed between %Rep and VL% for 60% (R2 = 0.77) and 80% (R2 = 0.74) 1RM protocols.
CONCLUSION: The highest intensity training protocol (80% 1RM) allowed to perform a lower number of repetitions and showed a lower VL% compared to the 60% 1RM protocol. Similar results have been previously reported in men (Rodríguez-Rosell et al. 2020), indicating that as loading magnitude increases, both, the number of performed repetitions and the magnitude of VL% progressively decrease in SQ exercise. However, the number of repetitions performed in our study by women was slightly higher and the VL% lower than those observed in men, for the same relative intensity. On the other hand, the relationships found between %Rep and VL% were strong enough to consider the VL% as an acute measure for quantifying the degree of effort in women.

### ACUTE EFFECTS OF COMBINED LOWER BODY ENDURANCE AND UPPER BODY STRENGTH EXERCISE ON EXPLOSIVE STRENGTH PERFORMANCE IN NATURALLY MENSTRUATING WOMEN

FEUERBACHER, J.F., DRAGUTINOVIC, B., SCHUMANN, M.

*GERMAN SPORT UNIVERSITY*

INTRODUCTION: We have previously shown that lower body high-intensity interval training (HIIT) does not reduce upper body explosive strength, while lower body HIIT combined with upper or lower body strength exercise has been shown to reduce both explosive squat and bench press strength[1]. Thus, it seems that adding strength exercise to lower body HIIT impairs the subsequent explosive strength performance irrespective of the muscle group, leading to a reduced exercise quality and consequently compromised adaptations. However, evidence on these effects have been addressed exclusively in men and data in women are lacking. Therefore, the purpose of this study was twofold: First, we aimed at investigating the acute effects of lower body HIIT on upper and lower body explosive strength in naturally menstruating women. Additionally, we assessed the combined effects of lower body HIIT and squat compared with lower body HIIT and bench press on both upper and lower body explosive strength.
METHODS: Twelve naturally menstruating women (age: 22.5±2.3 years, menstrual cycle length: 28.4±2.1 days) completed two concurrent training modalities consisting of HIIT (4x4 minutes at 80% of peak power output) followed by lower (HIIT+LBS) or upper body (HIIT+UBS) strength loading (3x5 followed by 3x3 repetitions at 80% of the one-repetition maximum) in a randomized order. Both exercise modalities were performed in two consecutive menstrual cycles within the follicular phase (days 5-10). Squat and bench press mean propulsive velocity was assessed before HIIT (T0), after HIIT (T1) and after the strength loading (T2).
RESULTS: Mixed factorial ANOVA indicated a significant effect for time (squat: $F(2,44)=10.845$, $p=.001$; bench press: $F(2,44)=10.845$, $p=.001$) but no interaction was present for neither squat ($F(2,44)=.332$, $p=.634$) nor bench press ($F(2,44)=1.642$, $p=.205$). Pairwise comparison showed that squat statistically decreased at T1 following HIIT (HIIT+LBS: -5.9±9.1% and HIIT+UBS: -4.1±5.0%, p=.013), while bench press remained statistically unchanged (HIIT+LBS: -0.6±4.5%, HIIT+UBS: -0.02±9.4%, p=1.000). Squat was found to be decreased at T2 compared to T0 in both conditions (HIIT+LBS: -7.3±3.0%, HIIT+UBS: -6.9±6.1%, p<.001) but not compared to T1 (p=1.000). Bench press was statistically reduced at T2 compared to T0 (HIIT+LBS:-7.7±3.7%, HIIT+UBS: -12.4±11.6%, p<.001) and T1 (HIIT+LBS:-7.0±3.4%, HIIT+UBS: -12.3±9.0%, p<.001) following both loadings.
CONCLUSION: These findings indicate that lower but not upper body explosive strength is reduced by lower body HIIT in naturally menstruating women. However, lower body HIIT combined with upper or lower body strength loading resulted in a reduction of both squat and bench press explosive strength. Importantly, the magnitude of reductions in explosive strength in the two loadings was similar to that previously shown in men.

### INFLUENCE OF MENSTRUATION/WITHDRAWAL BLEEDING ON SELF-REPORTED PHYSICAL AND PSYCHOLOGICAL DAY-TO-DAY PARAMETERS IN NORWEGIAN CROSS-COUNTRY SKIERS AND BIATHLETES: THE FENDURA PROJECT.

ENGSETH, T.P.1, OSBORNE, J.1, SOLLI, G.S.1,2, MORSETH, B.1, THOMASSEN, T.O.1, TAYLOR, M.1, WELDE, B.1, ANDERSSON, E.P.1

*1 SCHOOL OF SPORT SCIENCES, UIT THE ARCTIC UNIVERSITY OF NORWAY, TROMSØ, NORWAY, 2 DEPARTMENT OF SPORTS SCIENCE AND PHYSICAL EDUCATION, NORD UNIVERSITY, BODØ, NORWAY.*

INTRODUCTION: Menstruation, as well as the 1-4 days before bleeding has been reported to negatively interfere with sleep quality and motivation to train. Furthermore, around 50-70% of female athletes use hormonal contraceptives (HCs), with the reduction of menstrual-related symptoms as one common reason for using HCs. Although, previous studies provide initial insight, the influence of menstruation/withdrawal bleeding and pre-bleeding has not been investigated from a long-term perspective. The purpose of this study was there-

fore to investigate the influence of three different phases (pre-bleeding, menstruation/withdrawal bleeding, and non-bleeding) on self-reported readiness to train (physically and mentally), sleep quality, menstrual-related symptoms, sickness, and injury in female cross-country (XC) skiers and biathletes.
METHODS: A total of 67 XC skiers and biathletes stratified as HC and non-HC users (21 ± 3 y; 170 ± 5 cm; 63 ± 5 kg; 632 ± 111 annual training hours) volunteered to participate in a 12-month prospective cohort study. The athletes used an online training diary to report self-perceived menstrual-related symptoms, sleep quality, and readiness to train on a 1-10 scale, as well as menstruation/withdrawal bleeding, sickness, and injury on a day-to-day basis. Data were grouped into three phases, i.e., bleeding-days, 1-4 days pre-bleeding and non-bleeding days.
RESULTS: In total, 63% (n = 42) of the athletes reported using HC, with 76% (n = 32) preferring progestin-only HC. Menstrual-related symptoms were significantly more likely to occur during bleeding or pre-bleeding compared to non-bleeding for all athletes (cumulative probability of score >1 = 57% [bleeding]; 10% [pre-bleeding]; and 3% [non-bleeding], $p < 0.001$). Sleep quality was lower during pre-bleeding compared to bleeding- and non-bleeding days ($p < 0.001$), with no differences between HC-users and non-HC users ($p = 0.104$). Mental readiness to train was lower in non-HC users compared to HC users for all phases ($p = 0.025$). No significant differences in sickness, injury days or physical readiness to train were found between the different phases or between HC users and non-HC users.
CONCLUSION: In this study of highly trained endurance athletes followed during a 12-month period, we found sleep quality to be lower during the pre-bleeding phase compared to bleeding and non-bleeding phases, independent of HC use and non-HC use. Mental readiness to train was positively influenced by HC use.

### IS-PN03 Adding hypoxia in the sport and health practitioner's toolbox

#### ANALYSIS OF THE ROLE OF HYPOXIA IN ENHANCING MUSCLE GROWTH: CURRENT STATE OF KNOWLEDGE

FERICHE, B.

*GRANADA UNIVERSITY*

Resistance training in hypoxia has recently emerged as a potential stimulus favoring muscle mass development. There is an association between the production of metabolites and some ions and the activation of mechanisms related to the muscle mass growth by the recruitment of additional motor units, inflammatory response, protein synthesis or satellite cell proliferation. Several studies have focused on the hypoxic effect on protein synthesis and muscle cell proliferation, but the molecular mechanisms are largely unknown and the results on muscle hypertrophy and strength are not conclusive. This proposal will analyze the current state of knowledge about resistance training in hypoxia and its effect on muscle mass development.

#### RESISTANCE TRAINING IN HYPOXIA TO IMPROVE BONE AND CARDIOVASCULAR HEALTH IN OLDER ADULTS

TIMON, R.

*SPORT SCIENCES FACULTY. UNIVERSITY OF EXTREMADURA*

Bone and cardiovascular health deteriorates with age. Resistance training has been proposed as a fundamental tool to deal with these age-induced pathologies. The addition of hypoxic stress provides a beneficial synergistic effect on disease prevention and quality of life in older adults. The long-term effect of resistance training in hypoxia-induced adaptations will be analysed with a particular focus on metabolic biomarkers and inflammatory responses, bone remodelling and body composition, and physical condition and functionality in older people.

#### TARGETING PERFORMANCE AND HEALTH ENHANCEMENT WITH HIGH-INTENSITY HYPOXIC TRAINING

BROCHERIE, F.

*FRENCH INSTITUTE OF SPORT*

Among the panorama of altitude/hypoxic training methods, the "living low-training high" approach is becoming an important intervention for modern sport. In particular, systemic or local hypoxic training methods – or their combination – based on the repetition of "all-out" efforts can be used to induce a potent physiological stimulus, up-regulate signalling pathways and eventually maximize performance outcomes in a wide range of sports. Further, recent evidences suggest that such high-intensity exercise performed in hypoxia might be a valuable and viable "therapeutic strategy" in conditioning/rehabilitation or clinical setting. This presentation will therefore summarize and discuss the last "living low-training high"-based evidences related to performance or health enhancement.

### IS-AP02 Sport science and climbing: Welcome to the Olympic arena!

#### ROLE OF PSYCHOLOGICAL PROCESSES IN SPORT CLIMBING EXAMINED

SANCHEZ, X.

*UNIVERSITÉ DORLÉANS*

The influence of psychological factors in sport performance has, in general, been extensively demonstrated. However, the study of the role of the psychological aspects in the performance of climbing has not yet been systematically dealt with. Indeed, little research has examined the psychological requirements of climbing although these are vastly acknowledged by sport scientists, coaches and practitioners alike as being a key element in elite successful performance.
Even though climbing is considered unique from both scientific and sporting perspectives, this sporting discipline has not attracted much interest from sport psychology field until recently, when compared to other disciplines such as physiology, biomechanics, and motor control. The present talk will address research developed by the presenter examining the role of psychological processes in climbing. Identified climbing performance predictors will also be discussed. Lastly, a conceptual model with which to understand optimal climbing performance will be presented. As the sport of climbing continues to develop, the present talk will also provide a basis to develop further multidisciplinary research to examine most effectively how psychological aspects influence performance. From an applied perspective, the present talk will provide an opportunity to discuss how best to plan, design and deliver holistic and coherent training programmes aimed at enhancing competitive climbing performance.
The session will be of interest to researchers and applied scientists as well as sport practitioners with an interest in developing sport psychology work and applied performance interventions. The talk will also be of relevance to anyone interested in the field of psychology and behavioural sciences with an interest in the psychological processes engaged in the practice of sport; here climbing is used as a case-example.

#### CLIMBING FLUENCY AND INTER-LIMB COORDINATION

SEIFERT, L.

*UNIVERSITY OF ROUEN*

Skilled climbers ascend fluently – without excessively jerky movement – and are able to link together different sections of a climb without unnecessary stoppages. In competitive climbing, fluency is likely to be important in the lead climbing event because it relates to efficiency – useful when climbing long pitches (or multi-pitch routes) where economy is required. And, also in the speed climbing event because climbers want to maintain momentum as they ascend. Quantifying the spatio-temporal path of the climber over time allows us to assess learning and compare climbers of different skill levels. Fluency may not be so important in the bouldering event because of the limited number of moves and the nature of the routes that require fairly static periods and occasional dynos.
This session will discuss the assessment of movement fluency, through spatial (geometric index of entropy), temporal (stationary/motion ratio) and spatio-temporal measurements (smoothness of hip trajectory, i.e., jerk coefficient), and also the subsequent inter-limb coordination leading to this climbing fluency (notably through contact time on the wall and limb + body motions). We will examine the role of expertise, practice and climbing route setting. We will conclude with a discussion of current limitations and potential solutions.
The session will be of particular relevance to climbers but also to anyone interested in how we think about efficient movement of the body through the environment.

#### PHYSIOLOGICAL ADAPTATIONS IN CLIMBERS EXAMINED: ANTHROPOMETRY, STRENGTH, VO2, MUSCLE VO2, AND HEMODYNAMIC ADAPTATIONS

ESPAÑA-ROMERO, V.

*MEDICAL RESEARCH COUNCIL*

The popularity of the sport climbing as a recreational activity and as a training mode for rock climbing has been increasing over the last years. Due to such increase in participation, interest in improving personal climbing performance through specific practice and training is growing. Consequently, an increasing number of research outputs related to climbing performance has been produced lately; studies have focused on both physiological and anthropometric characteristics of the climbers. The present talk will examine the physiological adaptation in climbers such as aerobic capacity and muscular strength, as well as climbers' anthropometric characteristics. Moreover, knowing that climbing performance is largely dependent on the endurance of the forearm flexors, the present talk will also discuss the role of forearm flexor's specific hemodynamic adaptations in climbers.
Lastly, since the sport of climbing is also promoted as a regular activity to improve strength (e.g., by the American College of Sports Medicine), the talk will address how the physiological adaptations of the sport may help the general population when it comes to dealing with public health issues including depressive symptoms and back problems.
The session will be of interest to researchers and applied scientists as well as sport practitioners with an interest in developing strength and conditioning work, including local intermittent endurance. The talk will also be of relevance to anyone interested in the field of physiology and sport performance as well as sport and its health applications.

## Invited symposia

### IS-PN02 Catching your breath – the air we breathe, the food we eat, and respiratory health

#### COLD, HEAT AND THE LUNGS

KIPPELEN, P.

*BRUNEL UNIVERSITY LONDON*

Many athletes are routinely exposed to cold or hot environmental conditions while training and competing. In this presentation, we will explore the challenges faced by the respiratory system when athletes exercise in extreme thermal conditions. We will also discuss the potential implications to sport performance, and present various non-pharmacological options available to athletes to mitigate thermal-related respiratory issues.

One key role of the respiratory system is to bring inspired air to body conditions before it reaches the alveoli. As the ventilatory demand increases dramatically during exercise, the human body air-conditioning system can become overwhelmed. This is particularly the case when athletes exercise in cold air, as heat and water losses within the airways are then substantial. Heat and water losses within the airways often lead to dehydration of the protective airway surface lining, thereby promoting airway epithelial injury and airway inflammation. As a consequence, airway dysfunctions (such as exercise-induced bronchoconstriction) are particularly common in cold-weather athletes, and precautions to limit airway dehydration are warranted. After presenting how exercise could damage the fragile airway epithelium, we will present the pros and the cons of heat and moisture exchange masks on airway function and sport performance — those working with athletes will then to be able to make informed decisions as when, and how such face masks may be recommended.

At the other end of the thermal spectrum (i.e. in hot humid environments), there is a reduced risk for athletes to develop exercise-induced bronchoconstriction. However, when heat load becomes excessive, humans hyperventilate. When athletes exercise for prolonged periods of time and become hyperthermic, a ventilatory drift therefore occurs. While the underlying mechanisms and consequences of the so-called 'hyperthermia-induced hyperventilation' are still disputed, the potential impact of this excessive ventilatory response on blood gases homeostasis and sport performance will be explored.

#### AIR POLLUTION AND SPORT PERFORMANCE: IS THE RESPIRATORY SYSTEM THE WEAKEST LINK?

BOUGAULT, V.

*UNIVERSITÉ CÔTE DAZUR*

Climate change is accompanied by a growing release of pollutants in the air we breathe. In some parts of the world, pollution levels are dangerously high on a daily basis, while in other countries, the frequency and duration of peaks of pollution are increasing. Several events, such as the forest fires during the 2020 Melbourne tennis tournament or ozone pollution during the 1984 Los Angeles Summer Olympic Games, have raised concerned about the safety for athletes to compete in polluted environments. Many athletes indeed complained of respiratory symptoms – sometimes severe – during these events, which prompted some to withdraw from competition.

Since the 1984 Olympic Games and the well-known Los Angeles ozone fog, air measurements are taken to check pollution levels in the run-up to major sporting events. During the last Summer Olympic Games (Tokyo 2020), the organizing committees took measures to reduce car traffic and improve air quality. Such approach is however rarely in place for lower profile events. In this context, it is reasonable to wonder about the physiological and performance consequences of acute exposure to air pollutants. Due to the complexity of the research process, there is still very little literature on the subject. However, with the development of new tools for measuring pollutants, research under ecological conditions is growing.

In this talk, we will identify first the main pollutants that athletes encounter while exercising indoor and outdoor. We will then present the known effects of these pollutants on sports performance, and explore the possible mechanisms leading to performance decrement. We will finally discuss how the respiratory system – as the point of entry of the pollutants into the body – copes with these environmental insults, and consider preventative strategies to reduce pollution-induced respiratory issues.

#### HARNESSING THE GUT MICROBIOTA AND NUTRITION FOR RESPIRATORY HEALTH IN ATHLETES

WILLIAMS, N.

*NOTTINGHAM TRENT UNIVERSITY*

With the continued growth of evidence for the far-reaching health benefits of the gut microbiota, interest in the role of the gut for athlete health is not surprising. Respiratory issues, including respiratory illnesses and asthma, are a leading cause of training and in-competition time losses. The need to prevent illness and maintain health is paramount to both, athletic success and exercise adherence in the general population. The gut microbiota is implicated in areas that are pivotal to preserving respiratory health, such as: immunity, energy provision and defence against respiratory infections. There is emerging evidence that appropriate dietary strategies to target the gut microbiota could be a novel management tool for respiratory issues in the exercising individual – this will be the focus of the presentation.

Initially, the talk will present the beneficial effects that exercise has upon the gut microbiota. From increasing the number of beneficial microbial species to enriching the gut microbial diversity, exercise can help to maintain human health. Beyond the effects of exercise per se, we will highlight the proposed interaction between the gut microbiota and respiratory health, often termed the gut-lung axis, in athletes. In particular, we will focus on the latest evidence supporting the use of probiotics and prebiotics. There are now numerous studies reporting positive improvements in athlete's health – in particular, a reduction in the risk for upper respiratory symptoms (including infections), asthma and exercise-induced bronchoconstriction following probiotic and prebiotic interventions –, and the talk will critically discuss the existing evidence and apply it into sporting practice. An important message that the audience will be able to take away from this talk is that sports nutrition practices are not only fuelling the athlete, but also impacting on their gut microbiota.

## Invited symposia

### IS-MH01 Fragile do not touch! Role of antioxidant capacity, physical activity and exercise interventions in the management of frail older adults.

#### COENZYME Q10 AND PHYSICAL CAPACITY IN OLDER ADULTS, A DIRECT RELATIONSHIP

LÓPEZ-LLUCH, G.

*PABLO DE OLAVIDE UNIVERSITY*

Coenzyme Q10 (CoQ10) is an essential factor for mitochondrial activity and antioxidant protection of cells, tissues, and plasma lipoproteins. Its deficiency has been associated with aging progression in animal models and in humans. Some studies have determined that levels of CoQ10 in plasma correlate with the physical capacity of older adults (aged >65 years). We have observed that the levels of this compound are higher in people out of frailty scores in the senior fitness tests. Interestingly, CoQ10 is also higher in people able to maintain a healthy lifestyle related to physical activity as well as adequate fitness levels. On the other hand, CoQ10 levels show a strong inverse relationship with sedentarism and the up-and-go test. Gender differences will be revised, as there is evidence indicating stronger correlations in women than in men. Finally, we will highlight that the importance of the maintenance of CoQ10 levels in older adults can be related not only with muscle performance but also with vasculature endothelial function and senescent phenotype as high CoQ10 levels are associated with better endothelial antioxidant protection, low oxidative damage, and low inflammatory cytokines that affect muscle performance. The combination of CoQ10 with physical activity in older adults can be an important therapeutical procedure to reduce the progression of age-related sarcopenia and frailty.

#### ACCELEROMETER-ASSESSED ACTIVITY PATTERNS AS NOVEL BIOMARKER OF FRAILTY IN OLDER ADULTS

DEL POZO-CRUZ, B.

*UNIVERSITY OF SEVILLE*

Regular physical activity has an important role in maintaining health and functional status with ageing. Accelerometers allow detailed measurement of free-living quantity and patterns of physical activity and sedentary time. These devices, worn on different body locations, provide new opportunities to quantify detailed movement behavior throughout the 24-hour period. In this talk, I will present different ways to utilize and analyze accelerometer data and to measure movement behavior among older people, illustrating their potential to transform the way we investigate movement in older adults. I will first describe the role of overall physical activity and sedentary behavior to assess the level of frailty and physical function in older adults. Next, I will illustrate how to derive, analyze, and interpret data on complex and nuanced physical activity patterns. I will then present novel results describing the associations of physical activity patterns with frailty and mortality outcomes in older adults. To do so, I will utilize two well-known datasets: the Toledo Study for Healthy Ageing (Toledo, Spain; n=800 older adults with accelerometer) and the National Health and Nutrition Examination Survey, a population-based dataset with more than 3000 older adults with accelerometry and health measurements. Collectively, the presentation will address a variety of accelerometer methods, metrics, and analytical methods, which provide meaningful insights into physical activity behavior among people with advancing age.

#### PHYSICAL EXERCISE AS A DRUG FOR FRAILTY AND ENHANCEMENT IN QUALITY OF LIFE

GUADALUPE GRAU, A.

*CASTILLA-LA MANCHA UNIVERSITY*

The state of vulnerability that characterizes the geriatric syndrome of frailty exposes the older individual to an increased risk of morbidity, disability, inappropriate healthcare use, institutionalization, poor quality of life, and death. The old framework approaches frailty by treating diseases. Overcoming it by acting on functional issues arises from the main idea of detecting and intervening in the earliest phases of the functional deterioration leading to disability and dependence. Loss of muscle mass and its main functions (strength, power, and endurance) is fundamental to the concept of physical frailty. When older adults are frail or at risk of being frail, muscle power training reaches a higher level of relevance, since it is a cornerstone of the neuromuscular system and has a great influence on functional capacity during aging. The effectiveness of multicomponent training programs focused on muscular power in the prevention and treatment of frailty and multimorbidity will be discussed. Three possible scenarios of exercise programs implementation will be approached: online, healthcare (frailty management units), and sports centers.

### OP-GSSI GSSI Sport Award presentation session

#### UPTAKE AND UTILIZATION OF 15N-LABELLED DIETARY NITRATE BY SKELETAL MUSCLE

KADACH, S., PARK, J.W., STOYANOV, Z., BLACK, M.I., VANHATALO, A., WALTER, P.J., CAI, H., SCHECHTER, A.N., PIKNOVA, B., JONES, A.M.

*UNIVERSITY OF EXETER*

INTRODUCTION: The nitrate (NO3-) and nitrite (NO2-) stored in skeletal muscle may be important in the maintenance of systemic nitric oxide (NO) bioavailability, especially when NO requirements are elevated such as during exercise. At any given time, skeletal muscle NO3- concentration ([NO3-]) reflects the balance between metabolism of NO3- into other nitrogen-containing species, oxidation of NO produced via nitric oxide synthases (NOS), and NO3- uptake consequent to dietary NO3- ingestion. The purpose of this study was to use a stable

isotope tracer (15N-labelled NO3-) to investigate the metabolic fate of ingested NO3- through the determination of changes in NO3- concentration in skeletal muscle alongside other tissues at rest and following exercise.
METHODS: 10 healthy adults volunteered to participate in this double-blind, randomised, placebo-controlled study. Participants completed two experimental visits in which they consumed a beverage containing 12.8 mmol 15N-labelled potassium nitrate (K15NO3) or a potassium chloride placebo. Skeletal muscle (m. vastus lateralis) samples were collected at baseline, for 3 h post-supplement ingestion, and immediately following the completion of 60 maximal, unilateral contractions of the knee extensors over 5 min. All biological samples were analysed using ozone-based chemiluminescence to quantify total [NO3-] and [NO2-], and by mass spectrometry to determine the endogenous vs. exogenous origin of NO3- and NO2- (i.e., by determining the recovery of 15NO3- and 15NO2- in these tissues following the ingestion of K15NO3).
RESULTS: Neither muscle [NO3-] nor [NO2-] were altered following placebo ingestion compared to baseline. Following K15NO3 ingestion, muscle [NO3-] was elevated above baseline at both 1 h and 3 h (baseline, 35 ± 9 nmol.g-1; 1 h, 147 ± 71 nmol.g-1; 3 h, 105 ± 41 nmol.g-1; P<0.001). The majority of the increase in NO3- in muscle at 1 h was 15N-labelled (baseline: 0.9 ± 0.4 nmol.g-1; 1 h: 100 ± 63 nmol.g-1; 3 h: 50 ± 25 nmol.g-1; P<0.001). However, at 3 h, there was also an increase in skeletal muscle [NO3-] that was not 15N-labelled (baseline: 34 ± 9 nmol.g-1 vs. 3 h: 55 ± 21 nmol.g-1; P<0.05). Although there was no change in total skeletal muscle [NO2-] following the ingestion of the K15NO3 bolus, there was an increase in the contribution of 15N- labelled [NO2-] in skeletal muscle at 1 h (baseline: 0.02 ± 0.01 nmol.g-1 vs. 1 h: 0.12 ± 0.14 nmol.g-1; P<0.05), but not at 3 h, following NO3- ingestion. Exercise did not induce significant changes in total skeletal muscle [NO3-] or [NO2-]; however there was a reduction in 15N-labelled skeletal muscle [NO3-] from pre- to post-exercise (50 ± 25 vs. 28 ± 21 nmol.g-1; P<0.05).
CONCLUSION: This study shows for the first time that skeletal muscle rapidly and robustly takes up 15N-labelled dietary NO3-. This 15N-labelled NO3- appears to be utilized to support skeletal muscle metabolic processes, such as conversion to NO2- and NO, during maximal contractions.

## A HIGH-PROTEIN VEGAN DIET IMPROVES BLOOD-BORNE INDICES OF CARDIOMETABOLIC HEALTH BUT DOES NOT ALTER MICRONUTRIENT STATUS COMPARED WITH AN ISONITROGENOUS OMNIVOROUS DIET DURING RESISTANCE TRAINING.

VAN DER HEIJDEN, I., WEST, S., MONTEYNE, A.J., COELHO, M.O.C., FINNIGAN, T.J.A., STEPHENS, F.B., WALL, B.T.
*UNIVERSITY OF EXETER*

INTRODUCTION: A hypercaloric high animal protein diet is often advocated to meet increased macro- and micro- nutrient demands for optimal resistance training induced adaptations; though such diets are also associated with impairments in cardiometabolic health. Equivalent resistance-training induced increases in skeletal muscle mass and strength can be achieved consuming high-protein vegan diets which have also been used to improve markers of cardiometabolic health. Vegan diets, however, are potentially lower in key micronutrients required for optimal health and adaptation during prolonged training. In the current retrospective analysis, we investigated whether a hypercaloric, high-protein vegan diet consumed during high-volume resistance-training modulates blood-borne indices of cardiometabolic health or micronutrient status compared with an isonitrogenous omnivorous control diet.
METHODS: Twenty-two healthy young adults (age: 24±1 y, BMI: 23±1 kg·m2) undertook a 10-week progressive resistance training program (5-days/week), while following a high-protein (2 g·kg bm-1·day-1), hypercaloric (~10% daily energy surplus) omnivorous (OMNI: n=12; m=6, f=6) or mycoprotein-rich vegan (VEG: n=10; m=5, f=5) diet. Fasting venous blood samples were collected weekly to assess circulating glucose, insulin, micronutrient and lipid (using quantitative and targeted NMR-based metabonomics) statuses. Two-way repeated measures ANOVAs were performed to detect differences in each parameter. A false discovery rate of 0.276 was applied for metabonomics analyses.
RESULTS: Fasting plasma glucose concentrations remained unaltered, but serum insulin concentrations increased during training in OMNI only (from pre of 12±1 to post of 14±1 mU·L-1) resulting in an increased HOMA-IR index in OMNI (from pre of 2.4±0.2 to post of 2.9±0.2; P<0.05) but not VEG (from pre of 2.3±0.1 to post of 2.2±0.1; P>0.05). Out of 165 lipid targets, 5 differentially changed between groups throughout training (P<0.05). Large lipid classes (e.g. total cholesterol, triglycerides, phospholipids and fatty acids) did not change throughout training, but were higher in OMNI compared with VEG (P<0.05). Fasting serum ferritin concentrations decreased throughout training equivalently in both groups (OMNI: from pre of 54±14 to post of 38±9 µg·L-1, VEG: from pre of 73+31 to post of 52±20 µg·L-1, P<0.05) while serum vitamin B12, vitamin D and calcium concentrations did not change.
CONCLUSION: A hypercaloric and high-protein, mycoprotein rich, vegan diet can be followed during high-volume resistance-training to positively influence markers of cardiometabolic health without compromising micronutrient status when compared with a more traditional omnivorous dietary strategy.

## PRE-SLEEP PROTEIN INGESTION STIMULATES MITOCHONDRIAL PROTEIN SYNTHESIS RATES DURING POSTEXERCISE OVERNIGHT RECOVERY

VAN LIESHOUT, G., TROMMELEN, J., NYAKAYIRU, J., SENDEN, J., GOESSENS, J., GIJSEN, A., VERDIJK, L., VAN LOON, L.
*DEPARTMENT OF HUMAN BIOLOGY, NUTRIM SCHOOL OF NUTRITION AND TRANSLATIONAL RESEARCH IN METABOLISM, MAASTRICHT UNIVERSITY MEDICAL CENTRE+, MAASTRICHT, THE NETHERLANDS*

INTRODUCTION: Protein ingestion prior to sleep has been shown to stimulate myofibrillar protein synthesis rates during overnight recovery from exercise. Whether pre-sleep protein ingestion can also be applied to augment mitochondrial protein synthesis rates remains to be established. Furthermore, the impact of the type of protein to modulate overnight myofibrillar or mitochondrial protein synthesis rates has not yet been addressed.
The purpose of this study is to assess the impact of pre-sleep casein and whey protein ingestion on myofibrillar and mitochondrial protein synthesis rates during overnight recovery from a bout of endurance exercise.
METHODS: Thirty-six healthy, young men performed a single bout of endurance-type exercise in the evening (19:45 h) after a full day of dietary standardization. Thirty min prior to sleep (23:30 h), subjects ingested 45 g casein protein, 45 g whey protein, or a noncaloric placebo. Continuous intravenous L-[ring-13C6]-phenylalanine infusions were applied, with blood and muscle tissue samples being collected to assess overnight mitochondrial and myofibrillar protein synthesis rates. Overnight muscle protein synthesis rates were compared between treatments with a one-way ANOVA with a Bonferroni correction.
RESULTS: Protein ingestion resulted in higher mitochondrial (0.087±0.020 vs 0.067±0.016 %·h-1, P=0.005) and myofibrillar (0.060±0.014 vs 0.047±0.011 %·h-1, P=0.012) protein synthesis rates when compared to placebo. Casein and whey protein ingestion did not differ in their capacity to stimulate mitochondrial (0.082±0.019 vs 0.092±0.020 %·h-1, P=0.690) and myofibrillar (0.056±0.009 vs 0.064±0.018 %·h-1, P=0.440) protein synthesis rates.

CONCLUSION: Protein ingestion prior to sleep stimulates both mitochondrial and myofibrillar protein synthesis rates during overnight recovery from endurance exercise. There is no apparent difference in the capacity of pre-sleep whey or casein protein ingestion on overnight muscle protein synthesis rates.

### EFFECT OF ACUTE KETONE BODY SUPPLEMENTATION ON CARDIORESPIRATORY EXERCISE RESPONSES AND THE INFLUENCE OF BLOOD ACIDOSIS: A RANDOMIZED, CROSSOVER TRIAL

MCCARTHY, D.G., BOSTAD, W., BONE, J., POWLEY, F.J., RICHARDS, D.L., GIBALA, M.J.

*MCMASTER UNIVERSITY*

INTRODUCTION: Acute ketone monoester supplementation (KE) induces hyperketonemia and blood acidosis; both can affect exercise responses but the relative influence of each is unclear. We previously found that ingestion of 0.6 g/kg body mass KE increased heart rate (HR) and ventilation (VE) during cycling at ventilatory threshold (VT) compared to placebo (1). The present study used the same protocol (1) to examine the effect of KE on exercise cardiac output (Q) and the influence of blood acidosis. We hypothesized that KE vs placebo would increase Q and co-ingestion of a pH buffer would mitigate this effect.
METHODS: A sample size estimate (G*Power) determined n=12 provided 80% power to detect a change in Q (effect size f=0.4, alpha=0.05) with repeated measures analysis of variance (ANOVA). Trained adults (11 males, 4 females; VO2peak = 60±9 mL/kg/min) completed 3 trials in random order. Participants ingested 1 g/kg carbohydrate and 400 mL water 2 h before exercise, followed by either 0.20 g/kg body mass of sodium bicarbonate or a salt placebo 60 min pre-exercise, and a 0.6 g/kg bolus of KE or ketone-free placebo in 500 mL of fluid 30 min pre-exercise. This yielded 3 conditions: low blood ketone bodies and neutral pH [control (CON)], hyperketonemia and lowered pH (KE), and hyperketonemia and neutral pH (KE+BIC). Venous blood was sampled before and during exercise. Participants cycled for 30 min at VT intensity. Q was measured in duplicate over the last ~5 min using inert gas rebreathing (Innocor). After a 10-min rest, VO2peak and peak Q were determined. Data were analyzed using ANOVA and a Tukey post hoc test as appropriate with alpha=0.05.
RESULTS: Blood concentration of the major ketone body beta-hydroxybutyrate differed between conditions (CON: 0.1±0.0, KE: 3.5±0.1, KE+BIC: 4.4±0.2 mM, P≤0.001 for all). Blood pH was lower in KE vs CON (7.30±0.01 vs 7.34±0.01, p<0.001) and KE+BIC (7.35±0.01, p<0.001). Q during VT exercise was not different between conditions (CON: 18.2±3.6, KE: 17.7±3.7, KE+BIC: 18.1±3.5 L/min, p=0.4). HR was higher in KE (153±9 beats/min) and KE+BIC (154±9) vs CON (150±9, p<0.02 for both). VE was higher in KE vs CON (81±16 vs 74±17 L/min, p<0.0001) and KE+BIC (77±16, p<0.01). VO2peak was not different between conditions (CON: 4.55±1.05, KE: 4.34±0.94, KE+BIC: 4.39±0.91 L/min; p=0.2). Peak Q was also not different (CON: 21.8±3.8, KE: 21.5±3.7, KE+BIC: 21.1±3.9 L/min; p=0.3). Peak power output was lower in KE (359±61 W) and KE+BIC (363±63) vs CON (375±64, p<0.02). Peak HR was lower in KE vs CON (179±9 vs 181±9 beats/min, p=0.03) and KE+BIC (182±9, p=0.03).
CONCLUSION: KE increased submaximal exercise HR independent of acidosis and thus was seemingly affected by hyperketonemia. Q was not different between conditions despite differences in HR, which suggests stroke volume may have been altered. The higher cardiorespiratory stress after KE may have lowered exercise capacity such that peak power output at VO2peak was reduced.

### EFFECT OF ACUTE DIETARY NITRATE SUPPLEMENTATION ON CARDIOVASCULAR FUNCTION AND EXERCISE TOLERANCE IN WOMEN USING ORAL CONTRACEPTIVE PILLS

ROWLAND, S.N., JAMES, L.J., O'DONNELL, E., BAILEY, S.J.

*LOUGHBOROUGH UNIVERSITY*

INTRODUCTION: Dietary nitrate (NO3-) supplementation has been reported to lower systolic blood pressure (SBP) and improve exercise performance in males and mixed sex groups, but very few studies have assessed these responses exclusively in females. Synthetic exogenous hormone consumption, via oral contraceptive pill (OCP), is highly prevalent in young premenopausal women and is suggested to attenuate endogenously produced nitric oxide, but it has yet to be determined whether OCP use impacts the responsiveness to dietary NO3- ingestion. This study tested the hypothesis that dietary NO3- supplementation would lower brachial and central SBP and improve exercise tolerance in women using OCP.
METHODS: Eight healthy, normotensive, premenopausal women using combined, monophasic OCP were recruited. Following baseline measurements of brachial and central SBP, with the latter determined using pulse wave analysis via applanation tonometry, participants ingested 140 mL of concentrated NO3rich (BR; 13 mmol NO3-) or NO3depleted (PL) beetroot juice. Measurements were repeated 2.5 h post ingestion and a ramp incremental cycling test was subsequently completed. The four experimental trials, BR and PL ingestion in the inactive and active pill phases, were administered in a double-blind, repeated-measures, cross-over experimental design. Data were analysed using repeated-measures ANOVAs and paired-samples t-tests. Values are presented as means ± SD with statistical significance accepted as P<0.05.
RESULTS: There was a main effect for supplement for brachial SBP (P<0.001), but no main effect for pill phase or supplement x pill phase interaction (both P>0.05). Brachial SBP was lower 2.5 h vs baseline in BR compared to PL in the inactive (-6 ± 4 mmHg vs 0 ± 3 mmHg; P=0.003) and active (-4 ± 3 mmHg vs 0 ± 3 mmHg; P=0.002) pill phases. There was a main effect for supplement for central SBP (P=0.015), but no main effect for pill phase or supplement x pill phase interaction (both P>0.05). Central SBP was reduced 2.5 h vs baseline in BR compared to PL in the inactive (-7 ± 4 mmHg vs -2 ± 3 mmHg; P=0.014) and active (-4 ± 3 mmHg vs 0 ± 4 mmHg; P=0.038) pill phases. There were no main effects for supplement or pill phase and no supplement x pill phase interaction effects for peak aerobic power (PAP) or VO2peak (all P>0.05).
CONCLUSION: These results suggest that acute consumption of NO3rich beetroot juice is effective at lowering both peripheral and central SBP in women using combined OCP. However, acute dietary NO3- supplementation did not alter PAP or VO2peak in this population. These findings might have implications for attenuating the proposed elevated cardiovascular strain that accompanies synthetic exogenous hormone consumption in premenopausal women.

## OP-PN04 Muscle typology and volume

### MUSCLE FIBER TYPOLOGY IN NATIONAL LEVEL FOOTBALL AND ITS INFLUENCE ON IN-GAME FATIGUE

VAN DE CASTEELE, F., LIEVENS, E., VAN VOSSEL, K., HARDEEL, J., DEPREZ, D., DERAVE, W.

*GHENT UNIVERSITY*

INTRODUCTION: Physical game demands in football (soccer) are position-dependent and a large heterogeneity in muscle fiber typology exists among national level players (1). We could expect that it is advantageous for central midfielders, who cover a large total distance, to have a slow typology and for forwards, who sprint a lot, to have a fast typology. At the higher levels this could lead to a selection effect. Furthermore, it was shown that fast typology individuals (FT) fatigue more than slow typology individuals (ST) (2). Therefore, we investigated if muscle typology is different between national level football players who occupy other positions and secondly if FT experience more in-game fatigue than ST.
METHODS: Muscle typology was estimated in 147 male professional football players (24.7±4.8yr) by measuring carnosine in the soleus muscle via proton magnetic resonance spectroscopy (3). Players were classified as ST, intermediate typology individuals (IT) or FT based on carnosine content. Our sample comprised 17 goal keepers, 27 center backs, 20 full backs, 45 midfielders, 20 wingers and 18 forwards. Time-motion data were collected by a multi-camera system to measure in-game fatigue as the decay in running activities from the 1st to the 2nd half. Following categories were used: total distance; standing/walking 0-6 km/h; jogging 6-15 km/h; running 15-20 km/h; high speed 20-25 km/h; sprinting >25 km/h; max speed; medium and high acceleration 2 to 3 m/s² and >3 m/s²; medium and high deceleration -2 to -3 m/s² and <-3 m/s². Players' category values were averaged and adjusted for playtime, but only for 59 outfield players who completed at least 5 games with 75 min playtime or more. ANOVAs were used to determine differences in muscle typology between positions and differences in distances covered in each intensity category during the whole game, 1st and 2nd half and decay from 1st to 2nd half.
RESULTS: There were no significant differences in muscle typology between positions (p=0.412), indicating that the variance within positions was larger than between positions. FT covered more high acceleration distance in the whole match (+9.3%, p=0.042) and 1st half (+11.9%, p=0.008) than ST players, but no other differences were found between FT, IT and ST considering the whole game, 1st and 2nd half. However, several high-intensity parameters showed a larger decline from 1st to 2nd half in FT players (high speed -10.7%; high acceleration -12.4%; high deceleration -12.7%) than in ST players (high speed -4.3%; high acceleration -7.7%; high deceleration -7.8%; p<0.05) and IT players (high acceleration -6.8%; p=0.011).
CONCLUSION: Possessing a particular muscle typology is not required to play a certain football position at the national level. However, it seems that FT are worse at maintaining their high-intensity performance from the 1st to the 2nd half compared to ST.

### INFLUENCE OF MUSCLE FIBER TYPOLOGY ON LEG MUSCLE HYPERTROPHY AND DYNAMIC STRENGTH GAINS AFTER 10 WEEKS OF RESISTANCE TRAINING TO FAILURE

VAN VOSSEL, K., HARDEEL, J., WEYNS, A., VAN DE CASTEELE, F., LIEVENS, E., DERAVE, W.

*GHENT UNIVERSITY*

INTRODUCTION: Considerable heterogeneity exists in the individual hypertrophy and strength responses to resistance training. The high variability in muscle fiber typology across humans might be one of the missing elements in understanding this heterogeneity. A recent gene expression study demonstrated differences in the response of individual fast-twitch and slow-twitch fibers to resistance training (1). Moreover, fast typology individuals were found to recover slower and to be more vulnerable to overreaching (2,3). Therefore, we investigated if the adaptations to resistance training are dependent on the muscle fiber typology and if different training frequencies and volumes cause different responses in slow typology (ST) and fast typology (FT) individuals.
METHODS: Eleven untrained ST (21.9±2.9yr, 6 men) and 10 untrained FT (22.2±1.0yr, 5 men) performed 10 weeks of resistance training. Muscle fiber typology was non-invasively estimated in the calf muscles and vastus lateralis by measuring carnosine using proton magnetic resonance spectroscopy (4). Subjects performed 3-4 sets of leg extensions and leg curls to failure every training session (60%1RM). A within-subject design was used where leg A trained 3x/week (>=48h rest) and leg B trained 2x/week (>=72h rest). Changes in muscle volume of the 4 quadriceps muscles and 3 hamstring muscles were measured by MRI (Springbok Analytics). Increase in maximal dynamic strength was measured by 1RM determination. Paired and Independent Sample t-tests and two-way repeated measures ANCOVAs were used to detect pre-post changes, differences between ST-FT and the 3x and 2x/week conditions.
RESULTS: The training program induced significant hypertrophy and strength increases in all trained muscles (p<0.005). Individual changes in muscle volume and dynamic strength ranged resp. from 0.1%-11.4% and 4.17%-43.75% in the quadriceps and 2.1%-23.1% and 6.7%-90.0% in the hamstrings. However, no significant differences were found between ST and FT in the individual (per muscle) and mean (all muscles combined) hypertrophic and strength changes. In the 3x/week condition mean hypertrophy was 9.5±4.6% (ST) vs 8.3±3.2% (FT) (p=0.53), mean change in 1RM was 23.9±9.13% (ST) vs 28.8±11.9% (FT) (p=0.31). The 2x/week condition caused a hypertrophy of 7.3±3.3% (ST) vs 6.8±3.0% (FT) (p=0.68) and a mean change in 1RM of 23.7±10.3% (ST) vs 21.4±8.6% (FT) (p=0.62). No interaction effect was found between muscle fiber typology and training frequency.
CONCLUSION: The heterogeneous response to resistance training seems not dependent on the muscle fiber typology as training to failure leads to equal hypertrophy and dynamic strength changes in the leg muscles of untrained ST and FT. Additionally, the optimal resistance training frequency and volume do not differ between ST and FT.

### RESISTANCE-TYPE EXERCISE TRAINING COUNTERACTS THE IMPACT OF ANDROGEN DEPRIVATION THERAPY ON MUSCLE FIBRE CHARACTERISTICS IN PROSTATE CANCER PATIENTS

OVERKAMP, M.1,2,3, HOUBEN, L.H.P.1,2,3, AUSSIEKER, T.1, VAN KRANENBURG, J.M.X.1, MIKKELSEN, U.R.4, BEELEN, M.1,3, BEIJER, S.2,3, VAN LOON, L.J.C.1,3, SNIJDERS, T.1

*1: MAASTRICHT UNIVERSITY MEDICAL CENTRE+, 2: NETHERLANDS COMPREHENSIVE CANCER ORGANISATION, 3:TOP INSTITUTE FOOD AND NUTRITION, 4: ARLA FOODS INGREDIENTS GROUP*

INTRODUCTION: Androgen deprivation therapy (ADT) represents the cornerstone in prostate cancer (PCa) treatment. In addition to its inhibitory effect on tumor progression, ADT also causes several adverse effects including substantial loss of skeletal muscle mass. Resistance-type exercise training is an effective intervention strategy to counteract muscle mass loss during ADT. However, little is known about the impact of ADT on muscle fibre characteristics in PCa patients and the effect of resistance-type exercise training to reduce this impact. The objective of this study was to define the effect of resistance-type exercise training on ADT-induced changes on muscle fibre characteristics in PCa patients.
METHODS: Twenty-one PCa patients (72±6 y) starting ADT were included in the present study. Changes in muscle fibre characteristics were assessed in tissue samples collected from the vastus lateralis muscle at baseline and after 20 weeks of usual care (CON, n=11) or 20 weeks of progressive resistance-type exercise training (EX, n=10). Type I and type II muscle fibre distribution, fibre size, and myonuclear and capillary contents were determined by immunohistochemistry. Training-induced changes were analysed using a two-way repeated measures ANOVA with time (baseline vs 20 weeks) and fibre type (type I vs II) as within-subject factors and group (CON vs EX) as the between-subject factor. Significance was set at $P<0.05$ and all data are presented as means ± SDs.
RESULTS: A significant decrease in type I (from 7401±1183 to 6489±1293 µm2; $P<0.05$) and type II (from 6225±1503 to 5014±714 µm2; $P<0.05$) muscle fibre size was observed in the CON group. In addition, type I and type II individual capillary-to-fibre ratio (C/Fi) declined substantially (-12±12 and -20±21%, respectively; $P<0.05$) in the CON group. In contrast, significant increases in type I (from 6700±1464 to 7772±1319 µm2; $P<0.05$) and type II (from 5248±892 to 6302±1385 µm2; $P<0.05$) muscle fibre size were observed in the EX group. The training-induced muscle fibre hypertrophy was accompanied by an increase in type I and type II muscle fibre myonuclear content (+24±33 and +21±23%, respectively; $P<0.05$) and type I muscle fibre capillarization (capillary-to-fibre ratio +18±14%; $P<0.05$).
CONCLUSION: Twenty weeks of androgen deprivation therapy is accompanied by a decline in type I and type II muscle fibre size and capillarization in PCa patients. Supervised resistance-type exercise training offsets the negative impact of ADT and increases type I and II muscle fibre size and type I muscle fibre capillarization in PCa patients.

### THE DISTORTED MUSCLE SHAPE OF OLDER ADULTS IS ENHANCED BY THE DECLINE IN SKIN MECHANICAL PROPERTY

SUZUKI, J.1, OIWA, Y.1, MIYAMOTO, N., WASHINO, S.3, HIRATA, K.4, KANEHISA, H.5, YOSHITAKE, Y.1

*1 SHINSHU UNIVERSITY 2 JUNTENDO UNIVERSITY 3 NATIONAL INSTITUTE OF ADVANCED INDUSTRIAL SCIENCE AND TECHNOLOGY 4 WASEDA UNIVERSITY 5 KANOYA UNIVERSITY*

INTRODUCTION: Muscle physiological cross-sectional area (PCSA) decreases with age. Since PCSA is linearly correlated with maximal voluntary contraction force [1], specific tension does not change with age, possibly suggesting that muscle “quality” is comparable between ages. Therefore, it is not clear whether and why the decrease in muscle volume is not progressed in an analogous manner as the age-related loss of muscle mass is accompanied by a decrease in the pennation angle [2].
Our earlier study demonstrated that pennation angle and muscle shear modulus decreased after the removal of skin in Thiel-embalmed cadavers [3]. This study suggests that the skin should play a role to determine the shape and muscle mechanical properties. Since skin stiffness also declines with age [4], age-related distorted muscle shape is potentially due to an age-related decline in skin mechanical properties. On the basis that the facial skin is easily pulled down in old adults at the upright position [5], age-related distorted muscle shape might be affected by the orientation of muscle relative to the direction of gravity. The purpose of this study was to examine the relationship between age, skin mechanical property, gravity, and muscle shape.
METHODS: 15 young (YA) and 15 old adults (OA) laid in supine and prone positions to examine the effect of orientation of gravity on muscle shape. Skin shear modulus (SSM) was measured at the belly of the right medial gastrocnemius (MG) by shear-wave elastography. A 3D ultrasound technique was utilized to reconstruct MG geometry. Then, anteroposterior (AP) and mediolateral (ML) length of the cross section at 30% of proximal right lower leg length were calculated to evaluate MG shape. Two-factor factorial ANOVA was used to examine the effects of age and postures on SSM, AP, and ML length. After calculating the rate of changes in AP and ML length when posture was changed from supine to prone positions and averaging SSM between positions, the correlations between these values were analyzed.
RESULTS: SSM was lower in OA compared with YA ($P < 0.05$). AP length was smaller in the prone position than in the supine position for both age groups ($P < 0.05$). ML length was larger in the prone position than in the supine position for both age groups ($P < 0.05$) and ML length was larger for OA than for YA in the prone position ($P < 0.05$). SSM were positively correlated with rate of change in AP length ($r = 0.58$, $P < 0.05$) and negatively correlated with rate of change in ML length ($r = -0.53$, $P < 0.05$).
CONCLUSION: The results suggest that muscle shape was flatted for old adults more than young adults in the prone position. Distorted muscle shape should be facilitated due to lower skin shear modulus, which cannot maintain the muscle shape against gravity.

### IDENTIFYING THE DETERMINANTS OF PERFORMANCE DURING PACED AND MAXIMAL MIDDLE-DISTANCE RUNNING EVENTS

BELLINGER, P., LIEVENS, E., KENNEDY, B., ARNOLD, B., DERAVE, W., MINAHAN, C.

*GRIFFITH UNIVERSITY*

INTRODUCTION: Major championship 800-m and 1500-m races can be won in very fast times, with a sustained pace from the start, or in relatively slow times, but with an extremely fast last lap. It is likely that the underpinning physiological and speed/mechanical determinants would differ during these polarized middle-distance race scenarios. We conducted two separate experimental studies where we aimed to

identify the underpinning physiological and speed/mechanical determinants of performance during maximal and paced 1500-m (study 1) and 800-m running time trials (study 2).
METHODS: In study 1, 32 trained middle-distance runners (n = 21 male) completed a 1500-m time trial in the fastest time possible (1500MAX) and two paced trials whereby the mean speed during the 0–1100 m was reduced by 5% (1500MOD) and 10% (1500SLOW), whereas the last lap was completed in the fastest time possible. In study 2, 20 trained male middle distance runners completed an 800-m time trial in the fastest time possible (800MAX) and one paced trial, whereby mean speed was reduced by 7.5% (800PACE) relative to 800MAX, while the last lap was completed in the fastest time possible. In both studies, a series of additional laboratory and field tests were conducted to determine maximal sprint speed (MAXSS), VO2peak and the velocity corresponding with VO2peak (vVO2peak), running economy (RE), critical speed, maximal accumulated oxygen deficit (MAOD), and sprint force–velocity–power profiles. Carnosine content was quantified by proton magnetic resonance spectroscopy in the gastrocnemius and expressed as a Z-score to estimate muscle typology. Data were analysed using multiple stepwise regression analysis.
RESULTS: In study 1, 1500MAX time was best explained by RE and vVO2peak in female runners (adjusted r2 = 0.80, P < 0.001), in addition to the 0–1100-m speed relative to vVO2peak in male runners (r2 = 0.72, P < 0.001). Runners with a higher carnosine Z-score (i.e., higher estimated percentage of type II fibres) and greater MAOD, reduced their last lap time to a greater extent in the paced 1500-m trials. In study 2, MAXSS and vVO2peak best explained the variation in 800MAX time (r2 = 0.570; P = 0.020),whereas MAXSS was the best explanatory variable for the first 200-m time in 800MAX (adjusted r2 = 0.661, P < 0.001). Runners with a higher estimated percentage of type II fibres reduced their last lap time to a greater extent in 800PACE relative to 800MAX (r2 = 0.413, P < 0.001). A faster final 200-m time during 800PACE was associated with better maintenance of mechanical effectiveness during sprinting, a higher estimated percentage of type II fibres and vVO2peak (r2 = 0.761, P = 0.001).
CONCLUSION: These findings could inform the optimal racing strategies for middle-distance athletes with different physiological and speed/mechanical profiles and provide greater insight for coaches and sport scientists as to the training requirements to maximize performance in different types of middle-distance races.

#### INVESTIGATING CHANGES IN HEMATOPOIETIC STEM AND PROGENITOR CELL CONCENTRATIONS DURING AND AFTER CONTINUOUS VS. INTERVAL-BASED EXERCISE BOUTS

PRADANA, F., NIJJAR, T., MORGAN, P.T., PODLOGAR, T., LUCAS, S.J.E., WADLEY, A.J.
*UNIVERSITY OF BIRMINGHAM*

INTRODUCTION: Hematopoietic stem and progenitor cells (HSPC's) are donated by approximately 60,000 healthy individuals worldwide every year for patients with a variety of blood cancers and genetic disorders. However, barriers exist that limit the effectiveness of this process such as the time commitment to donate and side-effects of the drugs used to mobilise HSPC's (e.g., bone pain and headaches). A single bout of exercise can transiently increase the concentration of HSPC's in peripheral blood up to 2.5-fold; however, many of the exercise bouts used have been too long (30-45 min) to feasibly implement in a donation setting. HSPC kinetics appear to be driven by exercise intensity, yet the optimal balance between exercise intensity and volume to maximize mobilization of HSPC's is unclear. The current study aimed to compare changes in HSPC concentrations during and after bouts of high-volume high intensity interval training (HV-HIIT), low-volume high intensity interval training (LV-HIIT) and moderate intensity continuous training (MICT). Complete blood counts were conducted to determine whether HSPC mobilisation mirrored general leukocyte patterns.
METHODS: Ten males (mean ± SD: age 25 ± 7 years; BMI 25.7 ± 3 kg·m2; Wattmax 3.9 ± 0.8 W·kg-1) undertook bouts of MICT (30 min steady state, 65-70% of a maximum heart rate (HRMax)), HV-HIIT (4 x 4 min, 80-85% HRMax) and LV-HIIT (4 x 2 min, 90-95% HRMax) in a randomised crossover study design. HSPC's were enumerated in whole blood at rest, after each interval and 5- and 10-minutes post-exercise by employing a single-platform, flow cytometric method (defined as CD34+ CD45low SSClow).
RESULTS: HSPC concentrations (cell/ µL) significantly increased over time in response to all exercise trials (p < 0.0001). The peak response was highest after interval four of LV-HIIT (Pre-Exercise: 18.87 ± 2.50, post-Exercise: 34.00 ± 4.72, p = 0.01), but HSPC concentration was already elevated after just one interval (p = 0.0581, ns). Following the exercise trials, HSPC concentration decreased to resting concentration after 5 minutes of HV-HIIT (p = 0.0053), 10 minutes of MICT (p = 0.032), but remained sustained above rest 10 minutes after LV-HIIT (p = 0.0614). The peak fold change in HSPC's relative to rest (+1.80 ± 0.27) was not significantly (p > 0.05) different to total white blood cells (+1.66 ± 0.23) or lymphocytes (+1.89 ± 0.32).
CONCLUSION: LV-HIIT evoked a greater increase in HSPC concentration than MICT or HV-HIIT immediately post-exercise, with just one interval of LV-HIIT (2 minutes exercise) increasing HSPC concentration above rest. The increase in HSPC concentration was sustained for at least 10 minutes following LV-HIIT, but not MICT or HV-HIIT. These findings highlight that exercise intensity is a key factor driving HSPC mobilisation and sustainability in peripheral blood. Supporting some previous work, these changes largely mirrored the general mobilisation of leukocytes.

#### ETHNIC DIFFERENCES IN AEROBIC CAPACITY AND ITS HEMATOLOGICAL DETERMINANTS: THE CAUCASIAN-HAN CHINESE PARADOX

GUO, M., DIAZ-CAÑESTRO, C., DAI, H., MONTERO, D.
*UNIVERSITY OF HONG KONG*

INTRODUCTION: Maximal oxygen consumption (VO2max), a hallmark of aerobic capacity, is strongly associated with large decrements in cardiovascular events and all-cause mortality in the general population. Yet, to date, whether aerobic capacity is ethnic-specific and thus differences are inherently present in VO2max and its main biological determinants remains uncertain.
METHODS: Healthy young (< 35 yr) Caucasian (n = 18, 44 % females) and Han Chinese individuals (n=18, 44 % females) closely matched by age and moderate-to-vigorous physical activity (MVPA) were included in the study. VO2max was assessed with an established incremental exercise protocol. Exercise economy was determined at a moderate absolute workload (100 W). Hematological determinants such as blood

oxygen carrying capacity, blood volume (BV) and hemoglobin mass (Hbmass) were determined in standardized and controlled conditions using blood gas analyses and gas rebreathing methods.
RESULTS: Physical activity status, as represented by MVPA, was similar between Caucasian and Han Chinese individuals (6.2 ± 3.8 vs 6.3 ± 5.9 hr/wk, P = 0.936). VO2max was 22 % higher in Caucasian compared to Han Chinese individuals (43.8 ± 10.6 vs 35.9 ± 12.0 mL O2/kg/min, P<0.05) in spite of similar exercise economy as measured during submaximal exercise (19.3 ± 5.2 vs 21.0 ± 5.1 mL O2/kg/min, P = 0.342). With respect to hematological variables, BV (87.4 ± 9.5 vs 94.1 ± 10.5 mL/kg, P = 0.055) and Hbmass (11.5 ± 1.8 vs 12.1 ± 1.7 mL/kg, P = 0.240) did not differ between groups. Therefore, the BV/VO2max ratio was 23 % lower in Caucasian compared to Han Chinese individuals (2.04 ± 0.38 vs 2.51 ± 0.63 respectively, P < 0.05).
CONCLUSION: Large ethnic differences between young Caucasian and Han Chinese individuals are present in VO2max despite similar physical activity status and hematological phenotype.

**IRON DEFICIENCY ANEMIA AFFECTING VO2MAX DECREASE IN HYPOXIA**

KOSKOLOU, M.

*UNIVERSITY OF ATHENS*

INTRODUCTION: Anemia is common worldwide, particularly among women, with the most common underlying cause, iron deficiency, affecting 12–18% of apparently 'fit and healthy' women [Dugan et al. 2021, Anaesthesia, 76(Suppl.4): 56-62]. Physically active females often participate in sports and demanding physical activities performed in hypoxic conditions. Both anemia and hypoxia are factors affecting maximal oxygen uptake (VO2max) via decreases in arterial oxygen content (CaO2) and when combining these two stressors systemic oxygen delivery and peak power output are greatly impaired [Roach et al. 1999, Am. J. Physiol. 276(2): H438-H445]. The aim of this study was to explore whether physically active women with mild iron deficiency anemia would exhibit greater VO2max decrease in hypoxia compared to healthy controls.
METHODS: Two groups of young physically active women matched for age, body weight, height and fitness level participated in the study; one with normal hemoglobin (Hb) concentration and ferritin levels (C; n=15; [Hb]:13.23±0.5 g/dl; ferritin:28.33±16.9 ng/l) and another (IDA; n=15; [Hb]:10.96±0.5 g/dl; ferritin:7.25±2.8 ng/l) with mild iron deficiency anemia (10<[Hb]<12 g/dl, ferritin<12 ng/l). Both female groups performed progressively increasing cycling exercise to exhaustion under normoxia and hypoxia (FIO2 0.21 and 0.14) on two occasions, within the same phase of their menstrual cycle, separated by an interval of at least 24 hrs, and following a counterbalanced order. Cardiopulmonary parameters were recorded in all subjects, while muscle and cerebral oxygenation (NIRS) were monitored in a subgroup of subjects (n=16; 8 from the C and 8 from the IDA group). Data were analyzed using 2-way ANOVA and t-test for independent samples; p was set at 0.05.
RESULTS: Normoxic VO2max did not differ significantly between groups (C:40.4±2.5, IDA:37.8±4.3 ml/kg/min; p>0.05), but the VO2max drop elicited by hypoxia was more profound in IDA than in C (17.6±7.9 vs. 10.7±2.7%; p<0.01). In both conditions the two groups had similar maximal heart rate (p>0.05). At maximal exercise, oxygenated Hb (O2Hb) was lower across groups in hypoxia (p<0.01). Interestingly, higher values in deoxygenated Hb (HHb) were observed in the IDA compared to the C group, only under hypoxia (p<0.05). Cerebral tissue oxygenation index (TSI%) followed the changes in CaO2.
CONCLUSION: It appears that iron deficiency anemia exacerbates the detrimental effect of hypoxia on VO2max, possibly via the role of iron-containing proteins inducing impairment of cellular iron-dependent processes in oxygen utilization.

**EFFECTS OF THE MENSTRUAL CYCLE AND ORAL CONTRACEPTIVES ON ERYTHROPOIETIN LEVELS IN ENDURANCE-TRAINED FEMALES**

GUISADO-CUADRADO, I.1, ALFARO-MAGALLANES, V.M.1, ROMERO-PARRA, N.1,2, PEINADO, A.B.1

*1. LFE RESEARCH GROUP. DEPARTMENT OF HEALTH AND HUMAN PERFORMANCE. FACULTY OF PHYSICAL ACTIVITY AND SPORT SCIENCES. UNIVERSIDAD POLITÉCNICA DE MADRID, SPAIN. 2. DEPARTMENT OF PHYSICAL THERAPY, OCCUPA*

INTRODUCTION: Menstrual bleeding can affect circulating levels of available iron due to iron loss during the bleeding phase [1,2]. Results report that the lowest value of serum iron and transferrin saturation occurs during menses [1,2], concurring with the lower value of hepcidin, the main regulator of iron metabolism [2]. Conversely, another major hepcidin regulator and thus, iron metabolism is erythropoietin (EPO) [3]. Increased erythropoiesis stress and therefore, increased EPO levels could down-regulate hepcidin synthesis [3,4] through its suppression by erythroferrone (ERFE) to facilitate iron supply [3]. Nevertheless, evidence shows differences in iron availability among naturally menstruating compared to oral contraceptive (OC) endurance-trained females [1]. The aim of this study was to compare EPO levels throughout the different phases of menstrual cycle and OC phases in endurance-trained females.
METHODS: Nineteen eumenorrheic (30.8±6.5 years; 48.25±4.4 ml/kg·min-1) and fourteen OC users (25.8±4.8 years; 47.98±4.29 ml/kg·min-1) participated in this study. Blood samples were taken to analyze EPO just before (PRE) an interval running test, consisting of eight bouts of 3 min at 85% of the maximal aerobic speed, and 3 hours later (POST). The test was done in different sex hormonal environments: early follicular (EFP), late-follicular (LFP) and mid-luteal phase (MLP) for eumenorrheic women; and withdrawal (WP) and active pill phase (APP) for OC users. The three-step method was used to verify the menstrual cycle and OC phase [5]. Non-parametric test was used to compare the menstrual cycle and OC phases.
RESULTS: No significant differences were found between the menstrual cycle phases either PRE (EFP: 14.5±6.55 mU/ml; LFP: 16±6.45 mU/ml; MLP: 16.2±7.04 mU/ml) or POST (EFP: 11.9±6.56 mU/ml; LFP: 12.9±4.51 mU/ml; MLP: 13.1±6.24 mU/ml) or between OC phases either PRE (WP: 11.76±5.69 mU/ml; APP: 15.73±6.35 mU/ml) or POST (WP: 9.51±4.19 mU/ml; APP: 12.54±6.22 mU/ml). Additionally, no significant differences were observed between the menstrual cycle phases compared to OC phases.
CONCLUSION: Serum EPO does not appear to be affected by the different sex hormonal environments. Therefore, although EPO is responsible for the regulation of erythropoietic activity, and EPO may indirectly decrease hepcidin and increase plasma iron uptake [3,4], this lack of differences indicates that EPO levels seem not contribute to the reported changes in serum iron throughout the menstrual cycle.

**THE EFFECTS OF INHALING CARBON MONOXIDE PRIOR TO REPEATED SPRINT EXERCISE TRAINING ON CYCLING PERFORMANCE AND EXERCISE-INDUCED ADAPTATIONS**

CARDINALE, D.A.1,2, SUNDQVIST, C.1,2, ALONSO, J.2, ZUCCARELLI, L.3, GRASSI, B.3

*1 THE SWEDISH SCHOOL OF SPORT AND HEALTH SCIENCES ; 2 SWEDISH SPORTS CONFEDERATION ; 3 UNIVERSITY OF UDINE*

INTRODUCTION: Exercise-induced adaptations and athletic performance are improved more significantly following repeated sprint training in hypoxia than in normoxia. However, natural or artificial altitude training is expensive and not always accessible. Therefore, it is worthwhile to develop more convenient and less expensive training approaches that can induce both physiological adaptations and enhance athletic performance. When inhaled, carbon monoxide (CO) reduces the blood O2 carrying capacity and the O2 diffusion from capillary to muscle tissue, similarly to what happens in hypoxia. CO also regulates vascular and cardiovascular functions, stimulates anti-inflammatory response and mitochondrial biogenesis. Therefore, we hypothesized that, in association with improvements in repeated sprint ability (RSA), CO inhalation before sprint training would improve skeletal muscle oxidative function evaluated by determination in-vivo of skeletal muscle VO2 (VO2m) off-kinetics during the recovery from cycloergometer exercise.
METHODS: 23 endurance trained individuals age 33.2±6.9 years, body mass 78.3±11.0 kg, height 180.7±7.3 m, and VO2max 4.2±0.6 L·min-1 performed 9 supervised repeated sprint exercise sessions (3x5x10s all-out, 1:2 work to rest ratio) within 3 weeks. Cycling performance and physiological tests were performed within a week pre and post intervention. In a single blind fashion, the participants were randomly assigned to inhale either a bolus CO (INCO group) or placebo gas (CTRL group) before each exercise session. Analysis of covariance adjusted for baseline and sex was used to assess the effect of treatment on all variables.
RESULTS: The CO bolus administered prior to training increased HbCO to 5.5±0.4% from baseline and remained elevated (3.3±0.3%) following the training sessions. The training intervention increased the total work produced during RSA test by 26.7±10.3% (p= 0.001) with no difference between groups. RSA mean power decrement differed pre to post between groups (p=0.023) and was reduced in INCO (-2.7±7.9%) and worsened in CTRL (8.2±10.7%). HB-mass differed between groups pre to post intervention (p=0.038) and was preserved in INCO (-0.8±2.9%; p= 0.6) and reduced in CTRL (-4.9±3.5%; p=0.01). VO2m kinetic (tau) from a subgroup (n=10) differed between groups pre to post intervention (p=0.017), decreased in INCO (-38.8±32.9%; p= 0.05) and remained unchanged in CTRL (5.9±1.5%; p=0.72). No significant changes were found in other measured variables as VO2max and endurance performance.
CONCLUSION: These data indicate that CO inhaled prior to repeated sprint training induced beneficial effects on RSA and could be due to an improved mitochondrial function compared to placebo in amateur cyclists. This practice may also be beneficial to preserve HB-mass in periods when high intensity training is prioritized over large volumes of training. The effects of CO on performance and exercise induced adaptations could be advantageous in elite sport where even marginal gains are meaningful.

### OP-AP03 Swimming I

**CAN CRITICAL VELOCITY IN YOUNG SWIMMERS BE DETERMINED BY A 10X25M ALL-OUT SWIMMING TEST?**

MORGADO, J.P.1, CURTO, D.2,3, MATIAS, C.N.1,4, MONTEIRO, C.P.2,3, ALVES, F.B., REIS, J.F.2,3

*1- CIDEFES, UNIVERSIDADE LUSÓFONA, LISBOA, PORTUGAL 2– PHYSIOLOGY AND BIOCHEMISTRY LABORATORY, FMH-ULISBOA, PORTUGAL 3– CIPER, FMH-ULISBOA, PORTUGAL 4- BETTERY LIFELAB, BETTERY S.A., PORTUGAL*

INTRODUCTION: In swimming, Critical Speed (CS) is considered one of the key markers of aerobic capacity, which is important for monitoring training and competition. Recently, a 12x25m all out test was validated for CS determination in elite swimmers, a proxy of the 3 min all out test validated for other exercise modalities [1]. In young swimmers it may be pertinent to adjust the test to 10x25m so that the total duration approaches 3 min due to the lower maximal speed of the younger swimmers [2].
Our aim was to compare the CS calculated from the 10x25m with the traditional method using 200 and 400m efforts.
METHODS: Twenty national level swimmers (12 male, 8 female, age 14.5 ± 0.7 years) performed three evaluations, with 48 h in between. Swimmers completed ten 25 m all out front crawl swims from a push start separated by 5 seconds rest, with a maximum of 2 underwater butterfly kicks, in a 25m pool. Subjects were told to swim as fast as they could on each 25 m repetition and hold nothing in reserve for the rest of the test. The CS10x25 was calculated as the mean speed of the slowest two 25 m efforts in the last four repetitions [1]. In the second and third session, swimmers performed, respectively, 200m and 400m maximal but constant efforts. CS400-200 was calculated from the slope of the regression analysis between the distances performed and the correspondent time [3]. T-test for paired samples was used to compare CS10x25 and CS400-200 and Bland Altman analysis and Concordance Corrrelation Coeficient (CCC) were used to determine the agreement between both methods. Significance was set at p<0.05.
RESULTS: Despite a high correlation was observed (r=0.77; p<0.01), CS10x25 significantly overestimated CS400-200 (1.33±0.10 and 1.18±0.07 m·s-1, p<0.01, respectively). Bland Altman analysis showed that the mean difference between methods was 0.16 m·s-1 with wide limits of agreement (-0.03 to 0.29 m·s-1). CCC was 0.27, precision 0.77 and accuracy 0.36, which indicates a poor strength of agreement between the methods.
CONCLUSION: Although the 10x25m is a test that mimic training sets and can be easily integrated in the swimming sessions, our results suggest that in young swimmers the 10x25 all out test overestimates the critical speed and can not be used interchangeably with the classical method based on 200 and 400m maximal efforts. Future studies may consider 5-6x50 to acknowledge the specific physiological responses of young swimmers.

### PHYSIOLOGICAL AND KINEMATIC RESPONSES AROUND MAXIMAL LACTATE STEADY STATE IN SWIMMING

ESPADA, M.C.1,2, REIS, J.F.3, ALMEIDA, T.F.3,4, SANTOS, F.J.1,2,3, FERREIRA, C.C.1,5, PESSÔA FILHO, D.M.4,6, ALVES, F.B.3

*1 POLYTECHNIC INSTITUTE OF SETÚBAL; 2CIEQV; 3CIPER, FMH-UL; 4UNESP, BAURU; 5FCD, CÁCERES, UNEX; 6UNESP, RIO CLARO*

INTRODUCTION: Performance enhancement in sport is closely and decisively related to accuracy in identifying exercise intensities domains toward optimizing daily training [1] and kinematic parameters are particularly important in swimming since athletes´ classifications are often decided by tenths of a second. The aim of the present study was to evaluate the physiological and kinematic responses around maximal lactate steady state (MLSS) in swimming.
METHODS: Fourteen competitive male swimmers completed a maximal 400-m front crawl to use the average velocity between 50 and the 350-m as an estimate of the maximal aerobic velocity (MAV). In the subsequent days, swimmers completed an incremental step test (IST) comprising 5x250- and 1x200-m stages and afterwards, 30 min continuous swimming velocity (SV) tests were performed for MLSSv determination, followed by two 500-m constant SV bouts at 97.5% and 102.5% of MLSSv, for oxygen uptake kinetics (VO2k) evaluation. During all tests, VO2 was assessed through breath-by-breath gas exchange, blood lactate concentrations (BLC) were determined, and kinematic variables stroke rate (SR), stroke length (SL) and stroke index (SI) were evaluated.
RESULTS: SV associated with 4 mmol·L-1 in the IST (1.27±0.04 m·s-1) was significantly lower compared to MLSSv (1.30±0.04 m·s-1, $p<0.05$), but all physiological parameters SVs derived from IST and continuous tests were highly correlated. BLC associated with Log-log methodology (4.2±0.7 mmol·L-1) was significantly lower compared to Dmax methodology (4.9±0.8 mmol·L-1, $p<0.01$), the last was not significantly different from MLSS (4.6±1.1 mmol·L-1). VO2max (57.4±7.1 ml·kg·min-1) determined in the IST, was not significantly different from mean VO2 during 102.5% MLSSv swim trial (56.1±6.0 ml·kg·min-1), both were higher compared to mean VO2 at MLSSv (49.0±8.9 ml·kg·min-1). Mean VO2 were significantly different ($p<0.01$) 2.5% below and above MLSSv, the same was observed regarding SR, SL and SI. Considering the VO2k, the amplitude of the primary phase (Ap) was significantly lower below MLSSv compared to 102.5% (45.9±6.7 vs 49.5±6.9 ml·kg·min-1, $p<0.01$), contrary to the time constant of the primary phase (taup) (21.2±8.6 vs 19.0±7.7-s, $p>0.05$), despite high correlations observed between taup below and above MLSSv and SVs associated to physiological parameters. The same relationships were observed between the Ap and kinematic variables, but only at 97.5% of MLSSv.
CONCLUSION: Both the continuous and IST provide useful indexes of swimming aerobic potential, but they cannot be used interchangeably for MLSSv determination. This SV seems to represent the upper limit of stroke efficiency. MLSS cannot be associated to a fixed BLC, and gas exchange analysis should also be considered in swimming. Since swimmers evidenced a taup of around 20-s, coaches may prescribe training sets close to 80-s to endure VO2max, because 98% of the total VO2max is attained at four times taup [2].

### AGREEMENT OF LACTATE AND HEART RATE VARIABILITY THRESHOLDS IN SWIMMING

RAMA, L., LADEIRA, R.

*UNIVERSITY OF COIMBRA, FACULTY OF SPORT SCIENCES AND PHYSICAL EDUCATION*

INTRODUCTION: Heart Rate Variability (HRV) as a potential marker of athlete adaptation to training load has grown exponentially in recent years. The non-invasive character of this autonomic marker provides the basis for its use in the sports domain. The current research points to a close relationship between the thresholds assessed from HRV indexes and the blood lactate. It reinforces its utility to determine the exercise intensities in training prescription.
METHODS: 10 swimmers (4 male and 6 female) followed an incremental swimming protocol (5x200m freestyle), increasing the speed of each repetition from 80%, 85%, 90%, 95%, and >95% of their personal best performance in the distance (short course). The R-R intervals were collected with a cardiac heart rate band (Polar H10) and recorded with the heart rate monitor (Polar V800). Capillary samples were collected from the earlobe immediately, at the end of each repetition and after 3' and 5' after the last step, to determine the lactate values (Lactate Pro 2). HR data was analyzed through Kubios HRV Software. Fin). A vagal index, the standard deviation of the beat-to-beat instant variability (SD1) that reflects the short term HRV, was used for analysis. Lactate thresholds (LT) and the individual anaerobic threshold (IAT) values were determined through the speed-lactate relationship (Ergonizer Software.De).
RESULTS: The speeds for the Lactate and HRV thresholds do not differ statically ($p=0.203$ and $p=0.211$) for speeds of LT and IAT, respectively. For LT we found 1,26 ± 0.05m.s-1 and 1.27± 0.04m.s-1,( mean difference =0.02m.s-1; ES=0.04) and 1.36±0.08 m.s-1 and 1.39 ± 0.11 m.s-1 ( mean difference= 0.02; ES=0.06) for the speeds calculated from the SD1 HRV index and those determined from the lactate – speed curve respectively.
CONCLUSION: Like others before, which found agreement between HRV and Lactate Thresholds assessed through incremental protocols in running and cycling, this study also confirms the coincidence of the threshold's speeds evaluated in incremental swimming protocol. Although HRV analysis demands expertise to analyze the data and the investment in heart rate monitors able to r-r recording, this result reinforces alternative methods in assessing influential makers of monitoring and training prescription without traditional invasive procedures.

### ANAEROBIC TEST IN FOUR FREE SWIMMING TECHNIQUES THROUGH INERTIAL SENSORS

CHIRICO, E., TESSITORE, A., VANNOZZI, G., DEMARIE, S.

*UNIVERSITY OF ROME*

INTRODUCTION: Water sports performance optimisation relies on specific, reliable procedures to assess physiological and biomechanical improvement, useful for coaches to monitor the athlete's conditions and predict future performance. [1,2,3]. A new approach to swimming coaching has been offered by innovative wearable technologies and waterproof coatings. They provide not only reliable and objective analysis of stroke mechanics and race performance, but also of physiological qualities such as the anaerobic capacity, all directly in free swimming [5]. The present study aimed to assess if a free-swimming protocol with inertial sensors may provide an effective assessment of kinematic and functional capacity in swimmers, specialized in four different techniques, by measuring speed and stroke parameters and their correlation with race time.
METHODS: Twenty-five highly trained national level [4] swimmers (13 male, 12 female) were recruited for the study. An all-out 75m bout in each athlete competition swimming technique was performed by all subjects in a short course swimming pool. The athletes were instructed to reach maximal velocity as fast as possible and to keep it till the end of the trial. During the protocol, temporal and kinematic variables were recorded through a waist-mounted inertial sensor and analysed as previously described [5]. Blood lactate concentration and RPE were assessed after the end of the test.

RESULTS: Average velocity in all four techniques was significantly correlated with the Time Race on 50m (r = .959, p < .05) and 100m (r = .973, p < .05). The average velocity was strongly correlated with stroke length and stroke efficient index (r = .779 and r = .702, p < .05), demonstrating how velocity may be affected by these variables even over short distances. Concerning the Fatigue Index, a significant correlation was highlighted with the total blood lactate production recorded after the end of the test (r = .567, p < .05). Finally, a negative correlation between RPE and stroke length - stroke efficient index was found (r = -.716, r = -.658, p < .05).
CONCLUSION: Velocities were related to kinematic variables and to swimming performance in 50m and 100m competitions. Swimmers with higher fatigue index presented more blood lactate concentration at the end of the tests, those with worse kinematic qualities suffered higher perception of effort. Therefore, temporal, and kinematic variables measured by the inertial sensor in the 75m all-out tests may be applied to infer and predict swimmers' performance and functional capacity in all four techniques and can be used for training monitoring and planning during the season.

**TIME SPENT NEAR VO2PEAK AT THE MAXIMAL AEROBIC VELOCITY IN SWIMMING – CONTINUOUS VS INTERMITTENT SETS**

ALMEIDA, T.F.1,2, ESPADA, M.C.3, MASSINI, D.A.4, MACEDO, A.G.1, OLIVEIRA, T.P.4, REIS, J.F.2, ALVES, F.B.2, PESSÔA FILHO, D.M.1,4

*1UNESP, BAURU; 2CIPER, FACULTY OF HUMAN KINETICS – UL; 3POLYTHECNIC INSTITUTE OF SETÚBAL; 4UNESP, RIO CLARO*

INTRODUCTION: The maximal aerobic velocity (MAV) is usually used by coaches for the planning of training at high swimming intensity since it combines exercise economy and maximal oxygen uptake (VO2peak). Also, the time sustained near VO2peak (e.g., above either the second ventilatory threshold (t@VT2) or 90% VO2peak (t@90%VO2peak)) is associated to long term adjustments that enhance VO2max and performance [1,2,3]. This study aimed to compare the physiological responses when performing continuous vs intermittent sets at MAV to determine which reproduces swimming conditions with higher potential for aerobic capacity development.
METHODS: Thirteen well-trained male swimmers (16.5±1.9 years, 178.6±8.4 cm, 70.4±10.3 kg) completed a discontinuous incremental test [3] for VO2peak, VT2 and MAV assessment. On complementary days, two swimming trials at MAV until exhaustion, continuous (CT) vs intermittent (IT) sets composed of 100 meters repetitions (IT100) with 15 s breaks, were performed for maximal oxygen uptake (Peak-VO2), t@VT2 and t@90%VO2peak evaluation. Distance and time were recorded to determine the tests' time limit (tLim). Maximal blood lactate concentration [La-] and rate of perceived exertion (RPE) were determined. All tests were conducted using a breath-by-breath apparatus connected to a snorkel for pulmonary gas sampling, with pacing controlled by an underwater visual pacer.
RESULTS: VO2peak (4.0±0.4l L·min-1) was only reached in the CT (100.2±3.0 %VO2peak). Still, high values were reached at IT100 (96.3 ± 4.6 %VO2peak). VO2peak was highly correlated with Peak-VO2 during CT (r=0.94, p<0.01) and IT100 (r=0.89, p<0.01). Compared with CT, the IT100 presented significantly higher values for tLim (940.0±470.9 vs 243.6±59.3 s), distance (1215.4±612.5 vs 309.6±64.7 m), t@VT2 (419.7±196.7 vs 137.5±80.2 s) and t@90%VO2peak (290.7±214.7 vs 115.5±79.1 s). tLim between CT and IT100 were not associated. MAV (1.30±0.07 m·s-1) and Peak-V̇O2 during CT and IT100 correlated with the 400 m swimming performance (r=-0.55, r=-0.73 and r=-0.76 p<0.05, respectively). RPE and [La-] were not different between CT and IT100 (8.8±1.0 vs 9.5±0.8 and 7.5±2.9 vs 6.5±1.3 mmol·l-1, respectively).
CONCLUSION: MAV is suitable for planning swimming intensities requiring maximal oxygen rates whatever the exercise schedule (CT or IT). The times to exhaustion at this swimming intensity are not related to swimming performance, however, MAV and Peak-VO2 values were related to middle-distance performance, whatever the exercise schedule and therefore highlighting their role in training for performances requiring maximal aerobic power attainment. Therefore, the results suggest the IT100 as a preferable training schedule compared to CT for aerobic capacity training since IT100 presented a significantly higher tLim, t@VT2 and t@90%V̇O2peak (more ~697, ~282 and ~175 s, respectively), without demanding different cellular acidosis and RPE.

### OP-AP22 Endurance training and testing

**VALIDITY AND RELIABILITY OF HEART RATE VARIABILITY THRESHOLDS USING DFA A1**

SEMPERE-RUIZ, N., PASTOR, D., MOYA-RAMÓN, M., SARABIA, J.M.

*MIGUEL HERNÁNDEZ UNIVERSITY*

INTRODUCTION: The short-term scaling exponent alpha1 of detrended fluctuation analysis (DFA a1), a nonlinear index of heart rate (HR) variability (HRV), has been shown to change with increasing exercise intensity. Recent studies have demonstrated that a value of 0.75 and 0.5 correlates with first and second ventilatory threshold (VT1 and VT2), respectively [1,2], and a value of 0.75 has been related to LT1 [3]. On the downside, we have not found any study about reliability of DFA a1 to estimate intensity thresholds. Therefore, the aim of this study was to compare HR derived from a predefined DFA a1 transitional value, to that reached at VT1, VT2 and lactate thresholds, using a Polar H10 and a 3-lead ECG to record RR time series, in order to consider/test the validity of the heart rate monitor too. Furthermore, the study aims to assess the reliability of DFA a1 to measure intensity thresholds.
METHODS: 16 moderately trained volunteers performed two incremental exercise tests to exhaustion on a cyclergometer (Ergomedic 839E, Monark, Denmark). Respiratory gases (MasterScreen CPX, Jaeger, Germany) and HR (Elite HRV and BIOPAC) were measured continuously during cycling, and lactate measures were collected. HRV thresholds (HRVT1 and HRVT2) were defined as the HR reached at a DFA a1 of 0.75 and 0.5, respectively. To evaluate ventilatory thresholds a mixed method was used [4], and lactate thresholds were calculated with baseline +1.0 (LT1) and Log-Exp-ModDmax (LT2). A paired t-test was used to detect changes between methods as well as correlations

(Pearson's r), Bland-Altman plots, intraclass correlation coefficient (ICC), typical error (SEM) and coefficient of variation (CV) to determine validity and reliability. Significance was set at p<.05.
RESULTS: Mean HRVT1 with ECG was 158±14 bpm, compared to HRVT1 with Polar H10 of 155±16 bpm, VT1 of 129±16 bpm, and LT1 of 132±19 bpm. Mean HRVT2 with ECG was 170±10 bpm, compared to HRVT2 with Polar H10 of 170±12 bpm, VT2 of 163±14 bpm, and LT2 of 161±14 bpm. No significant differences were found between ECG and Polar H10 for HRVT1 (P=0.361), and HRVT2 (P=0.747). Moderate and low correlations were seen between methods, with Pearson's r values of 0.43 (HRVT1-VT1), 0.67 (HRVT2-VT2), 0.69 (HRVT1-LT1), and 0.64 (HRVT2-LT2). Bland-Altman analysis for HRVT1 and VT1 showed a mean difference of 33±14 bpm, for HRVT1 and LT1 of 15±11 bpm, for HRVT2 and VT2 of 7±11 bpm, and for HRVT2 and LT2 of 2±10 bpm. ICC was high for both HRVT1 (0.93) and HRVT2 (0.94). SEM for HRVT1 and for HRVT2 was the same (0.29), and CV was 6.7% for HRVT1 and 5.9% for HRVT2.
CONCLUSION: Polar H10 has shown to be a valid device to measure DFA a1 during an incremental cycling test. In addition, intensity thresholds assessed using DFA a1 were moderately correlated to ventilatory and lactate thresholds, showing high reliability.

### DEVELOPING A COURT-BASED ASSESSMENT OF MAXIMAL AEROBIC SPEED IN NETBALLERS

JOHNSTON, H.1, PROSTINAKOVA, T.1, CRANE, J.1, PARTRIDGE, N.2, ARMSTRONG, O.3, LUCAS, S.J.E.1

*1 SCHOOL OF SPORT, EXERCISE AND REHABILITATION SCIENCES, UNIVERSITY OF BIRMINGHAM, UK; 2 ENGLAND NETBALL, UK; 3 PERFORMANCE CENTRE, UNIVERSITY OF BIRMINGHAM SPORT, UK*

INTRODUCTION: Netball is a sport that places high physiological demands on athletes to sustain peak performance, especially at the professional level. Despite the increase in elite performance, there remain limitations regarding the accessibility, time-efficiency, and specificity of testing methods to assess key physiological requirements of the sport, in particular the fundamental component of a high aerobic capacity and maximal aerobic speed (MAS). The purpose of this study was to develop a valid and practical field-based fitness test, assessing the aerobic capacity of netball players, which was compared against the gold standard laboratory-based VO2max test. It was hypothesised that the speed at which VO2max was elicited during laboratory testing (vVO2max) would be similar to the speed at which a 30-court length time trial was completed.
METHODS: Eleven trained female netball players (19±1 years; 176±7.1cm; 67.9±9.3kg) completed a standardised incremental laboratory VO2max test on a treadmill, followed by three subsequent sessions involving a 30-court-length time trial on an indoor netball court (best performance compared to lab). MAS was measured as the speed at which VO2max was elicited on the treadmill (vVO2max) and calculated as the speed of completing the 30 court lengths (total distance/completion time). Heart rate peak (HRPeak) was measured via telemetry (Polar) during all sessions, and blood lactate concentration was obtained via blood samples at 1, 3 and 5-minutes post-cessation of the lab test and final court-based assessment. Paired t-test and linear regression examined the relationship of all outcome measures between the lab and court-based assessments.
RESULTS: Lab-based vVO2max was significantly higher than the court-based measure of vVO2max (4.29±0.30 vs. 3.75±0.25 m/s; p<0.001). HRpeak was also significantly higher during the lab test than the court-based assessment (193±9 vs. 189±10 bpm; p =0.048). Blood lactate was not different between lab test and court-based assessments (10.75±1.83 vs. 10.16±2.06 mmol/L; p =0.144). In addition, centre court players showed the highest vVO2max in both lab and court tests, whilst the goal shooter position displayed the lowest vVO2max values. Consistent with this, there was a very strong correlation between the lab and court-based vVO2max values (r =0.870).
CONCLUSION: In summary, the maximal aerobic speed achieved in the court-based assessment was not a direct reflection of lab-based vVO2max. Potential explanations for this difference include biomechanical factors of change of direction and running mechanics on a treadmill vs on-court, and the time-of-day differences between testing (court-based all early morning). Nevertheless, this is the first- and only-time efficient netball-specific testing method to be compared to gold standard VO2max testing, ultimately providing a tool for practitioners to profile individual players, develop tailored training programmes and improve the performance of elite netballers in the future.

### BREATH TOOLS: HOW TO INSTRUCT AND QUANTIFY ADHERENCE TO BREATHING PATTERN SOUND GUIDANCE DURING RUNNING

HARBOUR, E., VAN RHEDEN, V., SCHWAMEDER, H., FINKENZELLER, T.

*UNIVERSITY OF SALZBURG*

INTRODUCTION: Many runners feel physical distress and psychological discomfort due to exercise-induced dyspnea; this is especially true for female beginners. Breathing pattern (BP) guidance, such as breathing rate (BR) sound instruction, could help runners maintain stable BP during running. Instructing locomotor-respiratory coupling (LRC; synced step & breath) may be especially helpful since it is simple to learn and metabolically advantageous. We sought to examine female runners' adherence to novel BP instruction sounds during running and compare acute effects of the instruction to baseline BP.
METHODS: Two groups of 13 healthy beginner-intermediate female runners (age=27.0±6.7) participated in a series of treadmill and field runs at submaximal intensity. Baseline BP was collected from running without sound prior to each trial. In the first indoor experiments, various BR and LRC sounds were played at fixed tempos derived from each runner's baseline and at progressively slower rhythms (-15, 30%). In the second experiments, one LRC sound was step-synchronized and sonified via a smartphone application ("Breathtool") during a 30 min outdoor run and variable intensity treadmill runs (±10% self-selected speed). BP was gathered using Hexoskin (HX) shirts (Carré Technologies, CAN) and processed via a custom algorithm. Sound instruction adherence was estimated using BR cv (BRV), attachments, and MAPE as done previously. Repeated-measures ANOVA was used to estimate meaningful differences between sounds, within individuals, and experimental conditions. Pearson's correlation coefficients were used to calculate relationships between objective adherence and subjective experience questionnaires.
RESULTS: Baseline BP averaged BR=30.1±5.1 bpm and LRC=4.8±1.0 steps per breath across the experiment. BR sounds reduced BRV 16.5±5.2% to 9.0±3.4%, with overall excellent adherence (MAPE<2.5%, % time attached >85%), individual analysis showed a preference for more information-rich sounds (MAPE η2 =.21). Adherence was lower with slower BR (% attached η2 =.23). LRC sounds stabilized BRV from 15.3±4.0% to 7.2±3.1%. Adherence was moderate (MAPE=1.2-3.3%, % time attached=48.6-77.3%), and best for combined breath+step sound (η2 =.19). With Breathtool, runners exhibited much greater adherence indoors compared to the first study (% time attached=92.6±9.7 vs. 64.9±11.6%). There was lower adherence to Breathtool outdoors versus indoors (η2 =.45) and there was no effect of speed on adherence. LRC instruction resulted in lower respiratory variability (η2 =.16-.21) versus baseline across all conditions. Finally, we observed weak to moderate correlations between BR and RPE (r=0.52), % attached and perceived usability (r=0.31), and HR and subjective vitality (r=-0.36).

CONCLUSION: We suggest using information-rich, step-synced sounds to maximize adherence to BP instruction. Sound adherence can be effectively summarized with two metrics: % time attached and MAPE. Future work should determine if psychophysiological benefits result.

**VALIDATION OF A NON-EXERCISE METHOD FOR ESTIMATION OF VO2MAX BEFORE AND AFTER A PRE-SEASON TRAINING PERIOD IN SUB-ELITE AND ELITE FOOTBALL PLAYERS**

HANSEN, M.T., RØMER, T., LANGE, K., SAHL, R.E., BLOM, I., SCHMÜCKER, M., PETERSEN, M.L., IBH, A.E.P., LARSEN, M.N., HAWARI, Y.J.E., SCHMIDT, S.E., SØRENSEN, K., DELA, F., KRUSTRUP, P., HELGE, J.W.

*UNIVERSITY OF COPENHAGEN*

INTRODUCTION: The gold standard for determination of maximal oxygen consumption (VO2max) is by graded exercise testing (GET) with pulmonary gas exchange measurements and is regularly used to assess fitness status. However, this methodology requires time, maximal exercise and expensive equipment and are therefore not always suitable. These limitations also applies for semi and professional football clubs. A new non-exercise VO2max prediction model using seismocardiography (SCG) at rest in combination with demographic data is now available. SCG is a measurement of precordial vibrations using an accelerometer. The prediction model is validated in normal healthy subjects, but not yet in trained athletes. The aim was to investigate the accuracy of the SCG VO2max prediction model in sub-elite (SUB) and elite (Elite) football players and the detection of changes following a pre-season training period.
METHODS: 35 SUB players from the 3th and 4th best division and 10 Elite players from the best division in Denmark completed both pre and post testing. 12 SUB and 14 Elite players were lost to post testing. The SUB players were tested in 2021, hereafter the SCG VO2max prediction model was adjusted, before testing the Elite players in 2022. Testing included determination of body composition by a DXA scan (Pre: 79.0±2.3 kg and 83.1±5.2 kg (weight), 15.0±1.3% and 12.8±1.4% (fat), 66.9±1.8 kg and 68.5±4.2 kg (fat free mass) for SUB and Elite players, respectively (mean±95% CI)). Subsequently, VO2max was estimated at supine rest with the SCG recording device, SeismoFit®, placed on the lower part of sternum (Pre: 47.2±1.9 ml/min/kg (SUB) and 55.1±2.1 ml/min/kg (Elite). Lastly, a GET on a treadmill until voluntary exhaustion was performed for determination of VO2max (Pre: 57.1±1.6 ml/min/kg (SUB) and 57.8±3.3 ml/min/kg (Elite).
RESULTS: Accuracy of pre testing: SCG VO2max was lower (Student's paired t-test: $p<0.0001$) compared with GET for SUB, but not different for Elite ($p=0.123$). A positive Pearson's correlation of $r=0.56$ ($p<0.0001$) and a standard error of estimate (SEE) of 11.4 ml/min/kg between SCG and GET VO2max was found for SUB, whereas no correlation ($r= 0.50$, $p=0.138$) and a SEE of 5.9 ml/min/kg was found for Elite. Changes from pre to post: GET VO2max increased by 2.7±0.8 ml/min/kg (SUB, $P<0.0001$) and 1.6±1.2 ml/min/kg (Elite, $P=0.033$). SCG VO2max increased by 1.7±1.2 ml/min/kg (SUB, $p=0.011$) and 0.1±1.3 ml/min/kg (Elite, $p=0.921$). No correlation between changes in SCG and GET VO2max was found for either SUB ($r=-0.24$, $p=0.171$) or Elite ($r=-0.06$, $p=0.870$). Weight was unchanged for SUB and Elite ($p>0.05$).
CONCLUSION: The accuracy of the original SCG VO2max prediction model was poor in sub-elite football players. When the prediction model was adjusted the accuracy improved substantially and was good in elite football players. However, the SCG VO2max prediction model is not suitable for detecting changes in VO2max following a training period in a sub-elite and elite population.

**THE ROLE OF A NOVEL HEART RATE VARIABILITY MEASURE IN ESTIMATING THE FIRST VENTILATORY THRESHOLD**

MULLIRI, G., SAINAS, G., ROBERTO, S., MAGNANI, S., PINNA, V., DONEDDU, A., FANNI, M., GHIANI, G., CRISAFULLI, A.

*UNIVERSITY OF CAGLIARI*

INTRODUCTION: Evaluating the lactate threshold (LT) is of paramount importance for both training and clinical purposes. The first ventilatory threshold (VT1) has been extensively used as an alternative to LT. This method derives LT indirectly from oxygen consumption ($VO_2$), carbon dioxide production ($VCO_2$), and ventilation ($V_E$) during the incremental cardiopulmonary exercise test (CPET). In detail, VT1 corresponds to the level of exercise at which an increment of the ventilatory equivalent for oxygen ($V_E/VO_2$) without a concomitant increase of the ventilatory equivalent for carbon dioxide ($V_E/VCO_2$) takes place.
Since VT1 requires a laboratory with trained staff and expensive devices, different heart rate variability (HRV) parameters have been proposed in the past as surrogate measures. This approach is based on the assumption that when a subject reaches LT, there is an almost complete vagal withdrawal that corresponds to a great reduction of HRV indexes that are highly correlated with vagal tone. The present study aimed at evaluating a novel HRV index derived from standard frequency-domain HRV measures, namely the sum of the power of the low and high components of the HRV spectrum (LF-HFpower).
METHODS: 27 subjects (6 females) were recruited in this study. All participants underwent a CPET on a cycle ergometer to assess VT1, while LF-HFpower was determined from ECG traces recorded during tests. Then, the values from 10 randomly chosen subjects were utilized to conduct a Watt- LF-HFpower non-linear regression analysis, with the exponential decay being the mathematical model that best fitted the data as demonstrated by an Akaike Information Criterion evaluation.
Afterward, Watt/ LF-HFpower curves of the 10 subjects were calculated, and the average of values at the level of exercise that corresponded to VT1 for each subject were taken and used as a reference value (RF). In the end, the Watt/ LF-HFpower curves of the remaining 17 subjects were calculated, and the LF-HFpower threshold (LF-HFthreshold) was set at the level of exercise corresponding to the value that was closest to RF. Paired sample T-test, Pearson correlation, Bland-Altmann plot analysis, mean bias, standard deviation (SD) of bias, and limits of agreement (LoA) were employed to compare VT1 and LF-HFthreshold.
RESULTS: The paired sample T-test did not show any significant difference between the methods ($p=0.7$). Pearson analysis demonstrated a good correlation ($R2$ 0.79; $p=0.0001$). Bland – Altmanns plot showed good results with mean bias, SD of bias, and Loa equal to -2.06 Watt, 22,17 Watt, and -46,57/+42,56 Watt, with a more significant difference between methods for higher values.
CONCLUSION: LF-HFthreshold demonstrated a good correlation with VT1. Further studies with bigger samples are warranted to refine the ability of LF-HFthreshold to detect VT1 more accurately. However, this method could be a valid inexpensive alternative to VT1 in evaluating athletes and patients fitness.

## OP-AP23 Female Team sports

### ANTHROPOMETRIC AND PERFORMANCE CHARACTERIZATION OF U16 AND U18 FEMALE HANDBALL PORTUGUESE NATIONAL TEAMS

CARVALHO, A.M.1, GOUVEIA, P.1, MESQUITA, J.2, PINEU, I.1, SÁ, C.1,2, SÁ, P.1,2

*1-RESEARCH CENTER IN SPORTS SCIENCES, HEALTH SCIENCES AND HUMAN DEVELOPMENT, CIDESD, UNIVERSITY OF MAIA, ISMAI, PORTUGAL 2-PORTUGUESE HANDBALL FEDERATION, FPA*

INTRODUCTION: Handball is an invasion team sport, characterized with high levels of impacts, change of direction and intermittent efforts1. Due to all the dimensions that it comprises - technical, tactical, psychological/social and physical characteristics - handball is a very complex sport 2. Each player has its own unique cognitive or physical characteristics that somehow are more suitable for each playing position2. For this reason, it is important to highlight the features that coaches should search when pursuing those differentiated players that might be suitable for national team. This topic gains more importance when it comes to female handball, where research is only growing in the recent years 1,2. The purpose of this study was to characterize the physiological profile of the Portuguese young female handball players.
METHODS: 36 young female handball players belonging to the Portuguese National team participated in our study. We conducted several performance tests in the early phase of the 2021/2022 season (Vertical Jump: squat jump-SJ, Countermovement Jump-CMJ, Countermovement Jump free arms-CMJFA; Horizontal Jump-HJ; Medicinal ball throw-MBT; Handgrip-HG; Sprint ability-10m and 20m; Change of direction-COD). Players were divided by age (U16 n=18 body height (BH): 170,90±5,1 cm, body weight (BW): 68,88±12,88 Kg; U18 n=18 body height (BH): 171,94±6,6 cm, body weight (BW): 70,36±10,27 Kg). IBM SPSS 27 was used for descriptive analyses and differences between groups were analyzed with t-test ($p<.05$).
RESULTS: There were no significant differences in the anthropometric measures between the two groups. However, when looking for all the performance variables, significant differences were found in all the tests, except MBT. As expected, the older players perform better in all the tests, even in MBT.
CONCLUSION: From our results we may conclude that more mature players are better prepared for physical testing. Even though these two groups are only two years apart and not significantly different when referring to the anthropometric measures, the U18 athletes have already started their journey in the National teams a couple of years ago and have yet been present in an international competition. They seem better prepared in the early stages of the season, most of them are already playing in their senior teams, some of them playing the Portuguese first division. Further research should focus on comparing the beginning and the end of the season.

### RELATIONSHIPS BETWEEN LINEAR SPRINT PERFORMANCE, COD VELOCITY, AND COD-DERIVED MEASUREMENTS IN ELITE FEMALE RUGBY SEVENS PLAYERS

FREITAS, T.T.1,2,3, PEREIRA, L.A.2, MARÍN-CASCALES, E.3, MERCER, V.P.2, MOURA, T.B.M.A.2, ARRUDA, A.F.S.4, ARENHAR, I.4, ALCARAZ, P.E.1,3, LOTURCO, I.2

*1. UCAM RESEARCH CENTER FOR HIGH PERFORMANCE SPORT, 2. NAR-NUCLEUS OF HIGH PERFORMANCE IN SPORT, 3. STRENGTH AND CONDITIONING SOCIETY, 4. CBRU-BRAZILIAN RUGBY CONFEDERATION*

INTRODUCTION: In rugby, change of direction (COD) efforts are determinant during match-play as these actions frequently precede decisive game actions (e.g., a try). Thus, investigating players' ability to effectively accelerate, decelerate, and execute cutting and turning maneuvers in multiple directions is essential (1). When assessing COD ability, variables such as COD deficit (CODD, difference in percentage between a linear sprint test and a COD task of equal distance) and deceleration deficit (DD, difference between the time taken to accelerate and come to a complete stop when changing direction in relation to the linear sprint performance) have been shown to provide meaningful and complementary information for coaches (2,3). However, to date, no study has simultaneously assessed both CODD and DD in female rugby sevens. This research aimed to examine the relationships between linear sprint and COD velocities and indirect COD-derived measurements (i.e., CODD, DD) in a sample of elite female rugby athletes.
METHODS: Nineteen players (age: 23.7±3.5 years; body mass: 66.4±7.5 kg; height: 168±10 cm) from the Brazilian National Team performed linear sprint (i.e., 15-m) and 505 COD tests. Average velocities, CODD, and DD were computed from the sprint and 505 data. The Pearson product–moment analysis was used to test the correlations among the distinct variables.
RESULTS: Linear sprint velocity and COD velocity were not correlated ($r=-0.21$; $p>0.05$) but the former was largely associated with CODD ($r=0.78$; $p<0.05$). Large inverse relationships were observed between 505 velocity and COD-derived variables (CODD: $r=-0.77$; $p<0.05$ and DD: $r=-0.79$; $p<0.05$). Finally, a large relationship was observed between CODD and DD ($r=0.79$; $p<0.05$).
CONCLUSION: The findings indicated that, in this specialized sample, athletes with superior linear sprint velocities were not necessarily faster when completing the 505 task (highlighting the specificity of these physical capabilities). Nevertheless, faster players in linear sprinting actions tended to display superior CODD, which suggests that they were less efficient at changing direction (1). The strong negative correlations between 505 velocity and CODD and DD support that performance in this COD maneuver is highly determined by the athletes' capacity to abruptly (and quickly) decelerate and re-accelerate. From a practical perspective, to improve female rugby sevens' players ability to perform 180º directional changes, training strategies should aim to reduce CODD and optimize their deceleration ability instead of focusing on increasing linear sprint capabilities.

**PHYSICAL AND PHYSIOLOGICAL PROFILE OF PROFESSIONAL FEMALE HANDBALL PLAYERS**

RENOUF, F.

*UNIVERSITY OF PAU AND PAYS DE LADOUR*

INTRODUCTION: Physical profile of professional female handball (HB) team can help coaches and physical trainer to adapt and individualize physical training. Profile knowledges allow to know which fitness qualities are required for a high level of practice. Power, aerobic fitness, strength and an optimal body composition are required in a goal of success in different competition (1,2). To our knowledges, no study in professional female HB has investigated physical and physiological collective and individual profile of players. Therefore, the purpose of this study was (i) to describe collective and individual profile of a professional female HB and (ii) to compare the front line (FL) players composed by wings and pivots, and the rear line (RL) players composed by backs.
METHODS: 11 female HB players (4FL and 7RL), belonging to the French professional League 1 were recruited for the study. Mean values (±SE) of age, height, body mass, fat mass, and lean body mass were respectively 24.5 ±1.3 years, 178.2 ±2.5 cm, 70.5 ±2.2 kg, 20.6 ±0.9 % and 56.0 ±1.3 kg. Datas were monitored in the first week of the pre-season period. Power and strength were monitored on lower body with the iphone application (Apple Inc, USA) Myjump and a strength knee isokinetic test using the Con-trex machine (Medimex, Con-trex Multi-Joint MJ, Ste Foy-les-lyon, France). We assessed height (cm), power (W), strength (N) and speed (m/s) for Counter Movement Jump (CMJ) and Squat Jump (SJ). Isokinetic test has collected absolute and relative peak torque (PT and PT/kg) , peak power (PP) for quadriceps (Q) and hamstrings (H) , and H:Q ratios, using angular velocity of 240°/s (concentric Q and H), 90°/s (concentric Q and H) and 30°/s (eccentric H). Aerobic profile was monitored with the Vameval outside test and the 30-15ift. VO2max was estimated with the Vameval result (3.5 x velocity of the full last step). Anthropometrics datas were assessed by the Geonaute Scale 300 (Decathlon. France) for body mass. Percentage of fat mass was estimated from 4 skinfolds thicknesses technical (Harpenden Skinfold Caliper).
RESULTS: Our results show no significantly difference between FL and RL for absolute and relative PT, PP, Conventional and Functional ratios. Bilateral Force Deficit of FL was higher ($P<0.01$) than RL for H at 90°/s (FL: 20.6±4.1 ; RL: 4.7±1.8). No significant results for anthropometric and aerobic datas are shown between FL and RL players. Concerning jumps tests, power is higher ($P<0.05$) for FL on CMJ and SJ than RL (CMJ datas; FL: 2098.1±30.7W; RL: 1812.3±86.9W ; SJ datas ; FL: 2033.7±20.9W ; RL: 1722.0±93.5W). Strength is significantly higher ($P<0.05$) for FL players than RL players on CMJ (FL: 1560.5±45.8N ; RL: 1374.7±51.4N).
CONCLUSION: A better knowledge about the physical profil of female HB players may improve quality of individual training. Players in the same position can have a different physical profil which means that coaches and physical coaches have to adapt work on individual needs and not only according position.

**THE ANTHROPOMETRIC AND PHYSICAL QUALITIES OF FEMALE INTERPROVINCIAL RUGBY UNION PLAYERS**

CALLANAN, D., RANKIN, P., FITZPATRICK, P.

*INSTITUTE OF TECHNOLOGY CARLOW*

INTRODUCTION: Anthropometric and physical testing provides practitioners with valuable information on normative values for a particular cohort, individual characteristics and group trends (Jones et al. 2016). This information can assist with team selection, identifying areas for development, aid in more precise planning of training/physical preparation and dietary goals for athletes (Agar-Newman et al. 2017; Harty et al. 2019). To date, no study has investigated the anthropometric and physical qualities of female interprovincial rugby union (RU) players.
METHODS: Forty-one interprovincial female RU players (n = 41) from two teams playing in the interprovincial series 2019 volunteered to participate in this study. Each participant underwent anthropometric testing; height, body mass and skinfold assessment and physical characteristics tests; counter movement jump height, speed (5m, 10m and 20m), isometric strength levels and Yo-Yo intermittent recovery test level 1. Players were classified into forwards and backs and positional subcategory groups; front row (FR), second row (SR), back row (BR), half-back (HB), midfield (MF) and back three (B3). An independent t-test was conducted to examine any differences in anthropometric and physical qualities as a consequence of playing position (forward v back). A multivariate analysis of variance was conducted to examine differences in anthropometric profiles and physical qualities between positional category group.
RESULTS: Forwards displayed greater height ($p = 0.000$; $d = 1.47$), body mass ($p = 0.00$; $d = 1.56$), greater total of seven ($p = 0.001$; $d = 1.23$) and eight skinfolds ($p = 0.001$; $d = 1.17$) and a higher percentage of body fat ($p = 0.001$; $d = 1.25$) than backs. Backs were quicker for 10m sprint time than forwards ($p = 0.049$; $d = 0.70$). Further analysis into position groups illustrated differences for both anthropometric and physical qualities. The FR displayed the greatest levels of body mass ($p = 0.004$), with the SR recording the greatest height ($p = 0.041$). The FR reported the highest levels of sum of 7 skinfolds ($p = 0.021$), the greatest levels of sum of 8 skinfolds ($p = 0.024$) and the highest percentage of body fat % ($p = 0.017$). The B3 recorded the quickest 10m and 20m time ($p = 0.004$ and $p = 0.000$, respectively). For strength levels, the FR and BR recorded the greatest peak force ($p = 0.018$ and $p = 0.002$, respectively).
CONCLUSION: This study supports the concept that there are anthropometric and physical characteristic differences between forwards and backs and positional subcategory groups. The results of this study provides normative data for coaches and practitioners who are involved in the planning and preparation of female interprovincial RU players. This study will aid in creating physical profiles of forwards and backs and positional category groups, which has not been investigated to date.

Jones et al. (2016)

**ENERGY AVAILABILITY IN ELITE FEMALE AUSTRALIAN FOOTBALL PLAYERS**

CONDO, D., YOUNG, C., JARDINE, J., KELLY, M., SLATER, G., CARR, A.

*DEAKIN UNIVERSITY*

INTRODUCTION: Energy demands of the Australian Football League-Women's (AFLW) competition, combined with limited investment in nutrition support, may result in issues regarding energy availability (EA). There is little published data on EA in female team-sport athletes, with most research focusing on the risk of low energy availability (LEA), as inferred from subjective questionnaires likely due to the difficulty in quantifying energy expenditure (EE). The aims of this study were to quantify EA in AFLW players while contrasting outcomes against validated questionnaires and to investigate associations between dietary intake, EE and EA in AFLW players.
METHODS: Over 10 consecutive days during pre-season (including four training days), EI and EE were collected in 14 elite AFLW players. Weighed food diaries were recorded using the smartphone application Easy Diet Diary (Xyris Software, Australia). Exercise EE was quanti-

fied using individual algorithms, developed from accelerometer data (PlayerloadTM, Catapult Innovations, Scoresby Australia) and oxygen uptake during a maximal aerobic capacity test. PlayerloadTM data was collected during field training and the algorithm used to estimate EE. The SenseWearTM Armband was used to determine EE outside of field training. Fat-free mass (FFM) was measured via Dual Energy X-ray Absorptiometry (DXA, Hologic, QDR) and resting metabolic rate was measured via indirect calorimetry (Cosmed Quark, Italy), EA was calculated on training and non-training days, with LEA ≤30cal/kg FFM. The low energy availability in female's questionnaire (LEAF-Q) was administered to determine the risk of LEA. Generalized linear models were used to estimate the effect of dietary intake and EE on EA.
RESULTS: There was no difference in EA between training [44.3(14.0) cal/kg of FFM] and non-training [14(12.8) cal/kg of FFM] days. EI, carbohydrate (CHO) and protein intake were higher on training vs non-training days ($p<0.001$). Total daily CHO, protein and fat intake were associated with EA on both training ($\beta=0.070$, $\beta=0.077$, $\beta=0.133$, $p<0.001$, respectively) and non-training ($\beta=0.080$, $\beta=0.064$, $\beta=0.153$ $p<0.001$, respectively) days. There was an association between total daily EE and EA on non-training days ($\beta=-0.001$, $p=0.019$). On training days, 1/14 (14.3%) players were classified as LEA and on non-training days 2/14 (7.1%) of players were classified as LEA. The LEAF-Q classified 5/14 (35%) of players as at risk of LEA.
CONCLUSION: This is the first study to investigate EA using objective measures in female team-sport athletes. Irrespective of training, EA remained stable, whilst dietary intake differed, likely a result of the varying EE. The identification of AFLW players 'at risk' of LEA via LEAF-Q was higher compared to objective measures indicating that the LEAF-Q, validated in endurance athletes, may over-represent LEA in team sport athletes. To accurately assess EA in female team-sport athletes, a validated method to measure exercise EE and tool to assess the risk of LEA is required.

## Invited symposia

### IS-MH02 Lifestyle psychiatry: the potential of physical exercise and other healthy habits for severe mental disorders

#### AN ONLINE MENTAL HEALTH INFORMED PHYSICAL ACTIVITY INTERVENTION FOR EMERGENCY SERVICE WORKERS AND THEIR FAMILIES: A STEPPED-WEDGE TRIAL

MCKEON, G.

*SCHOOL OF PSYCHIATRY*

Background: Emergency service workers are at an increased risk of experiencing poor mental health including posttraumatic stress disorder due to prolonged, repeated exposure to potentially traumatic events. Promoting healthy lifestyle behaviours including physical activity and diet may help to mitigate some the consequences of emergency service work. This study aimed to evaluate the impact of an online physical activity and diet intervention on levels of psychological distress among emergency service workers and their nominated support partner e.g., spouse, family member.
METHODS: We delivered a 10-week intervention via a private Facebook group facilitated by exercise physiologists, a dietitian and peer-facilitators. Weekly modules on topics including overcoming barriers to exercise, reducing sedentary time, self-monitoring of activity and nutrition were delivered. Weekly group telehealth calls were conducted and participants were provided with a physical activity tracking device (Fitbit). A stepped-wedge design was applied to compare levels of psychological distress (Kessler-6) during baseline, to intervention by comparing slopes of change. Separate slopes were modelled for a) baseline; b) intervention slope 1; c) intervention slope 2; d) change in level of knot points. Secondary outcomes included a pre-post assessment of mental health symptoms, physical activity levels, quality of life, sleep quality and suicidal ideation.
Results: In total, N=90 participants (n=47 emergency service workers and n=43 support partners) were recruited in 4 separate cohorts (mean age 42.3(SD=11.5) years, 51% male). Levels of psychological distress did not change significantly during the baseline (control) slope, while during the first 6 weeks of intervention (intervention slope 1) levels reduced significantly. The interaction between baseline and intervention slopes were significant, $b=-0.351$, $p = 0.003$, (i.e., the trajectories of change were significantly different) and improvements plateaued until the 4-week follow up (intervention slope 2). Retention was high (92%) and participation was associated with improvements in mental health symptoms, weekly minutes of physical activity, sedentary time and quality of life.
Conclusions: A 10-week physical activity intervention delivered via social media is feasible and effective in improving psychological distress among emergency service workers and their support partners.

#### IMPLEMENTING AN EXERCISE PHYSIOLOGY CLINIC FOR CONSUMERS WITHIN A COMMUNITY MENTAL HEALTH SERVICE: A REAL-WORLD EVALUATION

MORELL, R.

*UNSW, SYDNEY*

Background: Physical activity significantly improves mental illness symptoms and physical health for people living with mental illness. Mental health services do not routinely provide their consumers with access to exercise professionals for physical activity engagement. Barriers exist to integrating physical activity as part of standard care including staff culture, finance, and resources. This study examines the feasibility of newly established exercise physiology clinic within a mental health service in Sydney, Australia.
METHODS: A single site, open trial was conducted in a community centre within a large mental health district. A meeting room was converted into a part-time exercise physiology clinic where individualised physical activity interventions were delivered by an accredited exercise physiologist. Outcome measures including BMI, cardiovascular fitness, and self-reported physical activity were collected.
Results: A total of 84 mental health consumers (17% of eligible consumers within the mental health service) participated in the clinic on average for one exercise session weekly. Moderate-to-vigorous physical activity significantly increased and sedentary time significantly decreased ($p < 0.001$).
Conclusions: Exercise physiology clinics are feasible within mental health services and should be incorporated as part of standard care.

**PHYSICAL ACTIVITY, SEDENTARY LIFESTYLE AND SLEEP, KEY FACTORS IN THE HEALTH AND WELL-BEING OF PEOPLE WITH SEVERE MENTAL DISORDERS**

BUENO-ANTEQUERA, J.

*UNIVERSIDAD PABLO DE OLAVIDE*

Psychiatric disorders, such as schizophrenia, major depression and bipolar disorder, are among the leading causes of all-cause death, and disability worldwide. The global economic burden of psychiatric disorders in 2010 was similar to that of cardiovascular diseases and higher than that of cancer, chronic respiratory diseases and diabetes and expected to more than double by 2030. Therefore, reducing the growing burden of psychiatric disorders is a global health priority.
To try to close this gap, exercise physiologists from the Universidad Pablo de Olavide promotes a line of research (called PsychiActive) and another for the transfer of knowledge to society (called PowerONyou) to help people with psychiatric disorders to improve their health-related quality of life through physical exercise and other healthy habits.
This talk summarizes two outstanding scientific contributions derived from the PsychiActive project, in detail, (1) the effects of a 18-month lifestyle changes, primarily increasing time engaged in physical activity and eating healthier, improved cardiovascular health and fitness, and reduced sedentary behaviour, body weight, severity of psychiatric symptoms and mediation use in a woman with bipolar disorder and (2) the effects of a 12-week group-based intervention of supervised aerobic and strength exercise training that was safe, feasible, and effective for improving cardiorespiratory fitness, muscular strength, and anthropometric parameters in psychiatric men inmates. Additionally, this talk will present recent results on scientific studies that addressed the changes related to physical activity, sedentary lifestyle and daily sleep in people with psychiatric disorders, applying a statistical technique called analysis of compositional data and the evolution towards the PowerONyou project.
In conclusion, the work carried out highlights the usefulness of physical activity, sedentary lifestyle and sleep to promote the health and well-being of people with severe mental disorder and the need to invest efforts in the transfer of knowledge to get the scientific message to society.

## Oral presentations

### OP-SH03 Learning in PE I

**CHALLENGE-BASED LEARNING INTERVENTION IN PHYSICAL ACTIVITY AND SPORT SCIENCES DEGREE FROM A GENDER PERSPECTIVE**

GONZÁLEZ-PEÑO, A., TRUCHARTE, P., OCETE, C., MARTÍNEZ-MAJOLERO, V., FRANCO, E.

*UNIVERSIDAD POLITÉCNICA DE MADRID; UNIVERSIDAD PONTIFICIA COMILLAS*

Introduction
Challenge-Based Learning (CBL) is an innovative learning methodology that consists of posing a challenge as the main didactic element (Nichols et al., 2016). This methodology has been addressed in different disciplines, although few studies have been carried out in physical activity-related educational (PAE) contexts. However, not only its implementation seems to be a challenge, but also the integration of the Information and Communication Technologies (ICT). A recent proposal in PAE context have been recently developed (Franco et al., 2020). The objectives of the present study were (I) to analyse the effect of implementing this methodology on university students learning outcomes; and to analyse differences in the impact of the intervention by gender.
Methods
The sample consisted of 94 students (71 male and 23 female) studying Physical Activity and Sport Sciences degree (M= 20.04 and SD = 1.74) between year one and year four. The intervention was implemented over 14 weeks. A pre-post questionnaire was administered, with a sample of 105 responses. Mann-Whitney and Wilcoxon tests were performed with each group.
Results
After the experience, significant differences were found between groups in CBL knowledge (M=-1,26 y DT =-1,52), ability to develop proposals with CBL (M=-1,35 y DT =1,44) and innovative proposals (M= -1,06 y DT =-1,42), and ability to use ICT (M=-1,20 y DT = 1,44). When deepening in gender differences, no influence was found.
Discussion
The results of the experimental group showed higher scores after the CBL intervention in all variables. It seems that experiential learning can promote teachers' self-efficacy in the implementation of such a methodology. When teachers perceive self-efficacy, they are likely to use creative teaching, for example, by implementing innovative methodologies or ICT. Finally, no significant differences were found according to gender. Although there is evidence that perceived experiences in PAE contexts differ according to gender, the present study did not found differences between women and men, fact that posits CBL as an excellent alternative regardless of teachers' gender.

**MANIPULATING CONSTRAINTS TO LEARN VOLLEYBALL SKILLS WITH NOVICES: ANALYSIS OF A REAL SITUATION**

PONS-OLIVER, M.1, LÓPEZ-ROS, V.1,2

*UNIVERSITAT DE GIRONA*

INTRODUCTION

Sport skills acquisition requires an effective interaction with the environment. Constraints-Led Approach (CLA) suggests that constraints shape the emergence of coordinated action through self-organisation processes [1]. In this study, we implemented a Volleyball Unit following the Integrated Technique-Tactical Model [2] in regular lessons of a Physical Education (PE) program. Following CLA, practice was designed to afford certain specific actions highlighting its functional key elements [3]. The aim of this study was to investigate the effects of three task constraints manipulation in the learning of overhand and underhand pass in volleyball with novices, considering two different skill levels of mastery: emergence/exploration and refinement [4].
METHODS
Forty-eight subjects (26F; 10-11Y) with no prior experience in volleyball, divided into two natural school classes (C1 & C2), performed 6 PE lessons (50') aimed at the learning of basic technique and tactic elements. During practice, task constraints (serve direction and trajectory, and pass precision required) were altered to provoke the emergence and refinement of functional movement patterns. An adaptation of Game Performance Assessment Instrument [5] was used to assess learning through collection of effective or ineffective executions (E_EX & I_EX respectively). Assessment task (3 vs 3 match) was conducted and recorded in sessions 1, 4 and 6. Two-way RM ANOVAs and Bonferroni post-hoc tests were performed to analyse the intervention effects. Significance was set at $P<0.05$. A qualitative analysis was used to determine the parameters varied within each constraint, their effects on the subject, and if they were directed to the skill emergence or refinement.
RESULTS
The overall results displayed an increase in E_EX and I_EX at the end of the unit in C1 and C2. C1 showed significant increases in E_EX between baseline and intermediate assessment ($p<0.05$) and final assessment ($p<0.05$). C2 significantly increased E_EX and I_EX between baseline and intermediate assessment ($p<0.05$) and E_EX between baseline and final assessment ($p<0.05$). The qualitative analysis revealed three key parameters modified: a) serve ball initial and final position, b) performer initial position, c) level of precision required in the pass. They affected mainly the impact spot, orientation and intention of the subject. Tasks aiming technique emergence presented different parameter variations than tasks aiming skill refinement.
CONCLUSIONS
The findings of this study suggest that a unit of intervention implementing constraints manipulation was effective to promote learning of the overarm and underarm volleyball skills with novices. The qualitative results show that constraints were shaped differently depending on whether the goal was to provoke the emergence of the movement pattern or to refine it.

**INCIDENTAL TEACHING STRATEGIES FOR LEARNING BASKETBALL THROUGH SMALL-SIDED GAMES**

CAMACHO LAZARRAGA, P.

*CENTRO UNIVERSITARIO SAN ISIDORO*

INTRODUCTION: Introduction
In recent years there has been an increasing number of studies that have tried to find out whether incidental teaching strategies favor learning and performance more than deliberate strategies in team sports-related skills, or if not, whether they produce the same benefits. Many studies conclude that in this type of sports, such as basketball, characterized by high uncertainty, time limits and high stress, incidental or intuitive strategies reduce the possibility of performance degradation under pressure, as the amount of conscious information processed by the brain (cognitive load) decreases, thus freeing resources for other important processes, such as decision making. Reduced games seem to be an ideal learning environment where players can develop both types of processing, those that allow a more deliberate thinking, when there is time to think, and those that activate other more intuitive or incidental processing, when there is no time to think, as they represent an approximation to the real game that allows players to regulate their performance according to each of the specific situations they face and must solve. The aim of the present study is to analyze whether the manipulation of practice conditions in reduced game situations in basketball without the explicit external intervention of the coach can provoke learning in the players and reduce the possibilities of performance degradation under pressure conditions.
METHODS: Methods
An intrasubject design with repeated measures pretest and posttest was elaborated on a reduced situation of collective 3x3 basketball game with temporal and functional limitation (number of bounces). Twelve participants belonging to a male basketball team aged 15-16 years (M=15.32; ±1.26) with more than 5 years of basketball practice participated. Four groups were randomized: incidental group, incidental control group, explicit group and explicit control group.
RESULTS: Results
The incidental group showed the same performance as the explicit and control group when time was not limited. On the other hand, it showed higher performance when the time to perform the actions was shorter. In addition, the incidental group showed a progressive reduction in the use of the pot and an increase in its efficiency under time limit conditions, thus showing an improvement in the use of this skill, and therefore a better learning.
CONCLUSION: Discussion & Conclusion
In general, we can affirm that reduced game situations in basketball represent an effective learning environment for the use of incidental teaching strategies, as they reduce the possibility of degradation of the players performance in conditions of increased pressure, and can also favor the achievement of learning of different specific skills in a real environment, with the advantages that this entails.

## OP-MH03 Physical activity promotion

### MODERATING EFFECTS OF AGE AND INDIVIDUALIZATION ON MHEALTH INTERVENTIONS TO REDUCE PHYSICAL INACTIVITY AND SEDENTARY BEHAVIOR IN CHILDREN AND ADOLESCENTS

BAUMANN, H., FIEDLER, J., WUNSCH, K., WOLL, A., WOLLESEN, B.

*UNIVERSITY OF HAMBURG*

INTRODUCTION: Children and adolescents increasingly do not meet physical activity (PA) recommendations. Hence, insufficient physical activity (IPA) and sedentary behavior (SB) among children and adolescents are relevant behavior change domains for using individualized mobile health (mHealth) interventions. The current review and meta-analysis investigates the effectiveness of mHealth interventions on IPA and SB with a special focus on age level of individualization.
METHODS: . The Review was preregistered on PROSPERO International Prospective Register of Systematic Reviews (CRD42020209417). PubMed, Scopus, Web of Science, SPORTDiscus, and Cochrane Library were searched for randomized controlled trials published between January 2000 and March 2021. mHealth interventions for primary prevention in children and adolescents addressing behavior change regarding IPA and SB were included. Included studies were compared for content characteristics as well as methodological quality and summarized narratively. In addition, a meta-analysis with a subsequent exploratory meta-regression examining the moderating effects of age and individualization on overall effectiveness was performed.
RESULTS: Based on inclusion criteria, 11 of the preliminary 825 identified studies were included for qualitative synthesis and 10 were included for the meta-analysis. Trials included a total of 1515 participants (Age (M, SD) = 11.69 ± 0.788; 65% male; 35% female) with self-reported (n = 4) or device-based measured (n = 7) health data on the duration of SB and IPA for an average of 9.3±5.6 weeks. Studies with high levels of individualization decreased insufficient PA levels significantly (d = 0.33; CI = 0.08, 0.58; z = 2.55; p = 0.01), whereas those with low levels of individualization (d = -0.06; CI = -0.32, 0.20; Z = 0.48; p = 0.63), or targeting SB (d = -0.11; CI = -0.01, 0.23; z = 1.73; p = 0.08) indicated no overall significant effect. Heterogeneity of the studies was moderate to low, and significant subgroup differences between trials with high and low levels of individualization ($\chi 2 = 4.04$; df = 1; p = 0.04; $I^2 = 75{,}2\%$) were found. Age as a moderator variable showed a small effect, but the results were not significant which might have been due to being underpowered.
CONCLUSION: Evidence suggests that mHealth interventions for children and adolescents can foster moderate reductions in IPA but not SB. Moreover, individualized mHealth interventions to reduce IPA seem more effective for adolescents than for children. Although to date only a few mHealth studies address inactive and sedentary young people and their quality of evidence is moderate, these findings indicate the relevance of individualization on the one hand and the difficulties in reducing SB using mHealth interventions on the other hand.

### EVALUATION OF THE FEASIBILITY, PSYCHOSOCIAL EFFECTS, INFLUENCE AND PERCEPTION OF ELASTIC BAND RESISTANCE BALANCE TRAINING IN OLDER ADULTS.

DAVIS, N.M.1, PRINGLE, A.1, KAY, A.D.2, BLAZEVICH, A.J.3, TESKEY, D.1, FAGHY, M.A.1, MINA, M.A.1

*1, UOD (DERBY, UK), 2: UON (NORTHAMPTON, UK) 3: EDITH COWAN UNIVERSITY (JOONDALUP, WESTERN AUSTRALIA)*

INTRODUCTION: Physical activity (PA) interventions improve balance, strength and coordination, positively contributing to independence and quality of life reducing the risk of falls in older adults (OA). However, PA interventions often consider efficacy as the primary outcome measure, whilst failing to integrate older adults into the co-design and co-production to ensure internal validity and improve participant enjoyment, satisfaction and adherence [1]. Therefore, the aim of this study was to develop and justify a novel PA intervention using different elastic band exercise techniques attached to the hip or chest to challenge balance using qualitative variables (feedback/opinion and perceptions) to create a practically feasible, accessible and cost-effective intervention specifically designed for OA to reduce the risk of falls.
METHODS: Twenty-three active participants (age = 66.5 ± 8.3 y, height = 1.6 ± 0.1 m, mass = 83.2 ± 14.9 kg) volunteered for the study. The participants completed 8 exercises (8-12 repetitions) using elastic bands designed to challenge postural stability in two conditions (HIP and CHEST) by providing lateral resistance and instability. Conditions were performed 15 min apart in a randomised counterbalanced order. Heart rate (HR) and rate of perceived exertion (RPE) were measured throughout with an interview conducted after to investigate the preferences, comfort and difficulty of the exercises performed. Template analysis was conducted to examine participant feedback with two-way repeated measures ANOVAs used for quantitative data with statistical significance set at $P < 0.05$.
RESULTS: Similar significant increases in HR (baseline 83-85 bpm; mid 85-88 bpm; post 88-89 bpm) and RPE (baseline 8-9; mid 10; post 10-11) occurred during the HIP and CHEST conditions. Interviews revealed that participants thought the interventions challenged balance and they perceived the exercises to be beneficial for stability and balance, confirming that the exercises were suitable for themselves and others. Participants' reported a positive experience and confirmed they would perform the exercises again, preferably in a group with the band placed at either the hip or chest region due to individual preference and comfort.
CONCLUSION: Participants reported key preferences contributing to the design of a PA intervention using elastic bands confirming the use of these exercises as a feasible, accessible and appropriate PA intervention set at low-to-moderate intensity for OA These qualitative variables will inform intervention design and delivery in future studies with the potential to improve balance and stability in OA with further research required to confirm its efficacy for altering balance and sway patterns.

### HIGH INTENSITY INTERVAL TRAINING IN SCHOOLS: METHODS FOR QUANTIFYING INTENSITY AND THE VALIDITY OF SESSION RATING OF PERCEIVED EXERTION

DUNCOMBE, S.L., STYLIANOU, M., PRICE, L., WALKER, J.L., BARKER, A.R.

*UNIVERSITY OF QUEENSLAND; UNIVERSITY OF EXETER*

INTRODUCTION: Few studies report the exercise intensity of high intensity interval training (HIIT) interventions in schools. When reported, heart rate (HR) is the most common measure, but the methods for quantification have not been consistent. Further, due to the setting, it will be important to understand the utility of quick, lost-cost measures when HR is not feasible. The aims of this study were to: 1) investigate the different methods used to quantify intensity via HR in school-based HIIT research and 2) assess the criterion validity of session rating of perceived exertion (sRPE) for quantifying the training load of school-based HIIT workouts.
METHODS: Ten-minute HIIT workouts were completed in 6 classes at 2 schools during health and physical education lessons for 8 weeks. HR (via Polar 10 monitors) and sRPE (via Children's Omnibus RPE scale) data were collected on average once per week during and immediately after HIIT workouts, respectively.
The following aspects were examined: 1) mean average and peak HR for all students and sessions combined; 2) percentage of time spent in various deciles (>80%, and >90% HRmax); 3) percentage of students with an average HR >80% and >90% HRmax; 4) variability within and between students; and 5) mean sRPE for all students and sessions combined. To assess criterion validity of session-RPE, a training impulse (TRIMP) for HR was calculated using the Edwards' method. To calculate sRPE (in arbitrary units), student's RPE was multiplied by the total duration (seconds) of the workout.
Means, standard deviations and frequencies were determined for HR and RPE quantification methods. Variability within and between students was examined using linear mixed models. Within-participant correlation (r) between TRIMP and session-RPE was calculated for validity of RPE.
RESULTS: In total, 761 measurements were collected from 132 students ($\bar{x}$ age 13.2 ± 0.6 years; 17 females) across 47 HIIT sessions. Mean average and peak HR were 79% ± 7% of HRmax and 92% ± 6% of HRmax, respectively. Students spent 38% ± 21% of time with a HR between 80-89% and 14% ± 20% of time with a HR of >90%. The mean percentage of students within a class with an average HR >80% was 53% ± 22%. The within person variation was 14.8 % points of HRmax for peak HR with a decrease of 0.42% per week ($p < 0.001$). Mean sRPE across all students and sessions was 5.9 ± 2.4 points. The within-person correlation between sRPE and TRIMP was 0.46 ($p < 0.001$).
CONCLUSION: Reporting intensity is necessary for understanding if the intervention was implemented as intended. Further, it is useful to report more than one outcome to showcase the variability in the data: across participants; throughout the session; and across the intervention timeline. Further work is needed to confirm our findings on the relationship between HR and RPE in a large, generalisable population of students, but results suggest the utility of using sRPE when HR is not a viable option.

### REPLACING SITTING WITH LIGHT-INTENSITY PHYSICAL ACTIVITY THROUGHOUT THE DAY VERSUS 1 BOUT OF VIGOROUS-INTENSITY EXERCISE: SIMILAR CARDIOMETABOLIC HEALTH EFFECTS IN MS

NIESTE, I., FRANSSEN, W.M.A., DUVIVIER, B.M.F.M., SPAAS, J., SAVELBERG, H.H.C.M., EIJNDE, B.O.

*HASSELT UNIVERSITY*

INTRODUCTION: Persons with Multiple Sclerosis (PwMS) are physically inactive and spend more time in sedentary behaviours than healthy persons. Reduced physical activity increases the risk of developing cardiometabolic diseases. In this proof-of-concept study, the cardiometabolic health effects of replacing sitting with light-intensity physical activity (LIPA) and exercise (EX) were investigated.
METHODS: In a randomised crossover study, 28 mildly disabled PwMS performed four 4-day activity regimens in free-living conditions: (1) CONTROL: 9.7h sitting/day, (2) SIT: 13.3h sitting/day, (3) LIPA: 8.3h sitting, 4.7h standing and 2.7h self-perceived light-intensity walking/day and (4) EX: 11.6h sitting/day with 1.3h vigorous-intensity cycling. During LIPA and EX, perceived exertion was monitored daily. On day 5, following each regimen, plasma glucose and insulin during a 2-hour oral glucose tolerance test, plasma lipids, inflammation, resting heart rate, blood pressure and body weight were measured.
RESULTS: Compared to SIT, significant improvements ($p<0.001$) after LIPA and EX were found for insulin total area under the curve (-17019±5708 and -23303±7953pmol/L*min), insulin sensitivity (Matsuda index +1.8±0.3 and +1.9±0.4) and blood lipids (triglycerides: -0.4±0.1 and -0.5±0.1mmol/L; non-high density lipoprotein cholesterol: -0.3±0.1 and -0.5±0.1mmol/L), with no difference between LIPA and EX. Triglycerides were also lower after LIPA compared to CONTROL (-0.4±0.1mmol/L, $p=0.011$). Heart rate was lower after LIPA compared to SIT (-3±1bpm, $p=0.05$) and diastolic blood pressure after EX compared to SIT and LIPA (-5±1 and -4±1mm Hg, $p=0.044$). Perceived exertion was higher after EX compared to LIPA (Borg scale [6-20]: +2.6±3.3, $p=0.002$).
CONCLUSION: Replacing sitting with LIPA throughout the day is more feasible and exerts similar cardiometabolic health effects as one daily bout of vigorous-intensity exercise in PwMS.

### THE EFFECT OF DOMAIN-SPECIFIC EXERCISE INTENSITY PRESCRIPTION ON MAXIMAL AEROBIC CAPACITY IN YOUNG HEALTHY INDIVIDUALS: A RANDOMIZED CONTROLLED TRIAL

INGLIS, E.C.1, IANNETTA, D.1, MACKIE, M.1, RASICA, L.1, KEIR, D.A.2, MURIAS, J.M.1

*1 UNIVERSITY OF CALGARY, CANADA; 2 WESTERN UNIVERSITY, CANADA*

INTRODUCTION: Exercise intensity is a key-factor modulating the magnitude of health- and performance-related improvements in response to exercise training. Despite this, the true contribution of exercise intensity to these changes remains elusive. This is because current exercise prescription methods, such as those based on percentage of maximal oxygen uptake (VO2max) or its surrogates (e.g., maximal heart rate), ignore differences in the position of individual-specific intensity thresholds (i.e., the exercise intensity domain schema) and consequently do not ensure a homogenous metabolic stimulus across individuals. Thus, this study assessed the effect of exercise intensity through individualized, domain-based exercise prescription on changes in VO2max. We hypothesized that domain-specific prescription, matched for total work, would elicit distinct improvements in VO2max that are proportional to the level of exercise intensity.
METHODS: Eighty-four young healthy participants (42 F, 42 M) were randomly assigned to six different groups (5 exercise, 1 control (CT); 14 participants per group). The exercise interventions consisted of three continuous cycling groups in the 1) moderate (MOD)-, 2) lower heavy (HVY1)-, and 3) upper heavy intensity (HVY2)- domain and two interval cycling groups including 4) high-intensity interval training (HIIT) in the severe-intensity domain and 5) sprint-interval training (SIT) in the extreme-intensity domain. All training groups, except SIT, were work-matched. Training participants completed three training sessions per week for six weeks with physiological evaluations performed before (PRE) and after (POST) intervention.

RESULTS: At PRE, there were no significant differences in relative (p=0.866) VO2max between groups. All training groups, except for MOD (+1.8 ± 2.7 ml/kg/min), had a significant increase in VO2max at POST compared to CT (+0.1 ± 1.2 ml/kg/min). HIIT demonstrated the highest increase in VO2max (+6.2 ± 2.8 ml/kg/min) followed by HVY2 (+5.4 ± 2.3 ml/kg/min), SIT (+4.7 ± 2.3 ml/kg/min) and HVY1 (+3.3 ± 2.4 ml/kg/min). The VO2max increases observed in HVY2, HIIT and SIT were all greater than MOD (p<0.05) while HIIT was significantly greater than HVY1 (p<0.05).
CONCLUSION: These results demonstrate that work-matched exercise training at well-defined exercise intensities elicit distinct improvements in VO2max. Specifically, the magnitude of these changes was greater with exercise intensities from the lower heavy- to the extreme-intensity domain when compared to that observed in the moderate-intensity domain and the control condition. Therefore, this study exemplifies the importance of exercise intensity for improving maximal aerobic capacity and supports the implementation of individualized, domain-based exercise intensity prescription to accurately deliver the desired metabolic stimulus and its associated adaptations across individuals.

### OP-PN01 Amino acids and proteins

#### COLLAGEN PEPTIDE SUPPLEMENTATION DURING RESISTANCE EXERCISE TRAINING DOES NOT INCREASE MYOFIBRILLAR AND MUSCLE CONNECTIVE TISSUE PROTEIN SYNTHESIS RATES

KIRMSE, M.1, LOTTMANN, T.M.1, VOLK, N.R.1, DE MARÉES, M.1, HOLWERDA, A.2, VAN LOON, L.J.C.2, PLATEN, P.1

*1 DEPARTMENT OF SPORTS MEDICINE AND SPORTS NUTRITION, RUHR UNIVERSITY BOCHUM;*

INTRODUCTION: Exercise has been reported to increase myofibrillar and muscle connective protein synthesis rates. Protein ingestion during recovery from exercise further increases myofibrillar protein synthesis rates and is typically applied by athletes to support the skeletal muscle adaptive response to prolonged resistance exercise training. The post-exercise increase in muscle connective tissue protein synthesis rates does not seem to be modulated by post-exercise protein ingestion. However, the latter may be attributed to the type of protein consumed. Due to the greater glycine and proline content of connective tissue, it has been hypothesized that collagen peptide ingestion may be (more) effective in stimulating muscle connective tissue protein synthesis rates. The present study assessed the impact of daily collagen peptide ingestion on myofibrillar and muscle connective tissue protein synthesis rates during one week of resistance exercise training.
METHODS: A double-blind parallel group design was used. Twenty-five male recreational athletes (24±3 y, 1.82±0.05 m, 76.9±6.4 kg) were selected to perform one week of resistance type exercise training (daily whole-body resistance exercises, drop jumps, and rope skipping) with (COL) and without (PLA) collagen peptide supplementation. Subjects were randomly assigned into a group receiving 15 g collagen peptides or a non-caloric placebo twice daily. Deuterium labeled water was applied throughout the intervention, with blood and muscle biopsies collected prior to and after the training period to assess both myofibrillar and muscle connective tissue protein synthesis rates. Welch´s t-test for independent groups was used to compare protein synthesis rates and a 2-way ANOVA was used to compare plasma amino acid profiles concentrations, daily food intake, and trainings loads between the groups.
RESULTS: Myofibrillar and muscle connective tissue protein synthesis rates averaged 1.34±0.19 and 1.97±0.47 %/d (COL) and 1.34±0.27 and 2.00±0.27 %d (PLA), respectively, with no differences between treatments. Muscle connective tissue protein synthesis rates were higher than myofibrillar protein synthesis rates (1.99±0.38 vs 1.34±0.23 %/d, respectively; p<0.001). No differences were observed in food intake and training load between treatments.
CONCLUSION: Muscle connective protein synthesis rates are higher than myofibrillar protein synthesis rates during one week of intense resistance exercise training in male recreational athletes. Collagen peptide supplementation (15 g twice daily) does not further increase myofibrillar or muscle connective protein synthesis rates during one week of intense resistance exercise training.

#### QUARK INGESTION INCREASES MUSCLE PROTEIN SYNTHESIS RATES AT REST AND DURING RECOVERY FROM EXERCISE IN HEALTHY, YOUNG AND OLDER MALES.

HERMANS, W.J.H.1, FUCHS, C.J.1, HENDRIKS, F.K.1, HOUBEN, L.H.P.1, SENDEN, J.M.1, NYAKAYIRU, J.2, VAN LOON, L.J.C.1, VERDIJK, L.B.1

*1. MAASTRICHT UNIVERSITY; 2. FRIESLANDCAMPINA*

INTRODUCTION: Ingestion of protein concentrates and isolates increases muscle protein synthesis rates, with exercise further augmenting the anabolic response to feeding. However, far less information is available on the muscle protein synthetic response following ingestion of (dairy) wholefoods. Our objective was to assess the impact of ingesting 30 g protein provided as quark on in vivo muscle protein synthesis rates at rest and during recovery from exercise in both young and older males.
METHODS: In this parallel-group intervention trial, fourteen healthy, young (24±5 y; BMI 24.0±3.5 kg/m2) and fifteen healthy, older (73±3 y; BMI 24.2±2.4 kg/m2) males ingested 291 g quark (30 g protein, 693 kJ) following a single-legged bout of resistance-type exercise on leg press (6 sets) and leg extension machines (6 sets). Primed, continuous intravenous L-[ring-13C6]-phenylalanine infusions were combined with the collection of blood and muscle tissue samples to assess both postabsorptive and 4-h postprandial muscle protein synthesis rates at rest and during recovery from exercise. Data were analyzed using repeated measures ANOVA with time and leg as within-subjects factors and age group as between-subjects factor, with an α level of 0.05, and appropriate post-hoc testing in case of significant interactions. Data represent means±SD; η2 was used for effect size.
RESULTS: Plasma leucine and total amino acid concentrations increased following quark ingestion, peaked at t= 1 h in both groups and returned to postabsorptive concentrations at t= 4 h (Time: P<0.001; η2>0.8), with no differences between groups (Time x Group: P>0.1; η2<0.1). In the rested leg, muscle protein synthesis rates increased following quark ingestion in both the young and older males from 0.030±0.011 to 0.051±0.011 %/h and from 0.036±0.011 to 0.062±0.013 %/h, respectively (Time: P<0.001). In the exercised leg, muscle

protein synthesis rates increased even further following quark ingestion in both the young and older males from 0.030±0.012 to 0.071±0.023 %/h and from 0.042±0.015 to 0.078±0.019 %/h, respectively (Time: P<0.001; Time x Leg: P=0.003; η2>0.3). No differences in postprandial muscle protein synthesis rates were observed between age groups (all Time x Group: P>0.3; η2<0.03).
CONCLUSION: Quark ingestion increases muscle protein synthesis rates at rest and during recovery from exercise in both young and older males. The muscle protein synthetic response following fermented dairy ingestion does not differ between healthy, young and older males when ample amounts of protein (30 g) are ingested.
This collaboration project is co-funded by FrieslandCampina BV, and the PPP Allowance made available by Health-Holland, Top Sector Life Sciences & Health, to stimulate public-private partnerships.

### PRE-SLEEP PROTEIN INGESTION STIMULATES MITOCHONDRIAL PROTEIN SYNTHESIS RATES DURING POSTEXERCISE OVERNIGHT RECOVERY

VAN LIESHOUT, G., TROMMELEN, J., NYAKAYIRU, J., SENDEN, J., GOESSENS, J., GIJSEN, A., VERDIJK, L., VAN LOON, L.
*DEPARTMENT OF HUMAN BIOLOGY, NUTRIM SCHOOL OF NUTRITION AND TRANSLATIONAL RESEARCH IN METABOLISM, MAASTRICHT UNIVERSITY MEDICAL CENTRE+, MAASTRICHT, THE NETHERLANDS*

INTRODUCTION: Protein ingestion prior to sleep has been shown to stimulate myofibrillar protein synthesis rates during overnight recovery from exercise. Whether pre-sleep protein ingestion can also be applied to augment mitochondrial protein synthesis rates remains to be established. Furthermore, the impact of the type of protein to modulate overnight myofibrillar or mitochondrial protein synthesis rates has not yet been addressed.
The purpose of this study is to assess the impact of pre-sleep casein and whey protein ingestion on myofibrillar and mitochondrial protein synthesis rates during overnight recovery from a bout of endurance exercise.
METHODS: Thirty-six healthy, young men performed a single bout of endurance-type exercise in the evening (19:45 h) after a full day of dietary standardization. Thirty min prior to sleep (23:30 h), subjects ingested 45 g casein protein, 45 g whey protein, or a noncaloric placebo. Continuous intravenous L-[ring-13C6]-phenylalanine infusions were applied, with blood and muscle tissue samples being collected to assess overnight mitochondrial and myofibrillar protein synthesis rates. Overnight muscle protein synthesis rates were compared between treatments with a one-way ANOVA with a Bonferroni correction.
RESULTS: Protein ingestion resulted in higher mitochondrial (0.087±0.020 vs 0.067±0.016 %·h-1, P=0.005) and myofibrillar (0.060±0.014 vs 0.047±0.011 %·h-1, P=0.012) protein synthesis rates when compared to placebo. Casein and whey protein ingestion did not differ in their capacity to stimulate mitochondrial (0.082±0.019 vs 0.092±0.020 %·h-1, P=0.690) and myofibrillar (0.056±0.009 vs 0.064±0.018 %·h-1, P=0.440) protein synthesis rates.
CONCLUSION: Protein ingestion prior to sleep stimulates both mitochondrial and myofibrillar protein synthesis rates during overnight recovery from endurance exercise. There is no apparent difference in the capacity of pre-sleep whey or casein protein ingestion on overnight muscle protein synthesis rates.

### BONE TURNOVER FOLLOWING HIGH-IMPACT EXERCISE IS NOT MODULATED BY COLLAGEN SUPPLEMENTATION IN YOUNG MEN

VAN DIJK, J.W., HILKENS, L., BOERBOOM, M., VAN SCHIJNDEL, N., BONS, J., VAN LOON, L.J.C.
*HAN UNIVERSITY OF APPLIED SCIENCES*

INTRODUCTION: High-impact exercise can increase bone formation, although the optimal frequency of such exercise has not been established. Furthermore, it has been suggested that collagen supplementation can further augment the positive effect of high-impact exercise on bone turnover. In the present study, we assessed whether collagen supplementation augments the effects of high-impact exercise on bone turnover and whether a higher exercise frequency is accompanied by a greater impact on bone metabolism.
METHODS: In this randomized, cross-over trial, 14 healthy males (age 24±4, BMI 22.0±2.1) performed once (COL1 and PLA) or twice daily (COL2) 5-min high-impact exercise during a 3-day intervention period. One hour before every exercise bout participants ingested 20 g hydrolyzed collagen (COL1 and COL2) or a placebo control (PLA). Blood markers of bone formation (P1NP) and resorption (CTX-I) were assessed in the fasted state before the ingestion of the initial test drink and 24, 48, and 72 h following the first exercise session. In PLA and COL1, additional blood samples were collected in the postprandial state at 0, 1, 2, 3, 4, and 12 h after the first exercise session. Two-factor repeated measures ANOVA were applied to assess whether bone turnover following exercise and test drink ingestion differed between conditions. Data are presented as mean±SD.
RESULTS: Over the first 4 hours following exercise P1NP decreased marginally from 98.6±37.2 to 93.2±33.1 ng/mL in COL1, and from 96.8±32.4 to 91.7±31.3 ng/mL in PLA, although this time-effect did not reach statistical significance (P=0.053). Serum levels had returned to baseline after 12 hours (COL1: 100.7±38.3 ng/mL, PLA: 99.1±40.6 ng/mL). Moreover, no differences in P1NP concentrations between COL1 and PLA were observed in the postprandial state (time x treatment, P=0.58). CTX showed a ~50% decline (time, P<0.001) in the postprandial state in COL1 (0.9±0.3 to 0.4±0.2 ng/mL) and PLA (0.9±0.3 to 0.4±0.2 ng/mL), without differences between conditions (time x treatment, P=0.17). Interestingly, fasted P1NP concentrations increased ~8% by daily jumping exercise (time-effect, P<0.01), without differences between conditions (time x treatment, P=0.71). Fasting CTX were stable over time (time effect, P=0.41), without differences between conditions (time x treatment, P=0.58).
CONCLUSION: Short, once-daily high-impact exercise in the morning is effective in stimulating bone formation, as indicated by an increase in fasted P1NP concentrations. The exercise induced stimulation of bone formation is not further increased by collagen supplementation or by increasing exercise frequency. Bone resorption does not seem to be affected by high-impact exercise with or without collagen supplementation.

## Invited symposia

### IS-AP03 Towards optimal force plate use in sport: theoretical underpinnings and practical recommendations for training prescription and return to sport

#### FUTURE CONSIDERATIONS FOR CONTEXTUALISING FORCE PLATE TEST RESULTS IN PROFESSIONAL FOOTBALL

MCMAHON, J.

*UNIVERSITY OF SALFORD*

Commercial force plate (FP) systems are now common in professional football codes and are often used daily to assess athletes. Practitioners, such as sport scientists and physiotherapists, are responsible for administering FP tests, but there are few quality resources and published studies available to guide their interpretation of the results. As professional football clubs are private companies, they are solely responsible for tests conducted with their athletes, without industry-wide performance standards or regulations to abide by. Various FP tests (mainly vertical jump and multi-joint isometric tests) are broadly applied in football for benchmarking athletes' performance, informing and evaluating exercise interventions, monitoring neuromuscular (NM) fatigue, and guiding injured athletes' return to play.
Jump height is mostly reported as the primary outcome measure for vertical jump tests, but it may mask subtle acute and chronic alterations in NM strategies which variables derived from FP measurements can illuminate. Also, jump height is biased towards lighter athletes and may not be a fair metric for comparing athletes' performances when there are large variations in body mass, such as is in rugby. Jump height alone will also not reflect any changes in body mass that occur between testing occasions, which is especially relevant for maturing youth athletes or adult athletes who complete a hypertrophy-focussed training programme. Additionally, youth athletes who grow in height between testing occasions will be afforded with a greater distance over which to apply force to their mass, which may alter their NM strategy and/or their jump height score. In multi-joint isometric tests, the peak forces attained may require scaling to body mass depending on the football code, position and intended application. Thus, there is a requirement to better contextualise popular FP test results in football to inform practitioner decision making.
The presentation will include key results from several ongoing FP studies that have been funded either by a leading commercial FP company or the English Football Association. A comprehensive FP testing battery has been completed for 200 professional football athletes across the domestic season and international tournaments. The data is contextualised to facilitate quick and accurate decision making via a variety of statistical approaches (e.g., standardised scores) and data visualisation tools (e.g., traffic light systems). The results highlight future considerations using FPs in football for benchmarking athletes' performances, seasonal monitoring to inform supercompensation and/or chronic fatigue, and acute fatigue monitoring both pre- and post-match and when fixture congestion is high. The target audience is sport science and medicine practitioners and researchers who routinely assess athletes with FPs, particularly footballers, and any delegate who is interested in conducting physical performance tests in sport.

#### UNDERSTANDING BIOMECHANICAL VARIABLES TO ANALYSE ISOMETRIC AND DYNAMIC TESTS: THE IMPORTANCE OF VERBAL CUES AND IMPULSE

SANCHEZ-SIXTO, A.

*CENTRO DE ESTUDIOS UNIVERSITARIOS CARDENAL SPINOLA CEU*

Athlete performance assessments are commonly conducted in several sports. An athlete's ability to apply force is one of the most frequent capacities evaluated by sport scientists. Force plates are widely used for this purpose because they are well accepted and yield good reliability and validity. Force plates measure the force that an athlete applies when they perform an action on its surface. Force plates can even register force production when the athlete remains static. For that reason, both isometric and dynamic tests are measured by force plates and the software used can automatically calculate many force variables, trying to simplify the analysis of the executions performed by participants. However, it is important to pay attention to how we measure and analyse the force data because most information is typically limited, and important variables are often discarded, which could lead to misinterpretation of the data.
When isometric or dynamic tests are performed, the researchers and coaches have to instruct how athletes must execute the tests. The verbal cues utilised modify the test results and most of the biomechanical variables that are relevant to explain the performance obtained by athletes. Most commercial force plate software can provide the most common discrete variables for standardised tests. However, discrete variables represent just a single point within a test and it is important to analyse more than one variable to provide information of the test performed by athletes. In addition, variables including information about the whole test performance are relevant to understand how athletes apply the force during the allotted time. Net impulse is a variable that is underutilised when evaluating isometric and dynamic tests with athletes. It is frequent to observe that test performance is evaluated by the maximum force applied or the maximum velocity obtained but to understand how this performance is achieved, it is necessary to understand how the impulse was produced by athletes. Furthermore, in current research articles, there is an increased use of continuous analysis to avoid discarding data from the executions performed by athletes. In that sense, statistical parametric mapping (SPM) is one of the most powerful analyses to compare force-time curves.
The presentation will include results from several studies showing how verbal cues affect the measures obtained from force plate tests and how sports scientists need to consider the proper instruction depending on the purpose of the test. Then, investigations will be presented comparing the use of impulse and discrete force variables, highlighting the importance of the variables selected to facilitate correct interpretations. Finally, investigations and the results of force plate tests carried out on athletes, with different verbal cues and evaluated through the SPM, will be presented, including an explanation of how to interpret the results.

#### ALTERED FORCE PRODUCTION STRATEGIES IN COUNTERMOVEMENT JUMPING FOLLOWING SEVERE LOWER LIMB INJURY

BAYNE, H.

*UNIVERSITY OF PRETORIA*

The measurement of vertical ground reaction force during jumping tasks is becoming commonplace in sports medicine and athletic performance centres and continues to gain popularity as the accessibility of equipment and software improve. The countermovement jump (CMJ) is one of the most widely used tests. Processing of the CMJ force-time data involves the calculation of acceleration and impulse from

the raw signal. Velocity, displacement and power are then calculated, and key events are identified to subdivide the jump into functionally relevant phases. Typically, these are the unweighting, braking, propulsion, flight and landing phases. Standard analysis relies on metrics such as phase-specific minimum, maximum or mean values, phase durations, and calculated ratios. When dual force plate systems are used, inter-limb asymmetry is also calculated. These metrics are used in profiling athletes, monitoring performance changes over time, and assessing rehabilitation progress to guide return to sport following injury.
While these metrics are important and useful to practitioners for evaluating jump performance, meaningful information may be lost by excluding large portions of the force-time curve. A variety of different propulsion phase force-time curve shapes have been observed which reflect different jump strategies. Researchers have categorised these as unimodal or bimodal based on the number of distinct force peaks, however, the evidence for practical implications of these two jump strategies has been mixed. Further subcategories of force-time curve shape have been proposed based on the relative magnitude and timing of propulsion phase force peaks, with some evidence for an association between an earlier peak and jump performance. This categorisation approach, however, still does not account for variation at each data point along the force-time series. A functional data analysis method, such as statistical parametric mapping, is needed to investigate between-athlete, within-athlete and between-limb differences across the entire time-series curve.
The presentation will include a summary and critique of force-time curve modality categorisations, with implications for practice. Novel research findings from investigations that apply a statistical parametric mapping approach to assess CMJ performance in athletes recovering from severe lower limb injury will be presented and discussed. The target audience would include sport science and clinical practitioners who are interested in objective measurements of performance to inform training prescription and rehabilitation, as well as researchers that collect biomechanical time-series data. The topic is of relevance to improve data-informed decision making in sport, in particular with regards to rehabilitation following serious injury. It will also enhance the awareness of methodological approaches to better understand the data that researchers and practitioners work regularly with.

### OP-BM03 Neuromuscular Physiology

#### H-REFLEX MODULATION BETWEEN SEATING AND STANDING IS NOT ASSOCIATED WITH POSTURAL CONTROL IN FALLERS AND NON-FALLERS

HENRY, M., DUCHATEAU, J., BAUDRY, S.

*UNIVERSITÉ LIBRE DE BRUXELLES*

INTRODUCTION: Previous work reported a greater decrease in the Hoffmann (H) reflex amplitude from seated to standing in older compared with young adults (1). This specific modulation likely reflects an age-related change in the neural control of upright standing (2). This may cope with the increase in postural instability (3), which is one of the strongest risk factors for falls (4). This study investigated the relation between postural control and the H-reflex modulation from seated to standing in older adults with (fallers) and without (non-fallers) a history of falls during the last 12 months. We hypothesised a lesser H-reflex modulation in individuals with poor postural control, especially in fallers.
METHODS: The path length of the centre of pressure (CoP-path) was measured (40-s epoch) in 9 fallers [mean (SD); 69 (4) yrs] and 13 non-fallers [69 (5) yrs] when standing on a force platform with eyes open. The maximal amplitude of the soleus H reflex (Hmax) was recorded in seated and standing postures and normalised to the M-wave maximal amplitude (Mmax). Correlations between the change in H reflex from seated to standing postures and CoP-path were investigated for each group.
RESULTS: The CoP-path was greater for fallers [318 (83) mm] than non-fallers [234 (44) mm, p=0.006]. The Hmax was lesser in fallers than non-fallers when seated [22.0 (10.1) vs 35.3 (13.7) %Mmax] and standing [17.1 (10.9) vs 26.5 (12.9) %Mmax; p=0.032]. The decrease in Hmax from seated to standing was similar between groups [-26% vs -21%; p=0.64], and no association was observed between the change in Hmax and the CoP-path ($r^2 < 0.13$).
CONCLUSION: As evidenced by the smaller Hmax in the two positions in fallers, the H-reflex pathway undergoes greater age-related changes in fallers than in non-fallers. However, these modifications do not seem specific to upright standing and postural control. In contrast with our hypothesis, Hmax was modulated similarly in both groups, and the extent of the modulation from seated to standing was not associated with CoP-path. Thus, the risk of falls may not be associated with the modulation of the H-reflex pathway.

#### EXPERTS VERSUS NOVICES: STIFFNESS REGULATION DURING VARIOUS STRETCH LOADS

WALDVOGEL, J.1, FREYLER, K.1, RINGHOF, S.1, RITZMANN, R.1, GOLLHOFER, A.1

*1 UNIVERSITY OF FREIBURG*

INTRODUCTION: High neuromuscular activity before and during ground contact (GC) are the prerequisites to benefit from energy saving mechanisms during stretch-shortening type actions (1). Especially time critical disciplines such as long jump (2) require immediate transition from eccentric to concentric muscle action (1). To meet such criteria athletes are highly involved in plyometric training. Therefore they have an exclusive neuromuscular control and stiffness regulation during the eccentric phase (3). During excessive stretch loads the eccentric activity is negatively affected possibly due to inhibitory influences (2,4). By directly comparing experts and novices the present study investigate the effect of expertise on the neuromuscular control and leg spring behavior in vertical jumps.
METHODS: By combining 3D motion capture system with electromyography of the shank and thigh muscles differences in biomechanical and neuromuscular control were elaborated between 13 professional youth elite track and field athletes and 13 sportive novices. All participants performed bipedal drop jumps from 25, 37, 49 and 61 cm. The seven trials with the highest reactive strength index (RSI) were selected for statistical analysis. Two-way Mixed-ANOVA (group x condition) was performed.

RESULTS: Significant interaction effect reveal higher RSI and leg stiffness in experts compared to novices. In both groups RSI is significantly reduced in 61 cm. Experts realize highest leg stiffness during low stretch loads; leg stiffness in novices remains constant. Overall experts demonstrate significant lower ankle and knee joint flexion compared to novices; both groups increase ankle and knee flexion with increasing stretch load. Significant interaction is evident for soleus (SOL), gastrocnemius medialis (GM) and vastus medialis (VM) with overall higher pre-activity in experts. During GC SOL activity is significant higher in experts; activity diminishes with increasing stretch load only in experts. During GC GM and TA activity is similar in both groups; GM activity diminishes whereas TA and VM activity increases with increasing stretch load. Further analysis revealed that RSI is positively correlated with leg stiffness ($r = .57$, $p < .01$) and eccentric SOL activity ($r = .51$, $p < .01$).
CONCLUSION: Our results reveal higher neuromuscular activity before GC in experts to achieve an immediate transition and high ballistic performance (2). Compared to previous experiments higher eccentric activity in experts is only evident for SOL (4). Although both groups compensate highest stretch loads by increasing joint flexion and VM activity, experts are able to achieve high stiffness which is associated with RSI. Immediate eccentric-concentric transition is more dominant in low stretch loads.

## DEGENERATION OF NEUROMUSCULAR CONTROL IN HUMANS IS DETECTABLE AFTER 10 DAYS OF LIMB SUSPENSION AND IS COMPLETELY RECOVERED AFTER A 21 DAYS TRAINING INTERVENTION

VALLI, G., SARTO, F., CASOLO, A., DEL VECCHIO, A., FRANCHI, M., NARICI, M., DE VITO, G.

*UNIVERSITY OF PADOVA*

INTRODUCTION: The multiple effects of disuse on skeletal muscle health have been described in several studies but limited literature exists about its consequences on neuromuscular control. In addition, neuromuscular control after disuse has been investigated only by invasive needle electromyography (EMG) and considering small hand muscles [1, 2]. Recently, the introduction of the high-density EMG (HD-EMG) allowed for non-invasive investigation of the MUs properties in vivo. Therefore, in the present study, HD-EMG was used to investigate how disuse affects neuromuscular control in the vastus lateralis, a large muscle with key functional implications. Moreover, we also tested whether and how the neuromuscular control is restored following a reconditioning training period.
METHODS: Eleven young male participants (22.1 ± 2.9 years, 22.87 ± 2.07 kg/m2) underwent 10 days of unilateral lower limb suspension (ULLS) followed by 21 days of moderate-intensity resistance training. Maximum voluntary isometric force (MViF), force steadiness and motor units (MUs) properties were measured at baseline, immediately after ULLS and after the training period. MUs were detected with HD-EMG during the execution of trapezoidal isometric contractions at 10, 25 and 50% MViF and tracked longitudinally across the intervention. Repeated measures ANOVA was performed to detect differences in MViF and steadiness while MUs properties were analysed with linear models.
RESULTS: MUs recruitment/derecruitment thresholds were reduced after ULLS at all contraction intensities, and the changes between the two variables were strongly correlated. After ULLS, MUs discharge rate (DR) was reduced at 10 and 25% but not at 50% MViF. The slope of the regression line representing the rate of change of MUs DR as a function of the rate of change of force (i.e., motoneuron input/output relation (I/O)) was increased after ULLS while the intercept was reduced. After resistance training, all the impairments were recovered and force steadiness even improved compared to baseline.
CONCLUSION: 10 days of ULLS can induce deterioration of neuromuscular control by affecting predominantly the DR modulation, while the strategies of MUs recruitment/derecruitment seem to be preserved. The motoneuron I/O after ULLS, and the different DR modulation at 50% vs 10 and 25% MViF, suggest a different motoneuron response depending on the level of presynaptic input . 21 days of resistance training were sufficient to restore, and slightly improve, the original neuromuscular control.

## CHANGES IN NEUROMUSCULAR JUNCTION TRANSMISSION STABILITY, MOTOR UNIT PROPERTIES AND RELATED GENE EXPRESSION WITH SHORT-TERM UNLOADING AND RETRAINING

SARTO, F., STASHUK, D.W., MONTI, E., ZAMPIERI, S., FRANCHI, M.V., VALLI, G., SIRAGO, G., CANDIA, J., HARTNELL, L.M., PAGANINI, M., MCPHEE, J.S., DE VITO, G., FERRUCCI, L., REGGIANI, C., NARICI, M.V.

*UNIVERSITY OF PADOVA*

INTRODUCTION: While there is convincing evidence that neuromuscular junction (NMJ) integrity is affected by unloading, whether NMJ transmission stability is also impaired is currently unknown. Moreover, electrophysiological alterations in motor units potential (MUP) properties and related molecular mechanisms are poorly understood. With this study, we aimed to investigate the neuromuscular changes in response to a short period of unloading and retraining (RT) in humans with a particular focus on NMJ function and MUP properties.
METHODS: Eleven healthy males volunteered for a 10-day unilateral lower limb suspension (ULLS) period, followed by 3-week RT based on resistance exercise. At baseline, after the unloading period and after RT, quadriceps femoris (QF) muscle size and knee-extensors maximum voluntary contraction (MVC) were evaluated by ultrasonography and isometric dynamometry, respectively. Activation capacity (AC) was assessed with the interpolated twitch technique. Intramuscular electromyography recordings were collected from vastus lateralis (VL) during submaximal contractions at 10% and 25% of the MVC. The NMJ transmission stability and MUP properties were assessed using decomposition-based quantitative electromyography. Blood samples and VL muscle biopsies were collected for the evaluation of NMJ damage (via c-terminal agrin fragment concentration, CAF), fibre type, diameter and muscle biomarkers of denervation (fibre type grouping, presence of flat-shaped/angulated and neonatal myosin positive fibres). RNA sequencing was also performed to study changes in the expression of gene pathways involved in the NMJ and ion channels regulation.
RESULTS: The ULLS induced QF muscle atrophy (4.5%) and impairments in MVC (29.3%) and AC (6.0%). Evidence of NMJ molecular instability (5.4% increase in CAF) was found with unloading, together with changes in the expression of many NMJ-related genes, including upregulation of acetylcholine receptors subunits and downregulation of Homer proteins. However, NMJ transmission stability, evaluated through the assessment of near fibre Jiggle and segmented Jitter, was unchanged, while alterations in MUP properties (decreased firing rate, MUP complexity and increased near fibre duration) were found after ULLS. A possible explanation for these electrophysiological alterations is skeletal muscle ion channels remodelling (as suggested by an overall downregulation of the related gene set), rather than marked innervation/reinnervation processes. The RT period restored most of these neuromuscular degenerations.

CONCLUSION: We showed that the human NMJ is destabilized at molecular level but remains functionally robust in response to short-term unloading. However, we observed alterations in MUP properties occurring after ULLS, possibly due to alterations in skeletal muscle ion channels dynamics. These maladaptations are reversed by three-week resistance training.

**FASCICLE BEHAVIOUR, KINEMATICS, AND ELECTROMYOGRAPHY OF THREE NORDIC HAMSTRING EXERCISE VARIATIONS**

RIPLEY, N., COMFORT, P., MCMAHON, J.J.

*UNIVERSITY OF SALFORD*

INTRODUCTION: Bicep femoris (BF) fascicle length (FL) is extremely adaptable to training, which is important for the reduction of hamstring strain injury risk [1]. The Nordic hamstring exercise (NHE) should be performed supra-maximally, with progressive overload resulting in a greater adaptive response [2]. Popular regressions using elastic bands or other devices can result in submaximal performance. Performing the NHE on an incline or decline surface could alter the force required for any given knee angle. The aims of the present study were to determine the effects of performing the NHE at different inclinations and the influence on the kinematics, hamstring EMG and BF fascicle dynamics.
METHODS: 13 physically active individuals (24.7±3.7 years, 79.56±7.89 kg, 177.40±12.54 cm) performed three repetitions of the NHE performed on neutral (0°), incline (20°) and decline (20°) surfaces. Three-dimensional lower limb data, ultrasound (US) videos of the BF, and EMG activity of BF and medial hamstrings (MH) were captured. Onset was identified when participants moved >5° of knee extension, breakpoint was identified with a knee angular velocity of ≥20°.s-1. Relative BF muscle tendon unit (MTU) length was calculated [3]. Raw EMG signals were analysed with an RMS filter and US videos were analysed using Ultratrack. Between-trial reliability was assessed using ICCs and CMCs. Peak measures (BF MTU length, BF and MH EMG and absolute BF FL) were compared between NHE variations using a series of RMANOVAs with Bonferroni post-hoc analysis, the same measures were time normalised (onset to breakpoint) and compared between NHE variations.
RESULTS: Peak and time-series data demonstrated moderate-good reliability (ICCs = 0.62-0.84; CMCs = 0.68-0.82). A significant main effect was observed for peak kinematic and fascicle dynamics ($p<0.001$). Pairwise comparisons revealed greater peak MTU length (1.00±0.04 & 0.91±0.02, $p=0.006$) and peak BF FL (7.34±0.18 cm & 6.91±0.16 cm, $p=0.013$) during the incline versus the decline NHE. There were no differences ($p>0.05$) in peak EMG between inclinations. EMG time normalised curves showed the incline NHE favoured BF, in comparison to the neutral and decline NHE favouring the MH. Time-normalised curves revealed peak EMG occurred between 65-89%, whereas peak MTU length and BF FL occurred between 98-100%. BF FL initially shortened for up to 38-40%.
CONCLUSION: The NHE performance angle manipulates the lever arm through which the centre of mass is acting. The incline NHE results in greater MTU length and BF FL, which could result in enhancement in resting BF FL via training, until athletes can perform the entire range of motion where additional overload will be required [2]. The differences in performance angle resulted in a change in the neuromuscular contributions of the BF and the MH, favouring BF for incline variations despite no differences between peak EMG.

### OP-PN31 Ketone ingestion and fat diet

**THE ACUTE EFFECT OF KETONE MONOESTER INGESTION ON CARDIAC FUNCTION AT REST AND DURING EXERCISE IN PEOPLE WITH TYPE 2 DIABETES MELLITUS.**

PERISSIOU, M., FEKA, K., EDWARDS, C., JAMES, T.J., SAYNOR, Z.L., CORBETT, J., MAYES, H., SHUTE, J., CUMMINGS, M., LITTLE, J., SHEPHERD, A.I.

*UNIVERSITY OF PORTSMOUTH FACULTY OF SCIENCE; QUEEN ALEXANDRA HOSPITAL, PORTSMOUTH HOSPITALS NHS TRUST; UNIVERSITY OF BRITISH COLUMBIA OKANAGAN, CANADA*

INTRODUCTION: Type 2 diabetes mellitus (T2DM) is a chronic progressive metabolic disease associated with an increased prevalence of cardiovascular events [1]. Insulin resistance impairs the body's ability to utilise glucose and leads to an increased reliance on the metabolism of less efficient fuel sources which ultimately leads to increased cardiac burden [2]. Recent evidence in people with heart failure, suggests that infused ketone bodies (β-hydroxybutyrate; βHB) leads to increased cardiac output and stroke volume [3]. Oral ingestion of ketone monoesters (Kme) has been shown to provide a rapid increase in blood ßHb levels within 30 min in healthy humans [4]. The aim of this study was to examine the acute effect of oral consumption of Kme on cardiac function in people with T2DM at rest and during incremental exercise.
METHODS: In a double blind, randomised, crossover design study, 13 people with T2DM (age, 66±9 yrs.; body weight, 90.3 ±15.2; HbA1c, 54±7 mmol/mol) attended the lab in 2 separate visits during which they ingested either a Kme drink (0.115 g/kg (R)-3-hydroxybutyl (R)-3-hydroxybutyrate) or a placebo drink. After 30 min from ingestion, participants underwent measurements of cardiac output (CO) and stroke volume index (SVi) via thoracic impedance cardiography and circulating [ßHb] at rest and during incremental cycling exercise.
RESULTS: Circulating [ßHb] was higher at rest (mean diff. 1.51 mM, 95%CI 0.68 to 2.12, $P=0.016$) and during exercise (mean diff. 1.38 mM; 95%CI 0.85 to 2.1, $P=0.001$) compared to placebo. Resting SVi (mean diff. 10.58 ml/m²; 95C%CI 3.85 to 20.3, $P=0.016$) and resting CO (mean diff. 1.38 L/min; 95%CI 0.28 to 2.48, $P=0.018$) were higher after Kme ingestion compared to placebo. Similarly, SVi (mean diff. 16.32 ml/m²; 95C%CI 5.28 to 27.3, $P=0.001$) and CO (mean diff. 3.34 L/min; 95C%CI 2.18 to 4.47, $P=0.001$) were higher during incremental cycling exercise after Kme ingestion compared to placebo. No significant HR differences ($P>0.05$) were observed at rest or during exercise between the two drinks.
CONCLUSION: Ingestion of Kme acutely improves cardiac function at rest and during incremental exercise in people with T2DM. Large scale chronic interventions are needed to establish whether Kme can be used as an adjunct treatment for improving cardiac health in people with T2DM.

**EXOGENOUS KETOSIS SUPPRESSES DIURESIS AND ATRIAL NATRIURETIC PEPTIDE DURING EXERCISE**

ROBBERECHTS, R., POFFÉ, C., HESPEL, P.

*KU LEUVEN*

INTRODUCTION: We have previously demonstrated that exogenous ketosis reduces urine production during exercise. However, the underlying physiological mechanism of this anti-diuretic effect remained unclear. Therefore, we investigated whether acute exogenous ketosis by oral ingestion of ketone ester (KE) during a simulated cycling race (RACE) affects the hormonal pathways implicated in fluid balance regulation during exercise.
METHODS: In a double-blind crossover design, 11 well-trained male cyclists participated in RACE consisting of a 3-h submaximal intermittent cycling (IMT180') bout followed by a 15-minute time trial (TT15') in an environmental chamber set at 28 °C and 60 % relative humidity. Fluid intake was adjusted to maintain euhydration. Before and during RACE, the subjects received either a control drink (CON) or the ketone ester (R)-3-hydroxybutyl (R)-3-hydroxybutyrate (KE), which elevated blood β-hydroxybutyrate to ~2-4 mM during RACE.
RESULTS: Compared with CON, N-terminal pro-atrial natriuretic peptide (NT-pro ANP) concentration during RACE was ~20% lower in KE ($p < 0.05$). KE also raised plasma noradrenaline concentrations during RACE. Performance in TT15' was similar between CON and KE.
CONCLUSION: Our current findings demonstrate exogenous ketosis to suppress diuresis during prolonged exercise. The underlying physiological mechanism remains, however, unclear. Interestingly, we also for the first time demonstrate ketone ester ingestion to suppress ANP secretion. Such effect could contribute to explain the previously reported effect of exogenous ketosis to lower circulating non-esterified fatty acid levels during exercise.

**SUPERCOMPENSATION CURVED KETO-ADAPTATION: NUTRITION AS QUICK-FIX OR STIMULUS FOR ADAPTATION?**

PRETORIUS, A.

*STELLENBOSCH UNIVERSITY*

INTRODUCTION: The supercompensation time-course of adaptation to training as stimulus is well-known (i.e., initial decline precedes physiological adaptation, resulting in enhanced performance). While the term keto-adaptation frames the ketogenic diet (KD) as a physiological stimulus, the supercompensation phenomenon has, to my knowledge, not been accepted in response to a nutritional intervention.
METHODS: To depict the time-course of metabolic keto-adaptations in energy system contributions, and changes in intermittent sprint fatigue, this study employed a time-series design. 15 Recreationally active participants (7 men, 8 women) performed cycle ergometer intermittent sprints (6 x 10 s separated by 2 min rest), while metabolic data were collected for the calculation of energy system contributions. Participants were tested prior to the KD intervention on their habitual diet (HD: 35% CHO, 45% fat, 20% protein) and subsequently every two weeks over a 6-week KD intervention (7% CHO, 66% fat, 28% protein).
RESULTS: While the anaerobic glycolytic energy contribution decreased at KD week 2 (-14.4 ± 28.16 Joule; P = 0.031; ES = -0.10) and remained suppressed throughout the 6-week KD, the phosphocreatine contribution gradually increased until it reached statistical significance at KD week 6 (+22.0 ± 43.15 Joule; P = 0.019; ES = 0.47). Intermittent sprint fatigue initially increased from HD at KD week 2 (8.8 ± 5.12% vs. 7.4 ± 3.92%; P = 0.720; ES = 0.31; CI = -0.42; 1.02), whereafter a very large decrease in fatigue occurred from KD week 2 to 6 (8.8 ± 5.12% vs. 5.7 ± 2.64; P = 0.066; ES = -1.17; CI = -1.91; -0.36) resulting in a net moderate decrease over the 6-week KD (HD vs. KD week 6; 7.4 ± 3.92% vs. 5.7 ± 2.64; P = 0.332; ES = -0.50; CI = -1.21; 0.24).
CONCLUSION: Collectively, steady upregulation of phosphocreatine energy metabolism over the 6-week KD, gradually compensated for lowered glycolytic energy, which aligns with the decline and subsequent supercompensation in intermittent sprint fatigue. Although the net decrease in fatigue at KD week 6 was not yet statistically significant, the phosphocreatine adaptations also did not plateau, suggesting further adaptation can be expected with longer KD interventions.

**EFFECT OF ACUTE KETONE BODY SUPPLEMENTATION ON CARDIORESPIRATORY EXERCISE RESPONSES AND THE INFLUENCE OF BLOOD ACIDOSIS: A RANDOMIZED, CROSSOVER TRIAL**

MCCARTHY, D.G., BOSTAD, W., BONE, J., POWLEY, F.J., RICHARDS, D.L., GIBALA, M.J.

*MCMASTER UNIVERSITY*

INTRODUCTION: Acute ketone monoester supplementation (KE) induces hyperketonemia and blood acidosis; both can affect exercise responses but the relative influence of each is unclear. We previously found that ingestion of 0.6 g/kg body mass KE increased heart rate (HR) and ventilation (VE) during cycling at ventilatory threshold (VT) compared to placebo (1). The present study used the same protocol (1) to examine the effect of KE on exercise cardiac output (Q) and the influence of blood acidosis. We hypothesized that KE vs placebo would increase Q and co-ingestion of a pH buffer would mitigate this effect.
METHODS: A sample size estimate (G*Power) determined n=12 provided 80% power to detect a change in Q (effect size f=0.4, alpha=0.05) with repeated measures analysis of variance (ANOVA). Trained adults (11 males, 4 females; VO2peak = 60±9 mL/kg/min) completed 3 trials in random order. Participants ingested 1 g/kg carbohydrate and 400 mL water 2 h before exercise, followed by either 0.20 g/kg body mass of sodium bicarbonate or a salt placebo 60 min pre-exercise, and a 0.6 g/kg bolus of KE or ketone-free placebo in 500 mL of fluid 30 min pre-exercise. This yielded 3 conditions: low blood ketone bodies and neutral pH [control (CON)], hyperketonemia and lowered pH (KE), and hyperketonemia and neutral pH (KE+BIC). Venous blood was sampled before and during exercise. Participants cycled for 30 min at VT intensity. Q was measured in duplicate over the last ~5 min using inert gas rebreathing (Innocor). After a 10-min rest, VO2peak and peak Q were determined. Data were analyzed using ANOVA and a Tukey post hoc test as appropriate with alpha=0.05.
RESULTS: Blood concentration of the major ketone body beta-hydroxybutyrate differed between conditions (CON: 0.1±0.0, KE: 3.5±0.1, KE+BIC: 4.4±0.2 mM, $P \leq 0.001$ for all). Blood pH was lower in KE vs CON (7.30±0.01 vs 7.34±0.01, $p<0.001$) and KE+BIC (7.35±0.01, $p<0.001$).

Q during VT exercise was not different between conditions (CON: 18.2±3.6, KE: 17.7±3.7, KE+BIC: 18.1±3.5 L/min, p=0.4). HR was higher in KE (153±9 beats/min) and KE+BIC (154±9) vs CON (150±9, p<0.02 for both). VE was higher in KE vs CON (81±16 vs 74±17 L/min, p<0.0001) and KE+BIC (77±16, p<0.01). VO2peak was not different between conditions (CON: 4.55±1.05, KE: 4.34±0.94, KE+BIC: 4.39±0.91 L/min; p=0.2). Peak Q was also not different (CON: 21.8±3.8, KE: 21.5±3.7, KE+BIC: 21.1±3.9 L/min; p=0.3). Peak power output was lower in KE (359±61 W) and KE+BIC (363±63) vs CON (375±64, p<0.02). Peak HR was lower in KE vs CON (179±9 vs 181±9 beats/min, p=0.03) and KE+BIC (182±9, p=0.03).
CONCLUSION: KE increased submaximal exercise HR independent of acidosis and thus was seemingly affected by hyperketonemia. Q was not different between conditions despite differences in HR, which suggests stroke volume may have been altered. The higher cardiorespiratory stress after KE may have lowered exercise capacity such that peak power output at VO2peak was reduced.

## OP-AP01 Power and strength

### THE INFLUENCE OF TRAINING TWO OR THREE TIMES PER WEEK ON HYPERTROPHY AND STRENGTH ADAPTATIONS IN INDIVIDUAL LEG MUSCLES AFTER 10 WEEKS OF RESISTANCE TRAINING TO FAILURE

HARDEEL, J., VAN VOSSEL, K., WEYNS, A., VAN DE CASTEELE, F., LIEVENS, E., DERAVE, W.

*GHENT UNIVERSITY*

INTRODUCTION: The influence of resistance training (RT) variables (e.g. training frequency) on muscle hypertrophy and strength gains has been extensively researched (1). The majority of analyses on hypertrophy effects focused on measuring whole muscle groups, rather than on responses on the individual muscle level. The American College of Sports Medicine guidelines recommend training 2 to 3x/week for novices (2). However, an additional training may not be beneficial for every individual muscle considering their heterogeneity (e.g. muscle typology). Therefore, this study aimed at investigating the difference between training 2 and 3x/week on RT-induced adaptations in individual muscles.
METHODS: Twenty-one untrained individuals (22.06±2.18yrs, 11 men and 10 women) performed a 10 week resistance training program. A within-subject design was used in which leg A and leg B were randomly assigned to either training 2x/week (>=72h recovery) or 3x/week (>=48h recovery). Every training session included a leg extension and leg curl exercise performed to failure (3 or 4 sets/exercise, 60% 1RM). Changes in dynamic strength were assessed by measuring 1RM. Magnetic Resonance Imaging (MRI; Siemens 3T) was performed and muscle volumes were calculated by an artificial intelligence-based 3D rendering technique (Springbok Analytics). Paired Samples T-tests were used to detect differences between training 2x and 3x/week.
RESULTS: Dynamic strength and muscle volume increased significantly in all trained muscle groups and individual muscles (p<0.005). No significant differences were found in mean strength increases between training 2x and 3x/week, neither for the leg extension (2x: 18.76%, 3x: 22.07%, p=0.25), nor for the leg curl (2x: 26.36%, 3x: 30.38%, p=0.173). No significant difference in mean hypertrophy was found between training 2x and 3x/week for the hamstrings (2x: 9.18%, 3x: 11.26%, p=0.056) on muscle group level and for semimembranosus (2x: 4.42%, 3x: 3.86%), rectus femoris (2x: 6.23%, 3x: 7.76%), vastus lateralis (2x: 5.74%, 3x: 7.22%), medialis (2x: 3.08%, 3x: 4.82%) and intermedius (2x: 4.83%, 3x: 7.05%) on individual muscle level. However, hypertrophy was significantly higher when training 3x/week compared to 2x/week for the quadriceps (2x: 4.94%, 3x: 6.58%, p=0.018) on muscle group level and for biceps femoris (2x: 8.86%, 3x: 12.18%, p=0.012) and semitendinosus (2x: 15.62%, 3x: 19.31%, p=0.045) on individual muscle level.
CONCLUSION: Training 2 or 3x/week causes similar strength gains in leg muscles of previously untrained individuals. However, with regard to hypertrophy, specific individual muscles (biceps femoris and semitendinosus) benefit more from training 3x/week. These muscles were found to have higher mean percentual increases in muscle volume, indicating that muscles that are more prone to hypertrophy may benefit more from an additional training session.

### PHYSICAL ACTIVITY INTENSITY DOES MATTER FOR RELATIVE MUSCLE POWER: THE TOLEDO STUDY FOR HEALTHY AGING IN MIDDLE AGE

LEAL-MARTIN, J., BALTASAR-FERNANDEZ, I., GARCÍA-AGUIRRE, M., SOTO-PANIAGUA, H., MUÑOZ-MUÑOZ, M., GUTIÉRREZ-REGUERO, H., ALCAZAR, J., LOSA-REYNA, J., ALEGRE, L.M., GARCIA-GARCIA, F.J., ARA, I.

*1 GENUD TOLEDO RESEARCH GROUP, UNIVERSIDAD CASTILLA-LA MANCHA, SPAIN; 2 CIBER FRAILTY AND HEALTHY AGING, SPAIN; 3 HOSPITAL VIRGEN DEL VALLE, SPAIN*

INTRODUCTION: Preserving adequate muscle power during senescence has already been associated with sedentary behavior (SB) and moderate-to-vigorous physical activity (1). The decline of muscle power in older adults often leads to a deterioration of functional capacity and loss of independence. It is therefore of great importance to be able to anticipate this problem in earlier stages such as middle-age adulthood. However, there are hardly any studies that have analyzed how lifestyle components related to SB and physical activity are associated with muscle power in this population. Therefore, the aim of this study was to investigate the association of SB and physical activity with relative muscle power in middle-aged adults.
METHODS: A total of 138 individuals (53.91 ± 1.46 years; 58% women) from the Toledo Study for Healthy Aging in Middle Age (TSHA-ma) were included. Relative muscle power was assessed using the 30-second Sit-to-Stand Muscle Power Test, while SB and physical activity were monitored for 7 days using GENEActiv (Kimbolton, UK) accelerometer devices placed on the non-dominant wrist. Multiple linear regression analyses were performed with relative muscle power as the dependent variable, while SB, light physical activity (LPA), moderate physical activity (MPA), and vigorous physical activity (VPA) were independent variables. The model was adjusted for sex, age, educational level, and number of valid accelerometry days.

RESULTS: Multiple linear regression analysis showed no association between SB (β: 0.000; 95%CI: -0.003, 0.003; p = 0.926), LPA (β: -0.001; 95%CI: -0.009, 0.008; p = 0.900) and MPA (β: 0.004; 95%CI: -0.005, 0.012; p = 0.388) with relative muscle power. Only VPA (β: 0.039; 95%CI: 0.009, 0.069; p < 0.05) significantly explained relative muscle power in middle-aged adults.
CONCLUSION: This study suggests that VPA appears to be the only physical activity component to be associated with increased relative muscle power in middle-aged adults. Conversely, neither the SB nor the LPA or the MPA appeared to be related. Therefore, future strategies focused on preventing relative muscle power loss in middle-aged adults should encourage the increase of VPA, as it may attenuate functional decline or loss of independence in old age. However, future experimental studies should confirm this hypothesis.

## MONITORING TRUNK INCLINATION IS ESSENTIAL TO DETERMINE MECHANICAL POWER OUTPUT DURING FIELD-BASED WHEELCHAIR PROPULSION

VAN DIJK, M.

*DELFT UNIVERSITY OF TECHNOLOGY: TECHNISCHE UNIVERSITEIT DELFT*

INTRODUCTION: Over the last decades, the abilities to monitor wheelchair sport performance have increased significantly. One important performance determinant in wheelchair sports is the mechanical power exchanged between the wheelchair athlete and the environment. However, a feasible method to determine power in the field is not yet developed. The aim of current study was to determine the mechanical power based on full-body kinematics during wheelchair propulsion on a treadmill. Subsequently, this power was compared to power estimated from two inertial sensors (at the trunk and at the wheelchair) and to a commonly used approach which uses only one inertial sensor at the wheelchair.
METHODS: Twenty-five healthy participants performed five different 120s-trials at 1.2 m/s in an instrumented sports wheelchair on a treadmill. The five trials differed with respect to mass (+0, +5 or +15 kg) or tire pressure (1.75, 3.5, 5.25 bar). Before each trial, body mass inertial parameters were obtained and wheel friction coefficients were determined based on drag tests. During the trials, inertial sensors were attached to the participants' trunk (thorax) and wheelchair (wheel), upper body kinematics were monitored using an optical motion capture system. Participants were instructed to maintain a constant push frequency induced by a metronome during the entire session, which consisted of 60s normal wheelchair propulsion and 60s wheelchair propulsion without trunk motion.
Based on the calculated instantaneous rolling friction and instantaneous center of mass (COM) kinematics and power per push were determined. The resulted power was compared to power predicted using more simplified approaches that used one and two inertial sensors, respectively. In addition, we assessed the influence of trunk motion on these comparisons.
RESULTS: Mechanical power output increased significantly with added mass and decreased tire pressure. Although power estimated from one inertial sensor differed significantly from power based on all kinematics, no significant difference was found for the method that used two inertial sensors. Trunk motion increased when rolling friction increased and was positively related to the difference in power between the methods. For the parts without trunk motion, differences between methods were negligible.
CONCLUSION: During wheelchair propulsion, the trunk moves considerably within each push cycle. As a result, the COM of the wheelchair-user system moves relative to the wheelchair. Also, rolling friction changes with mass distribution due to the differences between castor and rear wheels. In this way, trunk motion influences power output. Therefore, to be able to determine power during straight-line wheelchair propulsion in the field, at least wheelchair and trunk kinematics should be obtained, implying the use of two inertial sensors. Power based on wheelchair kinematics only is likely to be underestimated with trunk motion, leading to unfair comparisons between athletes with different abilities.

## RESISTANCE TRAINING CAN AFFECT MUSCLE STRENGTH, FAT MASS AND TESTOSTERONE LEVELS IN HYPOGONADAL MEN WITHOUT HORMONE REPLACEMENT THERAPY

SEDLIAK, M.1, KRALIK, M.1, PUTALA, M.1, BUZGO, G.1, TIRPAKOVA, V.1,2, BUJDAK, P.2, KOLLARIK, B.3, UKROPCOVA, B.4, UKROPEC, J.4, PAYER, J.5, KILLINGER, Z.5, RAASTAD, T.6

INTRODUCTION: Male hypogonadism is a clinical syndrome manifesting with low testosterone (TT) including symptoms like decline in lean mass, muscle strength, increased adiposity, visceral obesity and incidence of insulin resistance and metabolic syndrome. There are only few studies dealing with effect of physical activity on hypogonadal males [1]. The aim of the study was to examine the effect of 12-week strength training program on muscle strength, body composition and selected biochemical parameters in hypogonadal men without hormone replacement therapy.
METHODS: The effect of resistance training (RT) on hypogonadal patients without hormonal therapy (HP, n=6, 48.41±6.38 yrs, TT= 7.9±1.75 nmol/L) and control group of eugonadal males (EM, n=8, 49.31±5.84 yrs, TT= 15.81±3.99 nmol/L) was studied. The subjects performed RT twice a week, the training program consisted of 6 exercises at an intensity from 60-80% of 1RM. Muscle strength was assessed by predicted dynamic leg press 1RM from multiple repetition maximum. Body composition, more specifically relative body fat mass was measured by DXA, Fasting morning venous blood samples were collected. The blood serum parameters included glucose, total testosterone, SHBG and cortisol.
RESULTS: Subjects from both the HP and EM groups significantly decreased relative fat mass by 6.2 % and 4.91% ($p>0.05$ and $p<0.01$, respectively). Muscle strength of lower extremities increased in both group ($p<0,01$), from 148 ± 16 kg to 211 ± 20 kg and from 183 ± 17 kg to 224 ± 19 kg in HP and EM, respectively. When both groups were merger, a negative correlation between TT and fat mass ($p<0.01$) and TT and body mass ($p<0.01$) was found before and after the intervention in both groups. Correlation between SHBG and TT pre-training ($r = 0.52$, $P < 0.05$) and post-training ($r = 0.75$, $P < 0.01$) was also observed. Interestingly, TT level was significantly increased in HP from 7.90 ± 2.90 nmol/L to 9.6 nmol/L ($p<0.05$) and unchanged in HM. Resistance training also influenced glucose, when effect size with Cohen D was calculated (d= -0.54).
CONCLUSION: Resistance training protocol of 3-month duration significantly improved muscle strength and reduced body fat regardless of the total testosterone levels. A significant increase in circulating levels of TT after resistance training in the groups of hypogonadal men could be of high clinical relevance in male hypogonadism treatment when testosterone-replacement therapy is contraindicated.

**THE IMPACT OF TRUNK STRENGTH IN TEMPORAL AND KINETIC VARIABLES DURING VERTICAL JUMPING**

PETRIDIS, L., PÁLINKÁS, G., UTCZÁS, K., TRÓZNAI, ZS., KOVÁCS, B.

*HUNGARIAN UNIVERSITY OF PHYSICAL EDUCATION AND SPORT SCIENCE*

INTRODUCTION: The purpose of this study was to examine the relationship of trunk strength with kinetic and temporal measures of a countermovement vertical jump (CMJ). It was assumed that higher trunk strength will be associated with better performance in vertical jump. We also hypothesized that trunk strength will affect eccentric and concentric phases of the jump similarly, and the effectiveness of the elastic energy recoil from the eccentric to the concentric phase.
METHODS: N=45 male handball and basketball players participated in this study (mean age=17.4±0.3 years) performing CMJ on a force platform (HUR labs) and trunk strength testing. From force-velocity-time data we divided the jump into eccentric and concentric phases registering the time duration (Tecc and Tcon) and the average force (Fecc and Fcon) values for each phase. We calculated the average rate of force development during the eccentric phase (RFDecc) from the moment ground reaction force exceeded body weight. Trunk strength was measured with an isokinetic dynamometer (BioniX Sim3 Pro) at 30º/s angular velocity. Participants performed left/right trunk rotation (Rot), trunk flexion (Fl), extension (Ext), and left/right trunk flexion (Lat Fl). Maximal peak torque from the best attempt (out of three) was used in further analysis. Left and right sides were averaged. Data were analysed using multiple linear regression and Pearson-type correlation in SPSS 25.0.
RESULTS: The relationship of trunk strength with CMJ performance was from trivial to small (r=.017 to .028; p>.05). Using the trunk movements as predictors and CMJ measures as dependent variables, the regression analysis showed that trunk strength explained the 24.7% of the total variance for rel. Fecc (F=3.12; p<.05), 33.1% for rel. RFDecc (F=4.70; p<.05), and 9.9% for rel. Fcon (F=1.05; p>.05). Besides Fl, the rest movements had a moderate, but significant negative correlation with Tecc, while Tcon had slightly lower negative correlation with Ext and Lat Fl. Rel RFDecc showed large correlations with Lat Fl (r=.53; p<.01) and Ext (r=.50; p<.01) and moderate correlation with Rot (r=.41; p<.01). Fcon correlated only with Lat Fl (r=.35; p<.05).
CONCLUSION: Performance in CMJ was not related to trunk strength, nevertheless the latter seems to have a significant contribution during the two subphases of the jump. During CMJ, trunk muscles stabilize the upper body improving movement optimization and in consequence performance. This contribution was larger for the eccentric phase compared to the concentric, indicating that trunk strength contributes to a more rapid execution of the countermovement and a higher eccentric force and RDF. The higher (and more explosive) eccentric force may increase the stored elastic energy, which potentially may increase concentric force production. However, based on our results, we could not confirm the connection of trunk muscles with a more efficient strain energy recoil from the eccentric to the concentric phase.

### OP-PN06 Pulmonary and respiratory physiology

**DYSANAPSIS AS A DETERMINANT OF EXPIRATORY FLOW LIMITATION DURING PHYSICAL EXERCISE IN MASTER ATHLETES**

MONS, V.1,2,3, HADDAD, T.1,3, MESTE O.3,4, MAUROY, B.2,3, BLAIN, G.M.1,3

*1LAMHESS, UNIVERSITÉ CÔTE D'AZUR, FRANCE 2LJAD, CNRS, UNIVERSITÉ CÔTE D'AZUR, FRANCE 3CENTRE VADER, UNIVERSITÉ CÔTE D'AZUR, FRANCE 4I3S, CNRS, UNIVERSITÉ CÔTE D'AZUR, FRANCE*

INTRODUCTION: In older highly trained populations or master athletes, the decline in pulmonary function might play a role in limiting high-intensity endurance exercise performance. Increased airway resistance with aging can be associated during exercise with expiratory flow limitation (EFL), defined as the inability to increase expiratory flow despite increased transpulmonary pressure. EFL can lead to hyperinflation, lower inspiratory reserve volume, greater respiratory muscles work / effort, and therefore exercise intolerance. For a given lung size, the reduction of airway size increases airflow turbulence and resistance and might increase the prevalence and severity of EFL. The aim of this study is to determine how the uncoupling between lung and airway size, termed dysanapsis, determines EFL in master athletes during maximal exercise.
METHODS: Ten male master athletes, (mean ± SD; age, 68.5±5.7 years; VO2MAX, 51.9±7.7 mL.min-1.kg-1) performed a maximal and graded test to exhaustion on a cycle ergometer. The maximal flow-volume (MFV) curve was determined based on flow and volume measured at the mouth from maneuvers performed prior and after exercise. To determine operational lung volumes, participants performed inspiratory capacity (IC) maneuvers during each stage of the test. The end expiratory lung volume (EELV) was calculated by subtracting the IC volume from the forced vital capacity (FVC) volume. EFL was defined as the percentage of the tidal volume that intersected the MFV curve during expiration. Subjects were flow limited when the severity of EFL was >5%. Dysanapsis was estimated using the ratio (DR) between forced expiratory flow at 50% of vital capacity (FEF50) and the product of FVC and static recoil pressure at 50% of FVC (Pst50), [i.e. DR=FEF50/(FVC* Pst50)].
RESULTS: During the exercise test (peak power output (PPO): 256±33.7 W), all participants experienced EFL at workloads (WEFL) ranging from 50% to 100% of PPO (average: 70.2 ± 20.2%). EFL severity reached 48.3 ± 16.6% at the highest workloads. DR was significantly correlated to WEFL (r=0.72, p=0.02) and participants who experienced EFL at lower workload (LOW) had a significantly lower DR than participants who experienced EFL at higher workloads (HIGH) (0.31±0.03 vs. 0.43±0.08, p=0.01, respectively). At maximum exercise, the LOW group also had a significantly higher EELV relative to FVC compared to the HIGH group (38.1±8%FVC vs. 32.4±6%FVC, p< 0.05, respectively).
CONCLUSION: All master athletes experienced EFL during exercise and EFL was related to airway dysanapsis. A lower DR was associated with both an EFL occurring at lower relative exercise intensities and with a higher EELV at maximal exercise. These findings thus suggest that dysanapsis (uncoupling between lung and airway size) is an important determinant of flow limitation in male master athletes during exercise.

**FREEZING HYPOXIA AND EXERCISE: HOW DO THEY AFFECT LUNG FUNCTION AND RESPIRATORY MUSCLE FATIGUE?**

CALLOVINI, A.1,2, FORNASIERO, A.1,2, SAVOLDELLI, A.1,2, DECET, M.1,2, SKAFIDAS, S.1, PELLEGRINI, B.1,2, BORTOLAN, L.1,2, SCHENA, F.1,2

*1 CERISM, UNIVERSITY OF VERONA, ITALY*

INTRODUCTION: Cold temperatures (<-15°C) increase exercise-induced bronchoconstriction (EIB) [1], whilst cold and hypoxic environments exacerbate respiratory muscle fatigue (RMF) development during prolonged sub-maximal exercise [2]. The aim of this study was to determine the independent and combined effects of cold and hypoxia on lung function (LF) and RMF development after strenuous exercise.
METHODS: 12 trained male subjects (age 27±3; VO2max: 64±5 mL/kg/min) randomly performed a maximal cardiopulmonary exercise test (CPET) followed by an 8-min bronchoconstriction test (8-BT), under four environmental conditions: Normothermic Normoxia (NN: 18°C, 20.9% FiO2), Normothermic Hypoxia (NH; 18°C, 13.5% FiO2), Cold Normoxia (CN: -20°C, 20.9% FiO2) and Cold Hypoxia (CH: -20°C, 13.5% FiO2). Maximal workload (WL), ventilation (VE), respiratory frequency (Rf) and tidal volume (VT) were measured during exercise; maximal inspiratory pressure (MIP) and maximal expiratory pressure (MEP) were evaluated before and immediately after the CPET, whereas LF (forced expiratory volume in 1 second (FEV1), forced vital capacity (FVC), forced expiratory flow at 25%-75% (FEF25-75) and forced expiratory flow at 50% (FEF50)) was evaluated at baseline and 1,3, 6, 10 and 15min post the 8-BT.
RESULTS: Cold and hypoxia decreased maximal workload (both p<0.001), VE (p<0.001, p=0.017, respectively) and VT (p<0.001, p=0.004, respectively) at the end of CPET, whereas cold only decreased VE (p<0.001) and VT (p=0.003) at the end of the 8-BT. A time effect (p=0.025) was seen in MEP (Δ% pre to post exercise, NN:-6.8±11.9%; NH:-3.38±10.1%; CN: -8.14±16.7%; CH: -10.2±16.4%), independently from environmental condition. Cold*time interactions (p<0.01) were found in FEV1 (Δ% pre to post exercise, NN: -3.4±6.7%, NH: 3.9±6.3%, CN: -7.7±6.0%, CH: -8.2±7.1%), FEF 25-75% (NN: 3.2±11.5%, NH: 0.11±10.1%, CN: -12.9±8.7%, CH: -8.12±13.8%) and FEF50% (NN: 2.1±12.4%, NH: -0.4±11.6%, CN: -11.2±9.7%, CH: -13.3±17.1%). Multiple correlation analysis showed that lower peak ventilatory responses during both CPET and 8-BT were associated with a higher decrease (Δ %) in LF parameters (all p<0.001, descriptor: moderate (0.35 CONCLUSION: These data showed greater LF impairment after strenuous exercise in the cold with no additional hypoxic effect. On the other hand, RMF development after maximal CPET seemed to be independent from environmental condition. Further studies are needed to clarify the relationship between LF impairment and the reduced ventilatory responses in the cold.

**ASTHMA PREVALENCE IN NORWEGIAN ELITE ATHLETES**

MELSOM, H.S., RANDA, A., STANG, J., HISDAL, J., STENSRUD, T.

*NORWEGIAN SCHOOL OF SPORT SCIENCES*

INTRODUCTION: Asthma is a common problem among elite athletes and represents a health risk interfering with the athlete's performance status. This study aimed to evaluate the asthma prevalence in Norwegian summer and winter elite athletes and asthma prevalence across sport categories. We also aimed to examine if bronchial hyperresponsiveness (BHR), lung function, fraction of exhaled nitric oxide (FENO) and allergy differed between asthmatic and non-asthmatic elite athletes.
METHODS: We included Norwegian athletes qualifying for the Beijing Olympic Summer games 2008 (n=80) and the Vancouver Olympic Winter Games 2010 (n=55). The athletes performed clinical respiratory examination including lung function measurement, methacholine bronchial challenge for assessment of BHR, FENO and allergy assessed with skin prick test. Asthma was diagnosed based on respiratory symptoms and clinical examination including objective measurements.
RESULTS: Asthma was more prevalent among winter athletes (50%) than summer athletes (20%). Thirty-three (52%) endurance athletes, 3 (6%) team sport athletes and 7 (33%) technical sport athletes had doctor diagnosed asthma. Significantly lower lung function (p<0,001) and significantly higher prevalence of severe BHR (p<0,001) were shown in asthmatic athletes compared to non-asthmatic athletes. Allergy and FENO did not differ between asthmatic and non-asthmatic athletes.
CONCLUSION: Asthma prevalence is high in Norwegian elite athletes, with winter athletes and endurance athletes showing the highest prevalence. Asthmatic athletes were characterized by lower lung function and more severe BHR compared to non-asthmatic athletes. The high asthma prevalence in winter sport athletes and endurance athletes demonstrate a need for increased attention to prevent and reduce the prevalence of asthma among those athletes.
Athletes, medical staff, and coaches should be aware of the high asthma prevalence among athletes training in unfavourable environmental conditions such as cold and dry air, polluted air and in swimming pools with high concentration of chlorine combined with poor ventilation. However, it is still unclear if asthma, BHR and reduced lung function are persistent in elite athletes after retirement from elite sport and if respiratory health may be a limitation for physical activity and exercise after career end. Follow up studies are needed to evaluate how athletes' respiratory health are over time, and if the asthma diagnosis is reversible.

**EFFECT OF REPEATED SPRINT TRAINING WITH VOLUNTARY HYPOVENTILATION ON PERFORMANCE AND MUSCLE OXYGENATION**

IMAI, A., YAMAGUCHI, K., GOTO, K.

*RITSUMEIKAN UNIVERSITY*

INTRODUCTION: Repeated sprint training in hypoxic condition has been shown to improve repeated sprint ability. Moreover, repeated sprint training with voluntary hypoventilation at low lung volume (VHL) is growing attention as an alternative procedure for establishing hypoxic environment in the body. The training with VHL previously demonstrated further increase in repeated sprint ability compared with the same training with normal breath [1]. However, no direct comparison has not been conducted between "repeated sprint training in hypoxia" and "repeated sprint training with VHL". The purpose of this study was to compare the training adaptations between repeated sprint training with VHL and the same training in hypoxia.
METHODS: Twenty-four healthy physically active males (age, 21.9 ± 0.4 years; height, 172.9 ± 1.2 cm; weight, 71.0 ± 21.9 kg) performed repeated cycling sprints twice per week for three weeks (six sessions in total). All participants were randomly assigned to one of three different groups, (1) normoxia with normal breathing (NOR group; 23°C, FiO2 = 20.9%), (2) hypoxia with normal breathing (HYP group; 23°C, FiO2 = 16.4%), or (3) normoxia with breath holding (VHL group; 23°C, FiO2 = 20.9%). The repeated sprint ability (12 × 6-s maximal

sprint with 24-s rest periods between sprints) and maximal oxygen uptake (VO2max) were determined before and after the training periods. Power output, systemic oxygen uptake, and cardiac function were monitored during the repeated sprint test. Muscle oxygenation in vastus lateralis and respiratory muscle was also evaluated using near infrared spectroscopy.
RESULTS: Power output was significantly increased in VHL and HYP during the repeated sprint test (VHL, 575±21 W vs. 659±30 W, $p < 0.05$; HYP, 604±26 W vs. 671±35 W, $p < 0.05$), whereas NOR group did not show significant change after training period (592±32 W vs. 623±30 W, $p > 0.05$). After the training period, muscle oxygen saturation in vastus lateralis during the repeated sprint test was significantly decreased in VHL ($p < 0.05$) but not in HYP and NOR ($p > 0.05$). In addition, muscle oxygen saturation in respiratory muscle was slightly decreased in HYP ($p = 0.1$) but not in VHL and NOR ($p > 0.05$). VO2max significantly increased in VHL after the training period (46.2±1.3 mL/kg/min vs. 47.2±1.4 mL/kg/min, $p < 0.05$), but HYP and NOR did not show significant change (HYP, 47.0±1.5 mL/kg/min vs. 49.6±1.6 mL/kg/min, $p > 0.05$; NOR, 46.2±1.3 mL/kg/min vs. 48.7±2.6 mL/kg/min, $p > 0.05$).
CONCLUSION: Three weeks of repeated sprint training with VHL and same training in hypoxia further enhanced power output during repeated sprint test compared with the training with normal breath in normoxia. In addition, the training with VHL presented different tendency of muscle tissue oxygenation in vastus lateralis and respiratory muscle compared with the training in hypoxia.

### OP-AP21 Endurance

#### BAYESIAN MULTILEVEL REGION-SPECIFIC INVESTIGATION OF RISK FACTORS FOR ELIMINATION FROM FÉDÉRATION ÉQUESTRE INTERNATIONALE ENDURANCE RIDES DUE TO IRREGULAR GAIT AND METABOLIC PROBLEMS (2012–2019)

ZUFFA, T.1, BENNET, E.D.1, DOWSEY, A.1,2, PARKIN, T.D.H.1

*UNIVERSITY OF BRISTOL*

INTRODUCTION: Endurance is a popular equestrian sport with the second largest number of events among all Fédération Équestre Internationale (FEI) disciplines. At the international level, horse and rider combinations race over distances of 80 to 160 km, which puts a significant load on equine and human athletes' musculoskeletal systems and metabolism and gives rise to the risk of injuries and other issues. The sport is practised and regulated globally and organised within eight FEI Regional Groups (RGs). Despite common regulation, the sport's specifics vary among RGs, with RG7 - North Africa/Middle East hosting significantly faster and larger competitions, with a younger, predominantly male rider population and lower proportion of completed rides. To date, risk factors for the two most prevalent adverse outcomes, elimination due to irregular gait (FTQ-GA) or metabolic problems (FTQ-ME), have been investigated using global models or models for one or more countries across RGs. Such models, however, allow limited examination of RG-specific factors. This study focused on RG7 and aimed to identify regional risk factors for FTQ-GA and FTQ-ME, which may be specific or more important to rides in this area, and which have thus not been detected or investigated in detail in global or national models.
METHODS: This retrospective cohort study used data from the FEI's Global Endurance Database. The study included 30,138 starts made by 11,119 horses ridden by 4,649 riders in 568 one-day international competitions held in 10 RG7 countries. This represents 94% of all starts made in RG7 from July 2012 to December 2019. Bayesian Generalised Additive Multilevel Models were fit to investigate associations between the outcomes and 61 potential risk factors identified based on earlier studies and a priori hypotheses. Modelling accounted for clustering at horse, rider, trainer, competition, and venue level, nonlinear shapes of associations, and biologically plausible interactions.
RESULTS: The study identified multiple risk factors including horse and rider sex, age, eliminations history, competition frequency and progression. Fast riding speed was associated with a sharp increase in the likelihood of FTQ-GA (ELPD diff. 269.2, SE diff. 21.5), and the curve of the association was, on average, steeper for higher- compared to lower-level rides. Experience was associated with a decrease in the odds of FTQ-GA in both riders (38.6, 9.4) and horses (33.3, 8.7). Female riders were less likely to end with FTQ-GA (OR 0.84, 95% CI 0.73–0.98) and FTQ-ME (0.63, 0.49–0.80) than male riders, and junior rides were more likely to result in FTQ-ME than non-junior ones (2.16, 1.52–3.10).
CONCLUSION: Identified modifiable factors, including high riding speed and frequency, can be mitigated by appropriate rules, and considered by athletes when planning competition schedules or during the ride itself. Other factors can aid officials at in-ride inspections as additional inputs when assessing combinations' fitness to continue in the ride.

#### EFFORT DISTRIBUTION AND TACTICAL BEHAVIOUR ON THE MEN'S 1500 METRES AT THE WORLD ATHLETICS INDOOR CHAMPIONSHIPS BELGRADE 2022

CASAL GARCÍA, N., LÓPEZ DEL AMO, J.L.

*INEFC, UNIVERSITAT DE BARCELONA*

INTRODUCTION: The 1500 meters is a middle-distance discipline. Due the distance of the race, tactic behaviour is important to achieve a good performance. Placing yourself in the first positions at the start of the race can be overrated since the medallists are usually decided in the last laps due the final "kick"(Sandford, Day & Rogers, 2019) or also to the lower loss of speed in the last 200 meters (Hanley, Stellingwerff & Hettinga, 2019). The aim of this study is to analyse the distribution of effort and tactical behaviour during the high-level mens 1500-meter race.
METHODS: The men's 1500 metres competition of the 2022 World Athletics Indoor Championships Belgrade was analysed. Have been included all the athletes participating in the final (n=12). Official data has been obtained from the official results of the World Athletics Federation. The temporal and spatial variables analysed are final time (s), time of each 100 m. partial (s), partial time of every split (100,200,300,400,500,600,700,800,900,1000,1100,1200,1300,1400,1500) (s), number of splits in first position (n), number of 100 m. splits in first position (n) and position every 100 metres (n). Correlations between final time or final position and time of each 100 m. split (s), time of every split (s), number of changes in position during the race (n), position every 100 metres (n) and number of 100 m. splits in first position (n) were performed. Shapiro-Wilk test was performed for checking the sample normality. All data was analysed with JASP (0.16.1.0).

RESULTS: Mean final time was 3'41"79±12"31. Significant differences were found between a better split time in every 100 m. (s) and the final time in 100-200 (ρ 0,629,p<.05), 300-400 (ρ 0.895, p<.001), 1000-1100 (ρ 0.825, p<.01), 1100-1200 (ρ 0,736, p<.01), 1200-1300 (ρ 0,666,p<.05), 1300-1400 (ρ 0,695,p<.05) and 1400-1500 (R 0,601,p<.05).
No significant differences were found between final position or final time and number of changes in position during the race. On the other hand, inversely significance has been found between the number of 100 m. splits in first position (n) and the final position (n) (R -0,604,p<.05).
CONCLUSION: The last third of the race seems to be the most decisive for the final performance. The changes of position or the number of times in first position during the race do not seem to be determining for performance, so take the firsts positions towards the end of the race seems to be the best tactical behaviour.

## CHANGES IN VO2MAX AND MAXIMAL AEROBIC PERFORMANCE FOLLOWING 3H RUNNING VS CYCLING EXERCISE MATCHED FOR INTENSITY

SABATER PASTOR, F., FARICIER, R., METRA, M., BROWNSTEIN, C., MILLET, G.Y.

*UNIVERSITÉ JEAN MONNET, SAINT-ETIENNE*

INTRODUCTION: The variables that determine endurance exercise performance are often assessed in non-fatigued state. It has been previously shown that some endurance performance determinants, such as running economy or critical power, decrease following endurance exercise. However, it is unclear whether maximal oxygen uptake (VO2max) is negatively affected by previous endurance exercise, and if exercise modality plays a role in the magnitude of change. The purpose of this study was to assess whether VO2max decreases following 3h of endurance exercise, and to assess the differences in cycling vs running.
METHODS: Recreational athletes trained in both running and cycling (N = 17, 33 ± 8 yrs, 72.1 ± 5.3 kg, 178 ± 6 cm) visited the lab in four occasions. On visits 1 and 2 they performed a 30-s step incremental test to determine VO2max, gas exchange threshold (GET) and peak test performance (PTP, measured as average power output or speed during the last 30 s of the test). Heart rate (HR) and peak blood lactate concentration were also measured during each test. On visits 3 and 4 subjects cycled or ran during 3 h at 105% of GET after which the incremental test was repeated, and the same variables were measured. Only 11 subjects were able to perform both incremental tests on visits 3 and 4, the remaining 6 not completing them due to injury or pain. PTP data was normalized to the mean of the corresponding variable measured at pre to compare power and speed data. The changes in all variables at rest vs following the 3 h test were assessed using a two-way repeated measures ANOVA with two factors, time and modality. Data are expressed as mean ± SD.
RESULTS: There was a time × modality interaction effect for VO2max (p=0.004), with a significant decrease for running compared to baseline (4.28 ± 0.40 vs 3.92 ± 0.39 L/min, p=0.031) but no significant change for cycling (4.28 ± 0.50 vs 4.20 ± 0.58 L/min, p=0.859). There was a significant effect of time for PTP (p<0.001) but no modality or interaction effects. Specifically, PTP decreased significantly for running from 20.5 ± 1.2 to 17.9 ± 1.7 km/h (p <0.001) and for cycling from 407 ± 51 to 366 ± 52 W (p <0.001). Furthermore, there was no effect of time in maximal HR (p=0.115). There was a significant effect of time on peak blood lactate concentration (p<0.001), which decreased following both running (from 12.0 ± 2.4 t 6.3 ± 2.1 mmol/L, p<0.001) and cycling (from 14.0 ± 1.9 to 8.9 ± 3.6 mmol/L, p<0.001), but there was no interaction for this variable.
CONCLUSION: The main finding of this study was that running exercise lasting 3 hours at 105% of the GET has a negative effect on VO2max, but cycling exercise of the same duration and intensity does not lead to a similar VO2max reduction despite the reduction in test performance not being significantly different between exercise modalities. It is possible that a greater loss of efficiency in cycling may lead to the greater decrease in PTP relative to the smaller change in VO2max.

## CAN VIDEO- AND SENSOR-BASED FEEDBACK BY IMPLEMENTING A TERRAIN-SPECIFIC MICRO-PACING STRATEGY IMPROVE PERFORMANCE IN CROSS-COUNTRY SKIING?

SEEBERG, T.M.1,2, KOCBACH, J.1, TALSNES, R.K.3, MEYER, F.4, LOSNEGARD, T.5, TJØNNÅS, J.2, SANDBAKK, Ø.B.1, SOLLI, G.S.6

*1.NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY, 2.SINTEF DIGITAL, 3.TRØNDELAG COUNTY COUNCIL, 4.UNIVERSITY OF OSLO, 5.NORWEGIAN SCHOOL OF SPORT SCIENCES, 6.NORD UNIVERSITY*

INTRODUCTION: Cross-country (XC) skiers employ a variable pacing pattern with higher metabolic rates and power production during uphill than flat and downhill sections. To improve performance, refining XC skiers' micro-pacing strategy through adjustments of speed in specific parts of flat and downhill terrain sections can be beneficial. Therefore, the aim of this study was to investigate performance-effects of video- and sensor-based feedback by implementing a terrain-specific micro-pacing strategy in XC skiing.
METHODS: Following a simulated 10-km skating time-trial (Race1) on snow, 26 national-level male XC skiers were randomly allocated into either an intervention (INT, n=14) or control group (CON, n=12), before repeating the race (Race2) two days later. Between races, INT received video- and sensor-based feedback through a theoretical lecture and a practical training session aiming to implement a terrain-specific micro pacing strategy focusing on active power production over designated hilltops to save time in the subsequent downhill. CON only received their overall results and performed a training session with matched training load. During the races the skiers were equipped with wearable sensors (GNSS, IMUs, heart rate), and prior to the field test, performance and physiological measures were collected in the laboratory.
RESULTS: From Race1 to Race2, INT increased the total variation of chest acceleration on all hilltops (p<.001) and reduced the time spent in a specifically targeted downhill segment (mean group difference: -0.55 s, CI95[-0.9,-0.19 s], p=.003), as well as the overall time spent in downhill (-14.4 [-21.4,-7.4] s, p<.001) and flat terrain (-6.5 [-11.0,-1,9] s; p=.006) compared to CON. The increased speed in the specifically targeted downhill segment did not correlate with the skiers' laboratory measures or a 20-m on-snow speed test, implying that the increase in performance occurred independent of the skiers' physical capacities. However, there were an association between the skier's speed on the hilltop in Race1 with improved speed on the hilltop from Race1 to Race2 (R=-0.57, p=.036) and reduced time in the following downhill segment (R=-0.68, p=.007). This means that the skiers with lower speed on the hilltop in Race1 improved more than the skiers with higher

speed. There was also an association between race-time in Race1 and improvement in race-time, so that skiers with longer race-time in Race1 improved more than the faster skiers (R=0.86, p= <.001). No between-group differences were found for overall time spent in uphill terrain (-9.3 [-31.2,13.2] s, p=0.426) or total race-time (-32.2 [-100.2,35.9] s, p=.339).
CONCLUSION: Targeted training combined with video- and sensor-based feedback led to successful implementation of a terrain-specific micro-pacing strategy in XC skiing, which induced reduced time spent in downhill and flat terrain for INT compared to CON. However, no change in overall performance were observed between the two groups of XC skiers.

**THE FLYING RABBIT: THE USE OF A DRONE TO IMPACT PACING BEHAVIOUR IN 1500M RUNNING.**

VAN SON, B.L., VERHOEF, T., MENTING, S.G.P.

*LEIDEN UNIVERSITY*

INTRODUCTION: In middle-distance time-trial sports events, like 1500-m runs, pacing is a determining factor for performance [1]. Pacing is the decision-making process regarding the distribution of effort over the duration of the race [2]. The development of adequate pacing behaviour during adolescence is thought to be an important factor for future performance [3]. Currently, very few technologies are available to assist athletes with optimal pacing behaviour on the track. This study explores the use of a drone as a tool to help junior runners to better approximate their pacing plan in a 1500-m race.
METHODS: Eleven well-trained junior athletes (Male: n = 7, Female: n = 5; mean age, 17.4 years, SD = 2.4) performed four 1500-m races, while they tried to best approximate their personal pacing plan. The pacing plan described the 400m lap times and the 1500m finish time. The participants first ran two races as part of the familiarisation phase followed by two races as part of the experiment phase. All races took place on different days. In both phases, one race was self-paced (SP) by the athletes, the other was drone-paced (DP); a drone accompanied them on the track flying at the pace of the athlete's pacing plan. For all races, split times, finish times and rate of perceived exertion (RPE) scores were recorded. The deviation from the pacing plan and differences in RPE scores were compared between the SP and DP of the experiment phase.
RESULTS: Participants deviated less from the pacing plan in DP (M = 1.17, SD = 1.20) than in the SP (M = 3.05, SD = 3.34) ($F(1,86) = 12.30$, $p < 0.001$). The average deviation of the four set lap times from the planned lap times were compared, participants deviated on average less from the split times planned in the pacing plan in DP (M = 0.74, SD = 0.35) than in the SP (M = 1.23, SD = 0.65) ($F(1, 86) = 19.41$, $p < 0.001$). No significant difference was found between the RPE scores.
CONCLUSION: A drone can alter the pacing performance of youth athletes on the 1500m. Athletes adhered better to their pacing plan in the presence of a drone, while perceived exertion scores were unaffected. This leads to the conclusion that a drone can potentially be used to support the development of pacing and performance of junior runners. The introduction of a drone as a pace-setter is novel within the academic context, and is worth further exploration for potential application in athletic talent development programs.

### OP-AP16 Monitoring recovery

**COMPARISON BETWEEN DIFFERENT AFTER EXERCISE RECOVERY STRATEGIES–AN UMBRELLA REVIEW**

LI, S., KEMPE, M., LEMMINK, K.

*UNIVERSITY MEDICAL CENTER GRONINGEN, UNIVERSITY OF GRONINGEN*

INTRODUCTION: Numerous overview studies for individual recovery strategies, like for massage or active recovery, have been conducted in the field of sports sciences. However, only a few studies compared different types of recovery strategies or have a narrative rather than a systematic approach. Thus, the purpose of this study was to use an umbrella review to compare various types of post-exercise recovery strategies and provide a bird's view on the effectiveness of recovery strategies.
METHODS: Electronic searches of the PubMed, Cochrane Database of Systematic Reviews, and Web of Science databases were conducted for studies published up to April 2021 under the Preferred Reporting Items for Systematic reviews and Meta-Analyses (PRISMA) statement. Additionally, the AMSTAR 2 tool was used to assess the methodological quality of the identified studies.
RESULTS: Twenty reviews (nine systematic reviews and eleven meta-analyses) were fully reviewed out of the 130 identified. Methodological quality assessment via AMSTAR 2 revealed that two reviews had high quality, and eighteen had moderate to low quality. According to the outcome variables, we classified the various recovery metrics in physiological, psychological, and performance metrics following quantitative and qualitative synthesis. The included passive recovery methods (massage, nutrition, and foam rolling) indicated that carbohydrate, curcumin, and pomegranate supplementas provided a positive effect mostly on performance variables. Massage had a negligible or no effect on the recovery process. Regarding active recovery strategies (cryotherapy, varying combinations of submaximal activities), cryotherapy showed mixed results of effectiveness. Active recovery lasting 6-10 minutes improves performance. The effect of compression garments was the only strategy with beneficial effects (marginal to large) within proactive recovery (compression garments, alcohol consumption).
CONCLUSION: According to the criteria used in the current umbrella review, the majority of recovery studies have low methodological quality in terms of systematic reviews and meta-analyses. Most of the systematic reviews included in this umbrella review demonstrated that the recovery findings lacked adequate evidence, meaning that the majority of strategies are not helpful. Future original research on this subject should focus on improving experimental studies' methodological quality and design. Also, researchers should agree on standard outcome measures in the field of recovery to allow for a more objective assessment within and between the different types of recovery.

## INFLUENCE OF SECOND-GENERATION ORAL CONTRACEPTIVE USE ON MUSCLE RECOVERY FOLLOWING REPEATED BOUTS OF RESISTANCE EXERCISE IN TRAINED WOMEN

OXFELDT, M., BUNDGÅRD, A., HANSEN, M.

*AARHUS UNIVERSITY*

INTRODUCTION: Oral contraceptives (OCs) are the preferred type of contraception used by female athletes. The exogenous sex hormones from OCs suppress the endogenous secretion of sex hormones and thereby change the sex hormonal profile. Limited evidence suggests that the female sex hormone estrogen may have a protective role against muscle damage. However, the role of the exogenous administered sex hormones is still uncertain. In untrained women, the use of OCs is associated with delayed strength recovery and greater increases in markers of muscle damage after muscle-damaging exercise when compared to non-users of OCs in a few, but not all studies. Therefore, there is a need for a well-controlled study comparing muscle recovery in trained OC-users and non-users of OCs before any conclusions can be drawn. Thus, the aim of the present study was to investigate if OC use influences muscle recovery following repeated bouts of resistance exercise in trained women.
METHODS: Trained OC-users and - non-users of OC were recruited to perform three strenuous resistance exercise bouts within a 24-hour period. Before, and 3, 24, and 48 hours after the resistance exercise sessions, the participants completed measurements of maximal voluntary isometric (MVIC) and dynamic contraction (MVDC), vertical jump height, and Wingate power performance. All participants were provided with an energy-macronutrient balanced diet during the experimental period.
RESULTS: Results from eight OC-users and six non-users of OCs demonstrated that MVIC, MVDC, jump height, jump power, Wingate peak and average power were all significantly reduced following resistance exercise ($p < 0.05$). However, in OC-users a significantly greater reduction in MVDC was observed 24 hours after the last exercise session compared to non-users of OCs (interaction: $p < 0.05$). No other significant interactions were observed.
CONCLUSION: The results indicate that OC-users experience a greater deterioration of maximal dynamic strength compared to non-users of OCs following repeated bouts of resistance exercise. However, no significant difference was observed in the other performance parameters. To enhance the statistical power, further 26 subjects are recruited. The test period is scheduled to end in June 2022. The full data set will be presented at the conference.

## ASSOCIATION BETWEEN SLEEP QUALITY PERCEPTION AND FATIGUE, MENTAL, STRESS AND MUSCLE SORENESS IN HANDBALL ATHLETES BEFORE PRE-OLYMPIC GAMES

SÁ, C., MONTEIRO, S., OSÓRIO, S., CATARINO, P., SILVA, F., SOARES, M., SÁ, P.

*ISMAI/IPB/CIDESD*

INTRODUCTION: According to recent research, sleep is directly related to the individual's sports performance, which means that better sleep quality is an important element contributing to a better physical and emotional recovery for the athlete. However, stress and traveling may be factors that lead to poor sleep quantity and quality, which can be the cause of decrements in performance and increased risk of illness.
The aim of this study was to compare the sleep quality perception in handball players to their stress levels, fatigue, mental and muscle soreness perception.
METHODS: Twenty-four male Portuguese handball athletes completed a questionnaire based on the Hooper Scale, to assess the quality of the previous night's sleep, stress levels, fatigue levels and perceived muscle damage, during handball training before pre-Olympic games. This questionnaire consists of 5 self-rated items and each question is individually scored on a scale from 1 ("Very, very low or good") to 5 ("Very, very high or bad"). This relation was evaluated by Pearson correlation, statistical level of $p<0.05$ was accepted.
RESULTS: 24 athletes, in average, reported that sleep quality perception was 3.4±0.8, which 90,5% had a "good sleep". Fatigue level was 3.9±0.6; mental state was 4.5±0.8 and energy perception was 4.0±0.8. Athletes with better perception of sleep quality felt significantly less fatigue ($r = 0.465$; $p = 0.034$), felt psychological better ($r = 0.609$, $p = 0.003$), and reported a significantly higher level of energy ($r = 0.484$, $p = 0.026$) and nonphysical muscle soreness. Athletes with a that felt less fatigue had a significantly higher level of psychological state ($r = 0.726$, $p <0.001$) and energy perception ($r = 0.804$, $p = 0.000$). Athletes with higher psychological state had a significantly higher energy perception ($r = 0.822$, $p <0.001$).
CONCLUSION: Handball athletes, before pre-Olympic games, who report a good quality of sleep have a positive mental state, more energy perception, less level of fatigue physical and less muscle soreness. The process of monitoring will help prescribe the correct dosage of training in order to maximize athlete performance and to implement the appropriate recovery protocols (rest, nutrition, and others).

## MUSCLE OXYGEN SATURATION CONTRIBUTES TO DETERMINING THE RECOVERY TIME INTERVALS IN MAXIMAL STRENGTH TRAINING. CONTRIBUTION TO UNDERSTANDING THE TRAINING PROCESS OPTIMIZATION

TEIXEIRA, A.M., CARVALHO, J., RAMA, L.

*UNIVERSITY OF COIMBRA, NIF:501617582*

INTRODUCTION: Training for maximum strength is commonly based on manipulating great magnitude external resistances (80% to 100% of the 1RM). The literature suggests long rest times to ensure a complete recovery between each set to optimize the training process. This study aimed to verify the relationship between muscle oxygen saturation ($SmO_2$) in the vastus lateralis muscle and the rest interval using the performance analysis over a training protocol to improve maximal force capacity in the back squat exercise.
METHODS: Six male subjects experienced in powerlifting practice (mean ± SD: age, 24.1 ± 2.68 years; height, 147 ±71.4 cm; body mass, 83.9 ± 8.93 kg) participated in the study. On two separate days, 48hours apart, athletes come to the weight room at the same time of the day (10:00 – 12:00 AM). Athletes underwent a training task to improve their capacity to produce maximum strength (5 sets of 3 repetitions at 83%RM). The training, nutrition, and hydration regime of 48 hours before the performance assessment were maintained.
In the first moment (PT1), the rest time between sets was timed in 8 minutes to assure the reduction of muscular acidity produced by the muscular exertion. A NIRS sensor (Humon muscle oxygen sensor) was placed at the medial part of the right vastus lateralis muscle to assess the SmO2 in the muscle. In the second moment (PT2), the rest time was individualized according to the time needed to reach the plateau of SmO2 (time delay) observed in PT1. A linear transducer Encoder was used to control the velocity of each repetition. Capillary blood samples were taken from the earlobe immediately after each set for Lactate assessment. Heart rate and RPE were also controlled during the experiment.

RESULTS: The rest time between sets was reduced by around 2' from PT1 to PT2. The mean recovery %SmO2 does not differ significantly between moments 79,7±7.55% and 76,3±5,33%, respectively. Additionally, the % of the concentric velocity loss also did not differ between PT1 (50.6±24,8%) and PT2 (42.2±14.2%).
CONCLUSION: The mean values of the %SmO2 observed after the rest period align with the literature and suggest that the rest times based on the $SmO_2$ values allowed for a complete recovery. The observed percentage of mean concentric velocity loss suggests that this indicator of neuromuscular fatigue was not affected by the reduced recovery time.
Our findings lead us to conclude that the recovery periods estimated through the %SmO2 allowed for complete recovery between sets in maximal strength training in powerlifters avoiding the detrimental effect of accumulated fatigue.

**THE EFFECT OF MUSCLE CONTRACTION TYPE ON MUSCLE OXYGEN SATURATION DURING DYNAMIC VERSUS ISOMETRIC BACK SQUAT**

SANTARÉM, D.1, MACHADO, I.1,2, ABRANTES, C.1,2

*1.UNIVERSITY OF TRÁS-OS-MONTES E ALTO DOURO, VILA REAL, PORTUGAL; 2.RESEARCH CENTER IN SPORTS SCIENCES, HEALTH SCIENCES AND HUMAN DEVELOPMENT , UTAD, VILA REAL, PORTUGAL.*

INTRODUCTION: Exercise monitoring is indispensable for improving performance and for achieving the defined objectives. Physiological variables such as heart rate, oxygen uptake, or blood lactate concentration are considered the most widely used as global parameters (1), and muscle oxygen saturation, through near-infrared spectroscopy, has been gaining emphasis as a local muscle parameter (2). This pilot study aimed to compare the effect of the type of muscle contraction in the back-squat exercise in muscle oxygen saturation (SmO2) and total hemoglobin (tHb) during a dynamic contractions protocol (DCP) and an isometric contractions protocol (ICP).
METHODS: Seven voluntary participants (age: 26.4±6.1 years old; height: 176.6±9.7 cm; body mass: 76.7±9.6 kg) with back-squat experience were recruited. They were physically active and reported no musculoskeletal injuries to exercise. Before the protocols, one-repetition maximum (1RM) was determined (114.29±38.45 kg) with standard methodology. The DCP comprised 3 sets of 16 repetitions at 50% of 1RM (57.14±19.23 kg), with a 120-second rest interval between sets and 2 seconds per cycle of movement. The ICP comprised 3 sets of 1 isometric contraction with the same load and set duration (32 seconds) of DCP. NIRS derived parameters, i.e., minimum SmO2 (SmO2min), mean SmO2, and SmO2deoxygenation (% change from baseline) were assessed in vastus lateralis, soleus, longissimus, and semitendinosus muscles. Statistical significance was set at $p \leq 0.05$ and the results are presented as means ± standard deviation.
RESULTS: Although paired sample t-tests revealed no significant differences in mean SmO2 in vastus lateralis, longissimus, and semitendinosus muscles, soleus muscle had lower values in DCP but only in the first set ($p=0.023$). Related to SmO2min, just the soleus muscle presented differences ($p \leq 0.05$) and lower values in the DCP compared with ICP regardless of the set (1st: 27.3±8.9 % vs 44.2±10.2 %; 2nd: 26.1±11.4 % vs 38.6±17.6 %; 3rd: 24.5±12.7 % vs 40.5±16.4%) and an interesting point was that the minimum values in the four muscles analysed were reached after the end of exercise in 78% of the cases. The SmO2deoxygenation showed no significant differences between protocols in all analysed muscles. No differences were seen in tHb between DCP and ICP.
CONCLUSION: These findings suggested that the variation in the type of muscle contraction with the same load and exercise duration promoted a lower SmO2 in the soleus muscle in DCP, probably due to a higher demand of specific muscle activation, reflecting a more pronounced gap between oxygen supply and consumption. The identical behaviour of tHb between the protocols and the decreasing pattern along sets might be due to the similar intramuscular pressure.

**WEAK ASSOCIATIONS BETWEEN POLYGENIC RISK SCORE FOR PHYSICAL ACTIVITY AND AEROBIC CAPACITY IN HUNT 3 FITNESS STUDY**

TYNKKYNEN, N.1, PALVIAINEN, T.2, TÖRMÄKANGAS, T.1, KLEVJER, M.3, JOENSUU, L.1, KUJALA, U.1, KAPRIO, J.2, BYE, A.3, SILLANPÄÄ, E.1,2

*1, UNIVERSITY OF JYVÄSKYLÄ; 2, UNIVERSITY OF HELSINKI; 3, NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY*

INTRODUCTION: Both physical activity (PA) behaviour and aerobic capacity are heritable phenotypes. Polygenic risk scores (PRSs) can be used to estimate the individual's genetic propensity for a trait that is explained by variation in thousands of genetic variants. We have previously shown that PRS for PA (PRS PA) accounted for statistically significant but overall small proportion of the variation in PA in the Finnish cohorts (1). The purpose of this study was to investigate if genetic inheritance of PA affects aerobic performance and to replicate our previous findings using a cohort representing different genetic ancestry.
METHODS: Genotyped participants of the HUNT 3 Fitness Study with directly measured maximal oxygen uptake (VO2max) measurements (age 19-89 years, 49% males, N = 4,521) were included in analysis. PRS PA was calculated for self-reported moderate to vigorous PA (MVPA) minutes per week using UK Biobank genome-wide association study summary statistics and SBayesR methodology (2). In HUNT, self-reported PA was estimated using Kurtze score. A treadmill protocol was conducted to estimate VO2max (ml/kg/min). Linear regression models adjusted for age, sex and genetic principal components of ancestry were used to assess if standardized PRS PA predicts PA and aerobic capacity.
RESULTS: In fully adjusted model high PRS PA predicted higher PA in HUNT 3 cohort (ß = 0.104 per one SD change in PRS PA, SE = 0.042, P = 0.013). PRS PA independently accounted 0.13% of the variation (R2) in the in the Kurtze score. PRS PA was not associated with VO2max (ß = 0.099, SE = 0.103, P = 0.338).
CONCLUSION: PRS PA explained a minor proportion of variation in PA among HUNT cohort. This is probably because of low predictive value of the used PRS PA or low correlations among PA methods (MVPA minutes vs. Kurtze score). The fact that no statistically significant association was observed between PRS PA and VO2max may be explained by low predictive value of PRSPA or that the variants included in PRS

PA are mainly related to PA behavior and not to physiological determinants of aerobic capacity but also to the unreliability inherent in the self-reported PA measurement.

**TRANSCRIPTOMIC ANALYSIS OF MURINE SPLENIC CD3+ T CELLS AFTER ACUTE EXERCISE**

YE, X., LIU, R.

*SCHOOL OF PHYSICAL EDUCATION, CHINA UNIVERSITY OF GEOSCIENCES（WUHAN）*

INTRODUCTION: Exercise is a key factor that affects the immune functions. It is generally accepted that appropriate exercise could improve immune functions, while exhaustive exercise has been shown to impair the immune response. Acute exercise or overload exercise could cause an "open window" period (3 to 72 h after exercise) of weakened immune function[1], and the mechanism of exercise induced immunosuppression is still poorly understood. This study focused on the transcriptomic characterization of the effects of acute exercise on murine splenic CD3+ T cells by transcriptome sequencing (RNA sequencing, RNA-seq) technique.
METHODS: Mice were randomly assigned to the control, sedentary group, and the experimental groups, which performed a single bout of intensive and exhaustive treadmill exercise. Murine splenic lymphocytes were separated by density-gradient centrifugation after exercise.Cells were labeled with anti-CD3-PE antibody and sorted by a flow cytometry.The effect of exercise was evaluated by the immunological parameters (lymphocyte proliferation and cellular inflammatory factor secretion). The combination of flow cytometry and carboxyfluorescein succinimidyl ester labeling technique was used for determination of cell proliferation, and Th1/Th2 cytokines in the culture medium with cytometric bead array(CBA).Transcriptomic analysis of murine splenic CD3+ T cells was performed by RNA-seq technology, and differentially expressed genes were screened by the standard of |log 2 FC|>1 and P-adjust<0.05. Hierarchical cluster analysis was done for the screened differentially expressed genes, and gene ontology analysis (GO) and Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway enrichment analysis were performed for the differentially expressed genes.Experimental validation of the screened key expressed genes was performed by qRT-PCR.
RESULTS: Compared with the control group, exercise significantly reduced Con A-induced proliferation of CD3+ cells in vitro ($p < 0.05$), and increased the levels of IL-6, IL-5, and IL-13 in the culture medium ($p < 0.001/0.001/0.05$, respectively), down-regulated the level of IL-2 ($p < 0.05$). KEGG pathway enrichment analysis showed the effect of exercise were significantly enriched to cytoskeletal proteins and signal transduction mechanisms.Compared with the control group, exercise significantly increased the transcription level of the factors (SERCA2B, PKCθ, Cav3.3, Bcl-xL and FADD) in CD3+ cells.
CONCLUSION: Acute exercise has immunosuppressive effects, and its mechanism could be related to the regulation of the gene expression from the calcium signaling pathway, providing a theoretical basis for the further research into the mechanisms of exercise immunity.

**THE EFFECT OF TNF-A INHIBITOR ON THE INFLAMMATORY RESPONSE AFTER ONE-OFF EXHAUSTIVE EXERCISE**

LI, X.

*CHINA INSTITUTE OF SPORT SCIENCE*

INTRODUCTION: Acute inflammation caused by overtraining and insufficient rest can evolve into a chronic inflammatory response, leading to systemic immune response, inducing exercise fatigue, affecting performance and reducing athletic performance. TNF-α inhibitor (thalidomide) specifically inhibit TNF-α protein synthesis, acting by interfering with transcription, translation or affecting mRNA half-life. It is thus hypothesized that a reduction or inhibition of TNF-α contributes to a reduction in the validation response in exercise fatigue. In the present study, we investigate the effect of one-off exhaustive exercise on the TNF-α/NF-κB signaling pathway-mediated inflammatory response in skeletal muscle and the effect of TNF-α inhibitor intervention.
METHODS: Male 8-week-old Wistar rats were randomly divided into three groups: control group (EC group, n=10), exhaustive exercise group (EE group, n=10), and exhaustive exercise combined with TNF-α inhibitor intervention group (TEE group, n=10). The EE and TEE groups performed an exhaustive treadmill exercise at 16m/min with an incline of 0°after three days of acclimatization. The TEE group received 200mg/kg body weight of TNF-α inhibitor (thalidomide) by oral infusion 4h prior to each exercise. After 24 hours of exhaustive exercise, the serum CK, BUN, IL-1β and TNF-α were sampled and the expression of NF-κB, TNF-α and IL-1β was measured by western-blotting.
RESULTS: The exercise to exhaustion time was significantly increased in the TEE group compared with the EE group. Serum CK, BUN, IL-1β and TNF-α values were significantly higher in the EE group compared to the EC group, while serum BUN, IL-1β and TNF-α values were significantly lower in the TEE group compared to the EE group. The protein expression of NF-κB, TNF-α and IL-1β in the gastrocnemius muscle of rats was significantly higher in the EE group than in the EC and TEE groups.
CONCLUSION: TNF-α inhibitors reduced the TNF-α/NF-κB signaling pathway-mediated inflammatory response in rat skeletal muscle induced by one-off exhaustion exercise, prolonged the duration of exercise to exhaustion and improved the exercise capacity of rats.

**ASSOCIATION OF DAILY DIETARY INTAKE AND MYOKINES IN MARATHON RUNNERS**

CURY-BOAVENTURA, M.1, PASSOS, B.1, LIMA, M.1, DE SOUSA, C.1, PAZ, I.1, BARROS, A.1, SIERRA, A.2

*1CRUZEIRO DO SUL UNIVERSITY, 2UNIVERSITY OF SÃO PAULO*

INTRODUCTION: Daily food intake is crucial to determine endogenous fuel to practice endurance exercise and consequently to maintain muscle mass. Chronic low nutrients availability has been demonstrated to be one of the main factors related to endocrine and metabolic dysfunction. Myokines are chemical messengers release by skeletal muscle tissue during contraction and have autocrine, paracrine and endocrine effects modulating muscle mass and function. The aim of this study was to associate daily dietary intake with myokines response in marathon runners.
METHODS: Participated in this study sixty-one Brazilian male amateurs runners (age, 41 ± 7 years; height, 1.7 ± 0.01 m, body mass, 74 ± 14 kg). Blood samples were collected 1 day before and after São Paulo International Marathon. The plasma levels of myokines were determined using the Human Magnetic bead Panel. Dietary intake was determined using a prospective method of three food records in the week before marathon race.

RESULTS: Before race, energy and carbohydrate intake was correlated positively with musclin ($p<0.05$, $r=0.28$ and 0.38, respectively) and myostatin ($p<0.05$, $r=0.33$ and 0.40, respectively); and sugar intake with musclin ($p<0.05$, $r=0.30$). Musclin concentration also had a positive correlation with the micronutrients manganese ($p<0.05$, $r=0.28$) and vitamin C daily intake ($p<0.001$, $r=0.43$) and myostatin levels with vitamins B1, C and iron intake ($p<0.05$, $r=0.27$-$0.30$) before race. BDNF, IL-15, apelin, irisin, apelin, FSTL, FGF-21 levels were not associated with daily dietary intake before race. After race, daily sugar intake was correlated positively with BDNF, FSTL, IL-6 and FGF-21 concentrations, which are crucial to muscle recovery ($p<0.05$, $r= 0.31$-$0.33$); fiber intake with musclin and myostatin ($p<0.05$, $r=0.29$); and vitamin C with IL-15 ($p<0.05$, $r=0.26$). Cholesterol intake was correlated negatively with apelin and irisin levels ($p<0.05$, $r=-0.32$ and -0.27, respectively), sodium intake with BDNF and FGF-21 levels ($p<0.05$, $r=-0.30$ and -0.37, respectively) and protein intake with BDNF and apelin levels ($p<0.05$, $r=-0.26$).
CONCLUSION: The results highlight the importance of carbohydrate and fiber consumption in runners for good muscle recovery and alert to the adequacy of sodium and cholesterol consumption due to its negative correlation with BDNF, apelin and irisin levels. The data also could contribute to elucidate the mechanisms of beneficial effects of adequate intake in runners. In conclusion, daily dietary intake may influence some myokineslevels responsible to maintenance of muscle mass, such as myostatin, musclin, apelin and irisin, and to recovery of muscle mass and function, such as BDNF, FSTL, IL-6 and FGF-21.

### OP-AP18 Relative age effect

#### NEURO-MUSCULAR DEVELOPMENT AND AGE-RELATED PROFILING IN ELITE YOUTH SOCCER PLAYERS: CONVENTIONAL STATISTICS AND CONTRIBUTIONS OF MACHINE LEARNING

SCHWIETE, C., BROICH, H., MESTER, J., WIGGER, U., WAHL, P., BEHRINGER, M.

*GOETHE UNIVERSITY*

INTRODUCTION: From a neuromuscular perspective, soccer is characterized by the need to move ones own body mass at high speed. In addition, rapid changes of direction and quick responses to visual stimuli are needed. For these reasons, performance diagnostics often include jumping, tapping, balance and sprint tests and are supplemented by tests on changes of direction and visual information processing. However, little is known about the development of these skills in youth elite athletes. Therefore, this cross-sectional study investigated neuromuscular performance tests of elite youth soccer players across different age groups.
METHODS: 232 male elite youth soccer players (17.3±2.8 yrs) performed neuro-muscular tests including counter-movement jump (CMJ), squat jump (SJ), drop jump (DJ), star run (StR), chase next (CN), tapping (Tap), balance (Ba) and sprinting (Spr). For each athlete, 1-11 tests were carried out in a period of 4 years (number of tests: U15 = 88, U16 = 168, U17 = 263, U19 = 229, U23 = 192). The data were organized in a “data warehouse” and used for conventional statistics and machine learning, such as clustering and decision trees.
RESULTS: Conventional Statistics
There were significant differences between certain age groups (mean±SD) e.g. regarding CMJ, SJ, DJ, StR and Reactive Strength Index (RSI) as a key indicator for neuro-muscular reactivity. These differences, however, cannot statistically be related to biological age or age groups as the intraindividual or groupwise within variation is very high. So is the individual development in the context of soccer specific training. Thus an individual profiling is required.
Examples for groupwise results are: CMJ [cm]: U15 = 33.8±4.2, U16 = 36.6.1±4,6, U17 = 38.0±3.9, U19 = 40.6±4.5, U23 = 40.5±4.1. StR [s]: U15 = 18.4±1.2, U16 = 18.0.±1.1, U17 = 17.5±1.1, U19 = 17.3±1.2, U23 = 17.2±1.1). RSI [cm/ms]: U15 = 0.141±0.030, U16 = 0.148±0.033, U17 = 0.163±0.031, U19 = 0.182±0.035, U23 = 0.185±0.033).
Machine Learning
In order to obtain to gain a better understanding of complex key indicators a “dimension reduction” by means of factor-analyses with varimax-rotation was carried out. Two major factors with an explained variance of 39% were extracted, which can be associated with dominant reactive components (24%) and more coordinative features (15%).
CONCLUSION: The data show that neuromuscular performance differs between age groups, but that this difference is not simply a function of age. It is conceivable that the difference between and high variance within age groups is the result of individual training stimuli, causing some individuals to stand out from the rest over time. It turns out that the interindividual variance is primarily based on two factors that can be attributed to reactive or coordinative abilities. These results will help athletic trainers to understand the development of the neuromuscular performance in youth athletes, set appropriate priorities in training, and identify talent.

#### WHY ARE THEY ALWAYS OLDER AND STRONGER? RELATIVE AGE EFFECT AND TALENT IDENTIFICATION FACTORS IN YOUTH ELITE SOCCER PLAYERS.

RUBAJCZYK, K.

*UNIVERSITY OF HEALTH AND SPORT SCIENCES IN WROCŁAW*

INTRODUCTION: Assessment of the players motor potential for soccer is multidimensional. In most cases, testing set dedicated to youth players take into account the anthropometric, linear or curve sprinting characteristics, jumping and agility testing and the ability to rapidly change direction. Nevertheless, interpretation of the obtained data is disturbed by the phenomenon of relative age effect (RAE) and different maturity statuses in youth soccer players. There is a lack of studies that investigated the relationship between anthropometric profile, body composition, results of motor tests, and different methods of maturity-based banding for the Talent Identification (TI) process in soccer. The aims of the study were: a) examination of anthropometrical and motor performance with traditional age-grouping by chronological age (CA) and Midway Point methods (MP) proposed by Helsen and colleagues (2021), and b) identify the birth-date distribution in elite polish youth soccer payers.
METHODS: Two hundred thirty-six (236) elite youth soccer players aged 12-14 selected by Polish Football Association to National Development Camp (NDC) completed a physical performance battery with anthropometric and body composition analysis. Players biological maturity status was assessed with the age at peak height velocity (APHV) method. All data were compared to growth charts and distribution of birth dates for the Polish Population. Homogeneity of variance was checked, and no violations were found. The $\chi 2$ test was used to deter-

mine the differences between the observed and expected frequencies of a birth-date quartile. Differences in body height and match statistics were analyzed with ANOVA and Tukey`s post hoc test. The calculations used a confidence interval of $p < 0.05$. An independent t-test was conducted to determine the differences in anthropometric characteristics and performance tests results between grouping methods and the first and fourth birth quarter.
RESULTS: Before relocation RAE was identify in each sub-group (U13, $\chi2=13,5$, p=0,0023, V=0,3; $\chi2=14,34$, p=0,0025, V=0,29; U15 $\chi2=17,65$, p<0,001, V=0,33). Analysis shows the quarterly significant differences for U13 grup for body mass (p<0,05), body height (p<0,01), total body water (p<0,01), total protein mass, skeletal muscle mass and power peak output for 30 meters sprint (p<0,05). No significant differences in jumping abilities (SJ, CMJ) and results of CODAT Test. In addition, the study shows the quarterly difference in APHV for U15 (p<0,01). After relocating players with MP guidelines, results show that only 34% of player was correctly banded by age-grouping and over 47 % was older than their CA age-group.
CONCLUSION: The results of this study show that maturity status and CA are crucial in the TI and selection process in youth soccer. The method proposed by Helsen and colleagues (2021) may lead to fewer dropouts and thus a larger talented player pool, which benefits, in turn, the talent identification process for soccer academies.

**PHYSICAL DEVELOPMENT OF YOUTH FOOTBALL PLAYERS**

TINGELSTAD, L., LUTEBERGET, L., RAASTAD, T.

*NORWEGIAN SCHOOL OF SPORT SCIENCE*

INTRODUCTION: Due to the frequent high intensity efforts in football, well developed physical qualities are necessary to perform at a high level (Bradley et al., 2009). During youth years, athletes progressively improve in physical characteristics concurrently with growth and maturation (Malina et al., 2004). However, due to varying timing and tempo of growth and maturation in individuals, interpretation of physical qualities among youth is challenging. Several studies have characterized physical qualities at different ages in boys, but studies including girls and studies comparing sexes are scarce. Therefore, the aim of this study was to compare physical performance characteristics between age groups and sexes in youth football players.
METHODS: In a cross-sectional study design, 141 football players, boys (n=83) and girls (n=58), from U14, U16, and U18 age groups were tested. The test battery consisted of 30 m sprint, change of direction ability (CoD), countermovement jump (CMJ) with a force plate and yoyo-intermittent recovery test level 1 (YYIR1). An independent t-test was used for differences between sexes for each test, and one-way ANOVA were used to calculate the significance level between the groups.
RESULTS: Boys performed significantly better than girls in all tests (p<0.001); 30 m sprint (5.03 vs. 4.71 sec), CoD (10.96 vs 10.20 sec), CMJ (27.5 vs 31.6 cm) and YYIR1 (590 vs 908 m). Boys were also significantly better at all ages, and the difference between sexes increased with age for both 30 m sprint (U14: -3.5% p=0.03; U16: -6.9%, p<0.001; U18: -11%, p<0.001) and CoD (U14: -4.1%, p=0,001; U16: -7.9%, p<0,001; U18: -9.1%, p<0,001). The same trend was shown for CMJ, but there was no difference between the sexes in the U14 group (U14 = 10.7%, p=0.151; U16 = 15.5%, p=0,006; U18 = 31.8%; p=0,004). Though there was a trend for increasing differences with age also for the YYIR1, only the U16 had significant sex differences (U16 = 71%, p=0.003).
CONCLUSION: This study shows that boys perform better than girls at a wide range of physical qualities during youth years and that these differences increases as they get older. These results adds to the fact that girl's plateau in physical development at an earlier stage than boys, that suggests that sex differences should be taken into account in training prescription. However, there is a need for more research looking into longitudinal development to confirm this.

### OP-SH01 Psychology

**SELF-SELECTED VS. IMPOSED RUNNING INTENSITY AND THE ACUTE EFFECTS ON MOOD, COGNITION, AND BRAIN ACTIVITY**

BRAUNSMANN, L.1, BEERMANN, F.2, STRÜDER, H.K.1, ABELN, V.1

*1 GERMAN SPORT UNIVERSITY COLOGNE, GERMANY; 2 ALBERT-LUDWIGS-UNIVERSITÄT, FREIBURG, GERMANY*

INTRODUCTION. People state to go for a run because it helps them to 'clear their mind'. Based on the self-determination theory (Deci & Ryan, 1985), perceived autonomy is considered as key factor for positive effects of exercise on mood (Ekkekakis, 2009). Here, we investigate how two identical bouts of exercise with differing degree of autonomy influence the psychological and electrocortical outcomes. Because neuroscientific investigations revealed inconsistent results previously, we focus on aperiodic brain dynamics (1/f), which – to the best of our knowledge – have not been considered in sports science, yet. As a decrease of 1/f activity is associated with more efficient neuronal communication (Voytek & Knight, 2015), we hypothesize that there will be a reduction after exercise going along with improvements in mood and cognitive performance.
METHODS. 29 experienced recreational runners (aged 22 ± 2.5 years, 14 females) completed two 30-minute runs. During the first intervention, the participants chose their individual feel-good intensity in a self-selected run (SR). Four weeks later, during an imposed run (IR) under blinded conditions, the same running speed was externally prescribed, which should influence the perception of autonomy. The acute effects on mood (Feeling Scale, Felt Arousal Scale, MoodMeter®) and cognition (d2-R, digit span test) were examined using t-tests and Wilcoxon tests, respectively. Brain activity in the electroencephalogram (slope, offset, 1/f-corrected alpha and beta band) was analyzed using cluster-based permutation tests with repeated measures ANOVA and Bonferroni post-hoc tests.
RESULTS. Both running interventions were equal in terms of duration, running speed, heart rate and lactate concentrations. Activation in the Felt Arousal Scale increased following both runs (SR: p< .001, d= 1.27; IR: p< .001, d= 1.54). No acute changes were found in the Feeling Scale or MoodMeter®, but slight improvements were indicated in several dimensions, such as motivation after the SR (p= .054, r= 0.36),

which were not present after the IR (p= .306, r= 0.19). Cognitive performance improved after both runs in the d2-R (p< .05, r> 0.48). The scores in the digit span test remained stable after the SR (p> .05), but decreased after the IR (p< .05, r> 0.39). Brain activity increased only after the SR in the 1/f-corrected alpha band (p< .05), whereas it was reduced after both runs in the beta band (SR: p< .01; IR: p< .05), slope (each p< .001), and offset (SR: p< .001; IR: p< .05).
CONCLUSION. The IR did not clearly affect mood or cognition directly after running, but there are indications for deteriorations even though the physical workload was the same as for the SR. This highlights the potential relevance of perceived autonomy in exercise. Reduced aperiodic brain activity could reflect exercise-induced behavioral effects facilitated by improved neural communication and provide a neurophysiological explanation that running 'clears the mind'.

**SELF-CONTROL EXERTION AND GOAL PRIMING: EFFECTS ON TIME-TO-EXHAUSTION CYCLING PERFORMANCE**

HUNTE, R., COOPER, S.B., TAYLOR, I.M., NEVILL, M.E., BOAT, R.

*NOTTINGHAM TRENT UNIVERSITY*

INTRODUCTION
Prior self-control exertion has been shown to have a detrimental effect on subsequent physical performance (Hunte et al., 2021). However, interventions to attenuate these negative effects on physical performance are limited. The current study had two primary objectives: a) to investigate whether prior self-control exertion reduced subsequent performance on a time-to-exhaustion cycling task (TTE), b) to investigate if goal priming could help to attenuate the detrimental effects of self-control depletion on subsequent physical performance. In addition, the study examined the potential for any observed performance decrements to be explained by changes in perceptions of pain and motivation.
METHODS
Fourteen recreationally active males (22.9±3.1 y) completed three TTE cycling tasks at 80% VO2 max on an electromagnetically braked cycle ergometer (Lode Bike). Prior to each TTE participants completed a congruent Stroop task (non-self-control depletion condition) or an incongruent Stroop task (self-control depletion condition) for 4 min. During the TTE, participants were asked to watch a video on the screen in front of them. During this video participants were exposed to a goal priming sequence (intervention condition) or a random letter sequence (control condition). Participants' perceptions of pain and motivation were recorded every 3 min during the TTE task.
RESULTS
A one-way repeated measures ANOVA revealed that there was no significant difference in TTE task performance between all experimental conditions ($p = 0.28$). Furthermore, there were no significant changes in perceptions of pain ($p = 0.36$) or motivation ($p = 0.21$) throughout the TTE cycling task. However, a significant difference was demonstrated for participants cycling cadence ($p = 0.01$). Post hoc t-tests revealed that participants cycled at a statistically significant higher cadence in both the self-control depletion and goal priming intervention condition and non-self-control depletion and control condition when compared to the self-control depletion and control condition (both $p < 0.01$).
DISCUSSION
The findings indicate that prior self-control exertion does not negatively affect subsequent TTE cycling performance. In addition, the findings suggest that goal priming does not improve endurance performance or attenuate the effects of initial self-control exertion on subsequent physical task performance. However, participants cycled at a higher cadence when exposed to a goal prime related to self-control. Participant's perceptions of pain and motivation during the TTE task were not influenced by prior self-control exertion or a goal prime.

**FROM THE LAB TO THE FIELD: THE RELATIONSHIP BETWEEN INHIBITORY CONTROL AND SPORTS PERFORMANCE IN TAEKWONDO**

HSIEH, W.L., WU, C.T., KAO, S.C., WANG, C.H.

*NATIONAL CHENG KUNG UNIVERSITY*

INTRODUCTION
Inhibitory control has been shown to have to capacity the predict the success in sports. In terms of taekwondo, previous research has demonstrated the relationship between laboratory inhibitory control measures and taekwondo training experience. Despite this, the utility of field-based cognitive measures and on-field performance correlation remains unclear. To address this issue, the present study aimed to examine the associations of lab- and field-based inhibitory control measures with on-field performance.
METHOD
Twenty-five senior high school taekwondo athletes (aged 16.5 ± 1.5 years) with taekwondo experience of 8 ± 5 years were recruited to participate in this study. Lab-based inhibitory control was measured using a go/no-go task. A similar go/no-go task administered by a specific LED equipment was used to assess the field-based inhibitory control. On-field performance was evaluated using a 5-point Likert scale including six questions by two seventh dan grade and a fourth dan grade black belt certified by the World Taekwondo Headquarters. The correlations between lab and field-based inhibitory control and on-field performance measures were investigated using Pearson's Correlation analysis.
RESULTS
Results revealed a significant correlation between lab- and field-based inhibitory control evaluated by go/no-go task designs. Moreover, on-field performance was significantly correlated with inhibitory control selectively for the field-based measure but not for lab-based measure, indicating that a taekwondo athlete with a high level of sports performance also has better ability of field-based cognitive function than their low-level counterparts.
DISCUSSION
We observed that lab-based inhibitory control was related to the field-based, indicating that the validity and feasibility from the lab may copy to the real field by the medium (e.g., LED equipment). However, only the taekwondo athletes field-based inhibitory control correlates with the on-field performance by experts' ratings, indicating that field-based inhibitory control may be a more sensitive measure to reflect

real-world performance of taekwondo. In conclusion, the present findings provided a basis for field-based cognitive function applications in taekwondo.

**DOES IMPROVING PHYSICAL LITERACY LEAD TO ENHANCED FITNESS STATUS? A 12-WEEK INTERVENTION STUDY**

GILIC, B., SUNDA, M., SEKULIC, D.

*UNIVERSITY OF SPLIT*

INTRODUCTION: Physical literacy (PL) is believed to improve physical activity, physical fitness, and overall healthy lifestyle habits [1]. However, the concept of PL is not embraced in South-eastern European countries [2]. Thus, the goal of this research was to apply and evaluate the effectiveness of the specific 12-week intervention aimed at the improvement of PL (PL-intervention) among high school students in Croatia. The aim was to determine whether PL-intervention will lead to changes (improvement) in the physical fitness of adolescents.
METHODS: This research was conducted on 364 high school students (244 females), grouped into intervention group (n = 207), and control group (n = 157). The intervention group was educated on PL-related topics by online-educational materials for 12 weeks (3 min video-animated education delivered 3 times a week) as an addition to regular physical education classes (PE), while the control group participated in PE only. Variables included anthropometric indices (body mass, body height, and body mass index), and physical fitness tests (standing broad jump, sit-and-reach test, sit-ups, and multilevel endurance test). Two-way ANOVA for repeated measures (group × time) was calculated to determine the effects of PL-intervention.
RESULTS: Significant group × time ANOVA effects were evidenced for body mass index ($F=3.94$, $p<0.05$) with negative changes in the intervention group (i.e., decreased body mass index), and the multilevel endurance test ($F=23.71$, $p<0.001$), with positive changes in the intervention group.
CONCLUSION: A 12-week PL-intervention induced positive changes in indicators of cardiovascular and metabolic health. It is important to emphasize that PL-intervention was relatively short, not time-consuming, and conducted during the COVID-19 pandemic, a crisis of unprecedented scale. Thus, similar interventions should be applied as online education both during the normal and crisis situation and can be embedded in the PE curriculum to improve the physical fitness and general health of children and adolescents.

**MOTIVATION, EXERCISE AND EATING BEHAVIOR ENTANGLEMENT: A 12-MONTH'S CROSS-LAGGED ANALYSIS**

PALMEIRA, A.1, CARRACA, E.1, SANTOS, I.1, SILVA, M.N.1, SANCHEZ-OLIVA, D.2, STUBBS, J.3, HEITMANN, B.L.4, MATA, J.5

*1. UNIVERSITY LUSÓFONA; 2. UNIVERSITY OF EXTREMADURA; 3. UNIVERSITY OF LEEDS; 4. UNIVERSITY OF COPENHAGEN; 5. UNIVERSITY OF MANNHEIM*

Purpose
A healthy lifestyle involves several behaviors, such as regular exercise and balanced eating. Do changes in motivation for one health behavior affect other health behaviors? Previous research showed spill-over effects from intrinsic exercise motivation to eating and exercise behaviors among Portuguese women with obesity (Mata et al., https://doi.org/10.1037/a0016764). The current study extends these findings by examining reciprocal relations between motivation and health behaviors over time in a European group of men and women from the NoHoW trial, which tested behavior change sustainability mechanisms of action after an initial weight loss. We hypothesize that cross-lagged effects occur between exercise motivation, eating motivation, eating behavior, and physical activity (steps) during the 12-month trial.
Methods
The NoHoW trial includes data from 1627 adults seeking weight loss maintenance from the UK, Denmark, and Portugal. The present study involved 753 participants with complete data (66.3% women, 45.8 +-11.1 y). Eating motivation (REBS), exercise motivation (BREQ3), and Eating Behavior (TFEQ - Restraint and Disinhibition) were measured with validated questionnaires. Physical activity was operationalized as daily average of steps (FitBit Charge 2) in the 14 days after the baseline, 6- and 12-months measurements. We ran four cross-lagged panel models with Mplus, including exercise and eating autonomous vs. controlled motivation, steps, and restraint vs. disinhibition as variables.
Results
The models presented a good fit (RMSEA .023-.065) with an explained variance between R2 =.34 and .78. We found cross-lagged effects between steps and exercise autonomous motivation as well as eating behavior and eating autonomous motivation, suggesting cyclic increases in the quality of motivation, steps, and eating behavior. In contrast, cross-lagged effects among eating and exercise controlled motivations favored cyclic detriments on the quality of motivation. Disinhibition predicted exercise and eating controlled motivation. Higher exercise autonomous motivation at 6 months spilled over to increasing eating autonomous motivation, steps, and restraint. In the autonomous motivation models, motivation predicts behavior (i.e., cross-lag as expected). In contrast, behavior seems to predict motivation in the controlled models.
Discussion
This study partially replicated Matas spill-over results, providing extra layers of evidence. The results show that autonomous motivation predicts behavior. The "Whys" of the behavior are coherent with the behavior itself, hence less attrition. Interestingly, higher controlled motivation leads to a low-quality motivation spiral. In addition, disinhibition is predicting controlled motivation. Therefore, one can speculate that controlled motivations represent excuses for not being able to eat healthily instead of driving healthy behaviors. We will discuss results in light of behavior change maintenance theories

### OP-SH04 Learning in PE II

#### THE EFFECT OF THE AMOUNTS OF STUDENTS VERBAL COMMUNICATION IN JUNIOR HIGH SCHOOL PHYSICAL EDUCATION CLASSES ON LEARNING OUTCOMES

KONDO, Y.1, ASANO, Y.2, HOJO, A.1, UMEMURA, T.3, NAKAJIMA, T.4

*1: GRADUATE SCHOOL OF HOKKAIDO UNIVERSITY OF EDUCATION, 2: GRADUATE SCHOOL OF EDUCATION, HOKKAIDO UNIVERSITY, 3:HOKUSHO UNIVERSITY, 4: HOKKAIDO UNIVERSITY OF EDUCATION SAPPORO*

INTRODUCTION: In Japan, physical education classes are required to " To enable students to improve physical fitness and harmonious development of both body and mind through engaging in physical activities appropriately. " (1). Previous studies have argued that increasing time for verbal communication in physical education classes is related to the learning of skills (2). In this research, we investigated the relationship between the amounts of students verbal communication and changes in students thinking.
METHODS: The target was one physical education teacher working in K junior high school and 27 students in one class (17 boys and 10 girls) in charge of the teacher. In addition, one physical education teacher working in N junior high school and 35 students in one class (20 boys and 15 girls) in charge of the teacher were the target too. The two physical education teachers are those who are in a leadership position and have sufficient experience.
One unit (8 hours) of dance lessons was given in K junior high school, and one unit (9 hours) of volleyball lessons was given in N junior high school. Each lesson, the amounts of students verbal communication was measured with a business microscope of Hitachi, Ltd. It can measure verbal communications by body movements. The amounts of students verbal communication in all lessons was individually averaged and divided by quartiles, with the top 25 percent in the top group and the bottom 25 percent in the bottom group. Changes in students thinking read by worksheets in each lesson, and we compared the top group to the bottom group.
Results and discussion:
In K junior high school, students in both groups looked back on their own dances and described the joy of dancing with a number of people in worksheet in the seventh and eighth hours. In addition, the top group touched on variations of dance in the fifth and sixth hours and development of performances by communicating with others in the seventh and eighth hours.
In N junior high school, the teacher promoted students verbal communication. So students in both groups looked back their verbal communication in worksheet in the final. But, Compared to the bottom group, the top group specifically described what kind of communication produced what kind of results.
From these two results, it is considered that the difference in the amounts of students verbal communication in the physical education class influence the learning outcomes such as the changes in students thinking.

#### PHYSICALLY ACTIVE LEARNING AS A WAY TO MOVE BODY AND KNOWLEDGE IN SECONDARY SCHOOL STUDENTS?

SCHMIDT, S.K., TOFTHAGEN, F., RUUD, A., BRATLAND-SANDA, S.

*UNIVERSITY OF SOUTH-EASTERN NORWAY*

INTRODUCTION: Schools have been identified as a key setting to promote and implement more physical activity. Physically active learning (PAL) has become a popular approach where the curriculum is combined and/or integrated with physical activity in subject lessons [1]. Research about PAL is limited in secondary school, and it is unclear how physically active students are in such learning activities. This study aimed to examine students' physical activity in PAL activities in secondary school and explore their teacher's reflections on the use of PAL to fuller understand how PAL may or may not contribute to more physical activity in lessons.
METHODS: This study has a concurrent mixed methods design [2]. The participant group was one 10th grade class with 24 students and their teacher (male, 42 yrs.). Data were collected at four different times when students were taught Norwegian. Data collected in PAL activities: 1) Students' physical activity levels measured with accelerometers, 2) semi-structured observation of PAL activities, and 3) interview with the teacher post PAL activity.
RESULTS: During a 20-minute PAL lesson, the students spent on average 2.7 minutes in moderate to vigorous physical activity, 3.8 minutes in light activity, and 13.4 minutes in sedentary time. Girls were significantly more sedentary than boys ($p = 0.004$). In contrast, researchers evaluated the students' participation and engagement with the activities to be high, with positive energy and good moods based on the semi-structured observations. First, the teacher experienced PAL activities as a resource for teaching language and a valuable tool to create variation and interrupt sedentary time during school hours, even though those students have different needs, skills, and motivations. Second, the teacher expressed that his motivation for PAL is for the students to have fun. Thus, PAL is viewed as a way to "spice up" subjects' perceived as uninteresting by the students. The teacher's focus was on the activities themselves and less on the learning outcomes. Third, the teacher recognized that PAL could make some students feel both academic and physical performance pressure.
CONCLUSION: The PAL led to surprisingly low levels of executed physical activity compared to what was perceived by the researchers' observation. Further, knowledge on how to increase physical activity levels in general and for both genders and how to integrate the subject learning outcomes with physical activities is an important goal for future research in PAL.

**PHYSICAL EDUCATION: AN EMBODIED APPROACH TO IMPROVE CHILDREN'S MATHS ACHIEVEMENT**

TOSI, I., CASOLO, F., MARTA, G., MASPERI, G., GALVANI, C.

*UNIVERSITÀ CATTOLICA DEL SACRO CUORE*

INTRODUCTION: The viewpoint of embodied cognition holds that cognitive processes are rooted in the body's interactions with the world aimed at gathering and collecting as much information as possible: cognition is situated, body based and for action1. Therefore, embodied education research may have important implications for education because it highlights an approach to learning through whole-body engagement2. To date, there has been little agreement on the positive effect of classroom-based lessons integrating mathematics/geometry and physical activity3,4. The aim of this research was to examine the effect of embodied education on mathematical achievement and physical fitness (PF) level.
METHODS: The study was designed as a school-based controlled trial targeting primary school children and was carried out between October 2020 and May 2021. Pupils were divided into the experimental group (EG) and the control group (CG), involving 82 children in the first and 39 in the second group. The intervention lasted 8 months, with two 50-min lessons per week, for a total amount of 30 lessons, carried out in the gym or in an open space. The CG did traditional physical education (PE) lessons, whereas EG, through practical activities during curricula PE lessons, learned geometrical and mathematical concepts. The assessments, performed twice, at the beginning and at the end of the project comprised: a mathematical achievement evaluation with the "Test for the evaluation of calculating and problem solving abilities" (AC-MT 6-11)5; three PF measurements by the six min walking test (6MWT)6, the 4x10m shuttle run test (4X10m SRT) and the standing broad jump test (SBJ)7.
RESULTS: Mathematical skills significantly improved throughout the sample with a greater achievement in the EG compared with CG (EG: $X2=27.88$; $p<0.05$; CG: $X2=12.11$; $p<0.05$). Children in the EG were significantly more successful in problem solving ability in maths than the CG ($p=0.0120$). Children in both groups significantly ($p=0.0210$) improved their 6MWT distance (EG: 538±66 and 564±55m; CG: 550±62 and 562±47m), however no significant intervention effect on 4x10m SRT (EG: 15.8±2.2 and 15.7±2.2s; CG: 15.9±2.3 and 15.9±2.3s) and SBJ (EG: 111.0±19.8 and 116.5±18.3cm; CG: 116.1±18.9 and 118.5±17.8cm) was observed.
CONCLUSION: To the best of our knowledge, this study investigated innovative aspects of the embodied education, not yet deepened by the recent literature. Participation in a 8-month PE intervention improved math achievement among elementary school children. This research confirms previous findings4 and contributes to the understanding of the close relationship between perception and action, mind and body.

**EFFECTS OF SCHOOL-BASED PHYSICAL ACTIVITY INTERVENTIONS ON LANGUAGE SKILLS: A SYSTEMATIC REVIEW AND META-ANALYSIS OF RANDOMIZED CONTROLLED TRIALS**

MARTIN-MARTINEZ, C., MARTINEZ-ZAMORA, M.D., VALENZUELA, P.L., MARTINEZ-DE-QUEL, O.

*UNIVERSITY COMPLUTENSE OF MADRID*

INTRODUCTION
School seems to be an ideal context for the promotion of physical activity (PA), particularly given that children spend most of their school time sedentary [1]. School-based PA interventions appear as an overall beneficial strategy for the improvement of cognitive performance, general academic achievement or mathematical skills, but the evidence on their benefits on language skills remains unclear. Recent research proposes that language and action are both linked through the neural overlap between mirror neuron system for action and Broca´s area for speech articulation [2], [3]. We aimed to assess the effects of school-based PA interventions on language skills in children and adolescents.
METHODS: Relevant articles were systematically searched in PubMed, PsycINFO and Scopus from inception to December 2020. We included randomized controlled trials (RCTs) that performed a school-based PA intervention in children and adolescents (aged 3-18) and that assessed at least one outcome related to language skills (i.e., reading, spelling, vocabulary, verbal fluency and comprehension) or language academic achievement (i.e., school grades). A meta-analysis was conducted to determine the differences between groups (expressed as standardized mean difference [SMD] along with 95% confidence intervals [95%CI]) when ≥3 interventions assessed the same outcome.
RESULTS
Twenty-nine studies (14600 participants) were included, of which 16 performed an integrated PA intervention (i.e., performing PA along with the academic content), 10 a non-integrated one (e.g., extra physical education lessons), and three a combination thereof. Methodological quality of the studies was overall high. Significant benefits were observed for reading (SMD: 0.18; 95%CI: 0.09, 0.27), vocabulary (SMD: 0.65; 95%CI: 0.09, 1.21) and language school grades (SMD: 0.74; 95%CI: 0.23, 1.25), but no effects were observed for spelling, comprehension or verbal fluency (all $p>0.05$). No consistent differences were observed between integrated and non-integrated PA interventions, although sub-analyses were not possible for some outcomes.
CONCLUSIONS
School-based PA interventions appear as an effective strategy for improving different language-related skills and overall language school grades, although further research is needed to determine how interventions' and children's characteristics moderate these effects.
Key words: exercise; sedentarism; education; embodied learning; cognition.

## OP-AP26 High intensity interval training

### HIGH INTENSITY INTERVAL TRAINING PRACTICES IN COMPETITIVE FIELD-BASED INVASION TEAM SPORTS

GRASSICK, S., Ó CATHÁIN, C., KELLY, D., NÍ CHÉILLEACHAIR, N.

*TECHNOLOGICAL UNIVERSITY OF THE SHANNON: MIDLANDS MIDWEST, ATHLONE CAMPUS*

INTRODUCTION: High intensity interval training (HIIT) can be defined as alternating bouts of short duration exercise (e.g., 5s to 10 min) at near maximal or maximal intensities separated by complete rest or low intensity activity (1). Competitive field-based invasion team sports (FITS) such as rugby, soccer and Gaelic games demand high fitness levels in order to complement technical and tactical aspects of performance. Despite the high profile nature of FITS there remains a paucity of scientific literature examining training prescription practices of FITS coaches [2]. Given the potential of HIIT to elicit positive physiological adaptations and replicate match demands, the aim of this study is to investigate HIIT practices in FITS.
METHODS: A self-administered online survey consisting of 14 sections was developed to investigate coaches HIIT practices. Sections included coaches background information, general HIIT practices and practices specific to short intervals (SI's), long intervals (LI's), sprint interval training (SIT) and repeated sprint training (RST). Content validity of the survey was carried out using the modified Delphi technique. Fixed response questions were evaluated using a frequency analysis, with open-ended questions analysed using a thematic-analysis approach
RESULTS: Ninety-two coaches working across 9 FITS participated with 57% of coaches having more than 5 years coaching experience. In total, 80% of coaches (n=74) prescribed HIIT. While HIIT was used during all stages of the season by 77% (n=57), 86% (n=51) of coaches varied their prescription depending on the time of the season. Fitness levels (74%), injury (69%) and number of days since a previous match (61%) were frequently cited reasons for coaches adapting their sessions for individuals in the squad. SI's (n=65) and SIT (n=47) were the two most commonly used methods of HIIT. However, LI's (n=35) and RST (n=38) were also frequently implemented by coaches.
CONCLUSION: This study provides insight into the use of HIIT in FITS and identified that coaches implemented HIIT due to its time efficient nature, its ease of implementation and its sport specificity. Although the specific content of HIIT sessions (number of reps, work-rest ratio, intensity) was highly variable between coaches, the results of this study can be a valuable resource to FITS coaches when prescribing various HIIT formats during various stages of the season. In particular, this information can be beneficial to coaches who do not implement HIIT as one of the most commonly cited reasons for coaches not implementing HIIT included a lack of knowledge.

### EFFECTS OF INCLUDING HIGH-INTENSITY INTERVALS DURING REGULAR TRAINING ON MAXIMAL OXYGEN UPTAKE IN 12-YEAR OLD PHYSICALLY ACTIVE ADOLESCENTS - A RANDOMIZED CONTROLLED TRIAL.

GRENDSTAD, H., HALLÉN, J.

*NORWEGIAN SCHOOL OF SPORT SCIENCES*

INTRODUCTION: Maximal oxygen uptake (V̇O2max) increases during puberty in parallel with the increase in fat-free mass (1, 2). If high-intensity training (HIT) adds to the effects of growth and maturation is controversial (3). Therefore, the aim of this study was to investigate if inclusion of HIT during an 8-weeks training period was superior to either strength and coordination training (SC), or minimal training, in young adolescents.
METHODS: Thirty-five adolescents from a cross-country ski club (age: 12.3 ± 0.3) were randomized into a HIT group (HITgr) (n=22, girls=15) and a SC group (SCgr) (n=12, girls=8), while also including a group of less active or sedentary school children (age: 12.3 ± 0.3) (C, n=29, girls=15). HITgr performed high-intensity intervals (≥ 10 min work period, target heart rate ≥ 90% of HRpeak) twice weekly, while SCgr conducted low-intensity SC training. Training volume was reported through a training log, and training intensity assessed with a HR monitor. Physical activity (PA) was monitored with an accelerometer for one week. Fat-free mass (FFM), V̇O2max and hemoglobin mass (Hbmass) were tested pre- and post-training. A one-way and two-way ANOVA analysis were performed to detect mean group differences and pre-post changes, respectively. Level of significance was set to $p<0.05$, and results are presented as mean ± SD
RESULTS: The number of training sessions per week during the training period were higher for HITgr (5.4 ± 1.7) and SCgr (4.5 ± 1.2) compared to C (1.7 ± 2.0) ($p<0.05$). HITgr had 1.9 ± 0.2 interval sessions per week, while SCgr and C had none. At baseline, there was no difference between groups in FFM (HITgr: 31.7 ± 4.7kg, SCgr: 32.3 ± 3.4kg, C:33.5 ± 5.9kg), but both HITgr and SCgr had significantly higher absolute V̇O2max (ml·min-1) and V̇O2max relative to FFM (HITgr: 73.2 ± 6.1 ml·kgFFM-1·min-1, SCgr: 75.1 ± 5.8 ml·kgFFM-1·min-1, C: 61.0 ± 5.9 ml·kgFFM-1·min-1) compared to C ($p<0.01$). There were no differences in total Hbmass (g) or Hbmass relative to FFM between HITgr (13.5 ± 0.7 g·kgFFM-1), SCgr (13.7 ± 1.0 g·kgFFM-1) or C (13.0 ± 1.6 g·kgFFM-1). The change in V̇O2max absolute values was 6% ± 6% for HITgr ($p<0.01$), 5% ± 7 for SCgr ($p=0.13$), and 5% ± 13% for C ($p=0.13$) with no differences between groups. V̇O2max relative to FFM did not change significantly for either HITgr (3% ± 6%), SCgr (3% ± 7%) or C (4% ± 14%), due to the similar increase in FFM for HITgr (3% ± 2%), SCgr (3% ± 2%) and C (2% ± 3%). There were no changes in Hbmass relative to FFM for either HITgr (-2% ± 4%), SCgr (-2% ± 4) or C (3% ± 5).
CONCLUSION: The change in V̇O2max was similar in all groups, which suggests that development of V̇O2max over a short-term training period in a group of physically active adolescents is not affected by HIT. Both V̇O2max and Hbmass seems to increase parallel to the increase in FFM.

## OXYGEN UPTAKE AND HEART RATE BASED TIME-IN-ZONE ANALYSIS OF FOUR ISOCALORIC HIGH-INTENSITY INTERVAL TRAININGS WITH RESPECT TO FITNESS LEVEL AND SEX

STREPP, T.1, HALLER, N.1,2, STÖGGL, T.1,3

*1UNIVERSITY OF SALZBURG; 2UNIVERSITY OF MAINZ; 3RED BULL ATHLETE PERFORMANCE CENTER SALZBURG*

INTRODUCTION: Athletes use a variety of high-intensity interval training (HIIT) forms to improve endurance performance [1]. Maximizing time in the "high-intensity zone" (Z3) (≥90% maximal oxygen uptake (VO2max) or ≥90% maximal heart rate (HRmax)) is crucial for triggering positive adaptations [2]. Previous studies comparing different HIIT forms used mainly work-matched protocols with well-trained athletes [3,4]. To date, no study used an isocaloric approach (i.e., equal energy expenditure (EE)) to compare different forms of HIIT. Here, we compared the time-in-zone (TIZ) between four different isocaloric HIIT forms and the effects of fitness level and sex.
METHODS: Five untrained females (VO2max: 37.4±2.5 ml/min/kg.), 5 well-trained females (VO2max: 56.2±2.5 ml/min/kg), 5 untrained males (VO2max: 47.6±4.9 ml/min/kg) and 5 well-trained males (VO2max: 69.3±4.2 ml/min/kg) underwent a cycling ramp test to exhaustion to determine peak power output (Ppeak), VO2max, HRmax and lactate kinetics to set training intensities and zones (VO2Z3:≥90%VO2max, HRZ3:≥90%HRmax). Subsequently, three aerobic HIIT forms in counterbalanced order were performed using the EE of the first HIIT to ensure isocaloric EE for the following forms (1) "5x4"min at power output at 90%HRmax with 2.5min recovery at power output at 1.5mmol/L lactate (PLIT) (2) "30x30"s at 100%Ppeak with 30s recovery at PLIT (3) "15x1"min at 100%Ppeak with 1min recovery at PLIT and (4) speed endurance production (SEP) training with 40s intervals at 125%Ppeak and 4min 20s recovery at PLIT. There was at least 48 hours between all forms of HIIT. Breath-by-breath and HR data (Quark CPET, Cosmed, Italy) was measured continuously and resampled for one second values using linear interpolation. A two-factor repeated measures ANOVA was used to detect differences between programs as well as sex and fitness level. Effect sizes (ES) are expressed as partial eta-squared.
RESULTS: Mean VO2Z3 time was 179±298, 95±306, 91±162, 12±20s for 5x4, 30x30, 15x1 and SEP, respectively. No differences were found between forms (P=0.07, ES=0.391). Mean HRZ3 time was 793±406, 890±691, 927±588, 206±223s for 5x4, 30x30, 15x1 and SEP, respectively. Significant differences were revealed between forms (P<0.001, ES=0.871) with SEP achieving lower time compared with all other HIIT versions (P<0.001). No effects were observed for fitness level (P=0.81, ES=0.064) or sex (P=0.25, ES=0.248) on VO2Z3 time. Regarding HRZ3 time, a significant effect for sex (P=0.04, ES=0.447) with higher times in females compared with males but no significant effects for fitness level (P=0.54, ES=0.139) was observed.
CONCLUSION: Different isocaloric HIIT forms may lead to differences in TIZ parameters. TIZ regarding HR demonstrated a different pattern when compared with VO2. While sex had a significant effect on HRZ3, fitness level had no effect on either HRZ3 or VO2Z3.

## TIME SPENT ABOVE 90% VO2MAX DURING UPHILL VS. HORIZONTAL RUNNING DURING HIGH INTENSITY INTERVAL TRAINING: POLARIZATION IMPLICATIONS FOR ENDURANCE TRAINING

GIESEN, R., HELD, S., DONATH, L.

*GERMAN SPORT UNIVERSITY COLOGNE*

INTRODUCTION: Polarized training (POL) is an effective model of training intensity distribution (TID) for competitive distance runners to increase aerobic performance [1,2]. Thereby, less than 20% of the total weekly training sessions is high intensity training and spent above 90% of maximal oxygen uptake (VO2max). Athletes often spent less time than intended above 90% VO2max. Thus, real polarization seems partly violated as high intensities trend to threshold intensities. Compared to horizontal running, uphill running reduces the mechanical impact [3] and increases relative muscle activation [4]. However, comparative data on how and to which extend uphill running affects HIIT compared to horizontal HIIT running given as time spent above 90% VO2max is still lacking. Thus, the present study examined the effects of uphill versus horizontal HIIT on the relative percentage of VO2max.
METHODS: Nineteen well-trained distance runners (7 females, 9 males; 26 ± 7 y; VO2max: 62,4 ±4,6 ml/min/kg) had 4 randomly assigned lab visits in 4 weeks (one test each week) on a treadmill at uphill (8% incline) and horizontal (1 %): Prior to the HIIT protocols, an incremental exercise test were conducted to determine VO2max. Running speed associated with 90% VO2max and was applied. HIIT running comprised 4 x 5 min intervals, with 90 s rest in between while respiratory gas exchange was measured together with heart rates (HR), blood lactate concentrations and rate of perceived exertion (RPE). A repeated measures analyses of variances (rANOVA) was computed to detect interaction effects between the conditions and intervals (INT1-4). Bonferroni post-hoc tests were calculated in case of significant interaction effects.
RESULTS: Time spent running above 90% VO2max was significantly (p=0.001; SMD=0.95) higher for uphill HIIT (11.6 ± 2.9min) compared to horizontal HIIT (8.7 ± 2.5min). HR (p =0.17) and blood lactate (p =0.14) did not differ significantly. Interestingly, lower RPE levels (p =0.006, SMD=0.64) were observed for uphill HIIT (INT1: 13.6 ± 1.4; INT2: 14.8 ± 0.7; INT3: 16 ± 1.2; INT4: 16.9 ± 1) compared to horizontal HIIT (INT1: 13.9 ± 1.3; INT2: 15.6 ± 1.4; INT3: 17.5 ± 1.4; INT4: 18.6 ± 1.3).
CONCLUSION: Our findings indicate that uphill HIIT result in more time spent running at or above 90% VO2max at lower RPE with comparable HR and lactate levels. Thus, uphill HIIT can be seen as a valuable training approach fore successful training polarization at high VO2max levels and lower running impacts and mechanics.

## QUANTIFICATION OF IN-SEASON HIGH-INTENSITY RUNNING IN YOUNG SOCCER PLAYERS.

HIDALGO-DE MORA, J.1,2, LÓPEZ-SEGOVIA, M.1,3, CAMPOS-VÁZQUEZ, M.A.1,4, PAREJA-BLANCO, F.4

*CEU ANDALUCÍA UNIVERSITY, SEVILLA*

INTRODUCTION: During the past decade, high-intensity running has exponentially increased throughout soccer matches (1, 2), being considered a key factor in elite soccer (3). In this regard, elite soccer players spend longer times at low speeds across training sessions compared to those attained during matches (4, 5). Therefore, the aim of this study was to compare the training load and high-intensity running recorded during training sessions and official matches.
METHODS: On-field in-season training load during four training days was analyzed with respect to the number of days before or after a match (MD; MD+1; MD-4, MD-3 and MD-2) (5). A total of ten young soccer players from an U23 semi-professional team (22.4 years ± 2.0) and an U19 (17.9 years ± 0.6) elite team, having played at least 60 min during 14 matches, were included into this study. Running activity was collected with GPS (Catapult, EVO) and the following variables were analyzed: total distance covered (TD), distance covered between 19.9 and 25.2 km.h-1 (HID), distance covered at above 25.2 km.h-1 (SR) and peak speed achieved (PS).

RESULTS: Match demands were significantly higher to all training days in both teams ($p < 0.05$), except for PS which were not significantly different in MD-3, as well as SR for U23 team ($p = 1.000$). Multiple differences were found between teams, in particular, significant higher values of TD and HSR were observed during MD, MD+1, MD-4, MD-3 and MD-2 in U19 compared to U23. Moreover, no significant differences were found during MD-3 in SR and PS between teams ($p = 0.227$ and 0.195, respectively).
CONCLUSION: Our findings show that high-intensity running during training sessions are lower than those achieved during matches in young soccer players, regardless to their performance level. Moreover, MD-3 is the typical high-velocity training day, although it is not enough to stimulate the competitions demands in young elite teams.

### IS-MH03 Dimensions of health threats due to headers in soccer

#### BEHAVIORAL EFFECTS OF HEADER INDUCED HEAD IMPACTS IN SOCCER

HERMSDÖRFER, J.

*TECHNICAL UNIVERSITY OF MUNICH*

As behavioral assessments, still, are the most frequently used means to investigate potential header-related deficits, this presentation will first address the current evidence concerning behavioral impairments as a result of soccer heading and specifically focus on the most common methodological approaches. These typically rely on the administration of pre-specified test batteries (e.g., ANAM, CogState, etc.) to assess players' neuropsychological performance across several domains including attention, working memory, and executive functioning. Although performance decrements have been reported in active players after an acute bout of heading (Di Virgilio et al., 2016) as well as in retired soccer players (Prien et al., 2020), current systematic reviews argue that the empirical evidence for neuropsychological impairments as a result of to soccer heading remains inconclusive (Kontos et al., 2017; Tarnutzer et al., 2017).
In addition to these neuropsychological outcomes, we would like to emphasize the importance of expanding these behavioral assessments towards the inclusion of sensorimotor tests. While evaluation of sensorimotor performance across balance, gait or eye movement tasks revealed heading-related deficits in short-duration lab-tests (Caccese et al., 2021; Nowak et al., 2020), knowledge about potentially persisting sensorimotor deficits associated with soccer heading remains scarce due to the limited application of sensorimotor assessments in longer-term observational studies. However, as persisting motor deficits, such as impairments in fine motor control, have been commonly observed in contact sport athletes (e.g., American football players) following concussion (Pearce et al., 2015), they might also result from repetitive head impacts due to heading the ball.
Recently, we employed a prospective design to investigate the potential relationship between purposeful heading and behavioral changes in 22 female soccer players (mean age: 22.0 ± 3.9 years). Behavioral performance was assessed immediately before and after one competitive season by means of an extensive test battery consisting of neuropsychological as well as sensorimotor tests. Head impacts were registered using video recordings and miniaturized accelerometers affixed behind the players' ears. Multiple linear regression analysis revealed a statistically significant model with four factors ($R2adj = 0.65$, $p < 0.01$). A greater number of headers was associated with negative alterations in postural control ($ß = 0.49$, $p < 0.01$) and concomitant positive changes in working memory performance ($ß = 0.33$, $p = 0.03$) in a dual task as well as fine motor deficits in a writing task ($ß = 0.35$, $p = 0.02$ and $ß = -0.47$, $p < 0.01$). Our findings will be discussed in relation to the existing literature on neuropsychological and sensorimotor deficits due to soccer heading and with regard to further recommendations for the application of behavioral assessments in the context of head impact research.

#### STRUCTURAL AND FUNCTIONAL BRAIN CHANGES INDUCED BY HEADERS OVER 12-18 MONTHS

REINSBERGER, C.

*PADERBORN UNIVERSITY*

Heading the ball in soccer may be related to structural and functional brain changes as measured by (f)MRI. Regional brain volumes, cortical thickness and functional connectivity (FC) have been shown to be associated with repetitive head impacts (RHI), although causality, dose response relationships and clinical modifiers are still vividly debated. Most data have so far only been derived from cross-sectional studies and therefore contains some methodological flaws.
In this presentation data from a longitudinal study will be presented that included 14 active professional soccer players (mean age 20.36 ± 3.34 years). MRI scans (3T), neuropsychological and neurophysiological assessments were performed before and after an observation period of 12-18 months (median 17.2 months), during which each training session and game was recorded on video to allow characterization of each header performed by any player who participated in the study. Structural T1 images and resting state fMRI sequences were used to analyze changes in cortical thickness and functional connectivity between the two time points (controlled for age) with specific emphasis to the default mode network (medial prefrontal cortex, lateral parietal left and right, posterior cingulate cortex) representing the default mode network (DMN), as the DMN is one of the primary targets for RHI induced structural or functional brain changes. During the observation period between 146 and 943 (median 340.5) headers per player were recorded and used as a regressor for the imaging as well as neurophysiological and neuropsychological data. Cortical thickness measures in single clusters were higher before the observation, but no significant correlation with heading frequency was detected. FC changed significantly from pre- to post-observation in a cluster comprising the superior frontal gyrus and frontal pole bilaterally, but also without significantly correlating with heading frequency. Results will be discussed in relation to clinical, neuropsychological and neurophysiological data as well as characteristics of headers beyond frequency (e.g. playing situation, length of pass leading to header, header duel etc.) and clinical recommendations will be provided.

**PHYSIOLOGICAL BRAIN CHANGES AS A RESULT OF HEADER INDUCED HEAD IMPACTS IN SOCCER**

IETSWAART, M.

*UNIVERSITY OF STIRLING*

INTRODUCTION: Across the sporting world there is growing concern about long-term consequences of sport-related head impact on brain health. To date, relatively little attention has been paid to understanding mechanisms by which these chronic effects arise. In principle, however, the origins of long-term damage must first be evident in acute brain changes. This presentation will therefore focus on the acute physiological brain alterations that occur following routine head impacts in soccer, and what this means for the current understanding of brain health in contact sport.
Our research was the first direct demonstration that soccer heading disrupts the brain. Critically, we examined the impact of the modern football, because any effects of heading on brain health have often been dismissed as an issue of the past (related to old leather footballs being heavy in wet conditions). This presentation will show the direct evidence for brain and brain-to-muscle changes following the routine impacts of a standard soccer heading drill, utilises the neuroimaging technique of Transcranial Magnetic Stimulation (TMS). In this lab-based research, soccer players headed a modern football 20 times, as is typical in training sessions. The ball was fired from a ball machine to simulate the pace and power of a corner kick. Before and after the heading sessions we measured brain inhibition using TMS, as well as assessing players' memory function. We found that soccer heading resulted in immediate and measurable disruption to brain function: increased inhibition in the brain was detected in 74% of participants, and cognitive tests revealed memory performance was also reduced by 41-67%. In this presentation, we will also examine further research on the physiological brain changes following a standard heading drill. It is currently not known how much impact is safe in contact sport. We therefore examine the dose-response relationship of soccer heading and physiological changes at a brain level. Also unknown are the mechanisms through which changes to brain health in contact sport arise. In this presentation, we therefore look at the relationship between changes in brain chemistry following soccer heading and the physiological brain response when learning and attending. We will also look at how, by combining different neuroscientific methods linked to the effects of soccer heading on blood biomarkers of brain injury, we can develop the understanding of what happens in the brain when players head the ball and reveal critical evidence on cause and effect of brain health in contact sport. Our findings and research approaches will be discussed in relation to the existing neuroscientific and brain health literature and with regards to recommendations around the safety of routine head impact in sport.

## OP-PN07 Dietary Supplements

**THE EFFECT OF SHORT-TERM DIETARY NITRATE SUPPLEMENTATION ON SKELETAL MUSCLE CALCIUM HANDLING AND HIGH-INTENSITY INTERMITTENT EXERCISE PERFORMANCE IN HEALTHY ADULTS**

ALSHARIF, N.S.1,2, COCKSEDGE, S.P.1, ACTON, J.P.1, FERGUSON, R.A.1, CLIFFORD, T.1, MARTIN, N.R.W.1, MITCHELL, E.A.1, ØRTENBLAD, N.3, BAILEY, S.J.1

*1 LOUGHBOROUGH UNIVERSITY, UNITED KINGDOM; 2 KING ABDULAZIZ UNIVERSITY, KINGDOM OF SAUDI ARABIA; 3 UNIVERSITY OF SOUTHERN DENMARK, DENMARK*

INTRODUCTION: Dietary supplementation with nitrate ($NO_3^-$), which can undergo a stepwise reduction to nitrite ($NO_2^-$) and then nitric oxide, has been reported to improve performance in a variety of exercise settings. The ergogenic effect of $NO_3^-$ supplementation has been attributed to improved skeletal muscle calcium ($Ca^{2+}$) handling, based on data from mouse muscle indicating improved sarcoplasmic reticulum (SR) $Ca^{2+}$ release or reuptake after $NO_3^-$ or $NO_2^-$ administration, but this has yet to be tested in human skeletal muscle. This study tested the hypothesis that $NO_3^-$ supplementation would improve high-intensity intermittent exercise (HIIE) performance and skeletal muscle SR vesicle (SRV) $Ca^{2+}$ release and reuptake.
METHODS: In a randomised, double-blind, cross-over study design, 16 recreationally active adults (23 ± 2 yrs) consumed $NO_3$rich (BR, 13 mmol of $NO_3^-$ ) or $NO_3$depleted (PL, <0.1 mmol of $NO_3^-$) beetroot juice for 7 consecutive days. Muscle biopsy (n=6) and blood samples were collected on day 7 of supplementation at rest and after attaining 80% of task failure during a HIIE test, which was established during a preliminary HIIE performance test. The HIIE protocol consisted of repeated 15 s cycle intervals at 160% of maximal aerobic power interspersed with 30 s recovery. After 20 min passive rest, the HIIE protocol was repeated and continued until task failure. A paired samples t-test was used to analyse HIIE performance, with plasma [$NO_3^-$] and muscle SRV $Ca^{2+}$ handling data analysed with two-way repeated-measures ANOVAs.
RESULTS: Resting plasma [$NO_3^-$] (381 ± 105 vs 44 ± 22 uM, $p<0.001$) and the number of repetitions completed in the HIIE protocol (13 ± 5 vs 12 ± 4, $P=0.04$) were higher after BR compared to PL supplementation. While SRV $Ca^{2+}$ release rate was lower after HIIE compared to rest in the PL condition (1.5 ± 0.3 vs 1.7 ± 0.4 µmol/gr prot/min, $p=0.03$), there was no main effect for supplement or no supplement x time interaction effect on SRV $Ca^{2+}$ release rate ($P>0.05$). There was a main effect for supplement and a supplement x time interaction effect on the rate of SRV $Ca^{2+}$ reuptake ($p<0.05$). Compared to rest, SRV $Ca^{2+}$ reuptake rate was slower after HIIE in PL (31.1 ± 7.1 vs 35.7 ± 7.3 s, $p<0.01$), but not BR (30.0 ± 7.3 vs 29.9 ± 8.3 s, $p>0.05$). There was no difference in SRV $Ca^{2+}$ reuptake between BR and PL at rest ($p>0.05$), but SRV $Ca^{2+}$ reuptake was faster after HIIE in BR compared to PL ($p<0.01$).
CONCLUSION: Short-term $NO_3^-$ supplementation improved performance and speeded skeletal muscle SRV $Ca^{2+}$ reuptake during HIIE in healthy adults. While SRV $Ca^{2+}$ release rate was impaired following HIIE, this was not alleviated by BR. These observations improve understanding of the physiological mechanisms by which $NO_3^-$ supplementation may enhance exercise performance.

**INTERMITTENT EXOGENOUS KETOSIS FACILITATES THE REHABILITATION OF MUSCLE DISUSE ATROPHY**

POFFÉ, C., STALMANS, M., ROBBERECHTS, R., KUSTERS, M., COUDYZER, W., HESPEL, P.

*KU LEUVEN*

INTRODUCTION: Muscular disuse has debilitating effects on muscle mass and strength, and impairs functional capacity (1). Previous research indicated that elevated blood ketones can negate catabolic events during energy deficit (2). In addition, we recently showed ketone

ester ingestion to enhance the anabolic response post-exercise (3) as well as to stimulate exercise performance during endurance training overload (4). From this perspective, we hypothesized that ketone ester (KE) ingestion may be a potent strategy to attenuate the decline in muscle mass, strength, and functional capacity following muscle disuse as well as to stimulate subsequent rehabilitation.
METHODS: A randomized, double-blind trial was performed in young healthy volunteers (9 females and 15 males). Subjects underwent 2-weeks of immobilization of their dominant leg followed by a 4-week rehabilitation program involving unilateral resistance exercise (3 sessions/week). Half of the subjects received 3 x 20g of the ketone monoester (R)-3-hydroxybutyl (R)-3-hydroxybutyrate (KE) per day, whilst the others ingested a taste-matched, isocaloric placebo (CON). Before and after immobilization and after 2 and 4 weeks of rehabilitation, in both legs, muscle volume was assessed using a computed tomography scan, and maximal dynamic and isometric knee-extension torques were measured. Exercise capacity was evaluated by a graded exercise test on a cycling ergometer with the immobilized leg only. A two-way repeated-measures ANOVA was performed to evaluate differences between both groups and over time.
RESULTS: KE intake increased blood D-ß-hydroxybutyrate levels up to 2.9 ± 0.2 mM within 30 min, whereas in CON blood ketone levels remained at baseline (interaction effect, $p<0.001$). Immobilization decreased quadriceps muscle volume (~5%) and knee-extension torque (~15%) by the same magnitude in both groups. Compared with CON, KE intake stimulated the rehabilitation of muscle volume and isometric knee-extension torque by ~5% (interaction effects, $p < 0.05$). KE intake also gradually increased muscle volume in the contralateral leg (CON: +1.7 ± 0.8% vs. KE: +4.7 ± 0.7%, interaction effect, $p < 0.05$) without affecting knee-extension torque. Peak power output in the unilateral cycling test decreased upon immobilization in CON (pre: 133 ± 10W vs. post: 114 ± 9W) but not in KE (pre: 126 ± 12W vs. post: 121 ± 11W, interaction effect, $p < 0.05$).
CONCLUSION: These findings indicate that KE intake does not affect disuse muscle atrophy but attenuates the decline in functional capacity as well as facilitates rehabilitation of muscle mass and strength.

## MOUTH RINSING AND INGESTING SALTY OR BITTER SOLUTIONS AFTER HEAVY INTENSITY CYCLING DOES NOT INFLUENCE SPRINT PERFORMANCE OR NEUROMUSCULAR FUNCTION.

GRAY, E., SIEGLER, J.

*WESTERN SYDNEY UNIVERSITY*

INTRODUCTION: Previous research suggests that ingesting an unpleasant bitter tastant can enhance cycling sprint performance. However, the mechanisms facilitating changes in performance are unclear and it is not known if other unpleasant tastes could also be ergogenic. Therefore, the purpose of the present study was to explore the effect of unpleasant salty and bitter tastes on cycling sprint performance and neuromuscular function in different fatigue states.
METHODS: Eight trained male cyclists (age: 37 ± 9 years, weight: 82 ± 9 kg, VO2max: 55 ± 4 ml.kg-1.min-1) participated in five laboratory visits. In the first visit participants completed a cycling ramp test to determine VO2max and the respiratory compensation point (RCP). In the familiarisation and the three main trials participants cycled at 85% of RCP for 45 minutes and then, after a 5 minute rest, completed a maximal 1 minute cycling sprint. Neuromuscular function was assessed using two knee extensor maximal voluntary contractions (MVC) immediately before, between and after the cycling efforts. Participants mouth rinsed (5 s) and ingested a 25 ml test solution immediately before each MVC and the cycling sprint. Using a randomised cross-over design the test solution in the three main trials were salt (1 M), bitter (2 mM quinine) and a water control condition.
Differences between conditions in cycling performance were assessed using one-way repeated measures ANOVA. Differences in neuromuscular function were assessed using a time*condition repeated measures ANOVA. Bonferroni post-hoc comparisons located significant differences. Data are presented as mean ± SD.
RESULTS: Average and maximum power were not significantly different between conditions during the 1 minute cycling sprint (average: 512 ± 64 W, 513 ± 67 W, 515 ± 74 W, and 503 ± 80 W; maximum: 876 ± 86 W, 884 ± 136 W, 884 ± 145 W, 890 ± 108 W in the familiarisation, water, salt and bitter conditions, respectively). Additionally, there was no significant difference in average and maximum cadence during the sprint.
Maximal voluntary force and 100-200 ms impulse declined following exercise in all conditions, showing a significant main effect for time. However, for 0-50 ms and 0-100 ms impulse there was no significant main effect for time. Furthermore, there was no significant effect of condition or condition*time interaction for maximal voluntary force or any impulse variables.
CONCLUSION: Previous research has shown ingesting a bitter solution improves sprint performance when it is commenced without prior fatigue. However, the present study found no effect of a bitter taste on 1 minute cycling performance after heavy intensity cycling. Furthermore, the bitter taste had no influence on neuromuscular function at rest or in a fatigued state. Similarly, an unpleasant salty solution had no effect on cycling performance or neuromuscular function. Further research is required to determine if and how ingesting bitter, or other unpleasant tastes, may be beneficial for sprint performance.

## ARE THE ACUTE EFFECTS OF NEW ZEALAND BLACKCURRANT EXTRACT ENDURANCE PERFORMANCE-DEPENDENT IN TRAINED CYCLISTS: A HOME BASED STUDY.

MONTANARI, S.1, BLACKER, S.D.1, LEE, B.J.2, WILLEMS, M.E.T.1

*1 UNIVERSITY OF CHICHESTER; 2 COVENTRY UNIVERSITY*

INTRODUCTION: Acute intake of blackcurrant anthocyanins improved vascular function (1) and reduced oxidative stress post-exercise (2). Responses seem to be dose-dependent reaching a plateau at 310 mg of anthocyanins (1). No data is available on exercise performance with intake of such a dose. In December 2019, a novel coronavirus, named COVID-19, became pandemic forcing people to stay at home. Therefore, this study presents a novel approach testing the acute effects of 900 mg of New Zealand blackcurrant (NZBC) extract (315 mg of anthocyanins) on endurance cycling performance in a home-based environment using an online software.
METHODS: A randomized, double-blind, placebo-controlled trial was implemented. Thirty-four cyclists [(26 males and 8 females, age: 38 ± 7 years, V O2max: 57 ± 5 ml/(kg·min)] completed four 16.1 km time trial (TT) (two full familiarizations and two experimental trials) in the morning connecting their turbo-trainers to an online simulator (ZWIFT). Females reported symptoms on a menstrual cycle questionnaire (MCQ) before starting. Capsules containing 900 mg of NZBC extract or an equivalent placebo (PLA) were consumed 1.5 h before the TT. Time, power, speed, distance, heart rate, and cadence were recorded. Data were analysed as a group and for evenly separated faster

(<1400 s) and slower riders (>1400 s). Differences between conditions were assessed with a t-test. A repeated-measures ANOVA was implemented to analyse differences between distance points (4, 8, 12 and 16.1 km). Coefficient of variation (CV), typical error (TE) of the model and 95% CI were calculated. Significance was set at p<0.05 and data reported as mean ± SD.
RESULTS: Consumption of NZBC extract resulted in a faster TT compared to PLA, close to significance (1414 ± 91 s vs 1422 ± 104 s; 95% CI [-0.53, 17.06], p=0.06) with a small effect size (d=0.3). No difference was observed for power, speed, HR, RPM and RPE. The slower group (n=17) average time to complete the 16.1 km TT was 20 s faster with NZBC extract compared to PLA (1479 ± 83 s vs 1499 ± 91 s; 95% CI [4.18, 34.52], d=0.65, p=0.01,). Power profile across the whole TT in the slow group was higher with data close to significance at 8 km (PLA: 234 ± 54 W, NZBC: 239 ± 54 W, p=0.06, d=0.4) and being different at 12 km (PLA: 232 ± 54 W, NZBC: 239 ± 51 W, p=0.02, d=0.6). Slower group CV was 1.3% with a TE=20 s. There was no difference between conditions for time, power, speed, HR and RPM in the faster group. No differences between conditions for MCQ symptoms were reported.
CONCLUSION: Acute consumption of 900 mg of NZBC extract improved 16.1 km cycling TT performance in the slower group (>1400 s) with no changes in the faster group. However, variation within the model showed a ~20 s TE which is within the improvement observed. The effectiveness of anthocyanin-rich supplementation seems to be cycling performance-dependent, but more research is warranted to confirm these preliminary results.

**COMPARISON IN THE CONSUMPTION OF SPORTS SUPPLEMENTS ACCORDING TO COMPETITIVE LEVEL.**

SÁNCHEZ-OLIVER, A.J., PUYA-BRAZA, J.M., LÓPEZ-LEÓN, I., MORENO-LARA, J., SÁNCHEZ-TRIGO, H., SAÑUDO, B.
*UNIVERSIDAD DE SEVILLA*

INTRODUCTION: Powerlifting is a sport based on lifting the maximum weight possible in three exercises: squat, bench press, and deadlift (1). The range of consumption of supplements in sports (SS) is very wide and, currently, we place it between 30-95% (2). This variation in consumption can depend on various variables, mainly the type of physical activity or sport (i), the level of performance or competition of the athlete (ii), gender (iii), and age (iv) (3). The studies that collect the consumption of SS in powerlifters are scarce. Knapik et al (4), Petkova et al (5), and Al Saffan et al (6) show a high prevalence of use in this discipline with a percentage of consumption of 85%, 100%, and 73.1%, respectively. Currently, there is no research that studies the prevalence and pattern of consumption based on the variables that determine it in powerlifters. Thus, the objective of this study was to analyze possible differences in performance and consumption of SS in powerlifters of the international level (INT) with respect to the national level (NAT).
METHODS: 32 male powerlifters (10 INT, 22 NAT) completed a 72-hour supplement diary (2 training days and 1 rest day), as well as a questionnaire regarding SS consumption. In addition, the best performance in squat, bench press, and deadlift during a competition in the month previous to the study was recorded.
RESULTS: INT level athletes reported a higher total performance (+20,1%; p<0,001; ES=1,46) and in each of the exercises: squat, bench press and deadlift (p<0,05; ES=0,99–1,29). The 100% of the sample consumed SS, the most consumed being creatine monohydrate (63%), whey protein (59%), vitamin complex (34%), caffeine (25%) and branched-chain amino acids (19%), there being only differences in the consumption of whey protein by INT level athletes (90% vs 45%; p=0,024; OR=1,75 [1,11–2,76]).
CONCLUSION: INT level athletes reported higher performance. However, there were no significant differences in overall SS consumption.

### OP-PN08 The importance of Oxygen

**BOTH HIGH- AND LOW-FREQUENCY BLOOD-FLOW RESTRICTION WALK TRAINING INCREASE MAXIMAL AEROBIC CAPACITY INDEPENDENT OF BLOOD-VOLUME CHANGES**

THOMPSON, K.M.A., GAMBLE, A.S.D., KONTRO, H., BURR, J.F.
*UNIVERSITY OF GUELPH*

INTRODUCTION: At rest, the occlusion of leg blood flow (BFR) has been shown to cause an increase in sympathetic activity and circulating blood-volume regulating hormones. Given that fluctuations in blood pressure and ion concentrations affect blood-volume control, the perturbation of these regulating systems is likely amplified with the addition of exercise. Over time, repeated exposure to fluid retention hormones could lead to increases in total blood volume, which would explain how BFR exercise has repeatedly shown to improve maximal aerobic capacity (VO2max) in the absence of more localized muscular changes.
METHODS: To determine changes in serum copeptin and renin concentration, venous blood samples were collected from 23 subjects before and after an acute bout of BFR or time-matched walking exercise (5 sets x 3 min walking, separated by 1 min rest, 5% grade, 5km/hr, BFR condition used 100% of lowest occlusion pressure). Twenty of these subjects and an additional eight (n=28) were then divided into control (CON), high-frequency (BFRH) and low frequency (BFRL) training groups. CON and BFRH performed a twice daily walking protocol for 4 weeks, while BFRL performed a twice weekly walking protocol for 6 weeks. VO2max and blood volume (CO-rebreathe) were tested

at baseline (PRE) and following training (POST). Paired samples t-tests using changes in serum renin and copeptin concentrations (pre to post BFR/free-flow walking) were used to determine whether greater increases were observed following BFR walking. A repeated measures ANOVA was performed to compare changes in aerobic capacity and blood volume.
RESULTS: BFR walking resulted in significantly greater changes in serum copeptin (BFR: 5.5±2.9 to 57.8±99.4 pmol/L; free-flow: 6.3±3.8 to 6.7±4.0 pmol/L; p=0.02) and renin (BFR: 19.1±8.2 to 44.5±27.1 ng/L; free-flow: 19.41±7.2 to 28.5±15.1; p=0.001). Significant changes in maximal aerobic capacity were observed following training (p=0.03). Increases in VO2max were observed from PRE to POST for both BFRH (46.7±8.8 to 50.7±9.5 ml.kg-1.min-1, p=0.004) and BFRL (48.1±7.4 to 52.5±10.2 ml.kg-1.min-1, p=0.02) groups but not CON (48.8±9.4 to 49.2±8.6 ml.kg-1.min-1, p=0.6). No changes in blood volume were evident (BFRH: 83.4±12.3 to 82.0±10.5 ml.kg; BFRL: 76.6±12.8 to 78.2±13.9 ml.kg; CON: 77.3±9 to 78.4±8.7 ml.kg; p=0.7).
CONCLUSION: The current results support findings of improved maximal aerobic capacity following BFR exercise. Of note, mean improvements in VO2max were of a similar magnitude in both the high- (+9.6%) and low-frequency (+9.0%) BFR training groups. Despite large increases in circulating fluid retention hormones following an isolated bout of BFR exercise, blood volume over the training period did not increase in either group. The notable adaptations promoting greater endurance capacity with low intensity BFR exercise require further investigation to elucidate the mechanisms responsible.

### NRF2 AND NF-KB SIGNALLING, AND ANTIOXIDANT ENZYME ADAPTATIONS TO SPRINT INTERVAL TRAINING ARE POTENTIATED BY BRIEF ISCHAEMIA APPLICATION DURING THE RECOVERY PERIODS

GALLEGO-SELLES, A., GALVAN-ALVAREZ, V.1, MARTINEZ-CANTON, M.1, GARCIA-GONZALEZ, E.1, GELABERT-REBATO, M.1, GARCIA-PEREZ, G.1, SANTANA, A.2, MORALES-ALAMO, D.1

INTRODUCTION: *more authors: FERNANDEZ-GARCÍA, B.3, BOUSHEL, R.4,HALLEN, J.5, CALBET, J.A.L.1,4,5, MARTIN-RINCON, M.1
Reactive oxygen and nitrogen species (RONS) stimulate signalling pathways essential for the adaptative response to exercise. Nrf2 and NFkB transcription factors regulate over 150 genes involved in redox homeostasis, inflammation, and the antioxidant response. High-intensity exercise increases RONS and activates Nrf2, NFkB, and CaMKII signalling in human skeletal muscle (HSM), an effect potentiated by immediate ischaemia application (PMID: 32863217). It remains unknown how sprint interval training (SIT) modulates antioxidant enzyme expression and regulatory transcription factors. It is uncertain whether additional metabolic and RONS-mediated stress could further stimulate the adaptive response to SIT. We hypothesized that SIT would upregulate the basal and exercise-induced Nrf2 and NFkB signalling, with this effect being exacerbated by post-exercise ischaemia.
METHODS: Ten active subjects were tested before and after SIT (4-6 30s sprints, 4min recovery, 6 sessions in 2 weeks). Immediately after each sprint, the circulation of one leg was instantaneously occluded (300mmHg) for 30-50s. The main PRE and POST-training tests consisted of an incremental exercise to exhaustion (IE) followed by 90min rest and 6 bouts of supramaximal exercise to exhaustion at 120%VO2max (SPE) interspaced with 20s recovery, during which circulation of both legs was fully occluded. In addition, VL biopsies were taken at rest, 90 min after IE, and immediately after SPE unilaterally at PRE and bilaterally at POST from the leg training with free circulation (FCL) and the leg training with ischaemia (IS) for Western Blotting. Statistics: repeated-measures ANOVA
RESULTS: After SIT, basal protein levels of pSer536p65, IkBalpha, IkBbeta, pSer40Nrf2, Nrf2, Nrf2/Keap1 ratio, Catalase, SOD1, GR, pThr287CaMKII, and CaMKII were largely increased (∼2.3-fold) solely in IS ($p<0.05$). Besides, SIT increased basal protein levels significantly more in IS for pSer176/180IKK, p50, p65 (∼1.9-fold vs. FCL) ($p<0.05$). The acute upregulation following SPE observed at PRE and after SIT in FCL was blunted in IS ($p<0.05$) for pThr287CaMKII, IkBbeta, TrxR1, Nrf2, pSer40Nrf2, p65, pSer536p65, pSer176/180 IKK and pTyr705STAT3.
CONCLUSION: These findings show that Nrf2 and NFkB signalling and their downstream antioxidant enzymes are largely upregulated by additional time under oxidative stress during 2 weeks of SIT in HSM. Furthermore, we have shown that a marked elevation of the basal antioxidant response with training suppresses the acute exercise-induced activation of Nrf2 and NFkB signalling otherwise required in the non-trained state. This was achieved by employing a novel experimental approach where immediate ischaemia is applied after each bout in only one leg, exacerbating RONS and metabolite build-up, which may enhance the antioxidant capacity of HSM. Whether these adaptations are beneficial for performance or long-term adaptation to training remains to be evaluated.

### PREMATURITY AND MAXIMAL EXERCISE CAPACITY AT HIGH-ALTITUDE: EVIDENCE OF HYPOXIC PRECONDITIONING?

MANFERDELLI, G.1, NARANG, B.J.2,3, BOURDILLON, N.1, DEBEVEC, T.2,3, MILLET, G.P.1

*1: UNIVERSITY OF LAUSANNE, LAUSANNE, SWITZERLAND; 2: JOŽEF STEFAN INSTITUTE, LJUBLJANA, SLOVENIA; 3: UNIVERSITY OF LJUBLJANA, LJUBLJANA, SLOVENIA*

INTRODUCTION: Premature birth induces several long-term sequelae on the pulmonary and cardiovascular systems that contribute to reduced exercise capacity. However, preliminary data suggest that prematurity might, at least in-part, protect against some altitude-induced physiological alterations. Accordingly, we aimed to investigate the cardiorespiratory and muscle oxygenation responses to incremental exercise to exhaustion performed at sea level and at altitude in preterm and full-term born adults, to clarify the mechanism(s) underpinning prematurity-related impairments in exercise capacity.
METHODS: Healthy preterm (n=17; age, 21±1 years; gestational age, 29±1 weeks) and age-matched full-term (n=17; gestational age, 40±0 weeks) adult men underwent a hypoxic sensitivity test (i.e., random 1 to 8 consecutive breaths with 100% N2) to assess the hypoxic ventilatory response (HVR) and two incremental exercises to exhaustion on a cycle ergometer – one at sea level and the other at altitude (3375 m). Gas exchange, hemodynamics, and muscle oxygenation were assessed continuously by metabolic cart, transthoracic impedance, and near-infrared spectroscopy, respectively. Intramuscular matching between O2 delivery and utilization was assessed by the presence of a deoxygenation (Δ[deoxy(Hb+Mb)]) overshoot in the transition from rest to exercise.
RESULTS: The HVR was comparable between preterm and full-term adults (0.383±0.061 vs. 0.270±0.029 L/min/%, p=0.11). In normoxia, preterm demonstrated lower peak power output (276±10 W vs. 312±12 W, p=0.04) compared to full-term adults, but not in hypoxia (248±10 vs. 279±10 W, p=0.07 and 2.62±0.11 vs. 2.84±0.09 L/min, p=0.47), despite similar peak O2 uptake in both normoxia (48.5±2.6 mL/kg/min vs. 51.9±1.9 mL/kg/min, p=0.36) and hypoxia (36.4±1.6 mL/kg/min vs. 37.9±1.1 mL/kg/min, p=0.87). At peak, stroke volume (116±6 vs. 138±5 mL, p=0.02) and cardiac output (21.7±1.2 vs. 26.0±1.0 L/min, p=0.01) were lower in preterm compared to full-term adults in normoxia, but not in hypoxia (113±7 vs. 122±5 mL, p=0.53 and 21.1±1.2 vs. 23.2±0.9 L/min, p=0.35). Peak Δ[deoxy(Hb+Mb)] was increased from normoxia to hypoxia in full-term (11.0±1.5 vs. 16.2±2.1 µM, p=0.04) but not in preterm (13.5±2.5 vs. 13.7±2.0 µM, p=0.84)

adults. Intramuscular matching between O2 delivery and utilization was improved by hypoxia relative to normoxia in the preterm (1.9±0.6 vs. 0.3±0.2 µM, p<0.01) but not in the full-term (1.1±0.4 vs. 0.2±0.2 µM, p=0.13) group.
CONCLUSION: These data suggest that prematurity reduces exercise capacity primarily via impaired convective, rather than diffusive, O2 transport. However, hypoxia-induced impairments in physiological responses to maximal exercise appear to be attenuated in healthy preterm adult men, compared to their full-term counterparts. These findings lend further support to the potential hypoxic preconditioning effect of premature birth and/or perinatal treatment that warrant further scrutiny.

**EXERCISE-COGNITION INTERACTION IN HYPEROXIA DURING APPLIED UNDERWATER FIN-SWIMMING IN SCUBA-DIVING**

MÖLLER, F.1,2, JACOBI, E.1, HOFFMANN, U.1, VOGT, T.2
*GERMAN SPORT UNIVERSITY COLOGNE, COLOGNE, GERMANY*

INTRODUCTION: Executive functions (EF) positively interact with moderate and severe exercise intensity in laboratory studies, but this interaction might be modulated by environmental factors, oxygen supply, and resulting changes in prefrontal and muscle oxygenation (1–3). These aspects are combined in the applied setting of SCUBA-diving, where hyperoxia occurs when breathing air at depth, and gas mixtures with elevated oxygen fractions are commonly used (4). Intact EFs enable higher-level processes like goal-directed behavior and problem-solving, which are highly relevant in the demanding underwater environment, and especially in critical situations or rescue scenarios where additional exercise stress occurs. It was hypothesized that (I) the positive interaction between exercise intensity and EF performance would be amplified by an increased inspiratory oxygen pressure and (II) that environmental impacts and increased physiological demands might attenuate this effect during severe exercise intensity.
METHODS: Based on a priori power analysis (f = 0.5; Power 1-β = 0.9), 15 experienced SCUBA-divers (age: 27 ± 6 years; 7 females) performed 3 × 8 min of underwater fin-swimming (UFS; 4 m depth) at individual work rate intensities of 20 % (low), 30 % (moderate), and 55 % (severe) heart rate reserve. HRmax was derived from an incremental UFS step test. Eriksen Flanker tasks for inhibition, which is considered a core EF, were performed directly after rest and exercise at the pools edge (100 stimuli). This scenario was repeated on three separate days with different oxygen fractions in the breathing gas (21 %, 40 %, 100 % O2; double-blind). ANOVAs with repeated measures on the factor intensity (rest, low, moderate, severe) and gas were performed for the normally distributed variables accuracy (ACC) and reaction times that required inhibitory control (RTincom).
RESULTS: RTincom showed a significant main effect for intensity ($P < 0.001$; $\eta p2 = 0.4$) but not for gas. Significantly faster RTs were observed after severe intensity exercise compared to rest ($P = 0.022$), low ($P < 0.001$), and moderate-intensity ($P < 0.001$). ACC showed no effects.
CONCLUSION: The results comply with superior EF performance after severe exercise from elevated lactate and serotonin levels (5,6). Cerebral oxygenation was possibly maintained during exercise (7) despite environmental and exercise-dependent competing physiological demands (8), which hyperoxia might have met. In summary, EF performance was slightly elevated and remained intact during hyperoxic exercise settings in SCUBA-diving.

**THE FRACTIONAL UTILIZATION OF VO2MAX IS HIGHER IN HYPOBARIC HYPOXIA EQUIVALENT TO 2800 M THAN NEAR SEA LEVEL**

OBERHOLZER, L., AAMASS, N.S., HALLÉN, J.
*NORWEGIAN SCHOOL OF SPORT SCIENCES*

INTRODUCTION: The lower O2 availability at altitude leads to a 6% reduction in maximal oxygen uptake (VO2max) for every 1000 m of increasing altitude (1). In contrast, the decline in endurance performance with hypoxic exposure is variable, depending on the discipline and event duration. Typically, 800–10’000 m track and field performances are decreased by 0.4-2.4% at events above 1000 m of altitude (2), while time trial (TT) performances in cycling are also lowered at altitude but presumably to a lesser extent than VO2max (e.g. 3). Generally, a greater decline in VO2max than in endurance performance suggests a higher fractional utilization of VO2max (the VO2 over a given time or distance as a percentage of VO2max; %VO2max) at altitude, provided that anaerobic capacity and exercise economy are unaltered. Thus, it was hypothesized that the %VO2max is higher during a cycling TT in hypoxia than near sea level.
METHODS: Sixteen amateur cyclists (8 women, age: 31±7 years [mean±SD], body mass: 68±8 kg, VO2max: 60±8 ml.min-1.kg-1) underwent exercise testing in a hypobaric hypoxic chamber set to 300 m (976±2 hPa, 18.0±0.3 °C) or 2800 m (724±2 hPa, 17.9±0.3 °C). VO2max and maximal power output (Pmax) were assessed by an incremental test to exhaustion and average power output (Pavg) and average VO2 were determined during a 40 min all out cycling TT. The %VO2max was calculated as the average VO2 during the TT as a percentage of VO2max. All participants performed each exercise test at both altitudes.
RESULTS: VO2max and Pmax decreased from 4119±783 ml.min-1 and 349±49 W at 300 m to 3655±710 ml.min-1 and 313±44 W at 2800 m (-11.2±2.9%, p<0.001; -10.2±3.7%, p<0.001). Similarly, average VO2 and Pavg during the TT were lower at altitude, namely 3113±571 ml.min-1 and 223±39 W at 300 m and 2854±516 ml.min-1 and 199±34 W at 2800 m (-8.2±4.4%, p<0.001; -10.7±3.1%, p<0.001). The lower decline in VO2 than in Pavg suggests poorer cycling economy during the TT in hypoxia and indeed, VO2 per completed kJ was higher at 2800 m (+3.0±2.9%, p=0.001); all in all leading to an increased %VO2max at altitude (300 m: 76.0±4.5%, 2800 m: 78.4±4.2%, p=0.023).
CONCLUSION: As hypothesized, the %VO2max was higher during a 40 min cycling TT at altitude than near sea level. However, this was not explained by a lower decline in performance than in VO2max, but it is rather suggested that the poorer cycling economy during the TT is compensated by enhancing %VO2max at altitude. Future studies should address the mechanisms underlying the higher %VO2max with hypoxia.

### UPPER AND LOWER EXTREMITY CONTRIBUTIONS TO LOAD-VELOCITY PROFILES IN SEMI-TETHERED FRONT CRAWL SWIMMING

KELLER, S.1,3, WAHL, P.2,3

*GERMAN SPORT UNIVERSITY COLOGNE*

INTRODUCTION: In swimming, maximum speed is achieved by generating high propulsive forces while minimizing resistance. Although upper and lower extremities contribute to propulsion in all swimming strokes, it has been assumed that in front crawl swimming the upper extremities provide most of the thrust (Toussaint & Beek, 1992). However, findings from laboratory ergometer and tethered swimming suggest that the contribution of the lower extremities may be greater than previously thought (Morouço et al., 2015). As both methods differ substantially from the biomechanics of free-swimming, we aimed to estimate extremity contributions to propulsive force and speed using load-velocity profiles during semi-tethered swimming.
METHODS: Nine male and seven female well-trained swimmers (18 ± 3 yrs; 180 ± 10 cm; 70 ± 7 kg) performed five 20-m all-out semi-tethered swimming trials with increasing loads in whole-body front crawl swimming (W), upper extremity movement only (A) or lower extremity movement only (L) in a randomized order. Starting from 1 kg, resistance was increased by 2 and 1 kg in W, by 1 and 0.5 kg in A and by 0.5 in L for male and female athletes, respectively. Load was applied and velocity was recorded at 333 Hz by a robotic resistance device (1080 Sprint; 1080 Motion AB, Lindingö, Sweden). Theoretical maximum velocities (V0) and loads (L0) were calculated from the linear regression between load and velocity ($R^2$ = 0.99 ± 0.01 in W, 0.98 ± 0.03 in A and 0.97 ± 0.04 in L). For both parameters, all values were normalized to the sum of the lower and upper extremity values (100%) to calculate percent force and speed deficits and contributions.
RESULTS: V0 was 1.90 ± 0.07 and 1.68 ± 0.04 m·s-1 in W, 1.59 ± 0.06 and 1.36 ± 0.06 m·s-1 in A and 1.15 ± 0.10 and 1.10 ± 0.05 m·s-1 in L in male and female swimmers, respectively. L0 was 19.0 ± 2.4 and 15.5 ± 2.1 kg in W, 11.9 ± 2.7 and 8.6 ± 2.3 kg in A and 6.6 ± 1.9 and 6.0 ± 0.9 kg in L in male and female swimmers, respectively. Upper and lower extremity contributions to V0 were 58 ± 2 and 42 ± 2% in male and 55 ± 2 and 45 ± 2% in female athletes. For L0, contributions were 64 ± 9 and 36 ± 9% in male and 58 ± 9 and 42 ± 9% in female athletes. A speed deficit of -30 ± 4 and -32 ± 2% was found for V0 ($p < 0.001$), while L0 in W was similar to the sum of A and L (+4 ± 15 and +8 ± 15%, $p > 0.05$) in male and female athletes, respectively.
CONCLUSION: Our data show that the lower extremities contribute significantly to maximal force and speed in semi-tethered front crawl swimming in male and female athletes. While force production in W was similar to the sum of A and L, we found a substantial speed deficit. These findings highlight the importance of minimizing speed deficit by more efficiently converting force into propulsion or improving whole-body coordination, which has the potential to maximize swimming speed even at high performance levels.

### TUNING BETWEEN MUSCLE ACTIVATION AND TENDON OPERATING LENGTH FACILITATES ENERGY OUTPUT IN TRICEPS SURAE MUSCLES DURING HIGH WALKING SPEEDS

KHARAZI, M., BOHM, S., THEODORAKIS, C., ARAMPATZIS, A.

*HUMBOLDT-UNIVERSITÄT ZU BERLIN*

INTRODUCTION: Increased walking speed is associated with higher ankle joint moments (1), which suggest higher muscle force generation of the triceps-surae muscles (TSM). On the other hand, the generated TSM force is impaired due to its force-velocity relationship at walking speeds of ~2.0 m/s [2]. This indicates lower muscle forces at higher speeds. Our main purpose was to investigate experimentally the Achilles tendon (AT) force as a proxy of the TSM force generation and the mechanical work done at the ankle joint by the TSM with increasing walking speed. A secondary objective was to assess mechanics and energetics within the gastrocnemius medialis (GM) muscle-tendon unit (MTU). We hypothesized that decoupling between muscle and tendon regulated by an appropriate muscle activation would increase the muscular mechanical work despite lower muscle forces.
METHODS: In fifteen young adults, we measured the electromyographic activity (EMG) of the TSM during walking at speeds of 0.7 m/s (slow walking), 1.4 m/s (preferred walking), 2.0 m/s (transition walking) and maximum walking speed capacity (2.6±0.3 m/s) on a treadmill. Further, we measured the length of the AT tendon during walking with a combination of the ultrasound and motion capture systems and using the individual AT force-elongation relationship, we assessed AT force during the walking trials [3]. We calculated the moment generating at the ankle joint and the mechanical work done from all TSM. Finally, we investigated the mechanical work done by the GM-MTU, assuming a constant based on the physiological cross-sectional area contribution of GM muscle force.
RESULTS: We found a decrease ($p<0.05$) in the maximum AT force and AT strain energy recoil in the two higher speeds compared to the preferred one. With increasing speed, the net mechanical work done at the ankle joint from the TSM increased significantly ($p<0.001$, from -0.02±1.06 J to 7.63±0.36 J). In the transition and maximum velocity speed, a rapid increase in the EMG-activity of the TSM initiates muscular energy gain despite a continued elongation in AT. At the GM-MTU level, the rapid increase of the GM activity in the two higher speeds causes a shortening in the muscle belly while the tendon is elongated.
CONCLUSION: Our findings show for the first time that at walking speeds higher than the preferred, muscular work of the TSM provides a higher contribution than the AT energy recoil to the needed mechanical work. A rapid increase in the muscle activation at low tendon strain operating length introduces a decoupling between tendon and muscle belly resulting in an earlier muscular energy gain which increases the net muscle belly and MTU mechanical work. A part of this earlier muscular energy gain is transferred to the tendon despite the shortening of MTU and muscle belly.

**EFFECTS OF FATIGUE ON PERCEPTION OF VELOCITY DURING BACK SQUAT**

ROMAGNOLI, R.1, LISTA, M.1, CIVITELLA, S.1, PARIS, D.1, SANTILLI, R.1, SGRÒ, P.1, PIACENTINI, M.F.1,2

*1: UNIVERSITY OF ROME FORO ITALICO, ROME, ITALY; 2: VRIJE UNIVERSITEIT BRUSSEL, DEPARTMENT OF HUMAN PHYSIOLOGY AND SPORTS MEDICINE, BRUSSELS, BELGIUM*

INTRODUCTION: The two necessary key components to prescribe velocity-based training are the percentage of loss of velocity (VL) and the mean concentric velocity (MCV) of the fastest repetition[1]. However, electronic devices are necessary and this is impractical when several athletes train at the same time. Recently a subjective perception of velocity scale has been validated showing a high correlation between real velocity (Vr) measured with encoders and perceived velocity (Vp)[2]. The purpose of the present study was to investigate whether perception of barbell velocity is affected by fatigue induced by two different training protocols with the hypothesis that Vp would be unaffected despite changes in Vr.
METHODS: Resistance trained participants were randomly divided in two groups: the 10% velocity loss group (VL10) (6 males, 5 females, age=29±8.23 years; 1RM=118.36±38.51 kg;) and repetitions to failure group (EX) (6-males, 5-females, age=24.3±3 years; 1RM=119.05±26.97 kg). Both protocols included 5 sets at 75%1RM but differed in the number of repetitions performed, using the 10% velocity-loss method in one case and repetitions to failure in the other. The accuracy in perceiving concentric velocity Vp was assessed during a test with 3 blinded loads (heavy: MCV ≥ 0.4 m·s−1, medium: 0.6-0.8 m·s−1, light: ≥ 1m·s−1), in the Back Squat exercise on 2 different days, in random order. One day rested (REST) and one day immediately following one of the two designated training protocols (VL10 or EX)). Vr was measured by a linear position transducer (Vitruve, SPEED4LIFTS S.L., Madrid-Spain) and at the same time the subjects reported their Vp. The accuracy of the Vp was analyzed by calculating the delta score (DS), (difference between Vp and Vr). Data are presented as median ± interquartile range. Mann-Whitney tests were used to compare DS and Vr between conditions in the 2 groups, and separately for the 3 loads. Bland-Altman plots were used to represent the agreement between Vp and Vr in the 3 loads.
RESULTS: Vr and DS did not change between REST and VL10 conditions (Vr: REST= 0.57 ± 0.55 m·s−1, VL10= 0.6 ± 0.57 m·s−1 ($p > 0.129$); DS: REST= 0.04 ± 0.11 m·s−1, VL10= 0.04 ± 0.08 m·s−1 ($p= 0.704$). In the EX-group a significant decrease in Vr was found (Vr: REST= 0.61 ± 0.51 m·s−1, EX= 0.55 ± 0.50 m·s−1 ($p< 0.05$), but no difference in DS. The EX-group showed a significant reduction in Vr at light and medium loads ($p< 0.05$) compared to REST with no differences in DS. The VL10-group showed no difference in Vr and DS, at all loads.
CONCLUSION: This is the first study that investigates the effects of two different training protocols on Vp. Vr changed after the EX-protocol only. However, in both cases the delta score (the accuracy of the Vp) did not change. These results, although preliminary, are comforting demonstrating that Vp is a stable parameter on which athletes can base their training.

**THE EFFECT OF PELVIC STABILIZATION TRAINING ON DYNAMIC KNEE VALGU**

AMBRUS, M., WOLF, G., HORVÁTH, T., LACZA, Z.

*UNIVERSITY OF PHYSICAL EDUCATION*

INTRODUCTION: Pelvic instability is often associated with angular deviations of the lower limb and often causes valgus shift of the knee joint under load. In addition, non-contact ACL tears during sport activity are often caused by muscles weakness around the pelvis. Therefore, reinforcing the physiological function of the pelvic stabilizing muscles may counterbalance dynamic knee valves, hence decreasing ACL injury risk. The aim of this research is to increase the activity of the pelvic stabilizing muscles through a specific exercise program and to investigate its effect of dynamic knee valgus.
METHODS: Twenty-two subjects (male/female: 16/6) participated in the study. The aim of the six-week pelvic stabilization training was to strengthen the m. gluteus maximus, medius and m. vastus medialis obliquus and to harmonize the ratio of quadriceps and hamstring muscle strength. Before and after the training, dynamic knee valgus was determined on both sides using a Microsoft Kinect Azure camera and Dynaknee software. The software gives the medio-lateral displacement of the knee during single-leg squats as a function of leg length. The normality of the pre- and post-training knee displacement data was analyzed using the Shapiro-Wilk test and the difference was analyzed using Wilcoxons signed rank test.
RESULTS: Dynamic knee valgus decreased from 3.15 % to 1.03 % for the left knee and from 3.89 % to 1.26 % for the right knee. The magnitude of change was significant on both sides ($p<0.001$).
CONCLUSION: Strengthening the pelvic stabilisation muscles induced a substantial improvement in knee valgus, and thus reduced the risk of developing cruciate ligament injuries. This study provides a direct link between an easy diagnosed predisposing factor a common sports injury, and offers a simple countermeasure in the form of specific exercises, that may be included in the routines of athletes at risk for ACL injuries.

**PROSPECTIVE ASSOCIATIONS BETWEEN SPATIOTEMPORAL AND GROUND REACTION FORCE CHARACTERISTICS AND INJURY RISK IN 800+ LEISURE-TIME RUNNERS**

MALISOUX, L., DELATTRE, N., GETTE, P., THEISEN, D.

*LUXEMBOURG INSTITUTE OF HEALTH*

INTRODUCTION: Running biomechanics may be involved in the mechanisms underlying the development of some types of running-related injury. However, contrary to widespread beliefs, only few potential biomechanical risk factors have been prospectively associated with injury risk so far. Therefore, the main objective of this study was to identify injury risk factors among spatiotemporal and ground reaction force characteristics in leisure-time runners. The secondary objective was to investigate whether shoe cushioning modifies the association between these biomechanical factors and injury risk.
METHODS: This study is a secondary analysis of a participant and assessor blinded randomized trial in which 848 recreational runners were tested on an instrumented treadmill at baseline at their preferred running speed in randomly allocated, standardized running shoes (Hard or Soft cushioning, respectively). The most common kinetic and spatiotemporal metrics were derived from a 2-minute ground reaction force signal recording. Participants were subsequently followed-up for 6 months regarding running activity and injury. Cox proportional hazard regression models for competing risk were used to investigate the association between biomechanical risk factors and injury risk, including stratified analyses by shoe version.

RESULTS: The mean (±SD) participants' preferred running speed at baseline was 9.9 (±1.5) km/h. On average, 326 (±19) steps were analyzed per participant. During the follow-up, the participants reported 22 521 hours of running, and 128 participants (15.1%) sustained a running-related injury. In the crude analysis, greater injury risk was found for greater step length (sub-hazard rate ratio – SHR [95% Confidence Interval] = 1.01 [1.00; 1.02], p = 0.038), longer flight time (SHR = 1.00 [1.00; 1.01], p = 0.028), shorter contact time (SHR = 0.99 [0.99; 1.00], p = 0.030), and lower duty factor (defined as the ratio between contact time and stride time; SHR = 0.95 [0.91; 0.98], p = 0.005). In the stratified analyses by shoe version, adjusted for previous injury and running speed, lower duty factor was associated with greater injury risk in those using the Soft shoes (SHR = 0.92 [0.85; 0.99], p = 0.042), but not in those using the Hard shoes (SHR = 0.97 [0.91; 1.04], p = 0.348). No other significant association with injury risk was found.
CONCLUSION: Lower duty factor is an injury risk factor, especially when using softer shoes. Contrary to widespread beliefs, vertical impact peak, vertical loading rate and step rate were not injury risk factors in recreational runners. Duty factor is an interesting target for preventive measures in runners, as it can be easily monitored with wearable devices. Increasing duty factor may help reducing the risk of running-related injury, but this needs to be confirmed by intervention studies. Conversely, vertical impact peak, loading rate and step rate may not be the most relevant biomechanical factors for overall injury prediction.

#### THE ASSOCIATION BETWEEN MEASUREMENTS OF EXTERNAL LOAD AND BONE STRUCTURAL CHARACTERISTICS IN ELITE CRICKETERS AND FOOTBALL PLAYERS.

SCOTT, R.1, SALE, C.1,2, JAMES, R.1, BARNETT, C.1, VARLEY, I.1

*1NOTTINGHAM TRENT UNIVERSITY; 2MANCHESTER METROPOLITAN UNIVERSITY*

INTRODUCTION: Despite exercise being prescribed to benefit bone health [1], little is known about the specific external loading characteristics of exercise required to promote bone accrual. It Is not known how limb specific loading variables are associated with bone characteristics. We aimed to assess if quantified external loading is associated with tibial bone characteristics in elite cricketers and football players.
METHODS: Eleven professional cricketers (right-arm fast bowlers) and eighteen professional footballers (outfield) were monitored with Inertial Measurement Units placed on the anteromedial tibia at 14% of the distal length during a standardised training session. Six competitive overs for cricketers and a warm-up for footballers (hopping, sprinting, cutting) were performed. Peak tibial acceleration, peak positive acceleration (PPA), cumulative load and relative load were calculated as loading variables. Whole-body dual-energy x-ray absorptiometry (DEXA) and tibial peripheral computed tomography (pQCT; 4%, 14%, 38% and 44% of the tibial length) scans were performed on each leg to retrieve bone characteristics. Paired sample t-tests were performed on all variables between legs in each group. Correlations were performed between loading variables and bone characteristics for both groups.
RESULTS: Cricketers showed greater left leg external load variables (peak acceleration (+91 g, +53%) and PPA (+59 g, +38%)) than the right leg ($p<0.001$). The left leg of cricketers showed greater bone characteristics derived from DEXA (leg bone mass (+0.86 kg, +12%), relative leg mass (+0.78, +5%), total BMD (+0.08 g/cm2), leg BMC (+82 g; $p<0.028$)) and pQCT (bone mass (+0.22 kg, +4%), periosteal circumference (38% site; +2.07 mm, +2%) torsional strength (14% site; +214 mm3, +7%; $p<0.035$), and axial strength (14% site; +39 mm3, +3%: 38% site; (+111 mm3, +7%)) than the right leg. There were no differences between legs in football players or correlations between loading variables and bone characteristics in either group.
CONCLUSION: The greater bone characteristics in the left leg during a fast-bowling action may be reflective of the higher left leg loads experienced. No correlations were shown between loading and bone in either group, this likely to be due to factors, such as load frequency, which is known to influence bone accrual [2]. The unilateral aspect of cricket fast bowling causes the planting leg to experience consistently higher loads than the other leg, likely explaining the differences in bone between limbs. The bilateral movement patterns of football likely explain the lack of differences in this group.

#### BONE MINERAL DENSITY IN ELITE MALE AND FEMALE CYCLISTS AT DIFFERENT STAGES OF A PROFESSIONAL CYCLING CAREER

HILKENS, L., WEIJER, V.C.R., VAN SCHIJNDEL, N., BOERBOOM, M., VAN DER BURG, E., KEMPERS, R., PETERS, V., BONS, J., VAN LOON, L.J.C., VAN DIJK, J.W.

*HAN UNIVERSITY OF APPLIED SCIENCES*

INTRODUCTION: Bone health appears to be compromised in many elite male cyclists, while bone health in female, adolescent and retired, elite cyclists remaining largely unexplored. The lack of osteogenic stimuli and low energy availability may predispose elite cyclists to impaired bone health, although clear evidence for this presumption is lacking. In the present study we assessed the prevalence of low bone mineral density (BMD) in male and female elite cyclists at different stages of a professional cycling career, and evaluated potential predictors of low BMD in elite cyclists.
METHODS: In this cross-sectional study, 93 male and female early (n=31), advanced (n=42) and post (n=20) career elite cyclists underwent dual-energy X-ray absorptiometry for the assessment of total and regional bone mineral density and body composition. Proposed markers of low energy availability (IGF-1, T3) and bone metabolism (CTX-I, P1NP, 25-hydroxy vitamin D) were assessed in fasted blood samples. Training history and injury prevalence were assessed by a questionnaire, complemented with the bone-specific physical activity questionnaire (BPAQ). Backward stepwise multiple regression analysis was conducted to explore associations between BMD and its potential predictors in early and advanced career (i.e. active career) cyclists. Data are presented as mean±SD.
RESULTS: With a Z-score of -0.3±0.8, -1.5±1.0, and -1.0±0.9, low BMD (Z-score <1) of the lumbar spine was prevalent in 27, 68, and 50% of the early, advanced and post-career elite male cyclists, respectively. The lumbar spine Z-scores of -0.9±1.0, -1.0±1.0, and 0.2±1.4 in early,

advanced, and post-career elite female cyclists, respectively, indicated low BMD in 55, 45 and 20% of these female subpopulations. Remarkably, 59% of the active career elite cyclists, exceeded the P1NP reference range, while the CTX-I reference range was exceeded by 10% of these cyclists. Furthermore, 25-hydroxy vitamin D levels were inadequate (<50 nmol/L) in 13% of the active career elite cyclists. Statistical analysis revealed that BMI, past fracture incidence, past bone-specific physical activity, 25-hydroxy vitamin D and T3 were associated with lumbar spine BMD Z-score in the final model, $F(5, 49) = 8.314$, $P < 0.001$, adjusted $R2 = .40$. All retained variables significantly contributed ($P < 0.05$) to the final regression model.
CONCLUSION: Low bone mineral density is highly prevalent in elite cyclists, especially in early career females and advanced career males and females. These low BMD values may not fully recover after the professional cycling career, given the high prevalence of low BMD in post-career male cyclists. Exploratory analyses suggest that low BMD is associated with fracture incidence, lack of bone-specific physical activity and low energy availability in active career elite cyclists. Collectively, these findings provide direction for exercise and nutritional strategies to prevent or treat low BMD in elite cyclists.

**TRAINING AND DETRAINING EFFECT AFTER HOME-BASED EXERCISE PROGRAM ADMINISTERED AS MONITORED INDIVIDUAL HOME TRAINING OR SUPERVISED ONLINE GROUP TRAINING**

PINELLI, E., BARONE, G., BENVENUTI, F., ZINNO, R., SANTILLOZZI, F., AUDINO, G., BRAGONZONI, L.
*UNIVERSITY OF BOLOGNA*

INTRODUCTION: Osteoporosis is a disease characterized by low bone mass and is accompanied by increased risk of fracture resulting in pain, decreased physical and social functional capacity and quality of life. Many studies have shown that resistance training can safely increase both muscle strength and bone mass, and improve functional performance. On the contrary, cessation of training has been found to be associated with a loss of muscle mass and strength. The aim of the present study was to determine training and detraining effects on functional status induced by a specific combinate exercise program for 18 months and after a 6-month detraining period in osteoporosis women. The exercise program administered as monitored individual home training (MIHT) or supervised online group training (SOGT).
METHODS: 20 women with postmenopausal osteoporosis (age: 66 ± 5.7 years) were randomly assigned to an MIHT group (n = 10) or an SOGT group (n = 10). All participants completed 18 months of training consisting of two 1-hour sessions per week using small equipment and bodyweights. The SOGT performed the training sessions under the direct supervision of a trainer via a digital platform. The MIHT participants were instructed by the trainer on how to perform each exercise individually at home in one or two preliminary sessions and were also given printed educational material. In addition, the trainer contacted the MIHT participants at preset time intervals to encourage them to exercise regularly and to obtain information on their health status. Every 6-8 weeks, the exercise workload was reviewed and updated. Physical performance measures were administered at baseline, after 12-month and 18-month training, and after the 6-month detraining period. The function was evaluated with the 6-minute walking test (6MWT), sit-and-reach test (SRT), Wand test (WT), while the 30-second chair stand test (30CST) was used to measure muscle strength.
RESULTS: At the18 month follow-up assessment at the end of the exercise program, both MIHT and SOGT groups showed statistically significant improvements in 6MWT ($p \leq 0.05$); in the other tests an improvement was found in both groups but not statistically significant. In both groups, the 6MWT training-induced improvements remained significantly above baseline after the detraining period ($p \leq 0.05$), while WT indicated a statistically significant decrease in shoulder mobility ($p \leq 0.05$). The comparisons between MIHT and SOGT showed no significant differences after during and after the training or detraining periods for all variables ($p > 0.05$).
CONCLUSION: The exercise program administered as MIHT or SOGT improves gait function in women with postmenopausal osteoporosis in both groups. These gains were largely preserved after the cessation of the exercise program with the exception of shoulder mobility. Supervised or monitored online individual training at home can both be practical alternatives to home-based physical activity.

**RELATIVE MUSCLE POWER AS A PREDICTOR OF AREAL AND VOLUMETRIC BONE HEALTH IN OLDER ADULTS WITH LIMITED FUNCTIONAL CAPACITY.**

MORADELL, A., NAVARRETE-VILLANUEVA, D., FERNÁNDEZ-GARCÍA, A.I., GESTEIRO, E., ALCÁZAR, J., HERNÁNDEZ-MOCHOLI, M.A., ARA, I., CASAJUS, J.A., GÓMEZ-CABELLO, A., VICENTE-RODRÍGUEZ, G.
*UNIVERSIDAD DE ZARAGOZA*

INTRODUCTION: Muscle power (MP) declines with age faster than muscle mass and strength (1). It is an important determinant of functional ability, mortality and quality of life. It is known that muscle and bone metabolism are related both mechanical and metabolically. Thus, the objective of this study was to analyse if relative MP, as mechanical proxy, could predict bone volumetric and areal parameters considering it as an important predictor of other age-related physiopathologies such as osteoporosis.
METHODS: 110 older adults (mean age 80.7±5.7 y, 34 males) were evaluated in the framework of the EXERNET-Elder 3.0 study. To be included, all of them needed to score <10 points in the Short Physical Performance Battery which means they have a limited functional capacity. The sit-to stand test of 5 repetitions was used to assess the MP using the equation developed by Alcázar et al. (2). Height and weight data was also measure. Peripheral computed tomography was used to evaluate areal and volumetric cortical and trabecular parameters at 4% and 38% of the tibia length, respectively. Polar stress strain index (SSIp) and bending (Fracture Load) were also recorded. Linear regression analyses were performed to evaluate association between relative MP and bone variables, adjusted by sex and age.
RESULTS: Relative MP was associated to total bone mineral content at 4% (standardized $\beta=0.202$) and 38% of the tibia length (standardized $\beta=0.205$), cortical thickness (standardized $\beta=0.222$), Fracture Load X (standardized $\beta=0.200$) and SSIp (standardized $\beta=0.117$) (all $p<0.05$). No significant associations were found for bone area or bone mineral density variables.
CONCLUSION: Relative MP shows association with volumetric and fracture indexes of bone tissue in older adults with limited functional capacity, which may indicate that exercise-induce MP enhancement strategies could be associated with reduced fracture risk. However, further studies should be needed to determine if it could be a feasible measurement to determine risk of fractures in older adults.

### P1NP AND B-CTX-1 RESPONSES TO A PROLONGED, CONTINUOUS RUNNING BOUT IN HEALTHY ADULT MALES: A SYSTEMATIC REVIEW AND INDIVIDUAL PARTICIPANT DATA META-ANALYSIS

CIVIL, R.1,2, DOLAN, E.3, SWINTON, P.4, SANTOS, L.1, VARLEY, I.1, ATHERTON, P.J.5, ELLIOTT-SALE, K.J.1,6, SALE, C.1,6

*1 NOTTINGHAM TRENT UNIVERSITY, 2 UNIVERSITY OF BIRMINGHAM, 3 UNIVERSIDADE DE SAO PAULO, 4 ROBERT GORDON UNIVERSITY, 5 UNIVERSITY OF NOTTINGHAM, 6 MANCHESTER METROPOLITAN UNIVERSITY*

INTRODUCTION: Circulating biomarkers of bone formation and resorption are widely used in exercise metabolism research, but their responses to exercise are not clear. PURPOSE: To quantify group responses and inter-individual variability of P1NP and β-CTX-1 after prolonged, continuous treadmill running (60-120 min at 65-75% VO2max) in healthy adult males.
METHODS: The study's protocol was designed following PRISMA-IPD guidelines and pre-registered (1). Studies were identified from the list of articles included in a recent systematic review and meta-analysis on this topic (2) in accordance with pre-defined eligibility criteria. Changes in P1NP and β-CTX-1 relative to baseline were measured during, immediately after, and following exercise on an absolute scale (ng·ml-1). Typical hourly and daily variations were estimated from P1NP and β-CTX-1 changes relative to baseline during the hours/days in non-exercise (control) conditions. Responses were quantified based upon estimates of the mean and standard deviation (SD) of the difference, and the proportion of participants exhibiting an increased response. All models were conducted using a Bayesian framework with random intercepts to account for systematic variation across individual studies.
RESULTS: Levels of P1NP increased during and immediately after running, where the proportion of response was estimated to be close to 100 (75% CrI: 99 to 100%). P1NP levels returned to baseline levels within 1 hour and over the next 4 days, showing similar mean differences and SDs to the typical hourly (0.1 ± 7.6 ng·ml-1) and daily (-0.4 ± 5.7 ng·ml-1) variations. Levels of β-CTX-1 decreased during and for 4 hours after running, but these changes were similar to the typical hourly variation (-0.13 ± 0.11 ng·ml-1); there were trivial changes in β-CTX-1 over the next 4 days after running, which were also similar to the typical daily variation (-0.03 ± 0.10 ng·ml-1).
CONCLUSION: Transient increases in P1NP were likely caused by biological aspects (e.g., leakage from connective tissues) rather than being reflective of bone formation. Small decreases in β-CTX-1 were shown in control and running data, suggesting that these changes were due to the marker's circadian rhythm and not the running intervention. Hence, prolonged continuous treadmill running did not elicit bone responses, as determined by P1NP and β-CTX-1, in healthy adult males.

## OP-PN02 High intensity training

### THE UMEÅ HIT STUDY: A RANDOMIZED CONTROLLED TRIAL EVALUATING THE EFFECTS OF SUPRAMAXIMAL HIGH-INTENSITY INTERVAL TRAINING ON AEROBIC CAPACITY AND COGNITIVE FUNCTION IN OLDER ADULTS

SIMONSSON, E., SANDSTRÖM, S., HEDLUND, M., HOLMBERG, H., JOHANSSON, B., LINDELÖF, N., BORAXBEKK, C.J., ROSENDAHL, E.

*FACULTY OF MEDICINE, UMEÅ UNIVERSITY*

INTRODUCTION: Supramaximal High-Intensity Interval Training (HIT) is a time-efficient training method with health benefits potentially superior to traditional aerobic Moderate-Intensity Training (MIT). However, with all-out sprint efforts not being a feasible training method for everyone, this study aimed to examine the effects of controlled and regulated supramaximal HIT intervals adapted for older adults, as compared to MIT, on aerobic capacity, cognitive function, blood pressure, lower-limb muscle strength and subjective quality-of-life.
METHODS: Sixty-eight non-exercising older adults (65-78 years old, 44% males) were randomized to 12 weeks of controlled and regulated supramaximal HIT or MIT. HIT consisted of ten 6-second intervals with a total session time of 20 minutes, and MIT consisted of three 8-minute intervals with a total session time of 40 minutes. The participants exercised twice weekly in groups of 8-10, on stationary bicycles in an ordinary gym setting. Individualized target intensity was watt-controlled, with standardized pedalling cadence and individual adjustment of resistance load (1). Standardized escalation criteria regulated the gradual progression of resistance loading between the sessions. Primary outcomes were aerobic capacity (VO2peak) and global cognitive function (unit weighted composite score of 11 cognitive tests).
RESULTS: Overall attendance at exercise sessions was 88.1% with no difference between the groups. After 12 weeks of exercise regardless of intensity, a significant increase in VO2peak was observed (1.36 ml/kg/min, [0.52, 2.20]), with no difference in change between groups (0.05, [-1.17, 1.25]). No improvement was observed for global cognition (-0.03, [-0.13, 0.06]), nor any difference in change between groups (0.11, [-0.04, 0.24]). Significant between-group differences in change were observed for maximal isometric knee extensor muscle strength (0.07 Nm/kg, [0.003, 0.137]), and for working memory (0.32, [0.01, 0.64]), indicating an advantage for the HIT-group. Overall, regardless of group, there was a significant decrease in systolic blood pressure (-2.21 mmHg, [4.25, 0.18]), and a negative change in episodic memory (0.26, [0.45, 0.08]). No other significant effects were observed.
CONCLUSION: In previously non-exercising older adults, 12 weeks of supramaximal HIT with controlled target intensity appears to have a positive effect on muscle strength in comparison to aerobic moderate-intensity training. Further, our findings suggest that the HIT intervals improve aerobic capacity and blood pressure to a similar extent as MIT, but with only half the amount of training time. The effects of supramaximal HIT on cognitive function appears to be limited, mainly influencing working memory performance.

INTRODUCTION: High-intensity interval training (HIIT) represents an important constituent of athletes' training programs [1]. HIIT prescriptions, characterized by repeated short to long bouts, may be based on individual physiological responses to exercise to keep intensity close to the maximal oxygen uptake (VO2max). Although this approach leads to improvement in functional indexes of endurance performance, some studies failed to report evidence of performance benefits in this population [2]. Data from world-class runners suggest that individualizing training prescriptions according to a given percentage of the target race pace may maximize running performance due to the specific nature of the stimulus [3]. Thus, we compared the effects of the application of the 'physiological-based approach' (PHY) and 'race pace-based approach' (RACE) to HIIT prescriptions on cardiorespiratory adaptations and performance in distance runners.
METHODS: Thirty-one distance runners (20 men and 11 women, age: 38±9 yr, 10-km speed: 14.0±1.4 km/h) were tested before and after 8 weeks of training. The intervention consisted of performing 2 HIIT sessions per week (~25% of the training volume) prescribed using either RACE (n=16) or PHY (n=15). HIIT prescriptions for PHY were the same as those described in [2]. HIIT sessions in RACE consisted of bouts of one km at 110% of the 10-km race pace, interspersed by 300-m recovery distances to be covered in 2 min. The average intensity and distance of the intervals and recovery phases were comparable between PHY and RACE. VO2max and peak treadmill running speed (Vpeak) were determined through an incremental treadmill test, followed by a verification test, whereas 10-km performance was tested on a 400-m track.
RESULTS: VO2max improved significantly in PHY (+2.9 mL/kg/min, p≤.001, 95% confidence interval [CI]: +1.6 to +4.2) and decreased in RACE (–1.9 mL/kg/min, p=.009, 95%CI: –3.3 to –0.6), with a statistical difference of 4.8 mL/kg/min (p≤.001, 95%CI: 3.3 to ∞) between the groups. Vpeak improved significantly in PHY (+0.4 km/h, p≤.001, 95%CI: +0.2 to +0.6) with a statistical difference of 0.5 km/h (p=.002, 95%CI: 0.2 to ∞) between the groups. 10-km speed improved significantly in RACE (+0.5 km/h, p≤.001, 95%CI: +0.3 to +0.8) with a statistical difference of 0.4 km/h (p=.05, 95%CI: 0.0 to ∞) between the groups.
CONCLUSION: The approach adopted to individualize HIIT prescriptions impacts the type of training response in distance runners, leading to improved cardiorespiratory adaptations when based on physiological parameters and performance when prescribed according to race pace. Coaches should select a specific approach depending on the different goals of the training phase.

**TWO REPEATED INTERVENTIONS OF HIGH-INTENSITY INTERVAL TRAINING INDUCE DIFFERENT FUNCTIONAL AND MOLECULAR ADAPTATIONS OF SKELETAL MUSCLE IN MICE**

PILOTTO, A.M., BROCCA, L., CREA, E., BOTTINELLI, R., PORCELLI, S., PELLEGRINO, M.A.

*UNIVERSITY OF UDINE*

INTRODUCTION: In murine model a first exposure to hypertrophic stimuli, such as testosterone, mechanical loading or resistance exercise, has been shown to lead to faster and larger growth of skeletal muscle when subsequently repeated [1,2,3]. This mechanism, called muscle memory, has been related to the retention of acquired myonuclei or epigenetic modifications [4,5]. Interestingly, greater changes in mitochondrial content and biogenesis were also observed after repeated resistance training interventions [3]. Thereby, even mitochondrial adaptations might be influenced by muscle memory, and it remains to be explored whether repeated endurance training interventions can rely on the same mechanism. The aim of the study was to investigate functional and molecular adaptations of skeletal muscle to two repeated interventions of high-intensity interval training (HIIT) in mice.
METHODS: Twenty-four C57BL/6 adult mice were divided into 4 groups: untrained controls; trained; detrained for 12 wks after training; retrained after detraining. Each HIIT (10 bouts of 2 min separated by 2 min of recovery) intervention lasted 8 wks. Physiological adaptations were compared between initial training (TR) and retraining (RETR) by calculating the difference between controls and trained mice and detrained and retrained mice, respectively. Maximal running velocity (Vmax) was assessed 48 h prior to sacrifice by graded exercise test (GXT). Markers of mitochondrial biogenesis and content, and fusion-fission mitochondrial key factors were analyzed on gastrocnemius muscle by western blot and qPCR.
RESULTS: Vmax increased more in RETR than TR (+10.7 ± 3.3 vs +6.5 ± 1.9 m*min-1, respectively, p<0.001). Mitochondrial biogenesis increased in TR (PGC1α: +19%) but changes were larger in RETR (PGC1α: +72%, p<0.001), being also associated to pAMPK increase (+39%, p<0.05). Mitochondrial content resulted higher in RETR than TR (CS: +49% vs +10%, respectively, p<0.001). Mitochondrial dynamics during TR were characterized by no significant changes in fusion (+9% and +3% for OPA1 and Mfn1, respectively, p>0.05) and an increase in fission (Fis1: +51%, p<0.001) . RETR induced a significant reduction in fusion (-13% and -17% for OPA1 and Mfn1, respectively, p<0.05) and a larger increase in fission compared to TR (Fis1: +96% vs +51%, p<0.001).
CONCLUSION: Endurance performance improved to a greater extent after retraining than training. This functional adaptation was supported by a larger mitochondrial content resulting from a more pronounced mitochondrial biogenesis response after retraining. Interestingly, a shift toward fission rather than fusion was observed after retraining, highlighting a crucial role of detraining for these molecular adaptations. In conclusion, the present study corroborates the existence of muscle memory in response to HIIT endurance training affecting both mitochondrial biogenesis and dynamics.

**BASAL AUTOPHAGY SIGNALLING IS UPREGULATED BY SPRINT INTERVAL TRAINING (SIT) IN HUMAN SKELETAL MUSCLE, AN EFFECT POTENTIATED BY APPLICATION OF IMMEDIATE POST-EXERCISE ISCHAEMIA.**

MARTINEZ-CANTON, M., GALVAN-ALVAREZ, V., GALLEGO-SELLES, A., GARCIA-GONZALEZ, E., GELABERT, M., SANTANA, A., MORALES, D., FERNANDEZ-GARCÍA, B., BOUSHEL, R., HALLEN, J., MARTIN, M., CALBET, J.A.L.

INTRODUCTION: Autophagy is a cellular mechanism of self-renewal based on the degradation and recycling of damaged or dysfunctional cellular components, which is necessary for a normal skeletal muscle adaptation to training. Autophagy activation has been associated with high-intensity exercise, hypoxia, and exhaustion. However, little is unknown regarding the molecular signals regulating exercise-induced autophagy in human skeletal muscle. Therefore, this study aimed to determine the role of metabolic stress on the exercise-induced stimulation of autophagy. For this purpose, we used a novel experimental model in which ischaemia is applied to one leg for a few seconds after each repetition of an all-out exercise during a sprint interval training (SIT) program based on Wingate tests. We hypothesized that the application of post-sprint ischaemia during SIT would result in greater stimulation of basal autophagy than SIT alone.
METHODS: Ten physically active subjects were tested before and after a SIT program (4-6 30-s isokinetic sprints with 4 min recovery periods, 6 sessions in total, in 2 weeks). Immediately after each 30-s sprint, the circulation of one leg was instantaneously occluded (300mmHg) for 30-50s, followed by unloaded pedalling for the rest of the recovery interval. The main pre and post-training tests consisted of incremental exercise (IE) to exhaustion followed by 90min rest and 6 bouts of supramaximal exercise to exhaustion at 120%VO2max (SPE) interspaced with 20-s recovery periods, during which the circulation of both legs was completely occluded. Vastus Lateralis m. biopsies were obtained at rest (basal), 90 min after the IE, and immediately after SPE unilaterally at Pre and bilaterally from the leg training with free circulation (FCL) and the leg training with ischaemia (IS) at Post for Western Blotting analysis. Statistical analysis: repeated-measures ANOVA.
RESULTS: SIT induced upregulation of autophagy activating kinases in basal conditions, which was more marked for the leg training with post-exercise ischaemia, particularly pSer253-FOXO3, pSer2448-mTOR, pSer555-ULK1, LAMP2A, and the ratio pSer15/total Beclin1 (IS effect $p<0.01$). These changes did not occur in the FCL. Moreover, the stress kinases response to SPE was attenuated or blunted after SIT, more markedly in the IS trained leg. No significant changes were observed in basal pThr172/total AMPKa, p62 and LC3BII/I ratio.
CONCLUSION: This research shows that the application of post-exercise ischaemia immediately after each bout of sprint training further amplifies the stimulation of autophagy signalling observed in response to SIT by a mechanism involving the chaperone-mediated autophagy and independent of mTOR and FOXOs. Our experimental model indicates that the increased metabolite accumulation and RONS production caused by post-exercise ischaemia may enhance the basal autophagy response. The latter may accelerate the adaptive response to SIT.

INTRODUCTION: The addition of post-exercise blood-flow restriction (BFR) to sprint-interval training (SIT) induces greater homeostatic perturbations that acutely augment gene expression of key signaling transcripts compared with SIT alone [1]. Furthermore, 4-week SIT with BFR in trained individuals has been demonstrated to increase peak oxygen uptake (VO2peak) [1][2]. Despite these findings, the addition of BFR to SIT did not result in skeletal muscle phenotypic changes [2]. High-intensity training interventions are postulated to be a potent stimulus for improving mitochondrial respiration [3], however, this is yet to be investigated following combined SIT and BFR. The aim of this study was to examine the effects of 6-week SIT and BFR on mitochondrial respiration and markers of endurance performance.
METHODS: Trained males (n = 20; age, 25 ± 6 yrs) completed 6-weeks of SIT (2 x per week), performing repeated 30-s maximal sprints interspersed with 4.5-min rest (CON; n = 8) with 2-min BFR applied immediately post-sprint in the experimental group (BFR; n = 12). Prior to and following training, VO2peak and lactate thresholds (LT1 and LT2) were determined, and muscle biopsies were obtained for the determination citrate synthase (CS) activity, as a marker of mitochondrial content, and mitochondrial respiration parameters. ADP-stimulated phosphorylation (P) and uncoupled maximal electron transfer (E) states through mitochondrial complexes I – IV (CI – IV) were measured and corrected to CS activity.
RESULTS: Training increased VO2peak (CON, 52.1 ± 5.2 to 53.1 ± 5.1; BFR, 52.8 ± 4.3 to 54.5 ± 4.9 ml·min-1·kg-1; $p = 0.04$), LT1 (CON, 181 ± 44 to 192 ± 37; BFR, 201 ± 32 to 219 ± 31 watts; $p = 0.03$) and LT2 (CON, 198 ± 27 to 208 ± 20; BFR, 215 ± 39 to 227 ± 34 watts $p = 0.04$). However, BFR did not augment increases compared with CON ($p \geq 0.101$). A group x time interaction effect was observed for CS activity (mol·h-1·kg-1; CON = -4.6 ± 6.3 %, BFR = 12.1 ± 17.5 %, $p = 0.01$) , however, there were no differences between groups ($p \geq 0.27$). CS activity corrected mitochondrial P and E (pmol·s-1·CS-1; $p \leq 0.04$) were increased after training in both conditions. BFR enhanced improvements in CIIE (interaction, $p = 0.05$) and CIVE ($p = 0.01$) compared to CON with improvements in CIIE (2.6 ± 0.8 to 4.2 ± 1.3 pmol·s-1·CS-1; $p = 0.02$) and CIVE (11.9 ± 1.6 to 19.5 ± 2.8 pmol·s-1·CS-1; $p = < 0.001$) following training in BFR, but not in SIT (2.5 ± 0.7 to 2.7 ± 7.3 and 15.3 ± to 14.2 ± 5.7 pmol·s-1·CS-1, respectively; $p \geq 0.54$).
CONCLUSION: BFR augmented improvements in maximal mitochondrial oxidative capacity following 6-weeks of SIT. BFR did not, however, augment improvements in parameters of endurance performance.

## OP-MH01 Ageing

### SUCCESSFUL AGING: THE ASSOCIATION OF BODY COMPOSITION, MUSCULAR FITNESS AND PHYSICAL EXERCISE WITH COGNITION, BRAIN VOLUME, NEURODEGENERATION AND NEUROINFLAMMATION

VINTS, W.

*LITHUANIAN SPORTS UNIVERSITY*

INTRODUCTION: The proportion of physically inactive, old, obese and sarcopenic adults in our society is gradually increasing, and all of these are associated with a risk of cognitive decline. Cognitive disorders like dementias are the fastest increasing cause of disability and death in older adults. Notably, there is a wide variability between persons with respect to the speed of age-related cognitive decline. Therefore, a better understanding of the biological mechanisms that predict successful cognitive aging is of major interest. It was recently proposed that blood biomarkers may be mediating the link between body and brain. Specifically, inflammatory factors released from senescent cells and adipose tissue have detrimental effects, while neurotrophic and anti-inflammatory factors released from healthy muscle -especially during exercise- facilitate neuroplastic processes in the brain, promoting cognitive function.
METHODS: 74 older adults (60-85y) were enrolled in a 12 week leg resistance exercise program directed to improve understanding of blood-brain interactions that may mediate the association of body composition, muscular fitness and physical exercise with cognition, brain volume, and markers of neurodegeneration and neuroinflammation. Analysis was done with bio-impedance analysis, handgrip strength, knee flexion/extension peak torque, 8-Foot Up-and-Go test (8UG), the Montreal Cognitive Assessment (MoCA), brain magnetic resonance imaging (MRI) and brain proton magnetic resonance spectroscopy (1H-MRS). Peripheral inflammation was assessed with serum interleukin-6 and kynurenine, measured with ELISA.
RESULTS: Decreased handgrip strength was associated with elevated peripheral inflammation, markers of neurodegeneration and lower hippocampal gray matter volume. Also, higher body fat percentage was associated with signs of neurodegeneration and decrease of total, hippocampal and medial temporal gray matter volume. Contrary to what we expected, higher skeletal muscle mass index and better performance on the 8UG were also associated with elevated markers of neurodegeneration. No associations were found with MoCA results. Of interest, serum kynurenine was positively associated with signs of neurodegeneration and neuroinflammation. 12 weeks resistance training did not result in significant changes in peripheral inflammatory markers, brain volume or markers of neurodegeneration or neuroinflammation. However, a positive association between knee flexion and extension peak torque gain and neural density increase in the sensorimotor cortex was found.
CONCLUSION: Muscle strength corresponds to neurochemical correlates of brain health in older adults. Of importance, brain health seems to respond to resistance exercise in those showing muscle strength gain. Finally, it is critical to older adults' brain health to maintain a healthy body fat percentage.

### HEALTH-RELATED PHYSICAL PARAMETERS IN ACTIVE AND COMPETITIVE OLDER ADULTS OF DIFFERENT AGE

ZOPPIROLLI, C., MODENA, R., GILLI, F., SKAFIDAS, S., FORNASIERO, A., CALLOVINI, A., SAVOLDELLI, A., BORTOLAN, L., SCHENA, F., PELLEGRINI, B.

*UNIVERSITY OF VERONA*

INTRODUCTION: Previous literature has shown that older adults who exercise regularly have improved physical abilities compared to their sedentary counterparts and reduced age-related decline across ageing. In this study we aimed at investigating the effect of exercising for well-being or competitive purposes on physical and socio-emotional functioning across late adulthood, in healthy older adults.
METHODS: 17 male competitive cross-country skiers (COMP) and 17 active subjects (ACT) matched for age (8 subjects under 70 years old and 9 over, for both the groups) and amount of weekly physical activity (GPAQ questionnaire) were tested for body composition, health-related physical parameters (arm and leg maximal strength, flexibility, balance, reaction time to auditory stimulus, leg and armcycling efficiency) and socio-emotional functioning (perceived quality of life (SF-36 v.2 questionnaire) and sleep (PQSI questionnaire)). A two Way ANOVA test verified the effect of group (COMP vs ACT), age (under vs over 70) and their interaction.
RESULTS: COMP spent more time than ACT performing in vigorous exercise but less time in moderate daily work and active travelling (all $P<0.05$). Weight, BMI, skinfolds and % fat mass were lower in COMP compared to ACT (all $P<0.05$), arm and leg maximal strength higher (all $P<0.05$) while flexibility, reaction times, balance and metabolic efficiency were comparable. Physical and socio-emotional parameters of both groups were better when compared to normative data for sedentary older adults and did not show a worsening trend across age ($p>0.05$). Only balance was better maintained in COMP than in ACT (interaction: $P=0.05$).
CONCLUSION: Systematically exercising for both well-being and competitive purposes at comparable volumes (around 6000 MET/week) seems to improve health-related physical performances and life quality perception, attenuating the age-related natural decline and guaranteeing a successful aging. Exercising to compete provides further advantages as far as concerned body composition, arm and leg muscle strength, maybe due to more vigorous and targeted stimuli (around 1700 MET/week) but its suitability in relation to cardio-vascular heath must be verified by a specialized medical doctor.

### EFFECTIVENESS OF SUPERVISED CENTER-BASED VS. UNSUPERVISED HOME-BASED TRAINING ON MUSCLE POWER AND QUALITY OF LIFE IN OLDER ADULTS: A SYSTEMATIC REVIEW AND META-ANALYSIS OF RANDOMISED CONTROLLED TRIALS

GÓMEZ-REDONDO, P.1,2, VALENZUELA, P.L.3, MORALES, J.S.4, ALEGRE, L.1,2, ARA, I.1,2, MAÑAS, A.1,2

*1. GENUD TOLEDO RESEARCH GROUP, UCLM; 2. CIBERFES, MADRID; 3. PHYSICAL ACTIVITY AND HEALTH LABORATORY, 'IMAS12', PAHERG, MADRID; 4. MOVE-IT RESEARCH GROUP, UNIVERSITY OF CADIZ*

INTRODUCTION: Physical exercise is an effective tool for reducing the detrimental effects of aging. However, some older adults do not have access to a gym nor a center to perform exercise under the supervision of a specialist; thus, unsupervised home-based programs (UHB) might be a suitable option for this population. Although it has previously been shown that UHB can provide health benefits (1), we still do not know how effective an UHB exercise programme can be compared to one that is supervised.

METHODS: Two researchers systematically searched five databases (PubMed, CINAHL, PsycInfo, SPORTDiscus and Web of Science) up to 12/01/2022. The electronic search was supplemented by a thorough manual review. Randomized controlled trials that compare supervised center-based (SCB) versus UHB in older adults (≥60yrs) were included. The outcomes analysed were health-related quality of life (HRQOL) through different self-reported questionnaires (e.g. EuroQoL 5-D, SF-36, etc.) and lower limb muscle power using the sit-to-stand test.
RESULTS: A total of 8,068 articles were found. Finally, 16 studies were included in the final synthesis (N= 1,812; mean age 71). SCB training significantly improved muscle power measured through the sit-to-stand test (SMD=0.35, 95%CI=0.09-0.60, p=0.007) compared to UHB, with moderate heterogeneity (64.8%) and signs of publication bias (Begg's test p=0.012). Sensitivity analyses confirmed significance when removing each study at a time. No greater effectiveness was found in the HRQOL variable for SCB training compared to training without the supervision of a professional (SMD=0.06, 95%CI=-0.18-0.31, p=0.606), with no heterogeneity (19.5%) nor signs of publication bias (Begg's test p=0.484).
CONCLUSION: Our analyses suggest that SCB training improved measures of muscle power to a greater extent than UHB programs. Nevertheless, no additional benefits for training under the supervision of a professional in a center compared to training performed at home without direct supervision on the HRQOL variable were found. Although more quality evidence is lacking, whenever possible, SCB exercise sessions are recommended, whenever possible, to improve muscle power in older adults.

**COMPARISON OF WALKING EXERCISE ALONE OR TOGETHER WITH RESISTANCE EXERCISE AS HEALTHY AGING PROMOTING INTERVENTION: A PILOT STUDY**

JAMRASI, P.1, LI, X.1, KIM, D.1, AHN, S.1, KANG, Y.1, SUNG, Y.1, SONG, W.1,2

*1 DEPARTMENT OF PHYSICAL EDUCATION, INSTITUTE OF SPORT SCIENCE, SEOUL NATIONAL UNIVERSITY, KOREA; 2 INSTITUTE ON AGING, SEOUL NATIONAL UNIVERSITY, KOREA*

INTRODUCTION: The advancements in life expectancy in Korea have been raised the necessity for proper programs to improve the well-being and longevity of the elderly [1]. There is some evidence that maintaining the recommended physical activity could promote healthy aging [2]. However, there is a controversy over which type of exercise confers a greater functional benefit in the elderly. This study aimed to overcome aging-related disease by comparing two different types of exercise for improvement of muscle function and cognition in the elderly population.
METHODS: A total of 62 healthy elderly aged ≥65 years were randomly assigned to one of the following groups: aerobic(AG), resistance+aerobic(RAG), and control(CG) for a 12-week intervention. AG subjects were instructed to follow the walking exercise program and maintain their weekly goal of total walking steps. RAG subjects participated in strength exercise together with the walking program. And CG subjects performed stretching. Participants' body composition, Mini-Mental State Exam and Stroop test (ST), Physical Performance Battery (SPPB), timed up and go (TUG), maximal aerobic capacity (VO2max), handgrip strength (HGS) and knee strength isokinetic test were measured at baseline and at the end of 12 weeks.
RESULTS: As a result of our 12-week intervention, there was a significant difference between RAG and AG in the total score of SPPB (0.42±0.2, p=0.049). Within-group results showed a decrease in fat mass (p=0.038) and enhancement in congruent stimuli of ST score (p=0.043) which was observed in RAG. The walking program alone also improved both scores of neutral (p=0.033) and congruent (p=0.016) stimulus of ST in AG; however, a decline in HGS (p=0.034) and VO2max (p=0.034) was recorded. Moreover, the performance of CG in both the 5-time sit-to-stand test (p=0.020) and TUG (p=0.001) got worse.
CONCLUSION: Our 12-week walking exercise alone or combined with resistance exercise was effective in improving cognitive function and maintaining physical function of the elderly. However, the longer duration of intervention and larger sample size are required to compare which type of exercise is more beneficial for the elderly to maintain and enhance their physical and mental health.

### OP-AP17 Recovery strategies

**COLD AND HOT WATER IMMERSION IN ELITE YOUTH FOOTBALL PLAYERS: EFFECT ON RECOVERY OF PHYSICAL PERFORMANCE AFTER A SIMULATED GAME**

GUSTAFSSON, J.1, MONTIEL-ROJAS, D.1, EDHOLM, P.1, JOHANSSON, E.1, ROMARE, M.1, FOLKESSON, M.1, VENCKUNAS, T.2, CHAILLOU, T.1, PONSOT, E.1

*1: SCHOOL OF HEALTH SCIENCES, ÖREBRO UNIVERSITY, ÖREBRO, SWEDEN; 2: LITHUANIAN SPORTS UNIVERSITY, KAUNAS, LITHUANIA*

INTRODUCTION: Recovery in competitive team sport such as football is important. Cold Water Immersion (CWI) and Hot Water Immersion (HWI) have become a common practice based on the assumption that they can restore physical performance. While the use of CWI in football is well studied, there are fewer studies on HWI, or studies comparing HWI and CWI. Furthermore, it is important to account for the potential placebo effect in the design of studies assessing recovery. In this study, we investigated the effect of CWI and HWI after a simulated football match (SFM) on the recovery of physical performance in male elite youth football players.
METHODS: Forty male elite youth football players (15-19 years) were included in this study. They were randomized to either CWI (10°C, 10 min), HWI (42°C, 20 min) (immersion up to iliac crest), or placebo (PLA, 6 min, sham laser). The recovery modality was applied 1 h after a 90-min SFM (modified Copenhagen Soccer Test). Physical performance was assessed using the following tests: 20m sprint, submaximal Yoyo Intermittent Recovery Test 1 (until 4 min, i.e. stage 14.1), counter movement jump (CMJ), knee extension maximum isometric voluntary contraction (MIVC), time to exhaustion at 60% of MIVC and MIVC following time to exhaustion. All tests were performed at baseline, immediately after, as well as 21 and 45 h after the SFM.
RESULTS: During the SFM, no significant differences for distance covered, heart rate (HR), rating of perceived exertion (RPE) and blood lactate concentration [lactate] were observed between the three groups. Sprint performance, HR, RPE and [lactate] during the submaximal Yoyo test, as well as CMJ height were affected by time ($p<0.05$), but not by recovery modality. MIVC force was reduced by ~8% after the SFM vs baseline in the three groups ($p<0.05$). At 21 and 45 h after the SFM, MIVC was no longer significantly reduced in CWI (91.7 ± 11.9 and 94.1 ± 9.8% of baseline, respectively) and HWI (96.8 ± 8.9 and 93.8 ± 9.2% of baseline, respectively), while it remained decreased in

PLA (88.2 ± 6.5 and 90.8 ± 9.4% of baseline, respectively, p<0.05). However, no recovery modality effect was observed for MIVC. Time to exhaustion was reduced by ~30% immediately and 21 h after the SFM in all three groups vs baseline (p<0.01). At 45 h after the SFM, time to exhaustion remained reduced in PLA (73.0 ± 19.6% of baseline, p<0.01) and HWI (85.7 ± 19.4% of baseline, p<0.05) but not in CWI (96.3 ± 28.4% of baseline, p=0.95). For time to exhaustion, a main effect of recovery modality was detected (p<0.05), but no specific differences between groups were detected. MIVC following time to exhaustion was neither affected by time nor by recovery modality.
CONCLUSION: CWI and HWI did not improve recovery of sprint, submaximal running as well as jumping performance during a 2-day recovery period following a SFM, while these modalities may positively affect recovery of strength during this period. CWI may also have a beneficial effect on fatigue resistance after 45 h.

**THE EFFECT OF TRANSCUTANEOUS ELECTRICAL NERVE STIMULATION ON THE RECOVERY OF QUADRICEPS FEMORIS FATIGUE IN RECREATIONAL ROWERS**

XINYU, M.1, JIAYU, Z.1, YU, C.1, KAIYUAN, Q.1, ANQI, L.1, ZHIHAI, W.1, MINGMING, Y.1, XIAOWEN, C.1, XIN, Y.1, YINAN, Z., DAN, W.1

*SHANGHAI UNIVERSITY OF SPORT*

INTRODUCTION: Quadriceps muscle contributes significantly to the performance during rowing and is prone to fatigue easily. Transcutaneous electrical nerve stimulation (TENS) can effectively delay the onset of fatigue, and thus might play a role in fatigue recovery after exercises. Therefore, the objective of the study was to investigate the effect of TENS on quadriceps muscle post a rowing ergometer induced fatigue.
METHODS: Twenty-eight recreational rowers were evenly and randomly assigned to experiment (TENS intervention) and control group (placebo TENS intervention). Variables of ratings of perceived exertion (RPE), blood lactate, and peak torque of quadriceps were collected following a brief warm-up and the rowing ergometer induced fatigue program respectively. The rowing ergometer induced fatigue program included 2000m race on the Concept II rowing ergometer(Model D, Concept II Inc., USA). Then the experiment group received a 20-min TENS, and the control group received a 20-minute placebo TENS. One-way repeated measures ANOVA was used for data analysis. Significance was set at $P < 0.05$.
RESULTS: Participants in experiment (RPE: 17.79 ± 1.05, blood lactate: 18.56 ± 3.40 mmol/L) and control group (RPE: 18.50 ± 1.45, blood lactate: 17.82 ± 2.72 mmol/L) were fatigue after the rowing. When compared to control group, peak torque of the right (mean difference = 4.25 ± 0.45, $F = 3.535$, $P = 0.041$, $\eta 2p = 0.153$) and left quadriceps (mean difference = 3.91 ± 0.45 , $F = 4.305$, $P = 0.048$, $\eta 2p = 0.142$) increased, blood lactate decreased (mean difference = 8.73±0.73 , $F = 6.768$, $P = 0.015$, $\eta 2p = 0.207$) significantly in experiment group following TENS intervention. REP decreased from 17.79 ± 1.05 to 9.71±2.19.
CONCLUSION: TENS might be effective in fatigue recovery in quadriceps of recreational rowers. It could be utilized as an assistive strategy for fatigue recovery in recreational rowers.

**AETIOLOGY AND RECOVERY OF NEUROMUSCULAR FUNCTION FROM A PROFESSIONAL SOCCER ACADEMY TRAINING WEEK**

DEELY, C., TALLENT, J., BENNETT, R., WOODHEAD, A., GOODALL, S., THOMAS, K., HOWATSON, G.

*NORTHUMBRIA UNIVERSITY*

INTRODUCTION: We profiled the aetiology and recovery time-course of neuromuscular function in response to a mixed-content, standard training week in professional academy soccer players. We concurrently examined physical performance, cognitive function, and perceptual measures of mood and wellness states to identify a range of simple tests applied practitioners could use in the field as surrogate measures of neuromuscular function.
METHODS: Sixteen professional academy soccer players completed a strenuous training day (pitch and strength sessions), followed by a moderate training day two days later. Pre-, post-, and at 24, 48, and 72 h post-strenuous day, participants completed a range of neuromuscular, physical, perceptual, mood, and cognitive function tests. Maximal voluntary contraction force (MVC) and twitch responses to electrical stimulation (femoral nerve) during isometric knee-extensor contractions and at rest were measured to assess central nervous system (voluntary activation, VA) and muscle contractile (potentiated twitch force, Qtw,pot) function. Fatigue and perceptions of wellness and mood states were assessed via visual analogue and likert scales. Cognitive function was assessed via the Stroop task. Countermovement jump, reactive strength index, and bilateral isometric adductor contraction (adductor squeeze) were assessed to profile the recovery of physical function.
RESULTS: Strenuous training elicited decrements in MVC force post-session (−11%, $P = 0.001$) that remained unresolved at 72 h (−6%, $P = 0.03$). Voluntary activation (motor point stimulation) was reduced immediately post-training only (−4%, $P = 0.03$). No change in muscle contractile function (Qtw,pot) was observed post-training, though was reduced at 24 h (−13%, $P = 0.01$), and had not fully recovered 72 h after (−9%, $P = 0.03$). Perceptions of fatigue, muscle soreness, training difficulty and sleepiness increased post-training, and had recovered by 24 h (sleepiness) and 48 h (fatigue, muscle soreness, training difficulty). Perceived levels of energy and readiness to train were decreased at post-training, before recovering at 24 h (energy levels) and 48 h (readiness to train). Countermovement jump performance, though unchanged immediately post-training, declined at 24 h and took 48 h to recover. RSI decrements persisted at 48 h, before recovering by 72 h. No changes were evident in adductor squeeze measures, mood scores or cognitive function.
CONCLUSION: Elite youth soccer training elicits substantial decrements in neuromuscular function, which are still present 72 h post-strenuous exercise. Though central processes contribute to post-exercise neuromuscular alterations, the magnitude and prolonged presence of impairments in contractile function indicates it is the restitution of muscular function (peripheral mechanisms) that explains recovery from strenuous training in academy soccer players. Collectively the findings could inform training, preparation and recovery activities to maximise longer-term player development and athletic progression at this critical point in their maturation.

**EFFECT OF NAP OPPORTUNITY ON PHYSIOLOGICAL RESPONSES AND SPECIFIC ABILITIES IN ELITE BASKETBALL PLAYERS**

SOUABNI, M., HAMMOUDA, O., SOUABNI, M.J., ROMDHANI, M., DRISS, T.

*UNIVERSITY PARIS NANTERRE*

INTRODUCTION: Sleep disturbances are common among elite athletes on training days, night(s) before and following competitions in elite athletes. It was showed that sleep deprivation deteriorates athletes' physical and cognitive performance, increases muscle damage, im-

pairs the recovery from high-intensity exercise, and is associated with higher injury risk. According Souabni et al. [1], napping is a safe and non-invasive intervention in athletes' schedules. However, studies investigating the effect of napping on physical performance showed inconclusive and contradictory results. This study investigates the effect of 40-min nap opportunity on physiological responses and specific abilities in elite basketball players
METHODS: Each participant of twelve professional male basketball players accomplished randomly two conditions: 40-min nap opportunity (NAP) and control condition (CON). Wellness Hooper index was measured before and after both conditions. At 15:00 h, participants completed the shooting skills test (SST) (10 shots from the free throw line) followed by a 15 min standardized warm-up. Then, defensive (MAT) and offensive (CDT) agility, and upper body strength (MBCP) were tested. Next, participants played a 10min small sided game (SSG) followed by the shooting skills retest. RPE at the end of SST-test, SSG and SST-retest and heart rate (HR) during both nap and control conditions, SST-test, SSG and SST-retest were measured.
RESULTS: Better performance for MAT and CDT was obtained in NAP compared to CON condition ($p \leq 0.02$, $d \geq 0.74$, $\Delta \geq 2.7\%$). MBCP performance was higher in NAP ($p < 0.0005$, $d = 1.67$, $= 5.6\%$). Although no significant difference was reported in test session, SST performance was significantly higher in NAP compared to CON condition in retest session (74.2±12.4% vs. 59.2±11.6%, respectively) ($p = 0.003$, $\Delta = 20.2\%$). HRmean was significantly lower in NAP compared to CON condition during SSG ($p = 0.02$, $\Delta = 6.09\%$). HRpeak was significantly lower in NAP compared to CON condition during SSG ($p = 0.02$, $\Delta = 4.9\%$) and SST-retest ($p = 0.01$, $\Delta = 5.25\%$), however no significant difference was reported during SST-test. RPE score was significantly lower in NAP compared to CON condition for SSG ($p = 0.001$) and SST-retest ($p = 0.003$). Hooper's stress and fatigue score were significantly lower after nap compared to values before nap ($p = 0.009$ and $p = 0.01$, respectively), however no significant difference was reported in CON condition.
CONCLUSION: NAP had a positive effect on physiological response operationalized through lower HR values compared to CON condition. This resulted in lower RPE scores and could explain the improvement of shooting performance in retest session. In conclusion, NAP reduces sleepiness, stress and fatigue and enhances physical outcomes of specific skills in elite basketball players. It is also an effective strategy to overcome the deterioration in shooting performance caused by the fatigue induced during exhaustive gameplay situations.

**EFFECTS OF COMBINED INTERVENTIONS TO OPTIMISE RECOVERY DURING HIGH-INTENSITY EXERCISES IN TRAINED INDIVIDUALS**

BELTRAMI, F., HANSELMANN, L., SPENGLER, C.M.

*ETH ZURICH: EIDGENOSSISCHE TECHNISCHE HOCHSCHULE ZURICH*

INTRODUCTION: Team sports such as ice hockey offer the opportunity of recovery breaks between high-intensity work intervals. Strategies aiming to mitigate fatigue during intermittent physical activity are seldom investigated in combination, although several different mechanisms of action exist, which might be cumulative and therefore beneficial for athletes. This study examined the effects of seven combined recovery interventions (enhanced recovery package, ERP) on exercise capacity during intermittent high-intensity cycling.
METHODS: 16 trained men (age: 24.8 ± 3.4 y; maximal power output: 5.0 ± 0.5 W·kg-1) completed a repeated sprint exercise (RSE) protocol consisting of six 30-s cycling sprints with 3-min breaks between each sprint. The first sprint was always performed at a similar load, while sprints 2-6 were performed with the ergometer in cadence dependent mode (0.075 kg·kg-1). During the breaks, the ERP, Placebo, or Control protocols were applied, all on different days. The ERP condition combined 1) 3-min ice gel packs to the neck; 2,3) 5-s mouth rinsing of a 10% carbohydrate and caffeine (6 mg·kg-1), 4) ingestion of 50 mL of a 6% carbohydrate solution, 5,6) 30 s of all-out hyperventilation while breathing 100% O2 (hyperoxia); and finally, 7) potentiation manoeuvres via performance of 3 half-squats at 75% of one maximal repetition. The placebo intervention masked the interventions except for the ice packs and potentiation manoeuvres. Participants were told they were performing a simplified version with only the known beneficial interventions. Power output, heart rate, blood lactate concentration, rate of perceived exertion and gas exchange were compared between the ERP and Placebo conditions.
RESULTS: Mean power output (W) was significantly higher for the ERP condition compared to Placebo (570 ± 74 W vs. 560 ± 71 W, $t(15) = 4.603$, $P < 0.001$, 95% CI diff = 5 – 14 W, $dz = 1.15$). The rate of power decrement over sprints 2-6 was very similar between trials (ERP -14.2 W per sprint, 95% CI = -21.6 – -6.8 W; Placebo -17.4 W per sprint, 95% CI = -24.7 – -10.2 W per sprint, $P = 0.407$). Mean heart rate was higher (3 ± 4 bpm, $P = 0.012$) for the ERP compared to the Placebo condition, as was breathing frequency (2.4 ± 4.0 breaths·min-1, $P = 0.028$) and respiratory exchange ratio (0.12 ± 0.06, $P < 0.001$). Oxygen uptake was 80 ± 109 mL·min-1 ($P = 0.013$) lower for ERP. No differences were found with regards to the rate of perceived exertion or blood lactate concentration.
CONCLUSION: ERP optimised recovery when applied during the breaks of a high-intensity repeated sprint exercise and shows a small but consistent increase in mean power output. It is possible that the ERP prevented a loss of aerobic efficiency. A top-down approach when tailoring packages for individual athletes might overcome the issue of small improvements that are difficult to detect when strategies are tested in isolation.

## Oral presentations

### OP-AP29 Training and testing: Fatigue

**PERFORMANCE AND FATIGABILITY ACROSS DIFFERENT TRIATHLON RACE DISTANCES: FROM SPRINT TO IRONMAN**

PASTORIO, E., VILLANOVA, S., COLOSIO, M., MAZZOLARI, R., PILOTTO, A., MARCIANO, A., GATTI, M., PAPETTI, G., PORCELLI, S.

*UNIVERSITY OF MILAN*

INTRODUCTION: Triathlon is a unique endurance sport including swimming (S), cycling (C), and running (R) [1]. Classically, triathlon races are classified in Sprint (SP), Olympic (O), Half (H) and Full (F) distances [2]. Previous studies have demonstrated alterations in neuromuscular function after prolonged exercise [3] and a greater muscle contractile properties impairment with increasing exercise duration both in cycling and running [4,5]. Only one previous study investigated fatigue after a long-distance triathlon [6] but, how each discipline can impact neuromuscular function throughout different triathlon distances remains unclear. This study aimed to evaluate and compare the magnitude of neuromuscular function impairments in SP, O, H and F.

METHODS: Forty-two male triathletes (Age:39±9 yrs; VO2peak:54.4±5.6ml·min-1·kg-1) were enrolled in the study. Four triathlon races were selected: SP (n=12, 0.75Km S; 20Km C; 5Km R), O (n=16, 1.5Km S; 40Km C; 10Km R), H (n=11, 1.9Km S; 90Km C; 21.1Km R), and F (n=4, 3.8Km S; 180Km C; 42.2Km R). Performance fatigability was quantified by maximal voluntary isometric contraction (MVIC) force of the knee extensors performed: i) before the race (PRE); ii) during the transition phases after S (T1), iii) after C (T2) and iv) immediately after the end of the race (POST). Race speed was monitored by a GPS system.
RESULTS: Triathletes completed SP, O, H, and F in 77±7min, 158±14min, 400±48min, and 883±96min, respectively. Race speed did not change in S among the races, whereas it was higher in SP and O compared to H and F for both C (33±3 and 34±3Km/h vs 24±3 and 23±3Km/h, respectively; P<.05) and R (13±2 and 12±1Km/h vs 10±1 and 8±1Km/h, respectively; P<.05). MVIC force did not decrease significantly in T1 in any race, whereas it decreased significantly in T2 and POST, resulting at the end -19±9%, -23±9%, -29±15%, and -32±8% from PRE in SP, O, H, and F, respectively (all P<.05). In C, MVIC force loss was greater in SP compared with H (-17±11% and -6±10%, respectively, P<.05). Conversely, in R MVIC force loss was lower in SP than H (3±12% and -17±26%, respectively, P<.05).
CONCLUSION: Triathletes experienced a reversible decline in the ability to produce force which was progressively larger with increasing race distance. Neuromuscular function impairment was primarily affected by cycling in SP and running in H, suggesting an important interplay between exercise intensity and race distance on fatigability in triathlon. The present results will help coaches to select the most appropriate training program in accordance with the target race distance of their athletes.

## A COMPARISON OF THE NEUROMUSCULAR CONSEQUENCES OF EXERCISE WITHIN THE MODERATE AND HEAVY INTENSITY DOMAINS

BROWNSTEIN, C.G.1, SABATER PASTOR, F.1, MIRA, J.1, MURIAS, J.M.2, MILLET, G.Y.1,3

*1UNIV LYON, LIBM, UJM-SAINT-ETIENNE, SAINT-ETIENNE, FRANCE; 2FACULTY OF KINESIOLOGY, UNIVERSITY OF CALGARY, CALGARY, CANADA; 3INSTITUT UNIVERSITAIRE DE FRANCE*

INTRODUCTION: Performance fatigability is substantially greater when exercising in the severe versus heavy intensity domain (1). However, the relevance of the boundary between moderate and heavy intensity exercise, the gas exchange threshold (GET), to performance fatigability is unclear. This study compared alterations in neuromuscular function during work-matched exercise above and below the GET.
METHODS: Sixteen male participants completed work-matched cycling for 90, 110 and 140 min at 110, 90 and 70% of the GET, respectively. Knee extensor isometric maximal voluntary contraction (MVC), high-frequency doublets (Db100), low- to high-frequency doublet ratio (Db10:100), potentiated twitch force (Qtw,pot), voluntary activation (VA), motor evoked potential (MEP) and thoracic motor evoked potential (TMEP) were measured at baseline, 25, 50, 75 and 100% of task-completion. During the initial, baseline visit, and following each constant load bout, ramp-incremental exercise was performed, and peak power output and oxygen uptake ($\dot{V}O_2peak$) were determined.
RESULTS: While impairments in neuromuscular function occurred for all exercise intensities, the reductions in MVC (p=0.008) and Db100 (p=0.029) were up to 1.7-fold greater in response to the 110% GET trial relative to the 90% GET trial, with no difference between the 90% and 70% GET trials (p≥0.175). Voluntary activation and MEP were similarly reduced for all trials, while a reduction in TMEP was only observed for the 110% and 90% GET trials (p≤0.044). Peak power output and $\dot{V}O_2peak$ during ramp-incremental exercise were reduced by 7.0±11.3% and 6.5±9.3%, respectively following the 110% GET trial relative to the baseline ramp (p≤0.015), with no changes following the moderate intensity trials (p≥0.078).
CONCLUSION: When exercising at 70% or 90% GET, no differences were observed in fatigability for a given level of work. However, when the power output was elevated by the same magnitude between 90% and 110% GET, thus transcending the moderate-heavy domain boundary, fatigability was substantially exacerbated. These results indicate that even marginally exceeding the moderate-heavy domain boundary has negative implications for neuromuscular function, with evoked twitch responses to relaxed muscle indicating that the greater fatigability is due to intramuscular mechanisms. Moreover, the lower peak power output found only following the 110% GET trial suggests that prolonged heavy intensity exercise has negative implications for subsequent exercise tolerance.

## CHANGES OF AGONIST AND SYNERGIST MUSCLES ACTIVITY DURING A SUSTAINED SUBMAXIMAL BRAKE-PULLING GESTURE

MARINA, M., TORRADO, P., BOU-GARCÍA, S., BAUDRY, S., DUCHATEAU, J.

*INEFC BARCELONA*

INTRODUCTION: There is a need to consider functional grip tasks in research, ensuring that the setup and ergonomics of instruments are optimal for interpreting fatigue-induced changes on surface electromyography (sEMG) signals accurately. The braking gesture on a motorcycle can be considered as a “power grip” task that require the involvement of both flexor and extensor muscles of the forearm and arm to control finger flexion forces while handling the handlebar in a firm grip while stabilizing the wrist (1)
We aimed to analyze the course of changes in muscle activity of the prime mover and synergist muscles during a sustained a braking action on a motorcycle setup and to investigate the relationship between muscle activity and braking force fluctuation (FF).
METHODS: Thirty-two young adults performed a continuous fatiguing protocol (CFP) at 30% of maximal voluntary contraction (MVC) until failure, on a motorcycle setup that simulated a typical body position when riding a road motorcycle. Moreover, surface electromyography (EMG) was used to analyze root mean square (EMGRMS) values in the flexor digitorum superficialis (FD), flexor carpi radials (FC), extensor digitorum comunis (ED), extensor carpi radials (EC), brachioradialis (BR), biceps brachii (BB), and triceps brachii (TB). Ratios between agonist and antagonist muscles were also calculated for the fingers gesture (RatioFingers: FD/FC), the wrist (RatioWrist: FC/EC) and the elbow [RatioElbow: ((BB+BR)/2)/TB)]. The FF was normalized with the averaged signal of the same periods as a measure of steadiness (2).
All signals were synchronized online by an external analog-to-digital converter (Power 1401; Cambridge Electronics Design -CED-). The offline analysis was done with the Spike2 Software. A multivariate analysis of variance was performed to study the EMGRMS and FF changes across the CFP. The degrees of association and the relations between braking forces, sEMG and time variables were examined by regression analysis. The level of significance was set at 0.05.
RESULTS: The FF and EMGRMS both increased progressively during the CFP, with sharp increments occurring before failure (P<0.001). This was confirmed by a significant correlation between these variables (r = 0.995; P<0.001). At the time limit, the EMGRMS of the FD and FC muscles were comparable to the baseline MVC values (P<0.003). The three flexor/extensor ratios used to measure coactivation levels decreased significantly (P<0.001). The MVC force was still depressed (14±8%) after 10 min of recovery (P<0.001), in spite of the similar EMGRMS values (P>0.516) of the forearm flexors in comparison to pre-fatigue condition.

CONCLUSION: Overall, our results indicate that performance was mainly constrained by fatigue-related mechanisms located at muscle level in the prime movers when exerting a CFP in a natural and ecological setup aimed to reproduce the brake-pulling action on a motorcycle.

### THE SMILE REVOLUTION – A FACIAL ELECTROMYOGRAPHY APPROACH FOR FATIGUE EVALUATION DURING CYCLING AEROBIC EXERCISE TEST

IBRAHIM, R.1, KETKO, I.1,2, SCHEINOWITZ, M.1,3, HANEIN, Y.1

*1 FACULTY OF ENGINEERING, TEL-AVIV UNIVERSITY, ISRAEL; 2 IDF MEDICAL CORPS; 3 FACULTY OF MEDICINE, TEL-AVIV UNIVERSITY, ISRAEL ;*

INTRODUCTION: Recently, a novel, multiarray electrodes sticker was introduced, allowing continuous measurements of facial surface electromyography (sEMG) for long term recordings in freely behaving humans [1]. This sensor has been used for mapping spontaneous and "masked" smiles [2], and to detect facial expressions for emotional affect recordings [3]. Development of a, non-invasive, real-time capability to identify athletes' fatigue during exercise is important for performance enhancement and to avoid over-training and exercise-related injuries. Despite the increasing interest in facial expressions and facial sEMG for fatigue evaluation [4,5], this topic has not been widely studied. The aim of the current study was, therefore, to analyze the facial muscles activity patterns, while focusing on smiles, in response to graded exercise stress test, to exhaustion.
METHODS: 5 young, healthy, and recreationally active participants (3 males), performed an incremental cycling exercise test consisting of 3-minutes stages, below the lactic-acid based threshold, and increasing intensity every 1-min until exhaustion. Facial sEMG sensor, which was applied on the participant's left side of the face, covering the forehead, zygomatic, buccal, nasal, and labial regions by 16 embedded electrodes, was recorded continuously throughout the exercise stress test. Blood lactate and heart rate were documented at each stage. To evaluate the exercise intensity effect on facial expressions, participants were asked, during each stage, to smile spontaneously. The facial sEMG signal's envelope root mean square (eRMS) of the smile-event, recorded from each electrode, was calculated, and then averaged for each stage. The calculated eRMSs were translated into heatmaps and correlated with exercise intensities. Paired T-tests were used to analyze the differences of eRMS values between muscles (spatial variations) and during the exercise (temporal variations).
RESULTS: Average eRMS (obtained from 5 subjects X 16 electrodes each) showed a different stepwise increase with exercise intensity in the frowning muscles (FMs) reaching a maximal value of 2.40±1.14 [μV], versus 1.31±0.42 [μV] for light intensity ($p<0.05$). No significant differences were found between the Zygomatic and Buccal muscles (ZBMs) to exercise. Differences between the FM muscles and the ZBM muscles were only found during high intensity exercise ($p<0.005$).
CONCLUSION: Our data demonstrate that there is a smile signature for different exercise intensities during an incremental aerobic exercise test, in particularly an increased activity of the frowning muscles while smiling close to exhaustion. The data allow us to better understand the spatial and temporal relationships of the facial muscles during aerobic exercise.

### SEX DIFFERENCES IN FATIGABILITY DURING LONG-DISTANCE TRIATHLON RACE

VILLANOVA, S.3,5, COLOSIO, M.1,2,5, PASTORIO, E.2,5, DELLO IACONO, A.3, PILOTTO, A.4, MARCIANO, A.5, GATTI, M., PAPETTI, G., QUAGLIAROTTI, C., ROMAGNOLI, R., PIACENTINI, M.F., EASTON, C., PORCELLI, S.

*1INSTITUTE OF BIOMEDICAL TECHNOLOGIES, NATIONAL RESEARCH COUNCIL, SEGRATE, ITALY; 3INSTITUTE FOR CLINICAL EXERCISE AND HEALTH SCIENCE, THE UNIVERSITY OF THE WEST OF SCOTLAND, GLASGOW, UK*

INTRODUCTION: Human performance during athletic events is in part determined by an acute reduction of force or power in both men (M) and women (W) [1]. Physiological mechanisms responsible for this phenomenon, defined as performance fatigability, can involve inadequate central nervous system activation and/or altered skeletal muscle function, being potentially different between sexes [2]. Several studies demonstrated that W can be less fatigable than M after long-duration cycling [3] and running exercise [4] suggesting a primary role in muscle contractile impairments. Less is known about sex differences in performance fatigability and its determinants when different dynamic tasks are combined. Thus, this study aimed to characterize sex differences in central and peripheral determinants of performance fatigability during a long-distance triathlon.
METHODS: Twenty-two trained triathletes were recruited: 10W (age:41±12ys) and 12M (age:47±6ys). Subjects completed 1.9km of swimming, 90Km of cycling, and 21.1km of running (RACE). Neuromuscular function evaluations were performed before (PRE) and after (POST) the RACE by: i) maximal voluntary isometric contractions (MVIC) of knee extensors; ii) electrically evoked contractions by single (Pt) and doublets stimuli (Db100 and Db10) on a femoral nerve; and iii) countermovement jump (CMJ). The interpolation Twitch Technique was used to quantify the Voluntary activation (VA). The rate of perceived exertion (RPE) was monitored by Borg scale (1-10), speed and pace were obtained from GPS system.
RESULTS: RACE time was longer in W compared to M (7h16±41min; 6h38±43min; P=0.02). RPE was 8±2 for both participants at the end of RACE, with no differences between sexes. At PRE, MVIC torque and CMJ power were lower in W (123.9±38.7N*m and 1902±299W, respectively) compared to M (186.0±28.5N*m and 2674±484W, respectively; all P<0,001). At POST, W showed a smaller MVIC torque loss and CMJ power reduction (-14.4±9.9% and -0.8±7.2%, respectively) compared to M (-29.1±16.1% and -11.6±14.5%; all P<0.05). VA decreased less in W than M (-14.4±10.0% vs -24.9±11.6%; P=0.047) whereas Db100, Db10 and Pt decreased similarly for both sexes.
CONCLUSION: After a long triathlon race, W exhibited a smaller decrease in MVIC torque and CMJ power, suggesting a difference between W and M in performance fatigability. In addition to impaired contractile properties, the loss in torque and power was attributable to changes in central nervous system activation voluntary which differed between sexes. The present results will help coaches in identifying the optimal training patterns for men and women, promoting athletic excellence.

## OP-BM16 Youth and injury risk

### AGING AND RUNNING IMPACT LOADING IN DIFFERENT FOOTWEAR (PRESCHOOLERS VS. YOUNG ADULTS)

PLESEK, J., HAMILL, J., FREEDMAN SILVERNAIL, J., JANDACKA, D.

*UNIVERSITY OF OSTRAVA*

INTRODUCTION: Effects of various footwear on running impact loading was immensely studied adult population. However, there is lack of scientific knowledge about possible differences between different age groups (children, adolescent, adults). Running skill (technique) substantially develops in preschool children and most children achieved mastery level of running before sixth year of their life (1,2). Nevertheless, there is only one recent study which compared biomechanics during shod running between 10 preschoolers (3-6 year) and 10 adults (3). In abovementioned study, there were no differences in running impact loading, although study had several significant limitations, including small sample resulting in very heterogeneous group of preschoolers (from developmental perspective), non-standardized footwear etc. Therefore, this study aimed to compare impact loading among four groups of preschool children (crucial period of running skill development) and one group of young adult people (A) in three footwear conditions (B-barefoot, M-minimalist, SRS-standard running shoes).
METHODS: Sixty healthy participants (32 males/28 females) performed simple running game in three standardized footwear conditions (B-M-SRS). Participant were divided into 5 age groups (3-4-5-6-yr-old children and 20-24-yr-old adults). There were 12 participants in each group. Six recorded running trials for each participant were included into the 3-D biomechanical analysis. A two-way mixed ANOVA (5x3) was performed on vertical instantaneous loading rate (VILR). Consequently, a one-way ANOVA was used for each footwear separately to compare mean values of VILR among age groups followed by post hoc pairwise comparisons.
RESULTS: An interaction was found between age and footwear condition in VILR (P=0.010). Further analysis showed differences among age groups in both type of shoes; in M (3yr= 233, 4yr= 231, 5yr= 196, 6yr= 170 and A= 136 BW/s; P=0.008) and SRS (3yr= 225, 4yr= 220, 5yr= 164, 6yr= 149 and A= 74 BW/s; P=0.001). There were clear descending trends of VILR with increasing age in both shod conditions. No differences were found when B (3yr= 175, 4yr= 184, 5yr= 165, 6yr= 143 and A= 134 BW/s; P=0.254). Pairwise comparisons showed significant differences in M between 3yr-A (P=0.019), 4yr-A (P=0.023); and in SRS between 3yr-6yr (P=0.012), 3yr-A (P=0.001), 4yr-6yr (P=0.023), 4yr-A (P=0.001), 5yr-A (P=0.002) and 6yr-A (P=0.014).
CONCLUSION: Three and four-year-old children should use minimalist and running shoes gradually with cautious, at least during introduction to running on hard surfaces. It is in accordance with previous study (4) which showed that 3 and 4 had lower VILR in barefoot than in shod condition, on the contrary running shoes in the current study significantly reduced VILR in adults. It seems that barefoot running could be safely used in preschool age with relative less loading than during minimalist and standard shod running. 1)Plesek et al., 2021

### HIGH-LEVEL PATELLAR TENDON STRAIN AS RISK FACTOR FOR TENDINOPATHY IN ADOLESCENT ATHLETES – A PROSPECTIVE LONGITUDINAL APPROACH

MERSMANN, F., DOMROES, T., TSAI, M.S., PENTIDIS, N., SCHROLL, A., BOHM, S., ARAMPATZIS, A.

*HUMBOLDT-UNIVERSITÄT ZU BERLIN*

INTRODUCTION: The magnitude of strain applied to a tendon determines both sub-rupture fatigue damage progression and the balance of anabolic-catabolic signaling upon repetitive loading (1). High-levels of patellar tendon strain during maximum isometric muscle contractions have been observed in vivo in adolescent risk groups for tendinopathy (2), yet the direct association with tendon overuse has not been established. Therefore, in the present longitudinal study, we regularly measured in vivo patellar tendon strain in adolescent athletes from sports with a high prevalence of tendinopathy (i. e. handball, basketball and volleyball) and examined the hypothesis that athletes which develop tendon pain show higher levels of tendon strain than healthy athletes prior to becoming symptomatic.
METHODS: In 44 adolescent athletes (12-17 years), patellar tendon mechanical properties were measured by combining ultrasonography and inverse dynamics at four time-points during a competitive season. Fourteen athletes developed clinically relevant tendon pain (≥ 13 points reduction of VISA-P score; SYM), while 23 remained completely asymptomatic (ASYM). Tendon mechanical properties of SYM in the session prior to the development of symptoms were compared to a randomly selected ASYM time-point using Bayesian modelling. Cohens d was calculated to estimate effect sizes.
RESULTS: There was a large effect of group on tendon strain (d = 0.85) with a high probability of increased tendon strain in SYM compared to ASYM (mean difference [MD]: 1.17 %; 95 % credibility interval [CI]: 0.08 %, 2.26 %). While tendon force appeared to be similar in both groups (d = 0.18; MD: 0.30 kN; CI -0.95, 1.54 kN) a small effect on stiffness (d = -0.23) pointed towards slightly lower values in SYM, yet with considerable uncertainty (MD: -0.13 kN; CI: -0.57 kN, 0.32 kN). A subgroup analysis however indicated that tendon force likely increased prior to the development of symptoms in SYM (MD: 0.39 kN, CI: -0.08 kN, 0.87 kN), while remaining constant in ASYM (MD: -0.01 kN; CI -0.24 kN, 0.23 kN).
CONCLUSION: The present prospective study provides novel longitudinal evidence that high levels of tendon strain could be an important risk factor for the development of patellar tendinopathy in adolescent athletes. We suggest that inadequate adaptation of tendon stiffness to increases in muscle strength may occur if adolescent athletes with certain preconditions – e.g. a distorted tissue turnover (3) or reduced mechanosensitivity (4) – are subject to mechanical loading which does not offer effective tendon stimulation.

### EFFECT OF SEX ON MUSCLE-TENDON IMBALANCES AND MICROMORPHOLOGY IN ADOLESCENT ATHLETES – A LONGITUDINAL CONSIDERATION

DOMROES, T., WEIDLICH, K., ARAMPATZIS, A., MERSMANN, F.

*HUMBOLDT-UNIVERSITÄT ZU BERLIN*

INTRODUCTION: In male adolescent athletes, there is a high prevalence of imbalances between muscle strength and tendon stiffness (1) which may lead to tendon structural impairments and an increased risk of tendinopathy (2). As sex-specific hormone concentrations and hormone fluctuations related to the menstrual cycle may affect the adaptation of the muscle-tendon unit (3), it remains unclear if muscle-tendon imbalances are influenced by sex. The purpose of this study was to investigate the sex-specific development of quadriceps femoris muscle strength and patellar tendon stiffness during a competitive season with regard to potential imbalances and tendon micromorphological impairments in adolescent athletes.
METHODS: In 15 female (14.3 ± 0.7 yrs., 168.8 ± 7.7 cm, 63.1 ± 9.8 kg) and 13 male (16.0 ± 0.6 yrs., 186.3 ± 6.9 cm, 80.4 ± 10.3 kg) elite handball players, knee extensor muscle strength, patellar tendon stiffness and peak spatial frequency (PSF) of the proximal part of the tendon (as a measure of micromorphology) were determined at four time points during a competitive season using dynamometry and ultrasonography. A linear mixed model was used to analyze time- and group-dependent developments. The residuals to the model were used as a measure for fluctuations of the investigated parameters.
RESULTS: Males demonstrated significantly greater muscle strength ($p < 0.001$) and patellar tendon stiffness ($p = 0.018$) compared to females with no significant changes of both parameters during the season ($p = 0.346$ and 0.182). Tendon strain during maximum isometric contractions (iMVC) and PSF neither differed between groups ($p = 0.215$ and 0.583) nor changed over time ($p = 0.258$ and 0.558). We found greater fluctuations of muscle strength ($p < 0.001$) in males during the season but no sex-specific differences in the fluctuations of maximum tendon strain, stiffness and PSF ($p = 0.560$, 0.201 and 0.118 respectively). Descriptively, there was a similar frequency of athletes with high-level tendon strain (i.e. > 9%) in both groups (on average 42% in males and 38% in females).
CONCLUSION: Our findings show a similar development in the adaptation of tendon stiffness in relation to muscle strength in the two groups, as the greater muscle strength in boys is accompanied by greater tendon stiffness. Furthermore, sex did not seem to have any specific influence on musculotendinous imbalances in adolescent athletes, but the high frequencies of high-level tendon strain during iMVCs in both groups request the need for specific individual tendon training. The lack of an association between maximum tendon strain and PSF, however, indicates marginal effects on tendon micromorphological impairments in the investigated groups.

### INJURIES AND SPECIFIC MEDICAL SUPPORT IN AUSTRIAN YOUTH ATHLETES – A MIXED-METHODS STUDY

REIF, A.1,2, SCHARHAG, J.1,3

*1 INSTITUTE OF SPORT SCIENCE, UNIVERSITY OF VIENNA, VIENNA, AUSTRIA. 2 LEISTUNGSSPORT AUSTRIA, BRUNN AM GEBIRGE, AUSTRIA. 3 AUSTRIAN INSTITUTE OF SPORTS MEDICINE, VIENNA, AUSTRIA.*

INTRODUCTION: Already in youth competitive sport, high physical and mental demands in children and adolescence have been observed (Baur et al., 2008). Due to a large number of health-related issues adequate physical treatment and medical support is required. The aim of this study was to evaluate sports medical and performance assessment and especially of in young athletes.
METHODS: In this mixed-methods research, qualitative and quantitative methods have been combined. First, qualitative, semi-structured interviews were conducted with young athletes, coaches, medical employees and further supportive staff-members (N = 22). The transcripts of the interviews were then processed using the analysis method of Mayring (2015). Based on these results, an online questionnaire was created and answered by young competitive athletes of different sport disciplines (N = 300; 16.8±1.4 yrs; 47.7% female). The statistical evaluation using unpaired T-Tests was conducted using IBM SPSS (Vers. 27). Significance was accepted at $p<0.05$.
RESULTS: The average of total training time of the subjects was 13.1 (±6.7) hours per week. Athletes desired to have more medical support (61.2%) and sports scientific support (51.3%). Surprisingly, more than 40% of athletes had no resting and stress ECG examination for at least one year. It was shown that significantly more athletes have already suffered from an injury (85.3%) compared to uninjured (14.7%) ($P < 0.001$). The group of uninjured athletes was significantly younger than the group of those who had already suffered from an injury ($P = 0.009$). Most frequently injured body parts were lower extremities (ankle/foot/toes 59.0%; knees 45.3%) and upper extremities (forearm/hand/fingers 51.7%). The most common types of injuries are bruises (69.0%), muscle or ligament strains (58.0%), and inflammations (42.0%).
CONCLUSION: The results show that a large number of young athletes has already been injured and an association between the age and the appearance of injuries has been found. According to young athletes sports medical examinations are required more regularly and have to be standardised for different sports disciplines, in particular for internal and orthopedic examinations. Injury prevention programs which are fitted for the requirements of each sport should be implemented in the training to support young athletes and enable a successful career.

### HOW TO COMMUNICATE SLEEP AS A RISK FACTOR FOR SPORT INJURY AMONG YOUTH ATHLETES: A WAKE-A-THON TO CREATE AWARENESS AND INCREASE UPTAKE OF INJURY PREVENTION PRACTICES.

RICHMOND, S.A., PIKE, I., BABUL, S., JACOB, J., IPSIROGLU, O.

*UNIVERSITY OF TORONTO*

INTRODUCTION: Sport injury is the leading cause of emergency room visits among youth ages 10 – 14 in Canada and among developed countries around the world. Known risk factors such as decreased muscular strength and neuromuscular control are often addressed to reduce the risk of injury in sport; however, less is known about the importance of sleep and sleep deprivation on sport performance and injury risk among young athletes. Literature demonstrates that athletes with less than the recommended sleep per night have an increased risk of a sport-related injury; however, mechanisms to effectively communicate lack of sleep as a risk factor to athletes are lacking. There is a need to not only provide this information to both athletes and practitioners in sport injury prevention, but to have athletes acknowledge for themselves signs of sleep deprivation on performance.

METHODS: An innovative, participatory action initiative (Wake-a-Thon) that used the concept of vigilance and vigilance performance testing as a communication strategy on sleep deprivation and sport injury was co-developed with student athletes and sleep and injury prevention researchers. The Wake-a-Thon included games and activities that athletes used to assess their own vigilance and experience how sleep deprivation impacts performance. Measures included basic cognition such as hand eye coordination, motor skills, logical/critical thinking and memory in various game formats.
RESULTS: Interim results suggest the Wake-a-Thon was successful at increasing student athlete's ability to recognize and communicate signs of sleep deprivation and its effect on their performance, attentiveness and emotional state.
CONCLUSION: Increasing an athlete's ability to recognize signs of sleep deprivation and acknowledge its impact on performance can reduce the risk of sport-related injury. The Wake-a-Thon is an innovative initiative that allows athletes to both quantitatively and qualitatively monitor their vigilance over time and communicate strategies to address their lack of vigilance and its effect on performance.

## OP-AP24 Training and learning

### SKILL-TIME-RELATED TEST FOR BASKETBALL PLAYERS. EVALUATING RELIABILITY, USEFULNESS, VALIDITY AND CORRELATION OF TIME-RELATED TESTING PROTOCOLS

JÒDAR-PORTAS, A.1, LÓPEZ-ROS, V.1,2, PRATS-PUIG, A.1, BELTRAN-GARRIDO, J.V.1,3, MADRUGA-PARERA, M.1,4, ROMERO-RODRÍGUEZ, D.1,4,5, GONZALO-SKOK, O.6, FONT-LLADÓ, R.1

*1. UNIVERSITY SCHOOL OF HEALTH AND SPORT (EUSES); 2. UNIVERSITY OF GIRONA; 3. UNIVERSITY OF JAUME I; 4. FUTBOL CLUB BARCELONA; 5. INTERNATIONAL UNIVERSITY OF CATALONIA; 6. SEVILLA FC*

INTRODUCTION: Change-of-direction speed while bound dribbling appears to be of interest for on-court physical performance in basketball players. Several studies have assessed basketball change-of-direction tests. However, these tests do not consider other basketball-specific skills which are mainly involved in changes of direction during the game. Also, the effect of somatic maturity in change-of-direction speed while dribbling has not been studied yet. The main objectives were (1) to assess the test-retest reliability, usefulness and validity of VcutBk test in basketball players; (2) to analyse correlation of the VcutBk test with other time-related testing protocols and skill-time-related deficit in basketball players, (3) to describe skills-time-related deficits involved in VcutBk in basketball players considering somatic maturity.
METHODS: VcutBk test design was based on the Vcut test protocol (Gonzalo-Skok et al., 2015). Bounce dribbling was added to the execution of the test to assess a specific basketball skill. To examine test-retest reliability. Test reliability was assessed through absolute (typical error of measurement = TEM) and relative (intra-class correlation coefficient = ICC) reliability. In order to analyse correlations between the VcutBk test with other skills-time-related testing protocols, participants also completed 25m linear sprint (Sp) and 25m sprint while bound dribbling (SpBk). Test-derivated scores - dribbling deficit (Dd) = SprintBK – Sprint (Scanlan et al., 2018); change-of-direction deficit (CODd) = Vcut –Sprint (Nimphius, Callaghan, Spiteri, &Lockie, 2016); dribbling deficit with change of direction (DdCOD) = VcutBk – Vcut; change-of-direction deficit with dribbling (CODdD) = VcutBk – SprintBk, were used for the analysis.
RESULTS: Test-retest reliability and usefulness analysis does not show substantial between-trial differences in VcutBk (i. e., ES < 0.2). Related to convergent validity, the relationship between the VcutBk and the Vcut was very large [r (90% CL) = 0.85]. The usefulness is adequate TEM (0.35)0.51) to very large (r> 0.71). The effect size between pre-PHV and post-PHV groups of basketball players shows significant and large effect in the VcutBk (d = 2.04, MD = 2.59 95% CI [1.86, 3.32]). Also, significant main effect when comparing PHV groups was reported in all skill-time-related deficits (p< 0.001) with large effect sizes ($\eta$2p = 0.13 to 0.28).
CONCLUSION: The VcutBk is a reliable, useful and valid test to assess specific skill-time-related mastery in the change of direction during dribbling performance in basketball players. Additionally, VcutBk correlated larger when skills-time-related deficits were shown in a specific and simultaneous skills situation with change-of-direction deficit while bound dribbling. Performance in specific-skills-time-related deficits seems to be sensitive to somatic maturity.

### FORECASTING SOCCER INJURIES BY COMBINING SCREENING, MONITORING AND MACHINE LEARNING

HECKSTEDEN, A.1, SCHMARTZ, G.P.2, EGYPTIEN, Y.1, AUS DER FÜNTEN, K.1, KELLER, A.2, MEYER, T.1

*1 SAARLAND UNIVERSITY, INSTITUTE OF SPORTS AND PREVENTIVE MEDICINE, SAARBRÜCKEN, GERMANY 2 SAARLAND UNIVERSITY, CHAIR FOR CLINICAL BIOINFORMATICS, SAARBRÜCKEN, GERMANY*

INTRODUCTION: INTODUCTION:Acute, exercise related injuries and their negative consequences for player health and team performance are an important issue in football. Identifying players or circumstances associated with an increased risk of injury is fundamental for successful risk management. So far, a considerable number of risk factors have been identified. However, univariable predictive accuracy is low and from the few multivariable prediction models none has been scientifically verified outside the original setting. Of note, time-constant (screening) and volatile (monitoring) risk factors are so far generally considered separately resulting in a restricted set of explanatory variables. Consequently, improvements in predictive accuracy may be expected when screening- and monitoring-data are combined, especially when analysed with current machine learning (ML) techniques able to account for interactions
within a "web of determinants". Expectably, screening parameters will set a personal level for injury risk while monitoring parameters account for short term variations around it.
METHODS: This trial was designed as a prospective observational cohort study aiming to predict non- contact time-loss injuries in male professional soccer on a daily basis. Considering the expectable number of injuries, a panel of 12 explanatory variables (covering basic player characteristics, screening, monitoring and exposure characteristics) had been specified a priori. Injuries were registered according to the Fuller consensus. Gradient boosting was used for data analysis. Respecting the nesting of timepoints within players, cross-validation was performed on the level of players (not datapoints). Upsampling was implemented with the training set to account for the imbalance between days with and without injury occurrence, respectively. Different splits of the original dataset were used to probe the robustness of results.
RESULTS: Data of 88 players from 4 teams (German 3rd and 4th league) could be analysed. 51 non-contact, time-loss injuries could be included in the final analysis. The cross-validated (ROC area under the curve 0.66) and test set performance (ROC area under the curve 0.64) of the
gradient boosted model in forecasting injury occurrence was promising and superior to comparator models without integration of screening features. However, the variation of predictive accuracy and feature importance with different splits of the original dataset reflects the relatively low number of events.

CONCLUSION: It is concluded that injury prediction based on the integration of screening and monitoring data in combination with ML is promising. However, external prospective verification and continued model development with accumulating numbers of injuries are required before application in sports practice may be envisaged.

### METHODS: RESULTS: CONCLUSION: THE DURATION OF THE PREPARATION PHASE IS A PRE-DETERMINANT FACTOR OF BALL PERFORMANCE FOR SUCCESSFUL AND UNSUCCESSFUL FOREHAND STROKES IN TENNIS

BAYRAM, I.1, CERRAH, A.O.2, SOYLU, A.R.3, ERTAN, H.2, GIZZI, L.4

*1 ANADOLU UNIVERSITY, 2 ESKISEHIR TECHNICAL UNIVERSITY, 3 HACETTEPE UNIVERSITY, 4 STUTTGART UNIVERSITY*

INTRODUCTION: Understanding how a player perceives ball trajectory while the ball is approaching from the opponent and adjusting appropriate joint angles based on both visual and auditory information during forehand directly influence the stroke accuracy. The player consequently needs to create appropriate body positions based on the information also coming from muscle and joint receptors in an attempt to make a prediction on the ball's first bounce location. Detailed investigation of different phases and the total time of forehand could assist player skill development and possibly reduce the number of unforced errors within a real match. The purpose of this study was to identify time-based perception-action coupling differences in the phases of accurate and inaccurate forehand drive.
METHODS: 12 male tennis players who play tennis at the club level volunteered for the study. They were equipped with a total of 52 reflective markers and then performed 10 strokes to the balls sent by the ball throwing machine placed on the opposite side of the court. Motion Capture (MoCap) data were recorded with a semi-infrared MoCap System [Qualisys, Sweden] with 500 Hz. Perception-action times of the 4 stroke phases (preparation, backswing, forward swing, follow-through, and total stroke time) based on 5 events (ball release, racket swing star, racket backswing maximum, impact, and end of the stroke) of successful and unsuccessful forehand strokes to the balls coming with a constant speed (72-75 km/h) were evaluated for 4 stroke types (out, net, low, high).
RESULTS: The duration of the preparation phase was 298±44, 311±15, 227±105, 269±4; the duration of the backswing phase was 765±33, 802±8, 941±78, 840±46; the duration of the forward swing phase was 272±20, 279±1, 259±13, 264±13; duration of the follow-through phase were 459±91, 406±40, 363±5, 427±74 and duration of total time were 1794±13, 1798±18, 1790±8, 1801±74 for out, net, low and high strokes, respectively. Normality of the data set was tested via D'Agostino-Pearson and homogeneity of variances was tested via the Levene test. Two-way repeated-measures ANOVA (factors: ball performance vs. phase duration) revealed that despite total stroke times are not statistically different, unsuccessful strokes exhibited significantly ($p < 0.05$) longer delay during the preparation phase than successful shots, indicating this parameter was a determining factor for the stroke accuracy.
CONCLUSION: These findings demonstrate how the perception of the ball and just after action coupling during forehand stroke can influence the accuracy of strokes. The duration of the preparation phase highlights the need for an early start (but not too early) of backswing for a high-performance stroke. Our data shows that experienced trainers' consistent warning ''do not be late to open your racket'' is clearly true but there is an optimum time block.

### AUTONOMY-SUPPORTIVE TEACHING ON LEARN-TO-SWIM IN (SCHOOL)CHILDREN: AN EXPLORATIVE EMPIRICAL STUDY

OHLENDORF, L., STAUB, I., VOGT, T.

*GERMAN SPORT UNIVERSITY COLOGNE*

INTRODUCTION: It is demanding to design swimming lessons in which all children are motivated to participate and, thus, sustainably learn to swim regardless of their prerequisites (e.g. inclusion). The concept of "Autonomy-Supportive Aquatic Education" (ASAE) [1] is based on the Self-Determination Theory [2], linking autonomy support in teaching to a strengthening of intrinsic motivation. This explorative empirical study investigates hypothesised benefits of ASAE on autonomy support and intrinsic motivation.
METHODS: A quasi-experimental approach was used to conduct a study with non-swimmers (n=60; female 43.3%, age 8.6 ± 0.82) in five primary schools' regular swimming lessons. An intervention for five weeks (one lesson per week) compared autonomy-supportive teaching (AST) with instructor-centered teaching (ICT). AST learning objective contents including respective games and tasks were offered to participating children by choice with the teacher taking on an accompanying and moderating role. Whereas in ICT the identical learning objective contents, games, and tasks were instructed by a teacher taking on a guide-instructive role without any choices given to the participating children. Autonomy support [BPNSF scale; 3] and intrinsic motivation [SRQ-A scale; 4] were assessed using standardised questionnaires in each lesson.
RESULTS: Autonomy support and intrinsic motivation positively correlate (r=.345). AST led to an improved perception of autonomy support ($p<.05$; d=.351), while a strongly self-regulated intrinsic motivation revealed no statistical significance (p=.453; d=.104) despite a visible negative trend in ICT.
CONCLUSION: All children were highly and rather intrinsically motivated. AST implemented by the concept of ASAE supports autonomy in learn-to-swim as a promising approach.
With respect to this explorative design, further research will be necessary.
Funding: Prime Minister of North Rhine-Westphalia (8273-2021).

**CAPOEIRA TEACHING-LEARNING PROCESSES IN A SCHOOL IN SOUTHERN BRAZIL**

MARINHO, A., MARTINS, S.E., LUIZ, M.E.T.

*STATE UNIVERSITY OF SANTA CATARINA*

Introduction
Capoeira is a complex cultural manifestation, which involves elements of music, fight, and game. Coming from Afro-Brazilian origins, capoeira was born through black Africans who were brought to be enslaved in Brazil, from the 16th century onwards, as a form of resistance to the oppression and violence suffered. Currently, in Brazil, capoeira is part of the school environment as a subject, a content, or a method, and can be approached in partnership with playfulness. This last one, in its turn, is understood as a spontaneous and creative manifestation, which can be further elaborated for the construction of an alternative educational practice to traditional teaching methods, valuing the child and the culture. Thus, this research aimed to investigate the relationship between capoeira and playfulness in the teaching-learning processes at school.
Methods
The study included 18 students, aged between 6 and 9 years old, from a capoeira project that takes place after school in a public school in a city in Southern Brazil, as well as the teacher of that project. This is a descriptive-exploratory field research with a qualitative approach to the data. The instruments used were participant observations of the classes, semi-structured interviews with the teacher, and focus groups with the children. Data were organized using the N-VIVO 11 software and analyzed using the content analysis technique proposed by Bardin (2016).
Results and Discussion
Two categories of analysis were found: Playfulness experience in capoeira classes and Pedagogical strategies for capoeira classes. The playfulness is manifested in capoeira classes, through feelings of joy and tension, being enhanced by pedagogical strategies that value the character of the game present in capoeira. The feelings of joy and pleasure experienced in the context of capoeira classes and reported by the children were more emphatically observed in the moments of the class when they had more freedom of expression, indicating that these moments favored the playfulness experience. Although the project teacher uses more traditional teaching strategies, such as line formation and technicist repetition, it was also possible to perceive the use of pedagogical strategies that value the free expression of children, as well as the playful aspects that permeate the issue of playing and game.
Conclusion
The results indicate that capoeira has an intrinsic playfulness potential in its game aspect, which can be favored by the pedagogical strategies adopted by the teachers. This fact contributes to significant teaching-learning processes for children, and favors their development, leading them to better understand their own abilities and limits, as well as the cultural and historical aspects that surround them.

## OP-SH07 Mental Health

**MECHANISMS LINKING PHYSICAL ACTIVITY WITH PSYCHIATRIC SYMPTOMS IN YOUTHS: A LONGITUDINAL POPULATION-BASED STUDY**

RODRIGUEZ-AYLLON, M.1, NEUMANN, A.2,3, HOFMAN, A.1, JANSEN, P.W.4,5, VOORTMAN, T.1,6, LUBANS, D.R.7, VERNOOIJ, M.W.1,8, MUETZEL, R.L.4

*ERASMUS MC UNIVERSITY MEDICAL CENTER ROTTERDAM, THE NETHERLANDS*

INTRODUCTION: Participation in physical activity protects against psychiatric symptoms in youths. However, the underlying mechanisms remain underexplored. Lubans et al. suggested a conceptual model which postulates three groups of potential mechanisms (i.e. neurobiological, psychosocial, and behavioral). Few studies have explored whether any of these three mechanisms in isolation mediate the relationship between physical activity and psychiatric symptoms. Nevertheless, an integrated model examining the joint and independent contributions of the proposed mechanisms is lacking, making it difficult to obtain the overall picture.
Aim: To test an integrative model of the mechanisms linking physical activity with psychiatric symptoms in youths.
METHODS: We analyzed data from 4,216 children (6.0±0.4 years at baseline; 50.2% girls) at three-time points (TP) from the Generation R Study (around ages 6, 9, and 13 years). Physical activity included weekly frequency and duration of walking or cycling to/from school, outdoor play, and sports (TP1). Psychiatric symptoms (internalizing and externalizing symptoms) were assessed by the Child Behavior Checklist (TP3). The neurobiological mechanisms included total brain volume, white matter microstructure, and resting-state connectivity assessed using a 3T MRI scanner (TP2). The psychosocial mechanisms included self-esteem assessed by the Self-perception Profile, body image by the Development of the Children's Body Image Scale, and friendships by the Friendship Quality Questionnaire (TP2). The behavioral mechanisms included sleep assessed by the Children's Sleep Habits, eating behavior by the Eating Behaviour Questionnaire, and screen time in weekly frequency and duration of watching television and playing video games (TP2). First, we explored the correlation between physical activity (predictor) measures and psychiatric symptoms (outcome). Mediation analyses were performed using the Lavaan package in R when a correlation between predictors and outcomes exists ($p<0.05$). Baseline data of the outcome, parents´ education level, children's gender, ethnicity, age, body mass index, and intelligence quotient were modeled as potential confounders.
Results: Sports participation was negatively associated with internalizing problems at the age of 13 ($\beta=-0.025$; $p=0.031$). Only self-esteem (at the age of 9) mediated the relationship between sports participation and internalizing symptoms ($\beta=-0.009$; $p=0.002$). No other correlations were observed for other measures of physical activity and psychiatric symptoms.
Conclusion: This integrative model provides an overall picture of the mechanisms linking physical activity with psychiatric symptoms in youths. Only one psychosocial mechanism (i.e., self-esteem) mediated the association between sports participation in childhood and internalizing problems in adolescence. These findings may guide the design of future physical activity interventions which aim to improve mental health in youths

### ASSOCIATIONS OF PHYSICAL ACTIVITY AND FITNESS WITH STRESS REACTIVITY IN CHILDREN AGED 10-13 YEARS

MUECKE, M., GERBER, M., LUDYGA, S.

*UNIVERSITY OF BASEL*

INTRODUCTION: High stress reactivity can be detrimental for physiological and psychological health. According to the cross-stressor-adaptation hypothesis, physical activity has health-beneficial effects on psychosocial stress reactivity. However, studies investigating such effects in children are scarce. Therefore, our ongoing study (data collection continues until April 2022) aims to investigate the association of physical activity and aerobic fitness with physiological and psychological stress reactivity in children.
METHODS: Sixty healthy, right handed children aged 10-13 years (34 male, 26 female) were recruited from schools and through distribution of flyers in public places (target sample of the study N=108). On two different lab appointments, the Trier Social Stress Test for Children (TSST-C) and a non-stressful control condition were performed. Appointments were scheduled in randomized order. Before and after both conditions, salivary cortisol (samples directly before and 0 min, 15 min and 30 min after the stressor) and state anxiety (8-item questionnaire based on the state scale of the State-Trait Anxiety Inventory) were measured representing physiological and psychological stress, respectively. For cortisol analysis, the area under the response curve was calculated. Psychological stress was analyzed using a pre-post-stressor comparison. Actigraphs worn over the course of 7 days were used to quantify moderate-to-vigorous physical activity (MVPA), and aerobic fitness was measured using a submaximal bicycle ergometer test (PWC170).
RESULTS: A median split was performed on MVPA and fitness, respectively, and separate analyses of variance were performed. For both cortisol ($F(1, 49) = 8.45$, $p = .005$, $\eta p2 = 0.147$) and state anxiety ($F(1, 55) = 46.81$, $p < .001$, $\eta p2 = 0.460$), a significant main effect of condition was found. Significant interactions condition × MVPA indicated lower physiological and psychological stress reactivity in more physically active participants (cortisol: $F(1, 47) = 4.08$, $p = .049$, $\eta p2 = 0.080$) and anxiety: $F(1, 53) = 4.43$, $p = .040$, $\eta p2 = 0.077$)), while interactions condition × fitness were not significant for both cortisol ($F(1, 48) = 3.04$, $p = .088$, $\eta p2 = 0.060$) and anxiety ($F(1, 47) = 0.16$, $p = .695$, $\eta p2 = 0.003$)).
Discussion/CONCLUSION: Preliminary results of our ongoing study indicate health-beneficial associations of higher levels of MVPA with physiological and psychological stress reactivity. For aerobic fitness, neither beneficial nor detrimental effects on stress reactivity were observed. Further longitudinal and intervention studies are necessary to confirm potential causal relationships.

### INDEPENDENT AND COMBINED ASSOCIATIONS OF DOMAIN-BASED PHYSICAL ACTIVITY AND ULTRA-PROCESSED FOOD CONSUMPTION WITH ELEVATED DEPRESSIVE SYMPTOMS: A CROSS-SECTIONAL STUDY OF THE NUTRINET-BRASIL COHORT

WERNECK, A.O., COSTA, C.S., MONTEIRO, C.A.

*UNIVERSIDADE DE SÃO PAULO*

INTRODUCTION: Although physical activity (PA) is a recognized protective factor for depression, gaps still exist regarding the association between the different domains of PA and depression. In addition, the consumption of ultra-processed foods (UPF) can also be associated with depression by similar mechanisms to those of PA. However, how the consumption of UPF could affect the association between PA practice in different domains and depression is unknown.
METHODS: We used data from the NutriNet-Brasil cohort study, a web-based prospective cohort study, for a cross-sectional analysis including 25,501 adults (19,969 women), with a mean age of 43.3 (SD:12.9) years, who provided information on both outcome and exposure at the baseline. Depressive symptoms were assessed using the Patient Health Questionnaire-2. Domain-based PA (i.e., leisure-time, transportation, and occupational) was assessed through the Global Physical Activity Questionnaire. We used the highest tertile of each PA domain (gender-specific) as the cutoff point. Consumption of UPF was assessed using a validated short questionnaire containing 23 UPF subgroups, based on the Nova classification, during three non-consecutive days. The Nova-UPF score is a simple sum of the subgroups consumed in the previous day. We divided the score into quintiles. Gender, age, education, ethnicity, living status, month of the questionnaire completion, and consumption of fruits, vegetables, legumes, whole grains, and nuts were used as covariates. Poisson regression models were used for the association analyzes, reporting prevalence ratio (PR) and 95% confidence interval (CI). Multiplicative interaction was tested including interaction terms in the models, while additive interaction was tested through the estimation of relative excess risk due to interaction and attributable proportion.
RESULTS: In the independent models, leisure-time PA (PR: 0.74; 95%CI: 0.71-0.78) and transportation PA (0.94; 0.90-0.98), but not occupational PA (0.97; 0.92-1.03), were associated with a lower prevalence of elevated depressive symptoms. UPF consumption (reference: Q1 = Q2: 1.17; 1.09-1.26, Q3: 1.24; 1.16-1.33, Q4: 1.25; 1.16-1.34, Q5: 1.37; 1.28; 1.47) was associated with higher prevalence of elevated depressive symptoms. There were no multiplicative or additive interactions between domain-based PA and UPF consumption in the association with elevated depressive symptoms.
CONCLUSION: The association between PA and elevated depressive symptoms is domain-dependent, with leisure-time and transportation domains acting as protective factors, while a higher UPF consumption was associated with higher elevated depressive symptoms. However, the associations of domain-based PA and UPF consumption with elevated depressive symptoms were independent. Our findings highlight the need for interventions targeting increasing leisure-time and transportation PA as well as reducing UPF consumption.

### A PSYCHOLOGICAL STRESS ASSESSMENT MODEL BASED ON PHYSIOLOGICAL SIGNALS IN A VIRTUAL REALITY ENVIRONMENT

HUANG, Y.H., SUN, L.X., TAO, K.

*BEIJING SPORT UNIVERSITY*

A psychological stress assessment model based on physiological signals in a virtual reality environment
Yuhan Huang1, Lixin Sun1, Kuan Tao1
1 AI Sports Engineering Lab, School of Sports Engineering, Beijing Sport University
INTRODUCTION: With the development of virtual reality (VR) technology, virtual reality exposure therapy (VRET) offers a great opportunity to explore stress disorder recognition and treatment [1],[2]. With integrated sensors, VRET could acquire users' physiological data under specified stress. Physiological signals exhibit unique characteristics during stress, hence the extraction of features and classification of stress levels from signals are gaining enormous popularity and importance currently. Therefore, the aim of this study was to create a psychological stress assessment model based on physiological signals using the machine learning algorithm, which is adaptable to different stress conditions provided by VR.

METHODS: 57 adults (20.9±1.9 yrs) volunteered to participate in this study after signing informed consent forms. Participants were asked to first take the Short State Anxiety Inventory（SSAI）to assess benchmark stress states before putting on a heart rate belt, EDA (electro-dermal activity) wrist band and a VR head-mounted display. Then they logged into the self-developed VR stress training system, which comprises of three stressful scenes with two stress modes and sit peacefully in a chair for 3 min, during which benchmark values of EDA, heart rate and eye-blink rate were recorded. Participants then entered the three VR scenes in a random order and complete the SSAI immediately after the experience of each mode.
The physiological dataset was divided into training and validation sets (sample size ratio 8:2) respectively, and stress levels were labeled as "no stress"（1-2）, "low stress"（2-3） and "high stress"（>3） based on the score intervals from SSAI. Moreover, the statistics of EDA, heart rate, and eye-blink rate per participant were calculated as the feature vector to feed into the machine learning models.
RESULTS: Rest-state values were significantly lower than those in stress modes. Average heart rate and EDA were higher in the high-stress mode than the low-stress mode. As for the self-reported stress ratings, results showed that all three VR scenes produced a higher stress level. In addition, mean, median, standard deviation, maxima and minima of EDA, heart rate and maxima of eye-blink rate were used as an eleven-element feature vector to feed into the SVM, LR, RF, kNN, XGBoost and bagging supervised learning algorithms. The performance metrics of bagging algorithm achieved the highest scores on accuracy (0.742), F1-score (0.709) and recall (0.774).
CONCLUSION: This study revealed the relationship between physiological data and self-reported stress ratings and the psychological stress assessment model adopted the bagging ensemble learning algorithm for the best classification results, which motivates the further investigations of stress disorder recognition and treatment.

## OP-AP28 Tactical analysis

### ON ROUTE TO THE OLYMPIC PODIUM: A COMPARATIVE NEW ZEALAND YOUTH RUGBY SEVENS MATCH ANALYSIS

WINTERSHOVEN, K., BEAVEN, C.M., GILL, N.D., MCMASTER, D.T.

*UNIVERSITY OF WAIKATO - ADAMS CENTRE FOR HIGH PERFORMANCE*

INTRODUCTION: 9.6 million people play rugby in 124 countries and 40 teams will compete in the 2022 Rugby World Cup Sevens. Rugby Sevens (7s) has gained in popularity since its introduction to the 2016 Olympics and the 2018 Youth Olympics saw 11 countries from 6 regional associations compete at 7s. Rugby 7s school youth participation has grown by 185% between 2012 and 2020 in New Zealand. While microsensor technology has been applied to field-based sports, little is known about the physical demands of Youth Rugby 7s.
METHODS: Two New Zealand-based male academy cohorts (U15 n=13, 14.9 ± 0.3 y; U19 n=14, 16.9 ± 1.2 y) were monitored in 7 games during a national Rugby 7s tournament using 10 Hz VX Sport microsensor technology.
RESULTS: Time-motion and heart rate (HR) analysis across squads showed an average work rate (WRavg) of 111.4 ± 11.9 m/min covered at an average speed (Vavg) of 6.7 ± 0.7 km/h and 90.0 ± 0.04% HRmax. Players performed 41.6 ± 7.6 sprints per game with maximal speed (Vmax) averaging 27.6 ± 2.9 km/h, while a peak velocity of 33.7 km/h was measured. The U15 players demonstrated a higher WRavg than U19 (115.7 ± 13.3 vs. 107.8 ± 10.5 m/min [ES= 0.66]) at greater Vavg (6.9 ± 0.8 vs. 6.5 ± 0.6 km/h [ES= 0.66]) ($p<0.01$). Average HR intensity was statistically similar between U15 and U19 (90 ± 3 vs. 89 ± 4% HRmax), yet a small effect was detected for ActivityLoad 3D rate (cumulative X, Y, Z-accelerometry per unit of time: 5.2 ± 1.4 vs. 4.7 ± 0.6 AU, p= 0.06 [ES= 0.42]). No significant differences were found for any high-intensity (HI) running nor HI acceleration/deceleration measures. Both cohorts covered significantly different distances in different relative speed and HR zones (Vzones, HRzones), with most distance covered between 20-50% Vmax and >90% HRmax. Of note, 57.9 ± 24.1% (U15) and 56.8 ± 26.4% (U19) of game time was performed at >90% HRmax. The U15 players covered more distance than U19 in Vzone2 (55.9 ± 11.8 vs. 53.6 ± 9.0 m/min, p= 0.01 [ES= 0.51]) and Vzone3 (25.7 ± 8.8 vs. 22.5 ± 6.9 m/min, p= 0.04 [ES= 0.41]). Pairwise comparisons for distance and time spent in relative HRzones revealed no differences between cohorts.
CONCLUSION: Youth Rugby 7s games are characterised by very high physical demands. Different age cohorts demonstrate overlapping match characteristics with key differences on specific performance markers, relative to the metrics used. Younger players show higher values for speed and distance, which suggests greater loads could be placed on youth as compared to senior players and other cohorts described in the literature. Training approaches, including monitoring and classification of metrics, should be differentiated by target population, individualised, and complemented with age-specific performance targets. Practitioners should be aware that younger 7s players may undergo higher loading relative to older cohorts; thus, there is a need for clear developmental benchmarks.

### RECOGNIZING TEAM TACTICS USING REPRESENTATIVE SEARCH

SCHWENKREIS, F.

*BADEN-WUERTTEMBERG COOPERATIVE STATE UNIVERSITY STUTTGART*

INTRODUCTION: Team tactics are coordinated moves of team members as for example in team handball or soccer. In the past, the application of deep learning methods has been proposed to automatically recognize team tactics based on positional data of players and the ball. The spatiotemporal data of players and the ball can be collected for example using systems from Kinexon or Catapult. However, deep learning approaches need pre-classified data of team tactical moves as so-called training and test data. I.e., a class label must be manually assigned that identifies the class of the tactical move that is contained in the spatiotemporal data. Since deep learning approaches need a lot of training data to derive appropriate models, thousands of video clips need to be classified before the training might be able to produce a model with an acceptable recognition accuracy.
METHODS: Rather than directly training a deep learning network with pre-classified data, the approach presented follows the idea to identify segments of similar tactical moves first. Then, one move of each segment can be used as a representative of the segment it belongs to. Only the representatives are then evaluated by the experts to assign the class label. All moves belonging to the same segment also belong to the same class of tactical moves, thus getting the same label. Hence, the number of video clips that need to be evaluated corresponds to the number of classes of tactical moves rather than to the number of cases needed to train a deep learning network.

RESULTS: A mechanism to extract sets of spatiotemporal data that represent timeframes of interest, i.e., that contain at least potentially a tactical move of a team, will be presented. It will be shown how match information can be used to extract the interesting timeframes. A canonical representation will be introduced to avoid problems with changing origins of the coordinates, changing sides of the field, changing sequences of player coordinates and such. The canonical data is a prerequisite to be able to compare the data of the moves. Based on the spatiotemporal data of 275 attacks, three different clustering approaches have been compared. It has turned out that Hierarchical Clustering is the optimal method in case of offense tactics and Self-Organizing Maps are best to group defense tactics. Using these clustering techniques 22 clusters of offense tactics and 15 clusters of defense tactics have been identified and a representative of each cluster has been extracted to be classified by a professional handball coach.
CONCLUSION: Examples of representatives in terms of tactic videos are presented to visualize the results of the representative search. These "visual" representatives are used to identify the “tactical class” of a segment and thus of all members of the same segment. The key prerequisites for the approach are to define an appropriate distance function for tactical moves as well as a problem specific quality indicator for the extracted clustering models.

### AMPLIFYING SPACE EXPLORATION AS RESULT OF PITCH OBSTACLES DURING ASSOCIATION FOOTBALL LARGE-SIDED GAMES IN SEMI-PROFESSIONAL PLAYERS

COUTINHO, D.1,2,3, FOLGADO, H.4,5, GONÇALVES, B.4,5,6, SANTOS, S.1,2,3, TRAVASSOS, B.6,7, ABADE, E.2,3, SAMPAIO, J.1,2

*1. UTAD, VILA REAL, PORTUGAL; 2. CIDESD, VILA REAL, PORTUGAL; 3. UMAIA, MAIA, PORTO; 4. UNIVERSIDADE DE ÉVORA, ÉVORA, PORTUGAL; 5. CHRC, ÉVORA; 6. PORTUGAL FOOTBALL SCHOOL; 7. UBI, COVILHÃ, PORTUGAL*

INTRODUCTION: Football coaches design training tasks to optimize the team performance while amplifying the players’ ability to support their actions on the relevant information from the environment. To assist them, a wide body of research has explored how different rules affect players’ performance. However, there is scarce information on how adding specific location pitch obstacles may impact players’ behaviour. Thus, this study aimed to explore the effects of adding wall barriers on ball possession behaviours during Gk+9vs9+Gk football large-sided games.
METHODS: Twenty semi-professional players performed 3 LSG consisting of: 1) Control condition (CTR) - without any obstacle; 2) central wall barrier (MID), in which a 6m length wall barrier was placed 20m in front of each target; and 3) side-line wall barrier (SIDE), in which four 3m wall barriers were placed at each half, 4m from each side-line. The LSG was performed on a 70x50m natural turf pitch and consisted of 6-min interspersed with 2-min of passive recovery. Positional data were collected with GPS units while video analysis, allowed to compute multidimensional parameters.
RESULTS: Results revealed lower width in MID than in CTR (Cohen’s d with 95% of confidence intervals: -0.67 [-1.03; -0.3], p = .017), while in turn higher length in MID (-0.85 [-1.12; -0.47], p = .017). Also, there were higher values of length in the MID than the SIDE (-0.49 [-8.56; -0.1], p = .006). In addition, players covered more distance while walking and jogging in the MID than in both the SIDE and CTR (p<.001; and p< .001, respectively). From the technical analysis, players were further from the closest defender when performing a pass in the MID compared to the CTR (018 [0.12; 0.35], p = .041).
CONCLUSION: Overall, coaches may use centre pitch obstacles to emphasize the use of pitch length, while increasing the physical demands. Accordingly, having the obstacles in the middle zone may afford the offensive team to explore diagonal movements towards the opponents’ goal, while limiting the position of the defenders contributing to the highest distance compared to the CTR. Thus, this condition may be helpful to prepare matches against deep defending teams, whereas players usually have higher distances to the closest defenders and may have to explore movements in the longitudinal direction. In contrast, removing it emphasizes the use of the pitch width under lower physical demands. It may be expected that the defensive team close the space in the front of the target, which in turn may guide the offensive team to explore the wide channels. Thus, playing without obstacles can be used in the latter days of the microcycle due to the lower physical demands, while strategically enhancing the team ability to use the pitch width to develop offensive actions. Overall, coaches may vary the location and inclusion of obstacles to induce movement adaptability during ball possessions and enhance the players’ ability to sustain their actions on surrounding information.

### PHYSICAL AND PHYSIOLOGICAL RESPONSES OF SOCCER PLAYERS PERFORMING REPEATED MAXIMAL EFFORTS: THERMO-NEUTRAL CONDITIONS VS SIMULATED CONDITIONS OF THE FIFA WORLD CUP QATAR 2022

CHMURA, P.1, LIU, H.2, KONEFAL, M.1, CHMURA, J.1, ROKITA, A.1, ANDRZEJEWSKI, M.1

*1 WROCLAW UNIVERSITY OF HEALTH AND SPORT SCIENCES, WROCLAW, POLAND; 2 SOUTH CHINA NORMAL UNIVERSITY, GUANGZHOU, CHINA; 3 POZNAN UNIVERSITY OF PHYSICAL EDUCATION, POZNAN, POLAND*

INTRODUCTION: This year, for the first time in history, the FIFA World Cup in Qatar 2022 will be moved to November and December in order to make the climatic conditions more bearable and less thermally troublesome for players (Konefał et al., 2021). According to the calculations of climatologists, despite the fact that during the tournament there will not be extremely high temperatures as in June and July, it can still reach close to, or even exceed 30 C degrees (Chodor et al., 2021). This study aimed to assess the capacity for repeated maximal effort (RME) of soccer players in the thermo-natural conditions (NC) and in simulated conditions for the 2022 FIFA World Cup in Qatar (QSC).
METHODS: Twenty-four semi-professional soccer players participated in the study. The exercise test consisted of ten 6-second maximal efforts on a cycloergometer. A 90-second passive rest interval was used. The test was performed in a Weiss Technik WK-26 climate chamber under two different conditions: 1) thermo-neutral (NC - 20.5°C; 58.7% humidity); 2) simulated for the 2022 World Cup in Qatar (QSC - 28.5 ± 1.92°C; 58.7 ± 8.64% humidity). Power-related, physiological, psychomotor, blood, and electrolytes variables were recorded.
RESULTS: Results showed that, (1) players achieved higher peak power, needed less time to peak power, had higher values of fatigue slope in QSC than in NC (in each repetition of research protocol); (2) comparing to the 1st repetition, subsequent repetitions were observed many significant changes among physiological, blood-related, and electrolyte variables, but their direction was similar in both simulated conditions; (3) an 8°C of temperature difference between the climatic conditions did not significantly affect the physical and physiological responses of the soccer players in RME.
CONCLUSION: The current study provides a better understanding of the effects of different climatic conditions, with particular emphasis wide group of parameters to determine the different reactions of players on RME. Results can be used in the design of training programs to increase players physiological adaptations by simulating soccer-specific conditions of play in terms of anaerobic capacity, in particular

repetitive maximal effort. These findings will be useful during the upcoming FIFA World Cup in Qatar 2022 and in locations where high ambient temperatures are customary.

### "ONE SIZE DOES NOT FIT ALL!" HIGH-SPEED AND SPRINT RUNNING EXPOSURE DURING SIDED-GAMES TRAINING IN SOCCER PLAYERS: A STATE-OF-THE-ART SYSTEMATIC REVIEW AND META-ANALYSIS

DELLO IACONO, A.1, MCLAREN, S.J.2,3, MACPHERSON, T.W.1, BEATO, M.4, WESTON, M.5, UNNITHAN, V.B.1, SHUSHAN, T.6

INTRODUCTION: Sided-games (i.e., small- [SSG], medium- [MSG], large-sided [LSG]) involve tactical, technical, and physical elements and are therefore widely assumed as time efficient means for physical development and match preparation in soccer. The objective of this systematic review and meta-analysis was to: 1) synthesise the existing evidence on high-speed and sprint running exposure induced by sided-games in senior soccer players, 2) establish pooled estimates and intra-individual reliability for high-speed and sprint running exposure, and 3) explore the moderating effects of game format and playing constraints.
METHODS: A literature search was conducted in accordance with the Preferred Reporting Items for Systematic Reviews and Meta-Analyses 2020 guidelines. Four databases (PubMed/MEDLINE, Scopus, SPORTDiscus, Web of Science) were systematically searched up to 25 January 2022. Eligibility criteria were senior soccer players (population); an acute or chronic training programme incorporating sided-games (intervention); game manipulations including number of players, pitch dimension, game orientation (comparator); and high-, very high-speed and sprint relative (m·min-1) running distances and their associated intra-individual reliability (outcome). Pooled estimates for high-speed and sprint running exposure, and their intra-individual reliability, along with the moderating effect of running velocity thresholds, pitch dimension (i.e., area per player), and game orientation (i.e., score or possession), were determined via multilevel mixed effects meta-analysis. Estimate uncertainty is presented as 95% compatibility intervals (CI) with the likely range of relative distances in similar future studies determined via 95% prediction intervals (PI).
RESULTS: A total of 104 and 7 studies met our eligibility criteria for the main and reliability analyses, respectively. The range of relative distances covered across SSG, MSG and LSG was 14.8 m·min-1 (95% CI 12.3 to 17.3) to 17.3 m·min-1 (13.6 to 21) for high-speed running, 2.6 m·min-1 (1.8 to 3.5) to 3.6 m·min-1 (2.3 to 4.9) for very high-speed running, and 0.2 m·min-1 (0.1 to 0.4) to 0.7 m·min-1 (0.5 to 0.9) for sprinting. Across different game formats, 95% PI's showed future exposure for high-speed, very high-speed running, and sprinting to be from 0 m·min-1 to 48 m·min-1, 0 m·min-1 to 14.3 m·min-1, and 0 m·min-1 to 2.6 m·min-1, respectively. High-speed, very high-speed running, and sprinting showed poor reliability with a pooled coefficient of variation of 22.6% with distances being moderated by velocity thresholds, pitch dimension and game orientation.
CONCLUSION: Irrespective of format, sided-games do not replicate the physical demands of soccer match play; therefore, their application as a panacea for physical preparation is discouraged. Large intra-individual variability and the moderating influence of velocity thresholds, area per player and game orientation should be considered for the effective programming of SSG, MSG and LSG training games.

### IS-MH04 High-intensity interval exercise training for the promotion of health in children and adolescents

### HIGH-INTENSITY INTERVAL EXERCISE AS A MODEL FOR IMPROVING HEALTH IN CHILDREN AND ADOLESCENTS: INSIGHTS FROM LABORATORY-BASED STUDIES

BARKER, A.
*UNIVERSITY OF EXETER*

This talk will draw on recent observational data showing that as little as 10 minutes of vigorous intensity physical activity per day may drive improvements in health outcomes in youth. As a vehicle for promoting vigorous intensity physical activity, the talk will provide an overview of controlled laboratory-based studies using both acute and chronic exercise models to examine the efficacy of high-intensity interval exercise (HIIE) to improve health outcomes in children and adolescents. Specifically, a range of health outcomes will be explored, including blood markers (e.g. glucose, insulin, and triglyceride), blood pressure, lipid oxidation and vascular function both in the fasted and post-prandial states. Recent work examining exercise enjoyment and feelings of pleasure/displeasure in youth in response to HIIE will be evaluated, given their importance for future participation in exercise. Where possible, the talk will examine the effects of HIIE in relation to a comparative bout of continuous moderate intensity exercise, and recommendations for the prescription of HIIE will be provided.

### THE ROLE OF SCHOOL-BASED HIGH-INTENSITY INTERVAL EXERCISE FOR IMPROVING HEALTH IN CHILDREN AND ADOLESCENTS

WESTON, K.
*EDINBURGH NAPIER UNIVERSITY*

Over the last decade the application and evaluation of high-intensity interval exercise (HIIE) training within school settings has substantially increased, such that its use as a potential health promotion tool for children and adolescents is now being explored across different continents, climates and school systems. While it appears that school-based HIIE training can improve outcomes such as cardiorespiratory

fitness, its impact on other cardiometabolic risk factors and outcomes such as mental health and habitual physical activity is less clear. Accordingly, this talk will discuss contemporary evidence on the use of school-based HIIE training as a means of improving various health and fitness markers in children and adolescents, and offer perspectives and critical insight on the variety of school-based HIIE training models utilised to date. Important methodological issues associated with conducting HIIE interventions within schools will also be appraised. Specifically, challenges regarding study design, activity modes, exercise intensity monitoring, participant recruitment and scalability will be discussed; thus, bringing together the considerations of paediatric exercise scientists and practitioners. The overarching aim is to provide clear, evidence-based directions for future school-based HIIE training research, and create a platform for international and interdisciplinary collaborations on the topic.

**EFFICACY OF HIGH-INTENSITY INTERVAL EXERCISE TRAINING FOR MANAGEMENT OF PAEDIATRIC OBESITY**

INGUL, C.

*NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY*

Obesity in childhood predisposes individuals to cardiovascular disease and increased risk of premature all-cause mortality. Management of paediatric obesity mostly focus on the importance to prevent further weight gain, but should we focus on the improvement of the cardiometabolic profile through increased cardiorespiratory fitness rather than on weight loss alone? Very few children and adolescents meet current physical activity guidelines and children with obesity are less physically active compared with healthy-weight children. This talk will summarise the current knowledge about the effect of exercise intensity in the form of high-intensity interval exercise (HIIE) training in comparison to traditional moderate-intensity continuous exercise training on cardiometabolic health in paediatric obesity. Specifically, the effect of HIIE training on cardiac structure and function, body composition and cardiorespiratory fitness, their relationships and importance will be discussed. This session will be of relevance to researchers and practitioners interested in exercise training interventions as a lifestyle modification for obese children to prevent increased risk of morbidity and premature mortality as adults.

## Oral presentations

### OP-AP02 Fatigue

**MENTAL FATIGUE REDUCES TIME TO EXHAUSTION IRRESPECTIVELY FROM EXERCISE INTENSITY**

MARCIANO, A.1,2, PAPETTI, G., ARTHUR, R., GATTONI, C., VILLANOVA, S., MARCORA, S.M., EASTON, C., PORCELLI, S.

*1 UNIVERSITY OF THE WEST OF SCOTLAND; 2 UNIVERSITY OF PAVIA*

INTRODUCTION: It has been demonstrated that mental fatigue (MF) impairs exercise tolerance [1,2]. Although some authors have hypothesized that the higher the exercise intensity the lower the impact of MF [3], it is unclear whether physiological determinants of endurance performance at different intensity domains are modulated by ergolytic effects of MF. Thus, we evaluated the effect of MF on time to exhaustion (TTE) during cycling at heavy- and severe-intensity exercise.
METHODS: Twenty-three highly trained triathletes (26±5 yr; 71±6 kg) performed an incremental cycling test to exhaustion immediately followed by a 2-minute all-out test, enabling the detection of the Critical Power (CP) [4]. Each subject underwent four testing sessions on different days, involving either 45-min of intervention followed by TTE tests at heavy (90%CP) or severe (110%CP) intensity. Interventions consisted of a documentary watching (CTRL), used as control task, or a continuous Simon Task (SIM), used to induce MF. The time-course of reaction time (RT) and error-rate (ER) during SIM was monitored. Subjective rating of MF, assessed by VAS scale, and mental workload (MW), evaluated by NASA TLX questionnaire, were collected before exercise. Cardio-respiratory and metabolic responses to exercise were monitored.
RESULTS: Maximal oxygen uptake (V'O2max) and maximal work-rate were 53.5±8.0ml*min-1*kg-1 and 368±65w, respectively. CP was 279±58w. VAS score and MW were significantly higher after SIM than CTRL (VAS: CTRL 8.26±4.4 vs SIM13.2±4.3, $p<0.01$; WL: CTRL 23.3±22.9 vs SIM 74.5±15.4 $p<0,01$). During SIM, RT did not change over time ($p>0.05$) but ER increased significantly ($p<0.01$). TTE at heavy was significantly lower after SIM compared to CTRL (CTRL: 2004±903s; SIM: 1766±907s, $p<0.05$), whereas physiological responses to exercise were not different between conditions. TTE at severe was also significantly lower after SIM (CTRL: 438±270s; SIM: 393±248s, $p<0.05$) but led to a reduced V'O2 and heart rate values. No significant differences in performance loss due to MF between intensity domains were observed (H -9,2±25,7%, S -7,5±24,8%, $p>0,05$).
CONCLUSION: Completion of 45-min cognitive task significantly impaired cognitive function, induced significantly higher ratings of mental fatigue and mental workload, decreasing exercise tolerance to a similar extent in both heavy and severe domains. Thus, performance impairments induced by mental fatigue do not seem to be exercise-intensity dependent. Our results suggest avoiding tasks that may induce MF before activities and competitions irrespectively of their intensity above anaerobic threshold.

**THE INDIVIDUAL RESPONSE TO MENTAL FATIGUE: A SYSTEMATIC REVIEW AND META REGRESSION**

HABAY, J., UYLENBROECK, R., VAN DROOGENBROECK, R., DE WACHTER, J., PROOST, M., TASSIGNON, B., DE PAUW, K., MEEUSEN, R., VAN CUTSEM, J., ROELANDS, B.

*VUB*

INTRODUCTION: Mental fatigue, a psychobiological state that is induced when engaging in prolonged cognitive activity, affects both cognitive as well as physical performance. However, the significance and magnitude of these effects has recently been questioned. One of the underlying reasons could be the interindividual differences that are present in mental fatigue-effects. However, it's not known yet whether these interindividual differences are trait or state-related, or which internal and/or external factors mediate these interindividual differences. The aim of this systematic review and meta-regression was to give an overview of interindividual differences in the effects of mental fatigue on physical performance, and possible internal factors influencing this effect.
METHODS: Pubmed, Web of Science, SPORTDiscus and PsycINFO were searched for studies detailing the effect of mental fatigue on dynamic maximal whole body endurance performance. Studies needed to feature healthy participants with the inclusion of at least one

internal factor in participants' characteristics, and were required to include at least one manipulation check. The Cochrane crossover risk of bias tool was used to assess risk of bias. The meta-analysis and regression itself were conducted in R.
RESULTS: 29 studies were selected for inclusion, with 24 studies eventually added to the overall random-effects meta-analysis (with 34 distinct effects) based on the successful induction of mental fatigue. This meta-analysis showed a small but significant effect of mental fatigue on endurance performance (g = - 0.31, 95% CI [-0.44; -0.17], t = -4.83, p < 0.001). The multiple meta-regression analysis (incorporating 11 effects) showed a significant influence of physical fitness level on mental fatigue-effects (estimate = 0.18, SE = 0.06, t = 2.84, p = 0.0296). However, this effect was only present when incorporated within the model together with sex ratio, mean age and body mass index.
CONCLUSION: The present review confirms findings of the overall literature regarding the mediating influence of physical fitness level on the negative effects of mental fatigue on endurance performance. However, this influence is only apparent when different individual factors, such as sex, are taken into account. Moreover, multiple limitations still undermine these conclusions, from the overall underreporting of different participant characteristics to significant publication bias. An overall experimental study incorporating multiple different internal factors is therefore necessary to draw a definitive conclusion on this subject.

### SUBJECTIVE FEELINGS OF MENTAL FATIGUE DIFFERS BETWEEN COMPETITIVE PHASES IN SEMI-PROFESSIONAL SOCCER

DIAZ-GARCIA, J., RUBIO-MORALES, A., LÓPEZ-GAJARDO, M.A., PONCE-BORDÓN, J.C., GARCÍA-CALVO, T.
*UNIVERSITY OF EXTREMADURA*

Soccer game scenarios imply vigilance, decisions making, emotions or constantly processing information causing mental fatigue in soccer players (Coutts, 2016). Mental fatigue may impair soccer physical and technical-tactical performance (Badin et al., 2016; Coutinho et al., 2017). Therefore, controlling and limiting the presence of mental fatigue may be important for enhancing soccer performance. The present study aimed to check the influence of play a play-offs phase on the mental fatigue reported by semi-professional soccer. 53 players (Mage=24.59 years) for two semi-professional teams participated during the 2020/21 season. Mental fatigue was quantified with a Visual Analogue Scale during four trainings per week (Monday=MD+1, Wednesdey=MD-4, Thursday=MD-3 and Saturday=MD-1), with a competitive match on Sunday. The total duration of the study was 10-weeks (five dates of regular season – five dates of play-offs). A Linear Mixel Model was performed with R-studio, using the competitive phase as independent variable. The results showed that the mental fatigue reported by players was significantly higher during the play-offs phase that during the regular season. The play-offs phase is played by the best teams of a competition whereplayers usually have monetary recompenses by achieve the objectives or possibilities to sign better contracts the next season. Despite we have not the specific data to confirm this, the results suggest that the play-offs phase implies emotional demands that may increase the mental fatigue reported by players. Then, in agreement with Van Cutsem and Marcora (2021) we recommended coaches the possibility to use recovery strategies for mental fatigue during the play-offs phase (specially nearly the match day) and to avoid the presence of mentally fatiguing tasks nearly competitions.

### NO BRAIN, NO GAIN: ATHLETE MENTAL FATIGUE AND RECOVERY IN PRACTICE, WHAT DO WE KNOW AND HOW DO WE MANAGE IT?

RUSSELL, S.1,2, JOHNSTON, R.D.1,3, STANIMIROVIC, R.2, HALSON, S.L.1
*1. AUSTRALIAN CATHOLIC UNIVERSITY 2. AUSTRALIAN INSTITUTE OF SPORT 3. LEEDS BECKETT UNIVERSITY*

INTRODUCTION: INTRODUCTION: Mental fatigue and recovery have recently gained scientific attention in relation to sporting performance. The potential negative effects on physical, technical, tactical, and psychological performance determinants are demonstrated, however research has traditionally been critiqued for a lack of ecological validity. Whilst large scope exists for practitioners to manage mental fatigue and recovery to aid in maximisation of performance, little is understood about current practices used by performance staff in the daily training and competition environment.
METHODS : A mixed methods approach through a cross-sectional survey obtained perceptions from 156 high-performance practitioners working in a performance support, sports science, or sports medicine capacity. The public survey questioned practitioner knowledge and confidence, sources of evidence, perceived impact, assessment and management, role responsibility, and challenges. Descriptive outputs were analysed using RStudio with the R statistical programming language, and Braun & Clark's thematic analysis approach identified patterns in context of theoretical understanding.
RESULTS : More than 97% of respondents believed mental fatigue and recovery impacts training and competition performance. Deliberate inducement of mental fatigue was reported by 44.2%, and 54.5% reported deliberate enhancement of mental recovery. In training and/or competition practices, 38.5% and 23.7% reported assessment of mental fatigue and mental recovery respectively. A low number of respondents reported to be very knowledgeable on mental fatigue (11.5%) or mental recovery (5.1%). The minority reported being largely confident in applying their knowledge of mental fatigue (10.9%) and mental recovery (8.3%) to maximise performance. A multitude of staff were perceived as being responsible for the inducement and management of mental fatigue and recovery. Staff knowledge was the most common barrier to implementing mental fatigue or recovery protocols, followed by athlete buy-in and time-availability. In terms of accessing information, colleagues and published research, were the most common sources, interestingly, asking researchers was the fourth least frequently used source.
CONCLUSION : High-performance practitioners perceive mental fatigue and recovery to impact on training and competition, yet their knowledge, confidence in application and current assessment and management is limited. Researchers should endeavour to undertake research which builds a progressive evidence-base for the practitioner to assess and manage mental fatigue and recovery in athletes. Greater focus on education, and use of translational and behavioural change models to influence applied practice,

whilst targeting frequently used sources of evidence, and responsible practitioner roles, may aid in maximising performance through improved assessment and management of athlete mental fatigue and
recovery.

**METHODS: RESULTS: CONCLUSION: IS THE ACUTE MENTAL FATIGUE CAUSED BY DIFFERENT SPORT TRAININGS SIMILAR?**

RUBIO-MORALES, A., DÍAZ-GARCÍA, J., PONCE-BORDÓN, J.C., LÓPEZ-GAJARDO, M.A., GARCÍA-CALVO, T.

*UNIVERSITY OF EXTREMADURA*

Is the acute mental fatigue caused by different sport trainings similar?
Know the mental fatigue caused by trainings may help staffs to adequate the state of mental fatigue of their players correctly. This study aimed to compare how mentally fatiguing are two different trainings. Twenty-three physically active (Seventeen males: Mage = 24yr; 7 females: Mage = 22,57yr) performed two experimental sessions: (1)Physically fatiguing (PF): 30-minutes of cycleergometer work (at 65-75% of maximum heart rate), (2)Mentally fatiguing (MF): 30-minutes of an incongruent Stroop task. Pre- and post- fatiguing protocol were measured: Electroencephalogram (EEG) signals, subjective mental fatigue using a Visual Analogue Scale, ocular-manual reaction time using a Psychomotor Vigilance Task and cognitive performance with 45-seg of Incongruent Stroop. Furthermore, EEG was measured during the experimental protocols. Results indicated significant increments in the subjective perceptions of mental fatigue after the two tasks, although this increment was significantly different between protocols. Due to the increases in the perceptions of mental fatigue was significantly higher by MF, only MF caused significant impairments in reaction time. With regard EEG signals, the activity of the cerebral cortex – specifically at the pre-frontal area - was significantly higher during MF than PF. These results suggest that the use of PF and MF, should be avoided nearly competitions by the negative consequences that mental fatigue may cause on performance. Findings also showed more light about the brain areas that are more related with mental fatigue in sports.
Keywords: mental fatigue, cognitive fatigue, physical fatigue, sport practitioners, EEG.

## Oral presentations

### OP-PN09 Thermoregulation

**SEX-MEDIATED DIFFERENCES IN CORE TEMPERATURE AND THERMOREGULATORY SWEATING ARE NOT EVIDENT IN CHILDREN EXERCISING IN THE HEAT**

TOPHAM, T.H.1, SMALLCOMBE, J.W.2, CLARK, B.1, BROWN, H.A.1, TELFORD, R.D.1, JAY, O.2, PÉRIARD, J.O.1

*1 THE UNIVERSITY OF CANBERRA, AUSTRALIA; 2 THE UNIVERSITY OF SYDNEY, AUSTRALIA*

INTRODUCTION: Historically, both females and children have been perceived to be thermoregulatory disadvantaged, which may increase their vulnerability to hyperthermia during exercise in the heat. However, previous research comparing thermoregulatory responses to exercise between independent groups (e.g., males/females, adults/children) may have been limited due to a failure to account for differences in body size, which can confound the interpretation of findings. When isolating the effect of an independent variable (i.e., sex, age) on the change in core temperature and thermoregulatory sweating during exercise, work rate should be prescribed to elicit a matched rate of metabolic heat production (Hprod) per unit body mass and body surface area, respectively (1). To our knowledge, no prior studies have investigated whether a sex difference in exercise thermoregulation occurs within children using this methodology. Thus, we aimed to evaluate sex-mediated differences in the change in core temperature and sweating between boys and girls during exercise at a matched Hprod per unit body mass and per body surface area respectively.
METHODS: In two separate trials, 11 boys (mean ± SD: age 14 ± 1 yr; body mass 60.0 ± 9.1 kg; body surface area 1.69 ± 0.15 m2) and 11 girls (age 13 ± 2 yr; body mass 52.6 ± 8.5 kg; body surface area 1.53 ± 0.15 m2) walked for 45 min at a fixed Hprod per unit body mass (8 W·kg-1) and per body surface area (300 W·m-2) in 40°C and 30% relative humidity. Changes in gastro-intestinal temperature and local sweat rate (back and forearm) were measured continuously. Whole-body sweat loss was estimated from pre and post body mass and reported in grams per body surface area (g·m-2).
RESULTS: In the W·kg-1 trial, the change in gastro-intestinal temperature did not differ between boys (1.08 ± 0.40°C) and girls (1.23 ± 0.32°C; P = 0.358). In the W·m-2 trial, end-exercise local sweat rate on the back was not significantly different between the boys (1.24 ± 0.10 mg·cm-2·min-1; n = 9) and girls (1.10 ± 0.24 mg·cm-2·min-1, P = 0.096; n = 11). Similarly, local sweat rate on the forearm did not differ between the boys (0.85 ± 0.25 mg·cm-2·min-1; n = 7) and girls (0.75 ± 0.17 mg·cm-2·min-1, P = 0.340; n = 11). Whole-body sweat loss in the W·m-2 trial was not significantly different between boys (355 ± 47 g·m-2) and girls (334 ± 45 g·m-2; P = 0.315).
CONCLUSION: Our data indicate no significant difference in the core temperature change and time-dependent thermoregulatory sweating responses between boys and girls during exercise at a matched Hprod per unit body mass and per body surface area, respectively. These findings suggest that girls are not thermoregulatory disadvantaged when compared to boys during exercise matched to body size in a hot environment.

**MEASUREMENT OF THERMAL SWEATING AT REST AND STEADY-STATE EXERCISE IN HEALTHY ADULTS: INTER-DAY RELIABILITY AND RELATIONSHIPS WITH COMPONENTS OF PARTITIONAL CALORIMETRY**

PEEL, J.S.1, MCNARRY, M.A.1, HEFFERNAN, S.M.1, NEVOLA, V.R.1,2, KILDUFF, L.P.1,3, WALDRON, M.1,3,4

*1SWANSEA UNIVERSITY, UK.; 2DEFENCE SCIENCE AND TECHNOLOGY LABORATORY , UK.; 3WELSH INSTITUTE OF PERFORMANCE SCIENCE, SWANSEA UNIVERSITY, UK.; 4UNIVERSITY OF THE SUNSHINE COAST, AUSTRALIA.*

INTRODUCTION: Valid and reliable measurements of the thermal sweating response to exercise are important for accurate estimations of evaporative cooling and detection of heat acclimation. Indeed, changes in measures of thermal sweating, such as local sweat rate (LSR; ~30%) and sweat gland activation (SGA; ~27.9%) have been reported following heat acclimation [1]. Therefore, these measures, and their determining factors (metabolic heat production [Hprod] and evaporative requirement for heat balance [Ereq]), are fundamental to the

investigation of human thermoregulation. The purpose of the current study was to: i) evaluate the inter-day reliability of various sweat measurements, including the absorbent patch and modified iodine-paper techniques, at rest and a range of exercise intensities; ii) evaluate the effect of iodine-paper size and the method of establishing SGA (sweat gland counting or surface area covered) on reliability; iii) determine the relationships between all measurement techniques and Hprod or Ereq.
METHODS: Twelve healthy, non-heat acclimated males and females (29 ± 6 years, 175.0 ± 7.6 cm, 76.5 ± 11.6 kg) participated in an inter-day test-retest reliability trial. Participants were assessed for whole-body sweat loss (WBSL), LSR (absorbent patch technique) and SGA (modified iodine-paper technique) during rest and 30-min periods of sub-maximal cycling at Hprod ~200, ~250 and ~300 W/m2 while exposed to ambient heat (37.6 ± 0.4°C and 27.0 ± 5.9% relative humidity). Heat balance parameters, including Hprod and Ereq, were estimated for each exercise period via partitional calorimetry. Variations in iodine-paper size (1 cm2 to 9 cm2) were used to quantify SGA by counting sweat glands or determining surface area covered. The 'optimal' area of SGA was also determined within the 9 cm2 area, as the highest density of recruited glands.
RESULTS: Hprod and Ereq were positively related with all sweating response measures ($r = 0.53$ to 0.84; $P < 0.05$), with the 9 cm2 and 6 cm2 iodine-paper sizes observed to have the strongest correlation for SGA ($r = 0.66$ to 0.84). Inter-day reliability was greater for all measures during exercise (CV% = 7.8 to 30.0) compared to rest (CV% = 33.5 to 77.9). The modified iodine-paper technique was most reliable at 9 cm2 (CV% = 15.9) or when the 1 cm2 (CV% = 17.6) and 3 cm2 (CV% = 15.5) optimal area of SGA was determined, particularly when measuring the sweat gland number as opposed to surface area covered.
CONCLUSION: WBSL, LSR and SGA measurement techniques are sufficiently reliable during exercise - but not at rest - to detect the changes in thermal sweating typically reported. We recommend using 9 cm2 iodine-paper sizes or establishing the 1 cm2 or 3 cm2 optimal area using either sweat gland counting or surface area covered to determine SGA.

**CARDIOVASCULAR RESPONSES TO ORTHOSTASIS DURING A SIMULATED 3-DAY HEATWAVE**

FISHER, J.T., CIUHA, U., IOANNOU, L.G., SIMPSON, L.L., POSSNIG, C., LAWLEY, J., MEKJAVIC, I.B.
*INSTITUT JOZEF STEFAN*

INTRODUCTION: Global warming has caused an increase in the frequency, duration, and intensity of summer heatwaves (HW). Prolonged exposure to hot environments caused by these heatwaves, and orthostasis, may cause conflicting demands of thermoregulation and blood pressure regulation on the vasomotor system, potentially contributing to cardiovascular complications and heat strain. The type of heat strain produced may have severe impacts on athletes in competition, as well as workers in industry. The study assessed cardiovascular and skin blood flow (SkBF) responses to orthostasis before, and during a 3-day simulated HW.
METHODS: Seven male participants were confined to the Planica PlanHab Facility (Rateče-Planica, Slovenia) where they maintained a standard work/rest schedule for nine consecutive days split into 3-day segments; thermoneutral pre-HW (25.4°C), simulated HW (35.4°C), thermoneutral post-HW (25.4°C). Gastrointestinal (Tgi) and skin (Tsk) temperatures, cardiovascular responses, and SkBF were monitored during a 10-minute supine rest period and 10-minute 60° head-up tilt (HUT) period. SkBF, indexed using proximal-distal skin temperature gradient (ΔTskP-D), was also validated using Laser-Doppler Flowmetry (LDF).
RESULTS: During the HW, there was a significant increase in heart rate, cardiac output, and SkBF of the leg, in the supine position; whereas during HUT, there was an increase in SkBF of both the arm and leg, and all cardiovascular variables were significantly affected besides cardiac output. Significant regional differences in SkBF presented between the arm and leg in all conditions; the arm displaying vasodilation throughout, while the leg vasoconstricted in non-HW before shifting to vasodilation in the HW. Additionally, the validation of ΔTskP-D displayed a strong correlation with LDF ($r = -.78$, $p<0.001$).
CONCLUSION: Prolonged HW exposure and orthostasis elicited significant yet expected responses to cardiovascular variables and SkBF variables. In addition, varying regional blood flow responses were observed between the arm and the leg, suggesting the upper and lower vasculature receives differing vasomotor control. Combined cardiovascular alterations and shifts towards vasodilation indicate an increased challenge to athletes and industrial workers during HWs.

**ACCLIMATION PROCESS OF MARATHON ATHLETES FOR THE TOKYO OLYMPIC GAMES 2020**

CUPIDO SANTOS, A.1,2, AFONSO, J.1,2, GASPAR, A.R.2, DA SILVA, M.G.2
*UNIVERSITY OF COIMBRA*

INTRODUCTION: Women's marathon of Tokyo Olympic Games 2020 was held on the 7th of August in Sapporo, Japan. This region has recorded, exactly in this day its highest temperature in 21 years, at 6 a.m. at the start of the race, the sky was clear, the temperature was 25 °C and a relative humidity was 82%. The temperature rose during the competition to above 30°C with relative humidity above 80%, which means values of WBGT exceeding 30, already in the dangerous category. With this type of warning, the acclimatization process becomes essential in an athletes sports preparation, not only to improve sport performance but also to preserve physical integrity.
METHODS: In this study, two female athletes underwent a period of 15 days of acclimation. The process was carried out in the climatic chamber (CC) located at the laboratory of Industrial Aerodynamics (LAI) of the University of Coimbra. In all sessions, the duration was 60 min, temperature was 34.2°C±0.4, relative humidity 77.2% ±5.4%, and air speed was lower than 2.1 m s-1 at the chest level. A treadmill (HP Cosmos) was used for all sessions, VO2 max tests were performed on the first day of each acclimatization period using a gas analyser (Metamax cortex), to define the work intensity of the following acclimatization sessions (60% of VO2 max). Oxygen consumption tests were performed at days 1, 7 and 15. Urine temperature and density, body mass, heart rate variability before and after effort were controlled (Polar V800+H10 chest band). In addition, heart rate and lactate concentration (spectrophotometer Dr. Lange) and fluid consumption, loss of plasma volume and percentage of loss of body mass throughout each session were also controlled.
RESULTS: Due to the acclimatization process the following changes were observed: an increase of 3.3% in the athletes running velocity and a decrease in oxygen consumption around 2.1 ml/kg/min, for the same percentage of VO2max; plasma volume loss varied from 9.98% to 3.97%; a decrease of urine density (1013 to 1007.5) and heart rate (151 to 138 bpm), a 1073 ml/h increase in sweat rate; an increase of percentage of loss of body mass (1.12% to 2,72%); as regards Heart Rate Variability, a decrease in LF/HF ratio (3.46 ms2 to 1.38ms2), Mean RR increased (951 - 1203 ms) and LnRMSSD increased (3.69 ms to 4.44 ms). The core temperature after the exercise had not large variations. Its average was 38°C ±0.53°C, which is 2.9°C±0.38°C above the initial temperature, across all training sessions. Mean blood lactate was 1.23 ± 0.27 mmol/l.
CONCLUSION: The acclimatization process showed a clear improvement in performance indicators and the decrease in sympatho-vagal activity prior to exercise may suggest an adaptation to thermal adverse conditions. Additionally, decreases in the plasma volume loss, heart

rate, ventilation and oxygen consumption were verified for the same intensity which is essential to be able to maintain body thermoregulation and hight levels of performance in adverse weather conditions.

**THE INFLUENCE OF L-CITRULLINE SUPPLEMENTATION ON HYPOHYDRATED ENDURANCE RUNNING PERFORMANCE IN THE HEAT.**

CABLE, T.G., HUDSON, E.F., REYNOLDS, K.M., FUNNELL, M.P., JOHNSON, D.A., TAYLOR, L., BAILEY, S.J., MEARS, S.A., JAMES, L.J.

*LOUGHBOROUGH UNIVERSITY*

INTRODUCTION: 7 days L-Citrulline supplementation decreases oxygen uptake during cycling in a temperate environment through increased nitric oxide availability in the blood. During exercise in the heat, and/or where dehydration occurs and total blood volume and blood flow to the muscles are compromised, L-Citrulline supplementation may be ergogenic. Therefore, this study assessed the impact of 7 days L-Citrulline supplementation on 3 km running performance in the heat whilst in a state of hypohydration.
METHODS: 9 endurance runners (8 male, 1 female) (age 32 ± 7 y; V̇O2max 59 ± 6 mL/kg/min) participated in a randomised, double-blind, crossover trial with 7 days of L-Citrulline (CIT) (6 g/day) or placebo (PLA) supplementation. Participants completed a 50 minute running 'preload' at 65% V̇O2max in the heat (32°C, 50% RH) to induce hypohydration (~2% body mass loss) before a 3 km running time trial. Body mass, core and skin temperature, heart rate, perceptual responses, sweat rate and oxygen uptake were recorded during the preload and time trial.
RESULTS: During the preload and time trial, alterations in the physiological variables associated with thermoregulation and hypohydration (i.e. core temperature, skin temperature, heart rate and oxygen uptake) were increased, but were not different between trials (P≥0.150). Local sweat rate was similar between trials (CIT 2.99 ± 1.22 mg/cm2/min, PLA 2.71 ± 1.99 mg/cm2/min, P=0.563). Thirst, RPE, gastrointestinal comfort and thermal sensation increased throughout the preload but were not different between trials (P≥0.360). Thermal sensation was lower at the final stage of the time trial in CIT (CIT 7.0 ± 1.1, PLA 8.0 ± 0.9, P<0.010). Time trial performance was not different between trials (CIT 865 ± 142 s, PLA 892 ± 154 s, P=0.161). Pacing of the time trial was similar between trials for 0 – 1 km (CIT 298 ± 52 s, PLA 305 ± 54 s, P=0.254), 1 – 2 km (CIT 288 ± 49 s, PLA 288 ± 56 s, P=1.000) and 2 – 3 km (CIT 280 ± 42 s, PLA 300 ± 53 s, P=0.08).
CONCLUSION: 7 days L-Citrulline supplementation did not alter physiology or performance responses to running in the heat whilst hypohydrated. The lack of attenuation of core and skin temperature may be attributable to the intense nature of the environmental conditions. However, perception of thermal sensation was lower during the time trial, indicating that L-Citrulline may be used in an endurance context to reduce the perception of heat stress during competition. Further research should assess increased dosage of L-Citrulline in this context.

**NETWORK FUNCTIONAL CONNECTIVITY RESPONSE TO SUBMAXIMAL EXERCISE AFTER A SPORT-RELATED CONCUSSION**

COENEN, J., VAN DEN BONGARD, F., DELLING, C., REINSBERGER, C.

*INSTITUTE OF SPORTS MEDICINE, PADERBORN UNIVERSITY*

INTRODUCTION: Return-to-sport (RTS) after a sport-related concussion (SRC) is guided by clinical symptom presentation and assessments, however there is a need to explore and develop objective biomarkers. Resting state electroencephalography (rsEEG), may be a suitable technique to identify functional deficits in relevant networks that are assumed to be affected by SRC. The aim of this study is to explore rsEEG whole brain and network changes in response to submaximal exercise during RTS.
METHODS: Thirty-six athletes were recruited for this study; 18 patients post SRC (age: 24 ± 5, BMI: 24 ± 2, time since concussion: 2 – 140 days, symptom score: 1 - 87), and 18 matched controls (age: 25 ± 5, BMI: 23 ± 2). 128-channel rsEEG recordings were collected pre- and post- submaximal cycle exercise (70% of the athletes' age calculated maximal heart rate (HR)). Functional connectivity (FC) calculated by mean phase locking value (PLV), within the alpha band (7-13 Hz) was analyzed for whole brain (68 ROI, Desikan Killiany atlas), default mode network (DMN, 14 ROI) and central autonomic network (CAN, 24 ROI). Wilcoxon Signed Rank Tests were used to explore statistical significance between pre and post exercise.
RESULTS: For concussed athletes, there was a significant difference between pre- (Mdn = 0.258, IQR = 0.082), and post- (Mdn = 0.275, IQR = 0.079; Z = -2.635, p = 0.008, r = -.62) exercise for whole brain FC. In addition, concussed athlete's pre- (Mdn = 0.363, IQR = 0.060, and post- (Mdn = 0.370, IQR = 0.080) exercise FC within DMN differed significantly; Z = -2.678, p = 0.007, r = -.63, and within CAN pre- (Mdn = 0.298, IQR = 0.069), and post- (Mdn = 0.320, IQR = 0.081) exercise; Z = -2.809, p = 0.005, r = -.66. For control athletes, there was no significant difference between pre- and post- exercise FC within whole brain and selected networks.
CONCLUSION: Whole brain and network FC significantly increased pre- to post-exercise within the concussed patient group, but not the control group. There appears to be an altered response to submaximal exercise in SRC athletes, possibly driven by altered central network activity.

**THE FOOTBALL ASSOCIATION INJURY AND ILLNESS SURVEILLANCE STUDY: THE INCIDENCE AND SEVERITY OF INJURIES IN ENGLISH MEN'S SENIOR INTERNATIONAL FOOTBALL**

SPROUSE, B.1, ALTY, J.2, KEMP, S.2, COWIE, C.2, HENNIS, P.1, MORRIS, J.G.1, COOPER, S.B.1, VARLEY, I.1

*1 NOTTINGHAM TRENT UNIVERSITY, NOTTINGHAM, UK; 2 THE FOOTBALL ASSOCIATION, BURTON-UPON-TRENT, UK*

INTRODUCTION: Injury surveillance is an integral part of elite football given medico-legal responsibilities and the need to mitigate injury occurrence in the interests of player welfare. Long-term, large-scale studies characterising specific injury diagnosis in international football are scarce, with previous studies only examining international tournaments [1,2]. The aggregation of injuries into broad categories, a lack of injury severity analysis and the inability to assess specific match and training injury patterns limit the practical use of current literature. This study aimed to compare injury patterns and specific diagnoses in matches and training, and their associated incidence and severity, in English men's senior international football over 8 seasons.

METHODS: Time-loss injuries and match and training exposure were collected across 8 seasons (2012-20) in English men's international teams (U20/U21/Senior). Incidence (injuries/1000h), and severity (% of total days absent) of injury patterns and specific injury diagnoses were determined. Chi-square test was used to assess differences in the distribution of injuries between matches and training. Significance was set at P<0.05.
RESULTS: 215 injuries were recorded (match: 126, training: 89) over 8 seasons. The most common match injury diagnoses were lower limb haematomas (22%,7.0/1000h), hamstrings muscle/tendon (13%,4.0/1000h) and lateral ankle ligament injuries (10%,3.3/1000h). In training, lower limb haematomas (12%,0.4/1000h), hamstrings muscle/tendon (11%,0.4/1000h) and quadriceps and hip/groin muscle/tendon injuries (both 9%,0.3/1000h) were most common. There were no differences in commonality between matches and training (P>0.05). The most severe match injury diagnoses were ACL (19%), lateral ankle ligament (13%) and quadriceps muscle/tendon injuries (11%). In training, MCL (19%), quadriceps muscle/tendon (16%) and hamstrings muscle/tendon injuries (12%) were most severe. ACL and lateral ankle ligament injuries were more severe in matches than training (both P<0.001). Quadriceps muscle/tendon (P<0.001), MCL (P<0.001) and hamstrings muscle/tendon injuries (P=0.048) were more severe in training than matches.
CONCLUSION: No differences were shown in the patterns and specific diagnoses of injuries in matches compared to training, suggesting that the differing contextual factors between matches and training did not influence injury commonality. Lateral ankle ligament injuries were more severe in matches compared to training, potentially attributed to increased player contact through tackling and fouls in matches. The greater severity for hamstrings and quadriceps muscle/tendon injuries in training compared to matches warrants further investigation.

**DIFFERENT MOTOR RECOVERY PROGRESS BETWEEN ADOLESCENT AND ADULT RECREATIONAL ATHLETES AFTER ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION**

ALESSANDRO, C.1, TURATI, M.1,2,3, BENEDETTINI, E.1, BACCHIN, V.1, PIATTI, M.3,4, ALBANESE, F., ACCADBLED, F., RIGAMONTI, L.3,4, BIGONI, M.1,3,4

*1 UNIVERSITY OF MILANO-BICOCCA, 2 SAN GERARDO HOSPITAL, 3 TRANSALPINE CENTER OF PEDIATRIC SPORTS MEDICINE AND SURGERY, 4 POLICLINICO SAN PIETRO HOSPITAL*

INTRODUCTION: In recent years the incidence of anterior cruciate ligament (ACL) injuries in the skeletally immature population has grown [1]. Nonetheless, there is still a limited understanding of the recovery processes of these patients after reconstructive surgery, making it difficult to define appropriate criteria for their safe return to sport. The progress in motor recovery in ACL-injured patients is often evaluated using isokinetic tests [2]. Here, we compare for the first time the outcomes of these tests between adolescent and adult patients after ACL reconstruction (ALCR) with bone-patellar tendon-bone (BPTB) technique, providing critical insights into their different processes of motor recovery.
METHODS: Fifty-five adolescents (13-18 years old) and 76 adults (19-39 years old), who underwent BPTP ACLR, performed isokinetic tests 6 months after surgery. The outcomes of these tests were: (1) the maximum torque produced by hamstrings (H) and quadriceps (Q) muscles (i.e. muscle strength) during flexion and extension movements at 30°/s normalized by body weight; (2) the ratio of hamstrings to quadriceps strength (HQ ratio); (3) the ratio of muscles strength in the injured to the uninjured leg (limb-simmetry, LSI). Mixed models with repeated measures were used to compare the outcomes between adolescents and adults, and between legs within patients.
RESULTS: Both adults and adolescents exhibited a decrease of quadriceps strength in the injured compared to the uninjured leg (Δadolescents: -0.5±0.8 Nm/kg; Δadults: -0.8±0.9 Nm/kg; p<0.001), but no change in the hamstring strength (Δadolescents: -0.1±0.6 Nm/kg; Δadults: -0.1±0.6 Nm/kg; p=1). Interestingly, in adolescents this decrease was significantly lower than in adults (injured Q adolescents vs adults, p<0.05). As a result, in both populations the quadriceps LSI was lower than the hamstring LSI (p<0.001). Yet, quadriceps LSI of adolescents was higher than that of adults (p<0.001), with no significant difference between populations in hamstring LSI (p=1). The HQ ratio in the injured leg was significantly higher than in the uninjured leg in both populations (adolescents: 0.66±0.13 vs 0.53±0.07; adults: 0.74±0.15 vs 0.53±0.08; p<0.05). However, in adolescents this measure was lower than in adults for the injured (p<0.001) but not for the uninjured leg (p=1).
CONCLUSION: There were clear differences between the recovery progress in adolescents and adults. Since the hamstring muscles are synergistic and the quadriceps muscles are antagonist to the ACL [3], the lower HQ ratio in adolescents suggests that in these patients the reconstructed ligament may be subject to higher loads than in adults 6 months after surgery. Adolescents may therefore need a longer period of rehabilitation to have a safe return to sport.

**NEUROMUSCULAR CONTROL OF THE CONTRALATERAL LEG DURING JUMP LANDINGS FOLLOWING AN ACL INJURY**

CALISTI, M., MOHR, M., FEDEROLF, P.

*LEOPOLD-FRANZENS-UNIVERSITÄT, INNSBRUCK*

INTRODUCTION: After an anterior cruciate ligament (ACL) injury and subsequent repair, there is a high risk of sustaining a second ACL injury (1). Interestingly, the rates of contralateral ACL injuries exceed the rates of ipsilateral graft rupture (1). One underlying mechanism may be that the loss of afferent input from the ruptured, ipsilateral ACL leads to a reorganization of activity in motor areas of the brain, ultimately affecting neuromuscular function of both legs (2). The current study tested the hypothesis that dynamic postural stability, quantified through the time to stabilization (TTS) during jump landings, would be reduced for the healthy contralateral leg in individuals with a previous, unilateral, fully rehabilitated ACL injury in comparison to healthy controls. Further, effects of leg dominance were investigated.
METHODS: Twenty-three females with a previous ACL injury (8 dominant leg; 15 non-dominant leg) and eighteen healthy females (control group) performed unilateral horizontal jump landings over a 30cm hurdle onto a force plate (1000Hz) (3). They were instructed to stabilize as quickly as possible and remain still for 10 seconds. Medio-lateral TTS (TTS-ML) was calculated as the time required for the medio-lateral force to reach and remain within ± 1 SD of the subject's overall series mean for 1s. Independent t-tests were used to compare the ACL

leg/contralateral leg to the control group irrespective of leg dominance. Two Kruskal-Wallis and Bonferroni-corrected posthoc tests (alpha = 0.05) were used to compare injured, contralateral and control-group legs separately for the dominant and non-dominant side.
RESULTS: Average unilateral TTS-ML was significantly higher in the ACL injured leg (1.59s versus 1.26s; p=0.006; d= 0.90) and borderline significant in the contralateral leg (1.51s; p= 0.050; d= 0.68) compared to the control group. For dominant leg injuries a significant increase was found between injured and control-group legs (1.89s versus 1.30s; p= 0.006; r= 0.49) and contralateral and control-group legs (1.73s versus 1.26s; p= 0.034; r= 0.40). However, this was not found for injuries on the non-dominant leg.
CONCLUSION: Our results suggest an interaction effect: neuromuscular control was less effective in the contralateral leg compared to healthy controls if the injury had happened on the dominant leg. A deficit in contralateral leg control was not detectable if the injury had occurred on the non-dominant leg. Rehabilitation programs following ACL injury should also focus on neuromuscular training of the contralateral leg, and in particular so, when the patient's dominant leg was injured.

**EVALUATION OF POSTURAL STABILITY AND PROPRIOCEPTION IN SUBJECTS BEFORE AND AFTER TOTAL ANKLE REPLACEMENT**

BARONE, G., BRAGONZONI, L., ZINNO, R., VOCALE, E., DI PAOLO, S., SANTILLOZZI, F., PINELLI, E., CARAVELLI, S., MASSIMI, S., ZAFFAGNINI, S., BENEDETTI, M.G., MOSCA, M.

*UNIVERSITY OF BOLOGNA*

INTRODUCTION: Ankle osteoarthritis is a debilitating condition, which includes balance impairment, range of movements limitations and a consequence increased risk of falls. Conservative management is the first approach but for severe ankle osteoarthritis, total ankle replacement (TAR) should be taken into account. The aim of this study is to measure postural control and proprioception in subjects with primary TAR, before and nine months after the surgery.
METHODS: Subjects with ankle osteoarthritis admitted in the Istituto Ortopedico Rizzoli of Bologna (Italy) waiting for a TAR were recruited. Delos Postural Proprioceptive System (Delos S.r.l, Turin, Italy) was used to assess postural control and proprioception. All subjects performed the Static Riva test, which consists of maintaining a single leg stance with open and closed eyes. The parameter considered is the Stability Index (SI) which is a percentage score where 100% is a theoretical task performed with maximum stability.
RESULTS: Subjects recruited were 17 (12 male and 5 Female) aged 59.29 ± 10.83 years with a body mass index of 28.20 ± 2.45. The SI, of the operated limb, decreased from 68.22% ± 18.65 to 60.93% ± 18.86 with opened eyes (p = 0.16) and from 37.09% ± 14.14 to 34.24% ± 10.17 with closed eyes (p = 0.37). The SI of the contralateral limb, slightly decreased from 87.51% ± 4.10 to 86.75% ± 6.03 with opened eyes (p = 0.53) and from 53.19% ± 16.58 to 52.16% ± 13.89 with closed eyes (p = 0.67). Considering all tasks, the operated limb has significant lower results than the contralateral (p<0.001). There is a strong correlation between the open and closed eyes results in the operated limb both before (r = 0.79; p<0.001) and after surgery (r = 0.63; p<0.01). Same correlations are found in the contralateral limb. Age and BMI did not influence the SI.
CONCLUSION: The static Riva test with his open and closed eyes tasks is an indicator respectively of postural stability and proprioception. Subjects showed a consistent difference between limbs in all tests; therefore, we suppose that postural stability and proprioception are strongly influenced in a severe ankle osteoarthritis condition. Moreover, even if the current literature shows great results after TAR in terms of function and pain, 9 months seems is not to be enough to restore balance and proprioception.

### OP-MH05 COVID-19: Impact on exercise capacity, fitness and quality of life

**ASSOCIATION BETWEEN STRINGENCY OF COVID-19 CONTAINMENT MEASURES AND WALKING MOBILITY. AN ANALYSIS OF MOBILE DATA FROM 60 COUNTRIES.**

LUCIANO, F.1, CROVA, F.1, CANELLA, F.2

*1. UNIVERSITÀ DEGLI STUDI DI MILANO; 2. POLITECNICO DI MILANO*

INTRODUCTION: COVID-19 containment measures curb virus transmission, but increase the risk of physical inactivity [1,2]. Movement restrictions, travel bans, and stay-at home recommendations can hamper walking mobility, and reducing daily steps is a risk factor for non-communicable diseases and all-cause mortality [3]. The relation between stringency of containment measures and walking mobility has not been quantified; however, combined global-scale datasets on population mobility, containment policies, weather and solar light may allow to investigate it while controlling for major confounders. Our aim was to assess the dose-response relation between containment stringency and walking mobility across the 60 countries of the Apple Mobility Trends Reports (AMTR) dataset [4], and model the impact of the subsequent physical inactivity on health outcomes.
METHODS: Daily data on 60 countries from the 21st January 2020 to the 21st January 2022 were harmonized from open-access sources: AMTR, Oxford COVID-19 response tracker, and National Oceanic and Atmospheric Administration weather stations. Walking mobility was regressed over containment stringency in a mixed effect model, while controlling for weather factors. A non-linear model estimated how different containment levels impacted on the all-cause mortality hazard (expressed as hazard ratio, HR) due to physical inactivity, having as parametres the regression results, data on pre-pandemic walking mobility, and the association between daily steps count and HR.
RESULTS: A negative log-linear association was found between stringency of containment measures and walking mobility (-1.202·10^-2 [-1.221·10^-2; -1.183·10^-2]; fixed effect [95% CI]). Increasing the stringency of containment measures, thus deceasing walking mobility, incremented the modelled HR, with the greatest effect when starting from lowest stringencies and a maximum predicted HR of 1.42 [1.24; 1.60] (central value [95% CI]).

CONCLUSION: A higher stringency of containment measures was associated with lower walking mobility with a non-linear relation; such results agree with previous evidence from mobile data and self-reported physical activity [1,2]. As containment measures curb active mobility, they can increase the HR due to physical inactivity. The modelled HR reached a maximum with maximal containment measures, and the magnitude of its changes was comparable to that observed in large pre-pandemic cohorts of people who sustainedly reduced their physical activity level [5]. The present findings can help shaping balanced containment policies during pandemics and planning counter-measures against the subsequent physical inactivity. Besides, they serve as a model of how environmental factors jointly impact on active mobility worldwide.

**EPIDEMIOLOGICAL DATA AND PERSISTANCE OF CLINICAL SYMPTOMS OF COVID-19 POSITIVE ELITE ATHLETES**

DIEBOLD, K., ZACHER, J., SCHIFFERDECKER, I., SCHNEEWEIS, C., VASSILIADIS, A., PREDEL, H.G.

*INSTITUTE OF CACRDIOLOGY AND SPORTS MEDICINE GERMAN SPORT UNIVERSITY COLOGNE*

INTRODUCTION: The COVID-19 pandemic is posing profound challenges to the athletic community. While there are numerous studies investigating the SARS-CoV-2 infection and its consequences in the general population, there is a lack of data concerning elite athletes. The objective of this study was to evaluate the epidemiological data to identify contact mechanisms of SARS-CoV-2 and the prevalence of persisting symptoms with a focus on sport-restricting complaints 16 weeks after COVID-19 infection in elite athletes.
METHODS: 65 German Olympic Sports Confederation athletes (43 men, 22 women; age 23 ± 4.6), including 16 Olympic athletes, from various sports with laboratory-confirmed COVID-19 (via reverse transcription-polymerase chain reaction (PCR) or serum immune globulin G antibody against SARS-CoV-2) were included. Data were collected longitudinally between June 2020 and October 2021. Standardized questionnaires were used to collect data about contact mechanisms, number, type and duration of symptoms, severity of the disease, training suspension and the current perceived physical performance ability. SARS-CoV-2 antibody status was determined at the Institute of Cardiology and Sports medicine of the German Sports University Cologne.
RESULTS: 39 athletes (60%) were infected in Germany, whereas 22 (33.8%) were infected abroad. In 4 (6.2%) athletes the location of infection could not be determined. 48.8% of the infections occurred in the athletic context, with most (40.6%) being infected during a competition abroad. Combat sport athletes were most frequently affected (53.8%).
96.8% of the athletes experienced a symptomatic course. 93.8% had at least one Covid-specific symptom (e.g. cough), while 71.2% reported of other symptoms, that are not officially declared as COVID-specific. In 44.1 % of the symptomatic cases, symptoms lasted > 4 weeks, while 28.8 % and 20.3 % experienced symptoms lasting longer than 8 and 16 weeks, respectively. After 16 weeks, the majority of athletes (63.8%) reported not being symptom-free during physical exercise. Most frequently a reduction in physical performance ability (19%), fatigue and shortness of breath during physical exertion (15.5% respectively) and musculoskeletal complaints (6.9%) were notified. 78.1% of the athletes reported reduced performance ability at baseline. Of these, 42.2% indicated their performance to be reduced by 30% or more. 16 weeks after baseline, 42.6% had not regained their former performance level, but only 3.8% reported a reduction by 30% or more. In 80% of the cases, a training suspension of at least 4 weeks was recorded. None of the SARS-CoV-2 positive athletes required hospitalization.
CONCLUSION: The main cause of SARS-CoV-2 transmission in elite sports was competitions abroad. Although no hospitalization was required, a broad spectrum of clinical symptoms was evident in the studied cohort 16 weeks after confirmed infection, especially sport restricting complaints and performance limitations.

**PHYSICAL ACTIVITY AND SEDENTARY BEHAVIOUR CHANGE DURING THE FIRST COVID-19 'LOCKDOWN' IN AN ADULT ENGLISH COHORT WITH A BODY MASS INDEX ≥25 KG/M².**

KASS, L., WELLS, A., DESAI, T., CLARKE, A., HURST, R.

*UNIVERSITY OF HERTFORDSHIRE*

INTRODUCTION: The SARS-CoV-2 (Covid-19) pandemic, resulted in enforced 'lockdown' restrictive measures. Negative effects upon health promoting behaviours (physical activity (PA) and sedentary behaviour (SB)) are likely. A body mass index (BMI) ≥25 kg/m² has been associated with severe COVID-19 symptoms, research analysing the lockdown's impact within this population is limited. This study aims to investigate this contemporary area of research.
METHODS: Based on an online survey (n=818) incorporating the International Physical Acitvity Questionnaire Short From (IPAQ-SF), data from 376 participants with BMI≥25 kg/m² were analysed for self-reported daily walking time and weekday and weekend-day sitting time. Descriptive statistics and a contingency table using Pearson's-Chi square/Fishers exact test was carried out.
RESULTS: Daily walking time, X2= 281.6 and p<0.01, 42% increased, 21% decreased. Weekday sitting time, X2= 216.9 and p<0.01, 43% increased, 16% decreased. Weekend-day sitting time, X2=322.1 and p<0.01, 41% increased, 7% decreased. Large increases in sitting >10 hours/day (weekday, 105%; weekend-day, 194%).
CONCLUSION: The first COVID-19 lockdown increased both PA (daily walking time) and SB (weekday and weekend-day sitting time) amongst UK adults with a BMI ≥25 kg/m2 concurring with other studies from different countries.
Further analysis of the BMI categories showed that the obese category showed a 37% increase in daily walking time and the morbidly obese category showed a 33% increase in daily walking time, however 38% of the morbidly obese decreased their walking time.
Regarding self-reported weekday sitting time, 43% of the overall cohort increased and 16% deceased. Specific to weekday sitting time, 105% increased sitting time >10 hours/day and at weekend-days there was a 194% increase.
Distinguishing sitting time between weekdays and weekend-days is not well documented within current literature, however, the overall conclusion within this present study is that the COVID-19 lockdown has negatively influenced daily sitting time. It is widely accepted that sitting is a SB associated with all-cause mortality (impartial to PA), due to its dangerous impact upon metabolic and cardiovascular health. The increase in sitting time >10 hours/day for both weekday and weekend-days within the present study, shows the sobering negative effect the first COVID-19 lockdown has had upon SB amongst UK adults with a BMI ≥25 kg/m2.
With this increase in both PA and SB this change in behaviour concurs with the term 'active couch potato'.

### VERY LOW-VOLUME HIGH-INTENSITY INTERVAL TRAINING MAINTAINS CARDIOMETABOLIC HEALTH AND QUALITY OF LIFE AMONG HOME-OFFICE WORKERS DURING COVID-19 PANDEMIC: A 1-YEAR FOLLOW-UP STUDY

RELJIC, D., EICHHORN, A., HERRMANN, H.J., NEURATH, M.F., ZOPF, Y.

*UNIVERSITY HOSPITAL ERLANGEN*

INTRODUCTION: Initially, this study aimed to investigate the long-term effects of cycle-ergometer-based very low-volume high-intensity interval training (LOW-HIIT) performed over 1 year in a supervised worksite setting on cardiometabolic health and self-reported outcomes in a cohort of sedentary office workers. As the COVID-19 pandemic unexpectedly emerged during the study, training was discontinued and participants were given recommendations on how to continue exercising at home. One year after study onset, participants were invited for a follow-up examination to evaluate their physical actvity (PA) behaviour and outcome changes during lockdown.
METHODS: 114 sedentary office workers (50.2±10.1 yrs, 46% females) from a large company participated. All participants received a comprehensive baseline health examination (T-1) at our Research Center to ensure safe participation in exercise and to collect study outcomes. Examination included blood sampling, assessment of body composition, cardiopulmonary exercise testing including resting and exercise electrocardiography, blood pressure measurements and determination of maximal oxygen uptake (VO2max) and collection of self-reported data including quality of life (QoL, EQ-5D-5L VAS score) using validated questionnaires. LOW-HIIT (5x1 min intervals at 80-95% maximum heart rate, 14 min total session time including warm-up, cool-down) was performed twice weekly within the workplace at the companys sports center in supervised group classes. Outcome reassessment was conducted after 6 months (T-2, termination of supervised LOW-HIIT) and after 12 months (T-3, follow-up). T-1 and T-2 data were compared in a pre-/post intervention manner. T-3 data analyses were performed as subgroup analysis after dividing participants into 3 groups based on their PA behavior during lockdown: A) Continued with LOW-HIIT (HIIT), B) continued regular exercising but not with LOW-HIIT (EX) or C) discontinued exercise in general (NON-EX).
RESULTS: At T-2, data from n=72 were available. We observed significant improvements in VO2max (+1.4 mL/kg/min, p=0.002), mean arterial blood pressure (MAB, -4 mmHg, p<0.001), glycated hemoglobin A1c (-0.2%, p=0.005), high-sensitivity C-reactive protein (-1.5 mg/L, p=0.040) and QoL score (+5 points, p<0.001). N=57 (HIIT: n=19; EX: n=12; NON-EX: n=26) finished the T-3 examination . The HIIT-group maintained VO2max and QoL score and further improved MAB (-3 mmHg, p=0.032). The EX-group (mainly performing walking, moderate running and gymnastic exercises) maintained MAB and QoL but experienced a decrease in VO2max (-3.7 mL/kg/min, p=0.002). In the NON-EX group, VO2max (-5.8 mL/kg/min, p<0.001), MAB (+3 mmHg, p=0.035) and QoL score (+5 points, p=0.015) values deteriorated.
CONCLUSION: Six months of worksite LOW-HIIT improve VO2max, QoL and cardiometabolic health indices in sedentary office workers. Only participants who continued LOW-HIIT during COVID-19 lockdown for 6 months at home maintained VO2max and QoL and further improved blood pressure.

### MECHANISTIC BASES OF EXERCISE INTOLERANCE IN PATIENTS WITH POST-ACUTE SEQUELAE OF COVID-19: A TRANSLATIONAL APPROACH BY IN-VIVO AND EX-VIVO MEASUREMENTS

COLOSIO, M., BROCCA, L., GATTI, M., CADILE, F., CANEPARI, M., PELLEGRINO, M.A., POLLA, B., ROBERTO BOTTINELLI, R., PORCELLI, S.

*UNIVERSITY OF MILAN*

INTRODUCTION: Covid-19 has become a global health issue since December 2019. Although the clinical manifestations of COVID-19 may be life threating due to severe respiratory and cardiac failure in acute phase (1), previous studies showed persisting and often debilitating symptoms at long-term even in patients who develop the mild form of the disease (2,3). Patients report exercise intolerance, muscle weakness and fatigue that seem to be related to impairments in O2 supply and utilization by skeletal muscle (4). Aim of the study was to investigate the mechanistic bases of exercise intolerance in patients with post-acute sequelae of Covid-19 (PASC).
METHODS: At least 3 months after infection, non-hospitalized PASC patients (n=10, ys:52±9; PASC) and patients without long-term symptoms (n=8, ys:47±9; CTRL) visited the laboratory on three non-consecutive days. Spirometry, lung diffusion capacity and quality of life (5) were assessed at rest. Peak O2 consumption (VO2peak) was evaluated during cardiopulmonary incremental exercise test (CPX). Oxygen consumption (VO2) kinetics were determined by moderate-intensity exercises. Muscle oxidative capacity recovery rate constant (k) was assessed by repeated arterial occlusion by near-infrared spectroscopy. Mitochondrial respiration was evaluated by high-resolution respirometry in permeabilized muscle fibers from vastus lateralis using saturating substrates for complexes I+II combined (CI+II).
RESULTS: Pulmonary functions were within normal range in all patients. Quality of life was significantly lower in PASC vs CTRL (66±15 vs 91±2, respectively, P<.01). VO2peak was lower in PASC than CTRL (24.9±0.3 vs 33.7±0.5 ml*min-1*kg-1, respectively, P<.005). VO2 kinetics were slower in PASC than CTRL (43±2 vs 31±1 min-1, P<.05). k was lower in PASC than CTRL (1.64±0.57 vs 2.35±0.36 min-1, P<.05). O2 flux for CI+II in activated state of oxidative phosphorylation and maximal uncoupled state condition were lower in PASC (36.7±16.3 and 51.2±20.1 pmol*s-1*mg-1) than CTRL (56.9±11.7 and 79.6±15.6 pmol*s-1*mg-1, all P<.05).
CONCLUSION: Exercise intolerance of PASC patients is primarily due to impaired mitochondrial function as suggested by both functional in-vivo indexes of muscle oxidative metabolism and ex-vivo measurements on permeabilized muscle fibers.

## OP-BM20 Motor control: Ageing

### THE ASSOCIATION OF MUSCULAR STRENGTH AND GRAY MATTER VOLUME IN COGNITIVELY – HEALTHY OLDER ADULTS: THE AGUEDA TRIAL

COCA-PULIDO, A.1, SOLIS-URRA, P.1, SCLAFANI, A.1, TOVAL, A.1, MARTIN-FUENTES, I.1, GARCIA-RIVERO, Y.2, HILLMAN, H.3,4, CATENA, A.5, ERICKSON, K.1,6, MORA-GONZALEZ, J.1, ESTEBAN-CORNEJO, I.1

*1. PROFITH, UNI OF GRANADA, 2. BIOSANITARY RESEARCH INST., 3. NORTHEASTERN UNI., 4. NORTHEASTERN UNI., 5. UNI. OF GRANADA, 6. UNI OF PITTSBURG.*

INTRODUCTION: The association between higher cardiorespiratory fitness and gray matter volume in the hippocampus and prefrontal cortex led to the prediction that participation in greater amounts of physical activity might be associated with greater gray matter volume as well. Nevertheless, the role of muscle strength in brain structure is still unknown. Thus, this study investigated the associations of muscular strength and gray matter volume in older adults.
METHODS: A total of 86 cognitively normal older adults aged 65-80 years from the AGUEDA trial participated in the present cross-sectional study. Muscular strength was measured with a Handgrip Dynamometer (TKK 5101 Grip D, Takey, Tokyo Japan). The test was performed twice for each hand and the score was recorded in kilograms. The maximum scores of the left and right hands were averaged to calculate an absolute indicator of muscular strength (kg). T1-weighted images were acquired with a 3.0 T Siemens Magnetom Prisma Fit scanner and were pre-processed using Statistical Parametric Mapping software (SPM12, London, UK). Gray matter volume was determined by voxel based morphometric analysis. General linear models assessed the association between muscular strength and gray matter volume, controlling for age, sex and years of education. The statistical threshold for the cluster extent was calculated with AlphaSim, and further Hayasaka adjusted to account for the non-isotropic smoothness of structural images.
RESULTS: The main results showed that higher muscular strength was related to greater gray matter volume ($p<0.001$) in 3 clusters, including two clusters in the culmen (left: k=1286, t=5.42; right: k=261, t=4.02), and one in the left middle frontal gyrus (k=291, t=3.72). Muscular strength was not negatively related to gray matter volume in any brain region.
CONCLUSION: Muscular strength is associated with greater gray matter volume in the frontal lobe and the cerebellum in cognitively normal older adults. Future exercise-based randomized control trial should examine whether increases in muscle strength by an exercise program may positively influence the development of distinctive gray matter regions, and thus counteract the harmful effect of aging in this population.

### COMPARING THE EFFECTS OF TWO PERTURBATION-BASED BALANCE TRAINING PARADIGMS IN FALL-PRONE OLDER ADULTS: A RANDOMIZED CONTROLLED TRIAL

SCHWENK, M., HEZEL, N., ARAMPATZIS, A., BRÜLL, L.

*HEIDELBERG UNIVERSITY, HUMBOLDT UNIVERSITY OF BERLIN*

INTRODUCTION: The declining ability to successfully react to slipping and tripping is a key component of the multifactorial etiology of falls. There is increasing evidence that perturbation-based balance training (PBT) is highly effective for improving the ability to recover balance after an unexpected event such as a slip or a trip. However, it is unclear, which PBT paradigm is most effective. Two different paradigms of PBT seem to be promising: 1. Training of dynamic stability mechanisms in the presence of perturbations induced by unstable surfaces (PBT-unstable); 2. Technology-supported training on a perturbation treadmill (PBT-treadmill). The aim of this study was to compare the effects of both programs.
METHODS: Seventy-one adults aged 65 years and older with a verified fall risk were randomly assigned into three groups: PBT-unstable using unstable conditions such as balance pads, PBT-treadmill on a motorized treadmill and a passive control group. In both intervention groups, participants conducted a 6-weeks intervention with 3 sessions/week. Effects were assessed in balance ability (Brief-Balance-Evaluation-Systems-Test, Stepping-Threshold-Test, Center-of-Pressure, Limits-of-Stability), leg strength capacity, functional performance (Timed-up-and-Go, Chair-rise), gait (speed) and fear of falling (Short-Falls-Efficacy-Scale-International). Analysis of covariance (ANCOVA) was used to compare the effect of the intervention on outcome parameters at follow-up. Statistical analysis was conducted according to the intention-to-treat principle.
RESULTS: Fifty-one participants completed the study (74.8±5.9 years, 65% female). Training adherence was high in both intervention groups (91% for PBT-treadmill and 87% for PBT-unstable). The ANCOVA revealed an effect of group in the Brief-Balance-Evaluation-Systems-Test ($p=.009$) and in the Limits-of-Stability ($p=.020$) in favor of PBT-unstable and a group effect in the Stepping-Threshold-Test ($p<.001$) in favor of PBT-treadmill. The other outcomes demonstrated no effects.
CONCLUSION: Both training paradigms induced distinct task-specific effects. PBT-treadmill showed higher improvements in reactive balance, which might be promoted by the unpredictable nature of the included perturbations. PBT-unstable showed more wide-ranging effects in balance ability, although with a smaller magnitude. Leg strength was only affected significantly in PBT-treadmill. Advantages of both formats should be evaluated in the light of individual needs and preferences before recommending either format. Larger studies are needed to investigate the effects on falls.

### BOTH GAIT SPEED AND IN-GAME PERFORMANCE (IGP) IMPROVE AFTER A MIXED-REALITY TRAINING IN PEOPLE WITH INTELLECTUAL DISABILITY. A PRELIMINARY STUDY.

LALY, A.1, ROSNET, E.1, TIXIER, P.A.2, FERRARI, A.2, BIARD, J.C.2, HOUEL, N.1

*1 UNIVERSITÉ DE REIMS CHAMPAGNE ARDENNE, PERFORMANCE SANTÉ MÉTROLOGIE SOCIÉTÉ , REIMS, FRANCE; 2 LABORATOIRE DE RECHERCHE ET D'ETUDE SUR LE MOUVEMENT, NEVERS, FRANCE*

INTRODUCTION: People with intellectual disability (ID) often show motor impairments (1) due to their poor cognitive skills or their physical activity level which is frequently low (2). Long term consequences of altered motor skills might be severe. Falls occur more frequently in people with ID than in healthy pairs (3). Better motor skills might also help in everyday tasks and social interactions. In addition, gait speed is a relevant indicator of motor functioning (2). In recent years, new therapeutics such as Virtual, Augmented and Mixed Reality technolo-

gies developed (4). This study aims at investigating if adults with ID might increase their in-game performance and gait speed after a Mixed Reality (MR) training.
METHODS: Participants were 18 adults with ID from a home for disabled adults. They participated in a weekly intervention using the application PopBalloons (Actimage, France) on a Microsoft Hololens2 MR device for 15 to 25 minutes, for 9 weeks. Its purpose is to detect, walk to and pierce virtual balloons with the finger. Both cognitive and motor functions are thus stimulated. In-game performance (IGP) was assessed by the average time to complete a level (piercing 5 balloons) at first and last weeks. Gait speed was measured with a Zeno walkway gait analysis system before and after training.
RESULTS: Both IGP (in s; PRE: 255.4±181.9, POST: 163.7±136.0; P=0.002) and gait speed (in cm/s; PRE: 78.1±22.0, POST: 89.1±29.9; P=0.02) significantly improved.
CONCLUSION: Gait speed naturally tends to decrease with age (5). Thus, increased gait speed is evidence of improved motor functioning. This can explain the better IGP at the end of training. The low training load (15-25 minutes/week) may have been enough to induce motor improvement due to the novelty of the motor demand during the activity and the low initial physical activity level of the participants (2). The MR task also demanded cognitive involvement (attention, detection, space orientation, strategy elaboration etc.). Thus, cognitive-motor abilities might also have been improved thanks to the cognitive-motor MR training (5). This study shows that adults with intellectual disability can improve their motor functioning after a cognitive-motor Mixed-Reality training, despite a low training load. Further research should focus on the impact of such MR training on this populations motor skills and cognitive functions, in comparison with usual activity only, so they could be used as therapeutics. One might also wonder if performance increase in the activity is necessary to get motor improvement, or if practicing only is enough. The present study takes part in a larger project which tries to answer these questions.

### OVERWEIGHT/OBESITY IN CHILDHOOD AND ADOLESCENCE INVOLVES A REDUCTION IN POSTURAL COMPLEXITY

BUCHECKER, M., WIESINGER, H.P., MÜLLER, E., STÖGGL, T., BIRKLBAUER, J.

*UNIVERSITY OF SALZBURG*

INTRODUCTION: Department of Sport and Exercise Science (University of Salzburg, Austria),
Red Bull Athlete Performance Center (Salzburg, Austria)
Using techniques borrowed from dynamical systems theory (i.e., sample entropy, largest Lyapunov exponent, and detrended fluctuation analysis), we have recently reported postural control deficits in young overweight/obese children and adolescents (YO) during quiet bilateral standing (1). Indeed, the YO revealed a stiffening strategy for maintaining balance, which was interpreted as a less complex and, thus, less flexible control of posture. To further challenge this conclusion, the present work aimed to re-investigate our original records (employing a purely complexity-based procedure, that is, refined composite multiscale entropy (rCMSE) analysis (2).
METHODS: Nineteen YO and 19 carefully matched young normal-weight (YN) secondary school students were asked to stand as still as possible for 60 s, first on firm, and after a break of 2 min, on foam ground. Trunk acceleration signals in medio-lateral (ML) and anterior-posterior (AP) directions were captured with an inertial measurement unit and pre-processed to correct for tilt and noise. Resultant time series were then scrutinized with the rCMSE method, while the sum of the associated entropy values from scale 1 to 7 was considered as a complexity index (CI). ANOVAs and ICCs(1,1) were calculated to compare means and to address data reliability (test-retest design).
RESULTS: 2 (group) x 2 (task) x 2 (visit) ANOVAs revealed no significant main or interaction effect except themain effects of task and group ($p < 0.05$). Here, the post-hoc analysis revealed the following: first, standing on firm ground caused higher CI-ML and CI-AP values than standing on foam in each group (all $p < 0.05$), and, second, compared to their YN controls, the YO displayed lower CI values in the ML direction ($p < 0.05$) and tendentially also in the AP direction ($p < 0.10$) in both tasks. The reliability of the measures studied was fair to excellent [$0.44 \leq ICC(1,1) \leq 0.80$], except for the CI-AP variable [$ICC(1,1) = 0.38$] as regards the YN within the firm condition.
Discussion
The currently conducted rCMSE analysis successfully underlined our original notion that the YO would undergo a decline of postural complexity reflected as rigidity. Such less complex patterns are usually linked with diverse pathologies, are detrimental to compensate for internal or external perturbations, and are attributed to lower adaptability and task performance (see 3 for review). Without targeted balance stimuli, the YO likely end in a lifelong vicious circle of mutually dependent poor balance.

### LONG TERM ATHLETIC TRAINING AND MATURATION EFFECTS ON MUSCLE-TENDON PROPERTIES IN PREADOLESCENCE

PENTIDIS, N., MERSMANN, F., BOHM, S., SCHROLL, A., GIANNAKOU, E., AGGELOUSIS, N., ARAMPATZIS, A.

*HUMBOLDT-UNIVERSITÄT ZU BERLIN*

INTRODUCTION: Systematic research concerning the effects of long-term athletic training on muscle-hypertrophy and tendon stiffness in preadolescence is scarce. The purposes of this study were (a) to investigate training effects on triceps surae muscle strength, gastrocnemius medialis (GM) morphometrics and Achilles tendon stiffness in preadolescence and (b) to examine the development of these properties over 1-year with regard to potential imbalances between muscle and tendon adaptation in preadolescent athletes.
METHODS: We recruited 21 preadolescent artistic gymnastic athletes (9.2 ±1.7 yr, 14 Tanner stage I and 7 Tanner stage II) and 11 untrained participants (9.0 ±1.7 yr, 5 Tanner stage I and 6 Tanner stage II) as a control group. Muscle strength of the plantar flexors, GM morphometrics and Achilles tendon stiffness were measured over 1-year with 3-month intervals using dynamometry, ultrasonography and electromyography. Furthermore, we documented the training volume in athletes 3 months before the first measurement and for the entire period of

the investigation. A linear mixed-effects model for repeated measures was used to compare the outcomes between the two groups and to investigate their development over time.
RESULTS: The athletes trained on average for 20 h/wk. They demonstrated greater muscle strength ($p<0.001$) but no differences in GM pennation angle, thickness and fascicle length ($p>0.05$) compared to non-athletes. Muscle strength and GM thickness increased similarly in both groups during the 1 yr period ($p<0.001$). Achilles tendon stiffness neither differed between athletes and non-athletes ($p>0.05$) nor changed over time in both groups ($p>0.05$). Athletes showed greater fluctuations in muscle strength ($p=0.033$), pennation angle ($p=0.005$) and maximum tendon strain ($p=0.017$) than non-athletes over time. Further, the frequency of individuals that reached high-level tendon strain values (≥9%) during the 1-yr was higher in athletes (up to 67%).
CONCLUSION: We found higher muscle strength in athletes but no significant differences in Achilles tendon stiffness between the two groups, which indicates imbalances between muscle strength and tendon stiffness in preadolescent athletes. Similar to tendon stiffness, we did not find significant differences between groups in GM morphometrics despite a high sport-specific muscle-tendon loading. We propose that the hormonal status could be the limiting factor for both training-induced alterations in GM morphometrics and Achilles tendon stiffness in preadolescence (1,2). Our findings provide first-time evidence that athletic training in preadolescence is associated with higher fluctuations of Achilles tendon strain and a temporarily increased tendon mechanical demand. Therefore, we recommend the implementation of individual training concepts to preserve a balanced adaptation in preadolescent athletes.

### AGREEMENT BETWEEN TWO OBJECTIVE MEASURES FOR CATEGORIZING INDIVIDUALS AS SUFFICIENTLY ACTIVE BASED ON CONTINUOUS PHYSICAL ACTIVITY MONITORING

WESTERN, B., DEMMELMAIER, I., VISTAD, I., HENRIKSEN, H.B., NORDIN, K., BLOMHOFF, R., BERNTSEN, S.
*UNIVERSITY OF AGDER*

INTRODUCTION: Physical activity (PA) is a multidimensional concept, and PA level (PAL) can be presented in numerous ways. Wearable PA monitors are rapidly improving as technological developments increase their accuracy and ability to capture several PA dimensions. PA profiles, where activity level is conditioned on more than one dimension, may be the future of PA monitoring. Many sophisticated monitors allow for continuous wear and measurement. Continuous PA monitoring is increasingly used for research purposes, but also by the general population through various activity watches. Reaching 150min MVPA/week is a widely used threshold for categorizing individuals as sufficiently active, both in research and in public health promotion. However, this threshold may be inappropriate to use with continuous monitoring as the development of this recommendation was largely based on self-reported PA. PAL-values are also used for categorizing individuals as sufficiently active and represent total energy expenditure (TEE) relative to basal metabolic rate (BMR). A PAL of 1.75 are commonly used as the lower cut-off for being moderately active. The objective of the present study was to compare 150min MVPA/week and PAL 1.75 as thresholds for categorizing individuals as sufficiently active based on continuous PA monitoring.
METHODS: The SenseWear Armband (SWA) was worn ≥22hours/day for six consecutive days in 692 cancer survivors. Mean MVPA/day was used to estimate MVPA/week. The SWA calculates metabolic equivalents (METs) based on a tri-axial accelerometer and temperature sensors, and MVPA was defined as METs ≥3. PAL-values were calculated as TEE measured by the SWA divided on BMR calculated with the formula by Mifflin-St Jeor. Linear regression determined the association between PAL-values and time in MVPA and was used to predict the amount of MVPA corresponding with PAL 1.75. The ROC curve was used to assess the sensitivity and specificity corresponding with this predicted value.
RESULTS: Mean MVPA/week was 556.9±396.9min and mean PAL was 1.63±0.20. MVPA was significantly association with PAL ($R2=0.646$, $B=0.003$, $p<0.001$). With MVPA ≥150min/week, 91% were categorized as sufficiently active, while 25% of the sample had PAL ≥1.75. The likelihood of being categorized as sufficiently active based on PAL-value for a person having ≥150min MVPA/week was 28%. The predicted amount of MVPA corresponding with PAL 1.75 was 735 min/week, achieved by 27.6% of the sample, with a sensitivity of 76.9% and specificity of 85.0%.
CONCLUSION: Time in MVPA was significantly associated with PAL when assessed on a continuous scale, however, their thresholds for categorizing individuals as sufficiently active were not compatible. Time in MVPA corresponding with PAL 1.75 was approximately five times the current recommendations. When PA is monitored continuously, 150min MVPA/week appear inappropriate for categorizing someone as sufficiently active.

### ASSOCIATIONS OF SKELETAL MUSCLE MASS WITH OBJECTIVE AND SUBJECTIVE MEASURES OF PHYSICAL FUNCTION IN MEN TREATED WITH ANDROGEN DEPRIVATION THERAPY FOR PROSTATE CANCER

UMLAUFF, L., BLOCH, W., SCHUMANN, M.
*GERMAN SPORT UNIVERSITY COLOGNE*

INTRODUCTION: Androgen deprivation therapy (ADT) in men with prostate cancer (PC) is associated with a loss of skeletal muscle mass resulting in reduced muscle strength and physical function [1]. The disturbance of normal skeletal muscle function caused by ADT put individuals at a higher risk of falls and physical impairment [2]. However, studies have shown that the majority of men treated with ADT are unaware of these side effects and their potential long-term consequences [3]. In order to examine whether muscle mass determines the actual or perceived level of physical function during ADT, we assessed its associations with objective and subjective measures of physical function in men with advanced PC. Furthermore, we investigated the relationship between objective and subjective measures of physical function.
METHODS: Sixteen men (age: 65 ± 8 years; body mass index (BMI): 26 ± 3 kg·m-2) treated with continuous ADT for metastatic PC participated in this cross-sectional pilot study. Body composition measurements included bioimpedance analysis to assess lean body mass (LBM)

and panoramic ultrasound to assess muscle cross-sectional area (CSA) of the rectus femoris. Objective measures of physical function included muscle strength, which was assessed using a leg extension one-repetition maximum (1RM) test, as well as aerobic capacity (VO2max) and 400 m walking time. The activities-specific balance confidence scale (ABC-scale) was used to determine subjective physical function.
RESULTS: Neither whole-body LBM nor muscle CSA of the rectus femoris were associated with any objective or subjective measures of physical function ($p > .05$). Subjective ratings (ABC-scale: 88% ± 18) indicated a high level of physical function among the participants but were not associated with any of the objective measures of physical function ($p > .05$).
CONCLUSION: Despite the importance of skeletal muscle mass for overall health and physical performance, we did not find an association with any measures of physical function in our study. Interestingly, subjective physical function was also independent of objective measures such as maximal strength or cardiorespiratory fitness, indicating a potential mismatch between perceived and actual physical capabilities. Defining the determinants of physical performance in men with advanced PC treated with ADT may help to improve the design of future exercise intervention studies.

## CHARACTERIZATION OF THE COMBINED EFFECTS OF ACUTE EXERCISE AND IMMUNO CHEMOTHERAPY TREATMENTS ON SKELETAL MUSCLE IN MC38 COLORECTAL CANCER MICE

DAMON, M.

*UNIVERSITY CLAUDE BERNARD LYON 1*

INTRODUCTION: Colorectal cancer (CRC) usually leads to skeletal muscle cachexia, characterized by loss of skeletal muscle mass and function (Baracos et al., 2018). Treatment with immunochemotherapy (ICT) improves patient survival but induces muscle toxicity leading to increase in inter-cures time and/or to dose reduction (Feather et al., 2018). Aerobic exercise may increase tumor perfusion (Zhang et al., 2019). In addition, the combination of physical activity and ICT may be the most effective method to fight the adverse effects of cancer and treatment and could limit cachexia. However, so far, no studies have tested the effects of acute exercise-ICT interaction on CRC. Thus, the objective of this study is to investigate the effects of acute aerobic exercise on skeletal muscle pre-injection of ICT in a mouse model of colorectal cancer.
METHODS: Four weeks mice model of colorectal cancer (MC38) were divided in four groups (n=4/group): control (CTRL), immune-chemotherapy (TRT), exercise (EXE) and combined intervention (TRT-EXE). Mice in EXE and TRT+EXE groups performed daily aerobic exercise for one week on a treadmill at 60% of their maximal aerobic running speed. Mice in TRT and TRT+EXE groups received ICT treatment (anti-PDL-1 + capecitabine + oxaliplatine) five times for one week, just before the daily exercise for the TRT+EXE group. After one week, tibialis anterior (TA) and gastrocnemius (GAS) muscles were collected and weighed. Histological staining were performed to assess muscle characteristics. Results were given as mean ± SD with a p-value significance level below 5% ($p<0.05$). Muscle weight is given in mg and is related to the initial weight of the mouse.
RESULTS: All results will be available at the end of April 2022. Preliminary results on muscle mass show that TA mass for TRT group (1.74±0.04 mg) was significantly lower than the EXE group (2.01±0.06 mg, $p=0.003$) and the TRT+EXE group (1.96±0.04 mg, $p=0.01$). The GAS mass in the EXE group (5.32 ± 0.6 mg) was significantly higher than the TRT group (4.55±0.1 mg, $p=0.04$).
CONCLUSION: The pleiotropic effects of PA on muscle could explain the greater muscle mass in the exercise' groups of MC38 mice. Indeed, acute PA stimulates the Akt/mTOR pathway, responsible for protein synthesis, and thus may limit the muscle atrophy observed in cachexia (Aquila et al., 2020). This pre-clinical study may provide insights on the musculoskeletal parameters in response on the combined effect of pre-treatment exercise and immuno-chemotherapy in colorectal cancer.

## EFFECTS OF EXERCISE-CONDITIONED HUMAN SERUM ON THE IN VITRO GROWTH CHARACTERISTICS AND METABOLIC ACTIVITY OF HUMAN LUNG CARCINOMA CELLS

SOARES, C.M., MINUZZI, L.G., TEIXEIRA, A.M., URBANO, A.M.

*UNIVERSITY OF COIMBRA - FACULTY OF SPORT SCIENCES AND PHYSICAL EDUCATION & FACULTY OF SCIENCE AND TECHNOLOGY.*

INTRODUCTION: Cancer is a leading cause of death worldwide with an increasing incidence that could reach 28.4 million new cases by 2040. In spite of advances in diagnosis and treatment, prevention is still the most efficient measure against the progression of incidence and mortality (1). A large proportion of new cancer cases and cancer deaths are preventable by eliminating or reducing exposure to environmental risk factors and/or modifying lifestyles, namely by increasing physical activity (2). Higher levels of physical activity have been linked to a lower risk of many types of cancer. In the case of lung cancer, the leading cause of cancer death (1,796,144 of the 10 million cancer deaths in 2020), evidence is moderate (3). There is now some evidence that exercise-conditioned human serum reduces the viability of cultured cancer cells (4). The present study aimed at extending those findings, namely by evaluating whether serum conditioned by a bout of physical exercise affected the in vitro growth characteristics and metabolic activity of human lung carcinoma cells in ways that might explain the observed reduction of the relative risk of lung cancer.
METHODS: Blood was collected from master athletes prior to and 5 mins after a single bout of incremental exercise until exhaustion on a cycle ergometer. Cultures of human lung carcinoma A549 cells were exposed to pre-exercise human serum and exercise-conditioned serum and the effects of these exposures were evaluated in terms of proliferation (SRB assay), metabolic activity (MTT assay), and ability of single cells to grow into colonies (clonogenic assay). A paired t-test was used to compare the effects of pre-exercise and post-exercise human serum.
RESULTS: Compared with at rest serum, exercise-conditioned serum reduced significantly the cells' ability to form colonies, as evidenced by the significant reduction in mean colony area (48.5% reduction; $P < 0.01$) and total colony occupied area (46.71% reduction; $P < 0.05$). Regarding metabolic activity, the slight increase observed for a 24-h incubation was reversed when exposure was extended to 72-h.
CONCLUSION: These data suggest that acute exercise promoted systemic changes that significantly reduced the ability of A549 cancer cells to form colonies, i.e., that compromised their ability to undergo unlimited division, a hallmark of cancer.

**LATE CARDIO-METABOLIC TOXICITY IN TGCT SURVIVORS IS MODULATED BY HABITUAL PHYSICAL ACTIVITY**

AMIRI, A., KRUMPOLEC, P., CHOVANEC, M., MEGO, M., UKROPCOVÁ, B., UKROPEC, J.

*SLOVAK ACADEMY OF SCIENCES*

INTRODUCTION: Late chemotherapy-related toxicity could largely affect health and quality of life in cancer survivors [1]. Here we examined cardiometabolic toxicity in testicular germ-cell tumor (TGCT) survivors in relation with cumulative chemotherapy dose, post-treatment time and habitual physical activity. The aim was to evaluate if increased physical activity provides benefits for cardiometabolic health in this population.
METHODS: 195 TGCT survivors were stratified according to their habitual physical activity and examined for the prevalence of cardiometabolic health parameters, i.e. metabolic syndrome components, systemic immune inflammation, atherogenic risk and hepatic function markers. 98 of patients were further stratified into the three age- and BMI-matched groups differing in number of chemotherapy cycles (≤3 vs. >3) and post-treatment time (5-15 vs. 15-30 yrs.) and compared to healthy men (n=38). Subgroup of TGCT survivors who did not receive chemotherapy (n=17) were compared to matched population of patients treated with no more than 3 CHT cycles. The level of habitual physical activity (hPA) was assessed by validated questionnaire >5 years after treatment.
RESULTS: TGCT survivors with high hPA had lower waist circumference and systemic immune inflammation index and their habitual physical activity correlated positively with HDL cholesterol and testosterone and negatively with waist circumference. Irrespective of the chemotherapy dose (≤3 vs. >3 cycles) and post-treatment time (5-15 vs. 15-30 yrs.) TGCT survivors had higher prevalence of metabolic syndrome as compared to controls. However, the highest prevalence of metabolic syndrome was found in patients diagnosed and treated at younger age (23.2±5.6 yrs.) who were examined 15-30 years post-treatment. Interestingly, neither the number of chemotherapy cycles (≤3 and >3) nor its absence seemed to affect metabolic syndrome prevalence in TGCT survivors diagnosed and cured in their thirties and examined 5-15 years post-treatment. This implies the presence of disease-related chemotherapy-independent effects on the cardiometabolic health. Moreover, higher habitual PA correlates with lower waist circumference, and reduced atherogenic risk in the entire population of TGCT survivors and this relationship is specifically strong in TGCT survivors with ≤3 chemotherapy cycles.
CONCLUSION: Conclusions: Metabolic syndrome and cardiovascular risk were more pronounced in TGCT survivors, than in healthy controls. The risk progressed with time and was independent from chemotherapy dose. Cardio metabolic benefits of higher habitual physical activity were found in controls, in the entire population of TGCT survivors, and it was specifically strong in patients who received less than 3 cycles of chemotherapy and examined 5-15 years post-treatment.

**EFFECT OF DIFFERENT LEVELS OF ACUTE HYPOXIA ON ORAL GLUCOSE TOLERANCE, INFLAMMATION, OXIDATIVE STRESS AND APPETITE IN OVERWEIGHT AND OBESE MEN.**

SHEPHERD, A., PERISSIOU, M., JAMES, T., COMMO, B., YOUNG, J., CUMMINGS, M., MONTGOMERY, H., GROCOTT, M., SAYNOR, Z., TIPTON, M., CORBETT, J.

*SCHOOL OF SPORT, HEALTH AND EXERCISE SCIENCE, FACULTY OF SCIENCE AND HEALTH, UNIVERSITY OF PORTSMOUTH, PORTSMOUTH, UK.*

INTRODUCTION: Obesity is associated with increased inflammatory cytokines and insulin resistance. Hypoxia increases skeletal muscle glucose transport and disposal (Mackenzie & Watt, 2016), reduces appetite and increases metabolic rate (Palmer & Clegg, 2014). However, lower fractions of inspired oxygen (O2) have been shown to increase inflammation and oxidative stress compared to moderate hypoxia (Siervo et al., 2014). The aim of this study was to examine the effect of different levels of hypoxia on glucose tolerance, inflammation, oxidative stress and appetite in overweight and obese men.
METHODS: In a single blind, randomised, balanced, crossover design, 6 overweight/obese men (BMI; 27.8 ± 1.2 kg/m2) completed the study (a priori power calculation = 12). Participants attended 3 separate visits, during which they inspired different fractions of O2 (20.9%; [normoxia] 15.5%; 12.0%) for 1 h prior to a 3 h oral glucose tolerance test (OGTT; 75g). Plasma [glucose], [insulin], [ghrelin], [4-hydroxynonenal], [interleukin-6], systolic blood pressure (SBP), diastolic BP (DBP) and hunger were measured at baseline, after the intervention and at 30 min intervals during the OGTT. Arterial O2 saturation (SPO2) and expired gas analysis were averaged over each hour. Repeated measured ANOVAs (oxygen fraction x time) and post-hoc tests were performed.
RESULTS: SpO2 decreased as the degree of hypoxia increased ($p<0.0001$). Area under the curve (AUC) [glucose] (20.9%: 34.2 ± 6.5; 15.5%: 37.3 ± 6.6; 12.0%: 38.5 ± 7.5 mmol.L-1, $p=0.30$) and peak [glucose] (20.9%: 6.9 ± 1.6; 15.5%: 7.0 ± 1.3; 12.0%: 7.5 ± 1.3 mmol.L-1, $p=0.28$) were not different between conditions. Total energy expenditure was not different between conditions ($p=0.08$). There was a significant reduction in carbohydrate (CHO) oxidation at the highest level of hypoxia (20.9%: 345 ± 55; 15.5%: 283 ± 93; 12.0%: 263 ± 14 kcal.4h-1, $p=0.02$) but no change in fat oxidation ($p=0.12$) between conditions. There was no effect of hypoxia on hunger ($p=0.14$), SBP ($p=0.32$) or DBP ($p=0.40$).
CONCLUSION: Interim analysis suggests that high levels of hypoxia (12.0%) may reduce CHO oxidation in overweight/obese men, whereas peak plasma [glucose] and AUC do not change during an OGTT. Together this suggests that glucose storage may be increased with acute hypoxia.

### AEROBIC CAPACITY AND BODY COMPOSITION CHANGES INDUCED BY A COMBINED TRAINING IN ADULTS WITH TYPE 1 AND TYPE 2 DIABETES COMPARED TO HEALTHY ADULTS

SCOUBEAU, C., FAORO, V., KLASS, M.

*UNIVERSITÉ LIBRE DE BRUXELLES*

INTRODUCTION: Exercise is a key factor in the management of diabetes mellitus (1), but it remains unclear whether diabetes affects the response to exercise training as compared to normoglycemic individuals.
METHODS: Ten adults with type 1 diabetes (T1D; 43 ± 13 years), fifteen adults with type 2 diabetes (T2D; 53 ± 8 years) were matched by age and gender to two groups of healthy volunteers (CTL1: n = 10, 43 ± 13 years; CTL2: n = 15, 55 ± 11 years), All participants took part in a 12-week (3x/week) standardized but self-managed exercise training program performed in an easily accessible gym. Cardiopulmonary exercise testing on a cyclo-ergometer and body composition assessment, with dual-energy x-ray absorptiometry, were performed before and after the intervention. The training program consisted of 30 min of high intensity interval training on a stationary bike (8 bouts of 2 min at 90% of maximal heart rate interspaced with 2 min of active recovery) and ~30 min of strength training (3 sets of 10 repetitions of weight-lifting with 4 main muscle groups). Sessions were recorded using an activity tracker.
RESULTS: Statistical analysis revealed that the 4 training groups improved their cardio-respiratory fitness with a VO2max increase ranging from +9 to +18% ($p<0.05$) and an associated major increase of the first ventilatory threshold from +20 to +33% ($p<0.05$). In adults with T2D only, training decreased the ventilatory response and chemo-sensibility, as reflected by a smoothened VE/VCO2 slopes; (Pre: 29.9 ± 3.7; Post: 27.7 ± 3.0; $p<0.01$) but also improved the body composition; -4% of body fat mass, ($p<0.05$), -10% of visceral adipose tissue ($p<0.05$), +2.3% of lean mass ($p<0.05$). However, intergroup comparisons revealed a lower training induced increase of VO2max in T2D as compared to their age-matched controls (T2D +9%; CTL2 +18%, $p<0.05$). No other intergroup differences were observed.
CONCLUSION: The proposed combined aerobic and resistive training program improved VO2max in adults with diabetes regardless of the etiology. T1D patients responded similarly to healthy subjects, while adults with T2D exhibited limited VO2max improvements as compared to age-matched healthy controls. However, subjects with T2D benefit anyway from training, as it improves the ventilatory response to exercise, the lean mass and it decreases the total and visceral fat.

### THE EFFECTS OF AEROBIC AND RESISTANCE HEALTH-ENHANCING EXERCISE PROGRAMS ON GUT MICROBIOTA AND METABOLIC PARAMETERS IN WOMEN WITH METABOLIC SYNDROME

DROZDOVSKA, S.B., HURENKO, O.O., ANDRIEIEIVA, O.V., ORLENKO, V.L., KOLIADA, A.K., PORADUN, Y.M.

*NATIONAL UNIVERSITY OF PHYSICAL EDUCATION AND SPORT OF UKRAINE, V.P. KOMISARENKO INSTITUTE OF ENDOCRINOLOGY AND METABOLISM OF THE NATIONAL ACADEMY OF MEDICAL SCIENCES OF UKRAINE*

INTRODUCTION: Metabolic syndrome is a cluster of cardiometabolic risk factors, including obesity, atherogenic dyslipidemia, hypertension and hyperinsulinemia. Hypodynamia is considered one of the main risk factors for MS and its complications, so increasing muscular and cardiorespiratory fitness is an effective therapeutic strategy to influence the performance of carbohydrate and lipid metabolism, improve quality of life, prevention of MS. The aim of the study is to investigate the effectiveness of resistance and aerobic exercise and their impact on biochemical parameters of carbohydrate metabolism and gut microbiota composition in women with metabolic syndrome.
METHODS: The functional state (heart rate, blood pressure), the body weight, the BMI, body composition (the content of fat, the lean body mass, percentage of visceral fat) and body circumferences of 50 women with MS involved into health-enhancing exercise programs were evaluated before and after the 3-month exercise training. All women were divided into group I (20) and group II (30), which were engaged in aerobic and resistance programs. The body fat reduction and changes in the main markers of metabolic syndrome (HDL, LDL, TG, total cholesterol, blood glucose, HbA1c, insulin, HOM-IR index, AST and ALT) were assessed. Determination of microbiota composition at the level of major bacterial phyla was performed with quantitative real-time PCR (qRT-PCR) using universal primers targeting bacterial 16S rRNA gene, as well as primers specific for Actinobacteria, Firmicutes and Bacteroidetes.
RESULTS: Group I had significant changes in cholesterol, which decreased by 16.1% and triglycerides by 26.6%, while carbohydrate metabolism, HDL, LDL, BMI, body weight, fat mass and visceral fat remained without statistically significant changes. Group II had a significant decrease in the mean values in the following indicators: HbA1c decreased by 16%, Homa-IR by 16.7% and fasting glucose by 14%. Additionally, there is a decrease in average body weight by 6.6%, BMI by 7%, the percentage of fat mass and visceral fat by 7% and 15.6%, respectively. Indicators of cholesterol and triglyceride fractions in group II have a pronounced tendency to decrease, but not confirmed by statistical analysis. Bacteroidetes increased by 24.5% and the F/B ratio changed by 3.8%. Comparative analysis of the two groups revealed significant differences ($P<0.05$) of HbA1c, Homa-IR, glucose and ALT.
CONCLUSION: Physical intervention of resistance training had a more significant effect on improving carbohydrate metabolism, body weight, BMI, fat mass, visceral fat, increasing Bacteroidetes and changing the F/B ratio in individuals with metabolic syndrome. Thus, resistance exercise will allow to influence the course and treatment of MS more effectively and to prevent the development of concomitant pathological conditions.

### THE ROLE OF ISOMETRIC AND ISOKINETIC LEG STRENGTH IN MAXIMAL FAT OXIDATION IN TYPE 2 DIABETICS

OPAZO-DIAZ, E.1,2, PEREZ-BEY, A.1, MONTES-DE-OCA-GARCÍA, A.1, MARÍN-GALINDO, A.1, RAMIREZ-JIMENEZ, M.1, REBOLLO-RAMOS, M.1, CORRAL-ROMÁN, J.1, CASALS, C.1, PONCE-GONZÁLEZ, J.G.1

*1 UNIVERSIDAD DE CÁDIZ, SPAIN; 2 UNIVERSIDAD DE CHILE, CHILE*

INTRODUCTION: Type 2 diabetes (T2DM) directly affects muscle health, including muscle mass, strength, quality, and function. In fact, the loss of skeletal muscle mass is associated with a concomitant decline in muscle strength in T2DM. However, little is known if it can also influence fat oxidation, which is considered a biomarker of metabolic flexibility. Moreover, Cardiorespiratory Fitness (CRF) is a major influence on maximal fat oxidation (MFO) capacity, however this capacity also depends on muscle mass. Hence, this study aimed to analyse the influence of muscle strength on maximal fat oxidation capacity in a T2DM group.
METHODS: Fourteen volunteers (8 men) age 53.3 ± 8.7 years with T2DM from the EDUGUTION project were evaluated in an incremental exercise protocol in a cycle ergometer with two consecutive phases performed for MFO and VO2max using indirect calorimetry. The first phase aimed to determine MFO, and it consisted of 3 min steps of 15W increments with a cadence of 60rpm. The test was stopped when RQ ≥1. After 5 min rest, the second phase to detect VO2max began with steps of 1 min and the same incremental load until exhaustion. An

Isometric knee extension test (Isom) for 6 seconds and 15 repetitions of knee flex-ext at 120° per second (Iso120) were performed in an isokinetic dynamometer for peak torque and total work. Bioimpedance analysis was used to assess fat mass and muscle mass. Spearman correlation test and linear stepwise regression analyses were performed to explain MFO with a significance of 95%.
RESULTS: The correlation of MFO with Lean Mass (r=0.51), Isom Peak Torque (r= -0.46) and Iso120 Work in Flexion (r= 0.15) and Extension (r=0.04) was not significative (p>0.05). However, MFO correlates significatively (p<0.05) with VO2max/Kg (r=0.62) and fat mass (r= -0.55). VO2max had significative (p<0.05) correlation with leg lean mass (r=0.543) and Iso120 Work Flexion (r=0.60). When MFO normalized for body weight, the results were similar. The stepwise regression best model of MFO adjusting by Lean Mass and Leg Lean Mass include VO2max/LeanMass and VO2max/Leg Lean Mass, respectively (Beta standard 0.636 and 0.732, p = 0.015 and 0.03).
CONCLUSION: MFO was strongly influenced by CRF, and CRF is related to leg isometric and 120° isokinetic strength. However, the oxidative muscle capacity is more important for fat oxidation than the muscle isometric and 120° isokinetic strength in T2DM patients. More research is needed to understand the role of other strength manifestations and strength training in fat oxidation metabolism. **EFFECTS OF HIGH INTENSITY INTERVAL TRAINING ON METABOLIC SYNDROME IN BREAST CANCER PATIENTS RECEIVING ANTHRACYCLINE CHEMOTHERAPY**

GONZALO ENCABO, P.1,2, LEE, K.3, CHRISTOPHER, C.N.1,2, NORMANN, A.J.1,4, YUNKER, A.G.1,5, NORRIS, M.K.1, WANG, E.6, DIELI-CONWRIGHT, C.M.

*DANA FARBER CANCER INSTITUTE*

INTRODUCTION: Anthracycline chemotherapy is a commonly used treatment for breast cancer, however it can increase the risk of harmful physiologic outcomes, such as metabolic syndrome (MetS). High-intensity interval training (HITT) has been shown to improve MetS in other clinical populations such as patients with diabetes or cardiac rehabilitation patients, whereas the impact of HITT on MetS and associated biomarkers in breast cancer patients receiving anthracycline chemotherapy is still unknown. Thus, the aim of this secondary analysis was to evaluate the effects of an 8-week HIIintervention on MetS and associated biomarkers in breast cancer patients undergoing anthracycline chemotherapy.
METHODS: Breast cancer patients (n=30) were recruited prior to initiating treatment and randomized into HIIT (n=15) or control (n=15). The HIIT group attended
supervised cycling exercise sessions three days/week for eight weeks. The control group was asked to maintain their current level of physical activity. Body composition was assessed, and blood samples were obtained before and after the 8-week intervention. MetS z-score was calculated by assessing waist circumference, blood pressure, fasting levels of high-density lipoprotein cholesterol (HDL-C), triglycerides, and glucose. Circulating levels of MetS-related biomarkers were also measured, including total cholesterol, insulin, HbA1c, leptin, adiponectin and c-reactive protein (CRP). Linear regression models were used to estimate mean differences between groups post- intervention adjusted for baseline values.
RESULTS:At baseline, 70% of all patients had MetS, with non-significant differences
between groups. Post-intervention, MetS z-scores significantly improved in the HITT group compared to the control group (between-group difference, -7.60, 95% CI: -9.08 to -6.13, P<0.001). Importantly women in the control group increased MetS by over 13% over the course of treatment. Compared with the control group, HITT showed 27th annual ECSS Congress Sevilla/ Spain, 30 Aug –2 Sep, 2022 significant improvements in MetS variables (increased HDL-C and decreased glucose and triglycerides) and circulating MetS-related biomarkers (cholesterol, insulin, HbA1c, leptin and CRP), as well as an increase in adiponectin (P<0.001) at the end of the study. MetS variables (HDL-C and triglycerides) and all circulating MetS-related biomarkers remained significantly improved compared with baseline in the HITT group (P<0.01). In contrast, there were no significant differences between groups in body composition outcomes at the end of the study.
CONCLUSION: An 8-weeks HIIT intervention is an effective strategy to improve MetS in breast cancer patients undergoing anthracycline chemotherapy. Furthermore, changes in MetS and associated biomarkers were independent of changes in body composition. These findings have important clinical implications and support the incorporation of supervised HITT programs during breast cancer chemotherapy. NCT0245477

### OP-MH17 Frailty and falling in elderly

**SEX DIFFERENCES IN FRAILTY, FALLS RISK, AND INDEPENDENCE IN OLDER ADULTS. ROLE OF ADHERENCE TO EXERCISE PROGRAMMES.**

MILLAN-DOMINGO, F., GARCIA-DOMINGUEZ, E., CARRETERO, A., GARCIA-DOMINGUEZ, C., GONZALEZ-OLASO, G., TARAZONA-SANTABALBINA, J., VINA, J., GOMEZ-CABRERA, M.C.

*FRESHAGE RESEARCH GROUP- DEPT. PHYSIOLOGY-UNIVERSITY OF VALENCIA, CIBERFES-ISCIII, INCLIVA, VALENCIA 46010, SPAIN.*

INTRODUCTION: Despite having a longer life expectancy, the prevalence of frailty is higher among women (W) than men (M). This fact leads to a decrease in functional capacity, quality of life and independence. Also, with the decline in functional capacity comes an increase in the risk of falls. In a clinical trial (CT) involving 100 individuals (NCT02331459), we previously reported the benefits of a multicomponent, social, personalized, and supervised exercise intervention to revert age-associated frailty and prevent its transition to disability. Results of such trials should be confirmed by Real-Life (RL) experience.
METHODS: In this study, 33 women and 17 men aged 78.9±2 years participated in a RL intervention based on a successful previous CT. The RL intervention lasted six months and was performed outside the hospital setting and independently of the primary care centers. We used the same inclusion criteria as in the CT. For the statistical analysis, the t-student test was used for qualitative variables with normal distribution, and the Wilcoxon test was used for non-parametric ones
RESULTS: With the RL intervention we achieved an adherence of 79% (95%[CI]72%-86%) compared to the 47% (95%[CI]39%-56%) for the CT. W in the RL group reduced Fried`s frailty criteria from 4 to 0.7, p=0.0001, those in the CT from 3.4 to 2.0, p=0.0278 and those in the control group from 3.9 to 5.0. M in the RL group went from having 3.6 frailty criteria to 0.8, p=0.0001, those in the CT went from 3.2 to 1.8,

p=0.0349 and those in the control group from 3.7 to 4.0. W in the RL group improved the Barthel scale from 74.8 to 88.4, p=0.0001, those in the CT from 84.6 to 88 and those in the control group worsened from 86.6 to 78.8, p=0.0012. M in the RL group improved from 81.1 to 92, p=0.0007, those in the CT group went from 92 to 94.7, p=0.0138 and those in the control group worsened from 89.3 to 82.5, p=0.0021. On the Tinetti scale, W in the RL group increased from 18.1 to 23.4, p=0.0001, those in the CT group from 22.3 to 23.8 while those in the control group went from 22.9 points to 20.7. M in the RL group went from a mean score of 21 to 24.3, p=0.0001, those in the intervention group from 25 to 26 and those in the control group from 23.1 to 20.8, p=0.0397. Finally, W in the RL decreased the falls number from 1.6 to 0.5, p<0.0001, those in the intervention group from 0.8 to 0.2, p=0.0329 and those in the control group from 0.5 to 0.8. The number of falls in the RL group in W decreased from 1.4 to 0.1, p=0.0002 while those in the intervention group decreased from 0.6 to 0.3. The control group increased from 0.5 to 0.6.
CONCLUSION: The greater adherence to the RL programme resulted in greater benefits in both M and W, when compared to the CT. It has been found that the higher prevalence of frailty among women leads to a lower capacity to perform basic activities of daily living, as well as a higher number of falls. In the RL intervention we found the biggest improvement in the women group.

### INDIVIDUAL EFFECTS OF A SHORT CONCURRENT TRAINING INTERVENTION IN PRE-FRAIL AND FRAIL OLDER ADULTS AFTER 6 MONTHS OF DETRAINING PERIOD

GARCIA-AGUIRRE, M., BALTASAR-FERNANDEZ, I., MUÑOZ-MUÑOZ, M., SOTO-PANIAGUA, H., MARTIN BRAOJOS, S., UCETA, M.I., GARCIA-GARCIA, F.J., ARA, I., ALFARO-ACHA, A., ALEGRE, L.M., LOSA-REYNA, J.

*1GENUD TOLEDO RESEARCH GROUP, UNI DE CASTILLA-LA MANCHA. TOLEDO,2CIBER OF FRAILTY AND HEALTHY AGING.MADRID, 3DPT OF GERIATRICS, HOSPITAL VIRGEN DEL VALLE,TOLEDO 4MOVE-IT RESEARCH GROUP CADIZ*

INTRODUCTION: In the last decades, physical exercise has played an important role in improving physical function and frailty syndrome in older adults. However, individual effects after 6-month exercise cessation on this population still remains unclear. The aim of this work was to determine the individual response to concurrent exercise training after a 6-month detraining period.
METHODS: Quasi-experimental, non-randomized controlled training on frail and pre-frail older adults (82.5 ± 5.7 years). The intervention group (EX) performed a 6-week concurrent training program (Power-based resistance training + High-Intensity Interval Training) followed by a 6-month detraining period, whilst the control group (CON) conducted usual care. Short Physical Performance Battery (SPPB), absolute and relative sit-to-stand muscle power, frailty trait scale 5 (FTS5) and frailty phenotype were assessed in both groups at baseline, 2 months and 6 months from the beginning of the intervention program. The minimal clinically important difference (MCID) was used to interpret results and participants were classified into Responders (R) change > MCID + 99%CI and Non-responders (NR) change < MCID + 99%CI. Linear mixed models and independent samples t-test were used for contrasting the mean differences at baseline (CON group vs EX group) and after the detraining period (CON group vs NR vs R).
RESULTS: No significant differences were found between CON and EX group in baseline values, however, meaningful differences were found after the training period. The EX group showed 95% of the subjects responded with a minimal clinically important improvement to the intervention after 6 months of training cessation to at least one variable. Finally, the percentage of positive response was heterogeneous, 85% of participants in SPPB, 57% in absolute power, 69% in relative power, 75% in FTS5 and 45% in frailty phenotype.
CONCLUSION: This study showed that a short concurrent exercise training of 12 weeks provoked positive minimal clinically important differences after 6 months of detraining period in pre-frail and frail older adults.

### PHYSICAL ACTIVITY LEVELS AFTER FALLING – ASSESSMENT METHODS FOR OLDER ADULTS WITH AND WITHOUT COGNITIVE IMPAIRMENT

STUCKENSCHNEIDER, T., DUNKER, E., KOSCHATE, J., ZIESCHANG, T.

*CARL VON OSSIETZKY UNIVERSITY*

INTRODUCTION: Falls in older adults, especially in individuals with cognitive impairment (CI), may mark the starting point of a vicious circle affecting long-term health and quality of life. This vicious circle is characterized by functional decline, decreasing physical activity, and a progressive reduction of social participation. Therefore, it is essential to accurately assess physical activity levels of older adults with and without CI after a fall, as a change in PA level may be an early marker for future functional decline.
METHODS: The SeFallED study aims to recruit 450 patients, aged 60 years and older, who are treated in the emergency department at the “Klinikum Oldenburg” or the “Evangelisches Krankenhaus Oldenburg” after a fall without hospital admission. After an initial assessment within four weeks of the incidence, the participants will be observed for 24 months. Fall risk factors such as cognitive function and physical activity will be assessed. The Montreal Cognitive Assessment (MoCA) will be used as a screening tool for CI, which is defined as a score <25. Physical activity will be self-reported using the Physical Activity Scale for the Elderly (PASE) and objectively measured with an activity monitor (activPAL) worn for 7 days. Respective outcomes are a PASE score between 0-400 and average steps per day. We will correlate activity levels measured by questionnaire and by activity monitor and compare their level of agreement using Bland-Altman plot between individuals with and without CI. Further, we will explore the associations between physical activity levels and functional outcomes using the results of the short physical performance battery, which will also be assessed during the initial study visit.
RESULTS: 22 data sets (mean age: 74 ± 8 years, 31.8% females) have been analyzed thus far with 9 of the participants having a score of less than 25 on the MoCA. Pearson’s correlation revealed a strong association (r=.713, p=.002) between PASE scores (mean: 114.8 ± 65.3) and steps per day (mean 6778.5 ± 4003) in the total sample, but also in the two different groups with (r=.923, p=.09) and without CI (r=.706, p=.022). Further analyses will include the level of agreement between the two assessments sorted by group and its association with functional outcomes.
CONCLUSION: Preliminary results indicate a strong association between objectively assessed and self-reported physical activity levels in both; individuals after a fall with and without CI. With recruitment ongoing throughout 2022, sample size will increase significantly allowing for more detailed and further analyses. This will inform about the usability of different assessment methods. If a fast and easy to administer questionnaire can assess physical activity accurately, it may be used to identify individuals with low levels of physical activity in the future.

### DIETARY NITRATE SUPPLEMENTATION PREVENTS TRANSIENT REDUCTIONS IN MITOCHONDRIAL, BUT NOT MYOFIBRILLAR, PROTEIN SYNTHESIS RATES FOLLOWING SINGLE-LIMB IMMOBILIZATION IN MICE

PETRICK, H.L.1,2, VACHON, B.1, HOLWERDA, A.M.2, SENDEN, J.M.2, GIJSEN, A.P.2, VAN LOON, L.J.C.2, HOLLOWAY, G.P.1

INTRODUCTION: Skeletal muscle disuse rapidly decreases muscle mass, muscle protein synthesis, and mitochondrial content/function. The overexpression of mitochondrial calcium transporter has been shown to attenuate muscle denervation-induced atrophy, suggesting a relationship between mitochondria, calcium, and protein metabolism. Since dietary nitrate can alter cellular calcium homeostasis, we aimed to determine if nitrate supplementation could prevent immobilization-induced skeletal muscle maladaptations in mice.
METHODS: Female C57Bl/6N mice were subjected to unilateral hindlimb casting and randomized to consume standard drinking water (H2O) or water supplemented with 1 mM sodium nitrate (NO3). All water throughout the immobilization period (3- or 7-days) contained 4% deuterated water (2H2O). Red gastrocnemius was excised to measure mitochondrial respiration, protein content, reactive oxygen species (ROS) emission, and myofibrillar 2H-alanine enrichment. Vastus lateralis was excised for isolation of subsarcolemmal (SS) and intermyofibrillar (IMF) mitochondria. Data were analyzed using paired Student's t-tests at each time point (control vs. immobilized limb within H2O or NO3 mice) and expressed as mean±SD.
RESULTS: Immobilization (I) rapidly increased mitochondrial ROS, decreased mitochondrial respiration, and reduced mitochondrial protein content ~15-30% compared to the control limb (C) at both 3- and 7-days. Nitrate prevented these responses, suggesting a preservation of mitochondrial bioenergetics. Regardless of nitrate consumption, immobilization decreased myofibrillar 2H-alanine enrichment ~3-fold (3- and 7-days) and induced muscle atrophy. Given the preservation of mitochondrial bioenergetics, we aimed to examine if nitrate had beneficial effects on mitochondrial-specific protein synthesis. In the absence of nitrate, 2H-alanine enrichments in SS and IMF mitochondria were lower following both 3-days (H2O SS, C: 0.84±0.34 vs. I: 0.57±0.16 mole percent excess (MPE), p=0.006; H2O IMF, C: 0.62±0.22 vs. I: 0.42±0.10 MPE, p=0.03) and 7-days (H2O SS, C: 1.90±0.25 vs. I: 1.72±0.12 MPE, p=0.04; H2O IMF, C: 1.79±0.24 vs. I: 1.58±0.22 MPE, p=0.05) of immobilization. While nitrate did not prevent this response at 7-days, nitrate preserved mitochondrial 2H-alanine enrichments following 3-days of immobilization in SS (NO3 SS, C: 0.72±0.12 vs. I: 0.66±0.14 MPE, p=0.44) and IMF (NO3 IMF, C: 0.52±0.12 vs. I: 0.45±0.12 MPE, p=0.11) mitochondria.
CONCLUSION: Dietary nitrate mitigated the immobilization-induced impairments in mitochondrial bioenergetics (3- and 7-days) and mitochondrial protein synthesis rates (3-days) in female mice. While nitrate was not sufficient to prevent reductions in myofibrillar 2H-alanine enrichment or muscle atrophy, these data nonetheless suggest that nitrate supplementation may represent a promising therapeutic strategy to preserve mitochondrial function during skeletal muscle disuse.

### SINGLE-NUCLEUS RNA-SEQ OF THE HUMAN MUSCULOTENDINOUS UNIT REVEALS NEW COMPONENTS OF THE MYOTENDINOUS JUNCTION.

KARLSEN, A., YEONG, C., SCHJERLING, P., JAKOBSEN, J.R., KROGSGAARD, M.R., KJAER, M., MACKEY, A.L.

*INSTITUTE OF SPORTS MEDICINE COPENHAGEN & XLAB*

INTRODUCTION: The myotendinous junction (MTJ) is a highly specialized region of the musculotendinous unit, designed to transmit high force from muscle to tendon. Yet, paradoxically, the MTJ is also a common site of muscle strain injuries. Strain injuries are among the most frequent sport related injuries, and despite prolonged rehabilitation, these injuries are associated with a high risk of recurrence, indicating suboptimal healing at the MTJ.
Despite the high risk of injury, our knowledge on the molecular composition of the MTJ remains limited. Recent studies in mice report a specialized sub-cluster of myonuclei at the MTJ (MTJ-myonuclei), suggesting a requirement for transcriptional heterogeneity between myonuclei at the MTJ and the rest of the muscle. Here we sought for the first time to explore the MTJ-myonuclei in human tissue, and we hypothesized that examination of their transcriptional profile could lead to the discovery of new proteins at the MTJ.
METHODS: Using single nuclei RNA-sequencing, we profiled nuclei from semitendinosus muscle-tendon biopsies from 3 healthy males undergoing anterior cruciate ligament reconstruction surgery.
RESULTS: We identified 47 significantly upregulated pre-mRNA transcripts in MTJ-myonuclei, of which 24 have been reported in MTJ-myonuclei clusters in mice. Next, we examined by immunofluorescence if enriched pre-mRNA transcripts in MTJ-myonuclei translates to an enrichment at the protein level at the MTJ. This lead to the discovery of several new MTJ-enriched proteins, which together improves insight into the molecular composition of the MTJ, and further supports the idea that many proteins at the MTJ are produced locally by the MTJ-myonuclei. We also observed transcriptional heterogeneity within myonuclei in the MTJ-myonuclei cluster, and a further examination revealed 4 distinct MTJ-myonuclei sub-clusters. Interestingly, the MTJ-specific marker collagen XXII was only significantly upregulated in two of these four sub-clusters, suggesting different roles among the myonuclei belonging to this specialized domain of the myofiber.
CONCLUSION: Together, our results adds to the knowledge of the molecular composition of the MTJ and the role of the specialized MTJ-myonuclei, and provide the first transcriptomic resource of human MTJ-myonuclei that will contribute to advance the understanding of this complex region and its failure during injury and repair.

### VICIA FABA PEPTIDE SUPPLEMENTATION DOES NOT DIFFER FROM MILK PROTEIN IN MODULATING MUSCLE MASS LOSS DURING IMMOBILIZATION AND RECOVERY, BUT INCREASES MUSCLE PROTEIN SYNTHESIS RATES DURING RECOVERY

WEIJZEN, M.1, HOLWERDA, A.1, JETTEN, G.1, HOUBEN, L.1, KERR, A.2, DAVIS, H.2, KEOGH, B.2, KHALDI, N.2, VERDIJK, L.1, VAN LOON, L.1

*1 DEPARTMENT OF HUMAN BIOLOGY, SCHOOL OF NUTRITION AND TRANSLATIONAL RESEARCH IN METABOLISM (NUTRIM), MAASTRICHT UNIVERSITY MEDICAL CENTRE+, THE NETHERLANDS; 2 NURITAS LTD, DUBLIN, IRELAND*

INTRODUCTION: Muscle mass and strength rapidly decrease during short periods of immobilization (<7 d), after which they slowly recover during remobilization. Recent artificial intelligence applications have identified natural peptide networks (NPNs) within raw food materials

that appear to possess anabolic properties in in vitro assays. This study assessed the impact of dietary supplementation with plant derived NPN on muscle mass, muscle strength, and myofibrillar protein synthesis rates during 7 d of disuse and 14 d of subsequent remobilization.
METHODS: Thirty healthy, young (24±5 y) men were subjected to 7 d of one-legged knee immobilization followed by 14 d of ambulant recovery. Subjects were randomly allocated to ingest either 10 g milk protein concentrate (MPC; n=15) or 10 g Vicia faba NPN (NPN_1; n=15) twice daily throughout the study protocol. One day before casting, directly after cast removal, and 14 d after cast removal, quadriceps cross sectional area (CSA) was assessed using single-slice CT scans and knee extension strength was assessed using one-repetition maximum (1-RM) tests. Subjects ingested deuterium oxide (2H2O) daily with saliva and muscle biopsy samples being collected to measure myofibrillar protein synthesis rates during the immobilization and recovery periods. The primary outcome variable was quadriceps CSA. A two-way repeated measures (time x group) ANOVA was used to compare changes in quadriceps CSA, knee extension strength, and myofibrillar protein synthesis rates during immobilization and recovery. Data represented as mean±SD.
RESULTS: Leg immobilization decreased quadriceps CSA from 7.5±1.1 to 7.1±1.0 cm2 and from 8.1±1.0 to 7.6±0.9 cm2 in the MPC and NPN_1 group, respectively (P<0.001), with no differences between groups. Remobilization partially recovered quadriceps CSA (MPC: 7.3±1.0, NPN_1: 7.7±0.9 cm2, P=0.009), with no differences between groups (P>0.05). Knee extension 1-RM decreased during immobilization (P<0.001) and partially recovered during remobilization (P=0.008), with no differences between groups (P>0.05). During immobilization, myofibrillar protein synthesis rates were lower in the immobilized leg (MPC: 1.10±0.24, NPN_1: 1.07±0.24 %/d) compared with the non-immobilized leg (MPC: 1.52±0.20, NPN_1: 1.55±0.27 %/d, P<0.001), with no differences between groups (P>0.05). During remobilization, myofibrillar protein synthesis rates in the immobilized leg increased significantly in the NPN_1 when compared with the MPC group (1.53±0.38 vs 1.23±0.36 %/d, respectively: P=0.027).
CONCLUSION: Vicia Faba peptide supplementation does not differ from milk protein supplementation with regard to the decline in muscle mass and strength during short-term immobilization, or the regain in muscle mass and strength during remobilization. Vicia Faba NPN supplementation does not differ from milk protein supplementation in modulating myofibrillar protein synthesis rates during immobilization, but increases myofibrillar protein synthesis rates during remobilization.

### AMINO ACID TRANSPORTERS IN HUMAN SKELETAL MUSCLE ARE ALTERED WITH REGULAR RESISTANCE TRAINING IN YOUNG AND OLD

LANDER, E.1, HAMARSLAND, H.2, RAASTAD, T.1

*1: NORWEGIAN SCHOOL OF SPORT SCIENCE, DEPARTMENT OF PHYSICAL PERFORMANCE 2: INLAND NORWAY UNIVERSITY OF APPLIED SCIENCES*

INTRODUCTION: The postprandial availability of amino acids in the skeletal muscle is dependent on transmembrane bound amino acid transporters (AAT) transporting amino acids from the blood to the cell interior and its compartments. Increased intracellular amino acid availability facilitates and increases muscle protein synthesis (MPS). Metabolic dysregulation is proposed to cause attenuated anabolic muscle response to feeding in elderly and in sedentary adults, termed anabolic resistance, where the role of AATs may be critical. Therefore, this study investigated possible differences in AATs in young and old and whether regular resistance training changes the appearance of AATs and its regulators.
METHODS: Healthy young (n=15, 20-40 yrs) and old (n=12, 70-80 yrs) adults completed a 12-week whole-body strength training intervention (3/week). Before and after the intervention, lean leg mass (LLM) measured by dual energy X-ray absorptiometry and strength as one repetition maximum (1RM) in the leg press was tested. Muscle biopsies were obtained from m. vastus lateralis and fractionated and analyzed with western blots in the cytosolic (C), membrane (M) and nuclear (N) fractions for the AATs: CD98(C,M,N), SLC38A9(M,N), LAT3(C); and the regulator eIF2α (C,M,N). Data was analyzed using a two-way ANOVA for repeated measures.
RESULTS: For absolute changes, it was observed a time and age interaction effect (p<0.05) in 1RM and a time effect (p<0.0001) in 1RM and LLM. The young increased 1RM more than the old (78±32 kg vs 50±20 kg, p<0.0001). LLM increased similarly in young and old (1.0±0.6 kg and 1.0±0.6 kg) and there were no differences in the relative changes between the young and old. Before training, there were no differences between young and old in the levels of AATs in any fraction. For changes is protein levels, there was an interaction effect between time and age in CD98-M (p<0.01) and eIF2α-N (p<0.05), and a time effect in CD98-N (p<0.0001), eIF2α-N (p<0.0001) and SLC38A9-M (p<0.01). CD98-N levels increased for both groups (young: 66±123%, old:45±53%, p<0.05), whereas only the old increased in eIF2α-N (92±125%, p<0.001) and decreased in SLC38A9-M (-46±41%, p<0.01). The protein levels of LAT3-C did not change and no differences were found between the groups in the relative changes for neither protein. A correlation was found in the relative changes between SLC38A9-M and LAT3-C for the old (r=0.75, p<0.05) and between CD98-N and eIF2α-C (r=0.59) and eIF2α-N (r=0.66), eIF2α-N and eIF2α-C (r=0.63) and eIF2α-M and SLC38A9-M (r=0.60) for the young (p<0.05).
CONCLUSION: Resistance training induced increases in muscle mass and muscle strength which were accompanied by changes in CD98, eIF2α and SLC38A9 in both young and old. The observed changes in AATs and eIF2α may be related to alteration in stress response regulation or regulation of amino acid uptake. The increase in CD98 and eIF2α in the nuclear fraction was unexpected and the functional importance is currently unclear

### PHARMACOLOGICAL ACTIVATION OF AMPK ACUTELY INCREASES MITOCHONDRIAL ADP SENSITIVITY, BUT THE MECHANISM IS NOT CONSERVED IN FASTED MICE.

DESORMEAUX, G., FRANGOS, S.M., STEINBERG, G.R., HOLLOWAY, G.P.

*UNIVERSITY OF GUELPH*

INTRODUCTION: The transport of ADP across the inner mitochondrial membrane influences rates of oxidative phosphorylation and reactive oxygen species (ROS) production, representing a key control point affecting mitochondrial bioenergetics. Despite the importance of mitochondrial ADP transport/sensitivity to cellular homeostasis, very little is known about the regulation of this process. In the present study we aimed to investigate the possibility that 5'-AMP-activated protein kinase (AMPK), a key enzyme that has been shown to reside on mitochondrial membranes in response to cellular stress, regulates adenine nucleotide translocase (ANT), the inner mitochondrial membrane ADP/ATP counter-transport protein.
METHODS: C57Bl/6N mice were subcutaneously injected with either AICAR (500mg/kg) to pharmacologically activate AMPK or an equal amount of saline (n=10/group). After 60 minutes, permeabilized fibers from the red gastrocnemius were prepared for mitochondrial respiration (maximal respiration and ADP sensitivity) and the remainder of the tissue was snap frozen for further analysis. An additional cohort of C57Bl/6N mice (n=48) were randomized into an 18h-fasted group (8:00am-2:00am) or a 24h-fasted group (8:00am-8:00am) to assess

mitochondrial bioenergetics and Western blotting in the red gastrocnemius muscle, compared to a time-matched fed group. Known ANT amino acid sequencing was also utilized to predict AMPK binding motifs.
RESULTS: Although mitochondrial content and maximal ADP-supported respiration remained comparable between saline and AICAR treated mice, AICAR decreased the apparent ADP Km ~25% indicative of greater ADP sensitivity. Fasting for 18hrs did not alter pAMPK, maximal oxidative phosphorylation or ADP sensitivity. Mice fasted for 24h displayed a strong trend for increased AMPK phosphorylation (p=0.075), but surprisingly displayed a decrease in ADP sensitivity (+25% ADP Km) in the absence of changes in maximal oxidative phosphorylation, suggesting AMPK does not directly regulate ANT/ADP sensitivity. In further support of this assertion, ANT does not possess a known AMPK binding motif, however we identified possible binding motifs for protein kinase A (PKA) and calcium calmodulin-dependant kinase (CaMK). While mitochondrial ROS and acetylation have also previously been implicated as regulators of ANT, mitochondrial ROS emission, acetylation and CaMK-phosphorylation were not affected by fasting suggesting these mechanisms are not contributing to the changes in mitochondrial ADP sensitivity.
CONCLUSION: The present data provides evidence that pharmacological and biological activation of AMPK has diverse consequences on mitochondrial ADP sensitivity suggesting other/additional mechanism(s) are responsible for regulating this key moderator of metabolism. Future studies are required to elucidate additional regulatory components of mitochondrial ADP transport as these appear independent of CaMK, acetylation, and changes in redox balance.

## OP-AP30 Performance analysis and training optimization

### PERFORMANCE INDICATORS THAT PREDICT WINS AND LOSSES IN THE UNITED RUGBY CHAMPIONSHIP.

SCOTT, G., BROWN, M.R., KILDUFF, L.P., BEZODIS, N., WALDRON, M.

*SWANSEA UNIVERSITY*

INTRODUCTION: In recent years, advanced data analytic techniques have been utilised to determine performance indicators in professional rugby union. Typically, these studies report 20+ key PI's that collectively can be used to predict match outcome. Whilst, acknowledgement of the PI's is strategically important, their high number can impede the deployment of actionable interventions by practitioners. No key research has investigated the use of variable selection methods to build and validate simplified models capable of predicting successful performances. Equally, there has also been no evidence of research within the United Rugby Championship (URC). Therefore, the primary aim of this study was to investigate team level PI's associated with winning performances within the URC, through machine learning and feature selection methods. Secondary aims included to test differences between individual team PI's (isolated data) and team PI's relative to their opposition (relative data) and to examine whether variable selection can be used to simplify modelling processes.
METHODS: A range of 27 PI's were taken from all 96 matches within the 2020-21 URC season (formerly known as the PRO14). These PI's were selected to characterise different areas of the game, including attack, defence, set piece and infringements. Random forest classification modelling was completed on both isolated and relative datasets, using the binary match outcome (win/lose) as the response variable. Maximum relevance and minimum redundancy was used to locate an optimal subset of PI's that are mutually and maximally dissimilar and can represent the response variable effectively. Models were used in prediction on 53 unseen matches from the 2021-22 season.
RESULTS: Within the 2020-21 datasets, the full models correctly classified 83% (CI 77%-88%) of match performances for the relative dataset and 64% (CI 56%-70%) for the isolated set. When models were optimised by reducing the number of variables, these values were 85% (CI 79%-90%) and 66% (CI 58%-72%). In prediction, the reduced relative model successfully classified 90% of previously unseen match performances (CI 82%-95%). Within the relative data model, 5 PI's were significant in differentiating between wins and losses: kicks from hand, metres made, clean breaks, turnovers conceded and scrum penalties.
CONCLUSION: Indicators of success within the URC include increased kicks from hand, metres made, and clean breaks compared to the opposition, as well as less scrum penalties and turnovers conceded. Relative PI's are more effective in predicting match outcomes than isolated data. Simplifying to a smaller number of key variables does not degrade model accuracy, suggesting that smaller groups of PI's may be used as replacement for the wider dataset. In practical applications this could allow practitioners to focus on a select number of PI's, to allow for a more manageable approach to training and monitoring tactics.

### ARE THEY IN SYNC? A MACHINE LEARNING APPROACH TO OPTIMIZE TRAINING SCHEDULES

KEMPE, M.

*UNIVERSITY OF GRONINGEN*

INTRODUCTION: Coaches design training programs consisting of a variety of training types to optimally prepare their athletes. However, previous studies showed a possible misalignment between coaches' intentions and athletes' physiological reactions to training session. To investigate this misalignment, Machine Learning (ML) techniques were used to compare physiological responses between different training types, possibly revealing unique training type characteristics and allowing coaches to optimize their training programs design. Therefore, training types were predicted by classification models using internal and external training load parameters.
METHODS: Heart rate data, lap times and session Rating of Perceived Exertion (sRPE) were collected from 17 elite short track speed skaters during the 2019-2020 season. A Kruskal-Wallis test with Dunn post hoc test was performed to analyze differences between the short track speed skating specific TRaining IMPulse Short Track (TRIMPST) and the speed zone-based Speed Score between training types. Using TRIMPST and Speed Score along additional training load parameters, a K-Nearest Neighbors (KNN), Decision Tree Classifier (DTC), Random Forest Classifier (RFC) and Logistic Regression (LR) were computed. These classification models were used to predict training type using internal and external training load parameters. The models were evaluated using accuracy, precision, recall and F1 scores.
RESULTS: A Kruskal-Wallis test showed significant differences in TRIMPST and Speed Score between training types, $\chi^2(6) = 86{,}37$, $p<0.001$ and $\chi^2(6) = 126{,}71$, $p<0.001$, respectively. Accuracy scores for the classification models for external load were 0.75, 0.75, 0.71 and 0.49 for the KNN, RFC, DTC and LR models, respectively. Accuracy scores for the classification models for internal load were 0.37, 0.44, 0.38 and 0.46 for the KNN, RFC, DTC and LR models, respectively. The classification models using external load parameters performed well in predicting extensive interval (EXT INT) and intensive interval (INT INT) trainings, whereas the classification models using internal load parameters performed well in predicting extensive endurance (EXT END).

CONCLUSION: Our approach opens a novel perspective on training program evaluation and training load monitoring. Using external training load parameters, training types can be accurately predicted. However, our findings show that training types cannot be accurately predicted using internal load parameters. Furthermore, since there was high internal intraclass variance in the internal load parameters, physiological responses to training load appear to be highly individual. Since the internal and external load classification models are unable to predict training types with accuracy, there appears to be a misalignment between coaches and athletes. It appears more intense training sessions cannot be accurately predicted using internal load measures.

**EFFECTS OF THE COACH SUBSTITUTION ON THE TECHNICAL – TACTICAL AND PHYSICAL PERFORMANCE OF PROFESSIONAL TEAMS IN LALIGA.**

MARTÍN CASTELLANOS, A., MURIARTE SOLANA, D., MON LÓPEZ, D., MARQUINA NIETO, M., LÓPEZ DEL CAMPO, R., RESTA SERRA, R., GARCÍA ALIAGA, A.

*UNIVERSIDAD POLITÉCNICA DE MADRID, DEPARTMENT OF COMPETITIONS AND MEDIACOACH LALIGA*

INTRODUCTION: High-performance football is demanding and depends on several factors (1). The role of the coach is to achieve high levels of performance according to the club´s objectives, which are related with results (2). When the performance is not optimal, one of the strategies to address the problem is to change the coach, looking for a "winning effect" (3) in the following matches to improve the results achieved. The aim of the study is to analyse the effects of replace the coach, in the technical, tactical, and physical aspects, with the hypothesis that these performance variables would be increased.
METHODS: The coach substitutions were made during the 2020-2021 season in LaLiga Santander, Spanish 1st football division (n = 7). To compare the performance of the team with the old coach and the new one, the last 8 and 4 matches before and the 4 and 8 after the change of coach was taken, analysing a total of 103 matches. Variables per match of each of the teams were provided by LaLigaTM and extracted using Mediacoach® and TRACAB®. These variables were related with performance (points per game, goals for and against), technical (nº of possessions, passes, shots on goal and shots received), tactical (width and length team average, offensive and defensive centroid) and physical performance (total distance, sprint, and high sprint, the number of efforts in each category and speed in team and opponent own). To make the comparison, a paired t – test was carried out between the 4 and 8 weeks before and after.
RESULTS: An increase in the points achieved, the total distance travelled, and the number of sprints after the change of coach was observed in both situations (4 and 8 weeks). The number of efforts at high sprint and the sprint and high sprint distance presented an increase with the new coach in the comparison between 4 weeks, while in the 8 weeks comparison, teams scored more goals, shots on goal, and greater speed in their own field when the coach changed.
CONCLUSION: Although high sports performance can be influenced by many factors, coach substitution could be an effective strategy when the expected performance of the team is not obtained, giving rise to different technical and physical performance variables.

**BLOOD FLOW RESTRICTION TRAINING FOR STRENGTH, HYPERTROPHY AND ENDURANCE: A NETWORK META-ANALYSIS**

WIEDENMANN, T.

*GERMAN SPORT UNIVERSITY COLOGNE*

INTRODUCTION: Blood flow restriction (BFR) training is a complementary exercise mode in which the blood flow of extremities is partially restricted. The resulting effects of blood pooling have been linked to greater gains of strength [1, 2], muscle mass [1, 2] and aerobic capacity [3] compared to work and intensity
matched non-restricted training interventions. The objective of this network meta-analysis is to directly and indirectly compare and rank the effect magnitudes of different BFR interventions on measures of maximal strength, skeletal muscle hypertrophy and aerobic capacity.
METHODS: PubMed, Web of Science, Cochrane and SPORTDiscus were searched starting from journal inception until December 2021. (Randomized) controlled trials comparing pre- to post-test changes for strength, hypertrophy and aerobic endurance outcomes between intervention and control groups in healthy adults aged 18 to 55 years were included. Study quality was rated using the PEDro scale. Eligible interventions lasted at least one week and at least three sessions. Three distinct networks for strength, hypertrophy and endurance were synthesized and interventions were ranked for their efficacy using the P-score. Relative effects of the interventions were displayed via the standard mean difference (SMD) and 95% confidence intervals.
RESULTS: Ninety-Five trials (strength = 83; hypertrophy = 53; endurance = 10) with 2,376 subjects (strength = 2156; hypertrophy = 1421; endurance = 263) and 304 pairwise comparisons (strength = 171; hypertrophy = 107; endurance = 26) were analyzed. High load resistance training interventions with or
without BFR are most beneficial for maximal strength gains (SMD = 0.80 – 1.04; P-score = 0.779 – 0.962). BFR amplifies the effect of low load resistance training on maximal strength gains (SMD = 0.34vs. 0.64). Eccentric resistance training and low load, high volume resistance training with BFR are
most beneficial for skeletal muscle hypertrophy (SMD = 1.02, 0.96; P-score = 0.830, 0.917). BFR slightly amplifies the effect of low load resistance training on hypertrophy (SMD = 0.51 vs. 0.60). High intensity endurance training with and without BFR is most beneficial for the aerobic capacity (SMD = 1.04, 0.86; P-score = 0.842, 0.751). BFR amplifies the effects of low intensity endurance training (SMD = 0.21 vs. 0.68).
CONCLUSION: A BFR provides notable effects on maximal strength, hypertrophy and the aerobic capacity, especially when low training intensities are used. While a high resistance training load seems to be most important for the gain of maximal strength, a high training volume regardless of the load seems to be most beneficial for hypertrophy. High intensity endurance training or low intensity endurance training with BFR seem to be most beneficial for the improvement of the aerobic capacity.

## OP-SH09 Management and doping

### IMPORTANCE-PERFORMANCE ANALYSIS(IPA) ON SERVICE QUALITY OF YOUTH SPORTS TRAINING PROVIDERS: THE CUSTOMERS PERSPECTIVE

ZHU, Y., YUAN, S.Y., SHANG, W.T.

*DALIAN UNIVERSITY OF TECHNOLOGY*

Introduction
Youth sports training is an important way to relieve stress of diversified development needs. It plays an significant role in enriching youth sports activities and all-round development for health[1]. After the Chinese government introduce incentives, a large number of youth sports training providers have grown rapidly. At the same time, the customers have given them greater expectations, so they need to be more high-quality. Scholars have discussed the market governance and sustainability of them, but there are few based on quality evaluation from the perspective of customers[2]. So we plan to build a service quality evaluation system for it base on China's policy orientation and situation.
Methods
After the field research and deeply interviews with representatives of various participators in service process, the final system was designed as 6 aspects through the Delphi survey, includes management specifications, venue facilities, manpower allocation, curriculum design, ability training, security assurance. Then, 50 elements under these dimensions are made into questionnaires, which distributed nationwide, covering 26 provinces, 65 providers and 19 kinds of sports. There are 630 valid questionnaires were collected, the statistics passed the Confirmatory Factor Analysis(CFA) and Internal Consistency Analysis(KMO≥0.9,α≥0.9). Then, put it into the IPA model to analyze the relationship between the importance and satisfaction of consumers, used as grounds for prioritization.
Results
The average score of importance for the service quality is 4.327, and the satisfaction is 4.423. Among them, curriculum design(I:4.459/P:4.3535) and ability training(I:4.42/P:4.351) are showed by both high. Safety assurance(I:4.439/P:4.301）, site facilities(I:4.41/P:4.311), management norms(I:4.403/P:4.317), and manpower allocation(I:4.409/P:4.329) showed high importance and low satisfaction. At the same time, there are 30 elements in area of quadrant A(continuous maintenance), 11 in B(high priority improvement),7 in C(low priority improvement), 2 in D(excessive supply).
Discussion
Customers believe that the service quality of Chinese youth sports training is well, but there is still gap between the supply and demand. The advantages of curriculum design and ability training should be maintained, the dimensions of security, facilities, management, and manpower allocation should be supplement. Specifically , it should be improved in three points: (1) Enhance standardization and security; (2) Establish the supervision and management mechanism; (3) Optimize the service elements purposefully.

### THE IMPACTS OF EVENT SERVICE QUALITY, ATTITUDE, AND PAST EVENT PARTICIPATION ON OCR PARTICIPANTS' BEHAVIOURAL INTENTIONS: THE MEDIATING ROLES OF SATISFACTION

LUO, S., MEDIAVILLA, L., LI, J.

*UNIVERSIDAD POLITÉCNICA DE MADRID*

INTRODUCTION: As the popularity of amateur-level competitive sport events has increased these years, participatory sport-related travel has become a growing trend in the literature on sport tourism [1]. Active sport tourism has also been attributed to sport event participation, such as obstacle course racing (OCR), as the case discussed in this study. Behavioural intentions, such as destination/event revisit intentions and word-of-mouth recommendations, have been consistently discussed as it appears that they could evaluate the success of destination/event [2][3]. Understanding the variables that influence active sport tourists' behaviours within the context of participatory sports events still needs more empirical investigations. The purpose of this study was to investigate active sport tourists' behavioural intentions by examining the relationships among event service quality, attitude toward the event, satisfaction with the event, and past event participation.
METHODS: Data were collected from 182 runners in an obstacle course racing held in Madrid, Spain. On-site questionnaires were used to collect the immediate responses. A research model was proposed by using path analysis in which five hypotheses were developed.
RESULTS: The fit indices indicated an excellent fit of the path analysis model to the data. The overall model explained 52% of the variance on behavioural intentions while event service quality and attitudes explained 73% of the variance on satisfaction. The results revealed the mediation effects of satisfaction between event service quality and behavioural intentions, and attitude and behavioural intentions. This study also explored event service quality and satisfaction with the event that positively influenced behavioural intentions. Past event participation has no impact on behavioural intentions.
CONCLUSION: Theoretical relationships were examined in this study between event service quality, attitudes toward the event, satisfaction with the event, past event participation, and behavioural intentions by proposing a structural model. Satisfaction with the event was also found to be an important variable to influence behavioural intentions directly. Event service quality is critical for the evaluation of satisfaction and a direct predictor of behavioural intentions.

### HUMAN RESOURCES ARCHITECTURE MODEL FOR MANAGING VOLUNTEERS IN SPORT EVENTS

SERAJI, M., KARGAR, G.A., KESHKAR, S.

*ALLAMEH TABATABAI UNIVERSITY*

The growing emphasis on the importance of a more professional approach to the management of volunteers in sport events has led event organizers to implement human resources management methods and tools that have the potential to facilitate volunteer' engagement, commitment and performance. In this regard, the purpose of this study was to identify the affecting components and to determine how to use the Human Resources architectural model to manage volunteers in sports events.
The present study is a field-research in terms of data collection method. The study population was experts in the field of human resource management, volunteering and event management and 19 interviewees were selected as the research sample using snowball sampling method. The main method of data collection was semi-structured in-depth interviews. The validity of the research was confirmed by showing the process of analyzing the interviews to the experts and the research reliability in terms of methodology and content, the accuracy of different aspects of research from collection to analysis was confirmed by two experts in this field who had no connection to the research. By their confirmation on the procedures and methods of collecting and interpreting data, the research audit was approved.
Based on the interviews, 84 initial codes were obtained and divided into five main categories, including human resource management architecture drivers, human resource management architecture elements, human resource architecture development barriers, strategic human resource architecture systems, and human resource management architecture functions.
Based on the research findings, implementing the human resource architecture model in managing volunteers in sports events, through the optimal knowledge of the elements and drivers of volunteer human resource architecture, by using strategic systems of volunteer human resource architecture and trying to overcome Barriers in development of volunteer human resource architecture can lead to achievement of volunteer human resource architecture functions for event stakeholders. Eventually, by maintaining the motivation and commitment of the volunteers, the process of socialization of the volunteers will be facilitated, they will have sufficient expertise and will feel valuable. On the other hand, by improving the performance of volunteers, the efficiency and effectiveness of the event increases and a more favorable experience of the event is provided to the participants in the event.

### MORAL DISENGAGEMENT, SOCIAL NORMS, AND MOTIVATIONAL PROFILES INFLUENCE ON ATTITUDES TOWARDS DOPING AMONG SPANISH COACHES.

GARCÍA-GRIMAU, E., DE LA VEGA, R., CASADO, A.

*AUTONOMOUS UNIVERSITY OF MADRID*

INTRODUCTION
Coaches strongly influence athletes' attitudes toward doping and can shape athlete's beliefs, behaviors, and decisions to be for or against doping. Coached-centered studies examining multiple factors affecting coaches' doping attitudes and behavior are scarce. The Sport Drug Control Model (SDCM) is applied for the first time in coaches with the aim of assessing the reproducibility of the model in athlete support personnel (ASP). Secondary study purpose was to determine the factors in the SDCM that most influence coaches' attitudes and susceptibility toward doping, and their doping prevalence.
METHODS
Participants completed a cross-sectional online survey. 201 Spanish athletics competitive level coaches completed the survey, from whom 11.4% were female and 62.2% were aged between 30 and 59 years. The Spanish SDCM questionnaire which was previously used on athletes and provided validity and reliability, has been adapted for coaches. Structural equation modeling (SEM) was carried out to test the SDCM in coaches.
RESULTS
Coaches reported on average negative doping attitudes and low levels of susceptibility to doping and moral disengagement. Coaches stated on average a high self-efficacy to refrain from doping and moderate ego-oriented goals. Regarding social norms, they reported a high subjective norms. They believed that, on average, reference groups would disapprove doping behaviors. With respect to descriptive norms, coaches perceived an average doping prevalence of 19.5% (1.95 ± 1.74 [mean ± SD]). SEM showed a good fitness of the SDCM. Self-reported doping prevalence in coaches was 4.5%. Positive attitudes toward doping predicted high susceptibility to doping ($B = 0.39$, $p < 0.001$). Moral disengagement ($B = 0.58$, $p < 0.001$), descriptive norms ($B = 0.42$, $p = 0.001$), ego-oriented goals ($B = 0.34$, $p < 0.05$), and self-efficacy to refrain from doping ($B = 0.26$, $p < 0.05$) displayed a significant influence on attitudes toward doping.
CONCLUSION
These variables should be considered when designing anti-doping research projects and educational programs aiming at modifying coaches' attitudes toward doping. In the complex context of elite sport in which the influences of sport environment and reference group on athletes are crucial, the absence of doping prevention may involve the presence of risk of its use. Perhaps it is time to focus more efforts on coaches, without putting aside the athletes, and therefore turn coaches into reliable doping prevention factors. To this end, it is necessary to enhance coach-centered research, provide more assistance to sport coaches, and establish effective and mandatory anti-doping education in them so that they can perform their role as anti-doping educators in an effective, committed, and proactive manner.

### INVESTIGATING NARCISSISM AND COMPASSION IN THE CONTEXT OF DOPING

ZHANG, S.1, BOARDLEY, I.2

*1 UNIVERSITY OF DERBY, UK; 2 UNIVERSITY OF BIRMINGHAM, UK*

INTRODUCTION: Doping is a goal-directed behaviour influenced by a range of psychological factors including personality traits. However, to date, little research attention has been received in

understanding the role of self in the use of banned substances for performance enhancement.
In this study, we conducted the first investigation into the two competing self-concepts, i.e., narcissism (reflecting a willingness to construct and maintain a positive self-image) and compassion (reflecting a motivation to approach and accept negative self or related distress in a
peaceful mind), in the context of athletes' doping. We hypothesized that narcissistic personality is a risk factor and compassion is a protective factor of intentional doping.
METHODS: We recruited a cross-sectional sample of 178 athletes (M age = 24.44, M years of training = 7.1, all competing at regional level or above), involving male (n = 99) and female (n = 79), individual (n = 24) and team sport (n = 154), competing at regional level (n = 147) or national level and above (n = 31). All participants completed measures on grandiose and vulnerable narcissism, self-compassion, fears of compassion, and risks for doping.
RESULTS: Multivariate moderation analysis revealed a significant grandiose × vulnerable narcissism interaction in increased doping risks. Specifically, participating athletes reported higher-level doping moral disengagement and doping willingness when they were either high in grandiose or vulnerable narcissism or indeed both. Moreover, low self-compassion and fears of compassion also contributed to increased doping risks. High self-compassion appeared particularly beneficial in protecting against grandiose narcissism's risk of doping moral disengagement and against vulnerable narcissism's risk of doping willingness regardless of
one's fearful feeling towards self-compassion. However, fear of compassion from others towards oneself was detrimental to athletes' resistance to doping willingness even when their dispositional self-compassion was high.
CONCLUSION: Narcissistic personality traits are risks factors for doping. Self-compassion mitigates narcissism's doping moral disengagement and doping willingness. However, fear of receiving compassion from others magnify the risk of narcissism in doping, even when dispositional self-compassion is high. The findings offer new knowledge of narcissism-related doping risks and insights into integrating compassion for anti-doping.

### OP-SH13 Coaching and Gender

#### NORMALISING THE CONVERSATION: PLAYER AND STAKEHOLDER PERCEPTIONS OF MENSTRUAL HEALTH SUPPORT IN ELITE WOMEN'S SOCCER

MCHAFFIE, S.1, LANGAN-EVANS, C.1, MOREHEN, J.C.1, STRAUSS, J.A.1, ARETA, J.L.1, ROSIMUS, C.2, EVANS, M.2, ELLIOTT-SALE, K.J.3, CRONIN, C.J.1, MORTON, J.P.1

*1. LIVERPOOL JOHN MOORES UNIVERSITY 2. THE FOOTBALL ASSOCIATION 3.MANCHESTER METROPOLITAN UNIVERSITY*

INTRODUCTION: On the basis of varying symptoms (1) associated with menses and trivial reductions in exercise performance during the early follicular phase of the menstrual cycle (2; MC), it has been recommended that a personalised approach is adopted for menstrual health support in athletes. However, a standardised practical approach to managing menstrual health has yet to be developed. Therefore, the aim of the present study was to qualitatively explore the perceptions of female soccer players and associated stakeholders in relation to menstrual health support.
METHODS: Semi-structured interviews were conducted with 47 participants from the Women's Super League and English Football Association, inclusive of players (N=12), parents (N=9), coaches (N=9), sport scientists (N=7), nutritionists (N=5) and medical staff (N=5). Interviews were audio recorded, with questions centred on determining participants' perceptions of menstrual health support. All interviews were transcribed verbatim, and an inductive approach was employed for data synthesis and analysis.
RESULTS: Four themes were established that provide an insight into the current state of menstrual health support within the women's soccer: 1) Menstrual symptomology is not a "one-size-fits-all" approach, as players reported varying MC symptoms, some of which they perceived to impact performance. Whilst parents and staff also acknowledged these varying symptoms, some coaches did not perceive any impact on performance. 2) There was confusion about the purpose of MC tracking, as despite this practice being widely reported by all stakeholder groups, there was a lack of understanding as to how this should be practically applied. 3) Participants from all groups reported that the MC is still a taboo topic of conversation and identified a need for this dialogue to be normalised. Additionally, most players reported that they would be more likely to discuss the MC with a female staff member. 4) There were mixed levels of awareness about menstrual irregularities; sport scientists, nutritionists and medical staff consistently perceived secondary amenorrhea to be common amongst players, which was in stark contrast to the views of coaches, parents and the players themselves.
CONCLUSION: These findings identify a lack of menstrual health support (i.e., imposing an inappropriate "one size fits all" approach, tracking data without using it to influence practice, a taboo culture where MCs and menstrual irregularities are not discussed), despite a need for individualised support due to varied symptomology. This lack of support and awareness of the negative health implications of an irregular MC is underpinned by a culture where conversations about the MC are not normalised. Therefore, this identifies the need for organisational, stakeholder and player centred education programmes, in order to promote conversations about the MC and create an environment where players receive personalised menstrual health support.

#### UNDERSTANDING FEMALE COACHES' AND PRACTITIONERS' EXPERIENCE AND SUPPORT PROVISION IN RELATION TO THE MENSTRUAL CYCLE

BROWN, N., KNIGHT, C.J.

*SWANSEA UNVERSITY*

INTRODUCTION: As female coaches and sport science practitioners have likely experienced the menstrual cycle and some associated symptoms, it may be assumed they have greater awareness, understanding, or empathy for female athletes and that issues around discussing the menstrual cycle are specific to male coaches. However, personal experiences across the menstrual cycle may influence female coaches and practitioners' understanding and subsequent support provision for athletes due to societal embarrassment about the menstrual cycle,

which leads to secrecy about this topic. Yet, to-date, the impact of personal menstrual cycle symptoms and understanding of female coaches and practitioners' performance in relation to supporting female athletes has not been considered. This study aimed to develop an understanding of female coaches' and sport science practitioners' experience and support provision in relation to the menstrual cycle when working with female athletes.
METHODS: Following receipt of institutional ethical approval, 14 female coaches and practitioners (32.9±6.9 yrs) participated in individual semi-structured interviews. Interviews focused on questions ranging from participants' knowledge and understanding of the impact of the menstrual cycle in sport, their own menstrual cycle symptoms and experiences and the steps they took to support athletes. Each participants transcript was analysed by the first author using qualitative analysis procedures.
RESULTS: Following analysis, two themes were developed: 1) Knowledge and awareness, and 2) Support and management. Overall, it appeared that participants varied in their understanding and awareness of the impact of the menstrual cycle on sport performance, somewhat influenced by their own personal experiences. Participants' knowledge and awareness subsequently impacted the support they provided to female athletes. Additionally, individual experiences and perceived secrecy relating to the menstrual cycle impacted on the informational and emotional support participants provided.
CONCLUSION: Overall, the findings highlighted a variance in participant knowledge and awareness of the menstrual cycle in relation to sport, with individual experiences influencing and impacting tangible, informational, and emotional support provided to athletes. Consistent with recommendations that we need to create a society in which menstruation is less stigmatised, within sport, coaches and practitioners need to address their own discomfort regarding the menstrual cycle conversations and challenge against the need for secrecy. This highlights the importance of all coaches and practitioners to enhance their knowledge and understanding regarding the menstrual cycle and proactively providing support to athletes. Education to enhance coaches' and practitioners' knowledge and understanding will help to create a more open and supportive environment in sport, hopefully allowing for personal discomfort regarding the menstrual cycle to be addressed.

### WHEN UNPLEASANT BECOMES PLEASANT AND PLEASANT BECOMES UNPLEASANT: A LONGITUDINAL INTERPRETATIVE PHENOMENOLOGICAL ANALYSIS OF COMPETITIVENESS IN ELITE DISC GOLF

FURRE, R., SOLSTAD, B.E., JOHANSEN, B.T.

*UNIVERSITY OF AGDER, KRISTIANSAND, NORWAY.*

INTRODUCTION: Disc golf, as golf, is a low intensity, fine motor skill sport with long lasting rounds which require shift of focus to prevent fatigue. Through a competitive season, the athletes' experiences of events and social situations can fluctuate due to contextual changes and development over time. During competitions in sport, athletes may appraise an array of potential stressors, such as demands of the sport being played and psychological demands. To understand the dynamic factors of perception and performance during a competition, it is important to gain an inside perspective of an elite athlete during a competitive season. Therefore, the purpose of the present study was to investigate how elite disc golf athletes experience and perform during competitions through a disc golf season.
METHODS: Participants were purposive homogeneous sampled through Norway's American Sports Association, with both male and female perspectives. Two elite disc golf athletes (n=1 male; n=1 female) took part in semi-structured interviews and were observed during three different competitions over the course of a competitive season. The participants were interviewed three times connected to each competition: before (T1=2 days), straight after (T2=15 minutes to 2 hours), and after (T3=4 to 9 days). They were also interviewed before (T1=45 minutes) and after (T2=15 minutes) a training session. Observation was done from an onlooker's point of view at the three competitions (M = 10 holes each per round) with instant commentary in a Dictaphone. The data available for data analysis were 26 semi-structured interviews (13 per participant) and descriptive and reflective field notes related to observation in the three competitions. A longitudinal interpretative phenomenological analysis (LIPA) was used to capture temporal and dynamic changes of the participants' experiences.
RESULTS: Three themes with sub-themes stood out from the LIPA analysis: The perception of competitions (unpleasant and pleasant); the experience of performing during disc golf competition (importance of confidence, ability to reset, and difference in feelings but not in result); and evaluating disc golf competition. Findings showed that the level of confidence affects the perception of and mindset in competition, which affects the performance. Confidence is gained through mastery in training and competition.
CONCLUSION: The findings showed how elite disc golf athletes perceived and performed during a competitive season. Whereas the female athlete went from an unpleasant to a pleasant experience, the male athlete went from a pleasant to an unpleasant experience during the competitive season. The difference between these two elite athletes were appraisal of the competition setting and demands. Indeed, our findings provide an inside perspective of elite athletes' performance during competition and provides empirical evidence on how performance is perceived at the elite level in a fine motor skilled sport.

### A MIXED-METHOD INVESTIGATION OF YOUTH FOOTBALL COACHES´ BEHAVIOURS AT HALF-TIME

RAYA-CASTELLANO, P.E., REEVES, M.J., CÁRDENAS, D., FRADUA, L., MCROBERT, A.P.

*UNIVERSITY OF GRANADA; UNIVERSITY OF CENTRAL LANCASHIRE; LIVERPOOL JOHN MOORES UNIVERSITY*

Introduction
Invasion games involve limited opportunities to affect performance during competition. Half-time breaks have been suggested as appropriate occasions to intervene, with coaches' non-verbal expressions changing players' perceptions of first-half performance (Van Kleef et al., 2019). Moreover, coaches' verbal communication at game breaks have typically been analysed during time-outs, end of quarters, and half-times in combination or have been examined qualitatively (Avugos et al., 2018). Therefore, a mixed-method approach was employed to explore the verbal behaviours of youth-elite coaches and their underpinning knowledge exclusively during half-time talks.
Method
Three qualified, youth-elite Spanish coaches (Miguel, Manuel, and Joaquín) working with U9, U13, and U18 players, respectively; consented to participate. Four half-time talks per age-group were filmed and coded using an adapted version of the CAIS, and coaches were interviewed to explore their behaviour rationales. Mean percentage time (%) of behaviours were calculated for each coach individually and interviews were analysed utilising thematic analysis procedures.
Results and discussion
Manuel and Joaquín were engaged in 'instruction' (35.72, 45.58 %) and 'feedback' (16.93, 12.77 %) for longer compared to 'player-talk' (10.00, 2.43 %), whereas Miguel exhibited an opposite tendency (instruction: 23.52, feedback: 7.85 %; and player-talk: 27.17 %). This behaviour was greater for coaches who displayed higher 'divergent' than 'convergent' questions (Miguel: 7.02, 3.90 %; Manuel: 4.32, 3.43 %).

Miguel and Manuel suggested 'divergent questioning' enabled understanding of players' emotions, whereas Joaquín rationalised his lower values (3.11 %) as an approach 'for avoiding divided opinions within the group'. Coaches highlighted their tone and volume regulation suggesting the 'level of play' and 'score' as the main factors strengthening or attenuating their message's intensity. Only Manuel's assistant was actively involved during talks and was purposefully empowered to provide instructions or complement Manuel's messages when required.
Conclusion
These results suggest similarities and differences in coaches' behaviour due to a combination of their individual beliefs, contextual factors, and age-groups coached. Questioning behaviours and player-talk were employed more frequently by Miguel and Manuel and vocal factors seemed to be more relevant that actual behaviour type for inferring meaning to messages.

**AN EXPLORATION OF RECIPROCITY AMONG TEACHER AND STUDENTS IN FEMALE PRE-ELITE BALLET: A SHARED REALITY THEORY PERSPECTIVE**

SOLSTAD, B.E., HARALDSEN, H.M., FREDRIKSEN, D., GUSTAFSSON, H., NORDIN-BATES, S., KNIGHT, C.J.
*UNIVERSITY OF AGDER*

Introduction
The teacher-student relationship is acknowledged as the heart of performance coaching, and a good quality relationship is deemed essential to enhance well-being and performance development. To establish such a quality relationship, a shared reality of mutual understandings, interests, and goals, as well as established trust and good communication appear vital. Despite the importance of this relationship, within the context of dance, it appears that there is an inconsistency between the ideal and actual in dance teaching, where teachers seem to overestimate the quality of their own teaching behaviors compared to their students' perceptions of the same teaching behaviors. However, there is a lack of theoretical understanding as to how and why such differences in perceptions arise and develop. Therefore, developing a more in-depth understanding of the establishing and quality of shared realities in asymmetric relationships, such as those between teachers and students in the performing arts, is particularly warranted.
Methods
A longitudinal narrative design with multiple interviews was adopted over an eight-month period. Three female pre-elite ballet dancers between 17-18 years (Mage = 17.3) and their primary ballet teacher were recruited to the study using purposive sampling. The interview guides were guided by the conceptual framework of Shared Reality Theory and previous research focusing on interpersonal trust. Hence, a theoretical lens was used deductively. Data were analyzed using narrative thematic analysis to interpret in what ways the participants made sense of ongoing episodes, actions, and relations in their life story as teacher or student.
Results
Findings indicated that there was established shared reality only on the epistemic level (i.e., a professional, but not on an emotional/personal level) across the teacher-student relationships. This was achieved by a common perception of what matters in the world of ballet education and that the students found their teacher trustworthy. It appeared that achieving a shared reality between the teacher and the students at a relational level might be challenging within the authoritarian apprenticeship culture in ballet. Hence, the culture set the frame for a professional and distanced relationship where teachers should give clear instructions and feedback, and where the students' role is to adapt to the teacher's feedback.
Conclusion
Extending earlier research in performance psychology, the findings demonstrated the influence of ballet culture on the perceptions of what constitutes a relationship that develops between students and teacher. It appears that greater consideration of relationship quality is needed within ballet education and further research is warranted to understand the perception of shared reality in more depth and its implication for the physical and psychological well-being of young ballet dancers.

**SMART ALPINE SKIS**

RUIZ-GARCÍA, I.1, NAVARRO-MARCHAL, I.2, MORENO-PÉREZ, J.A.1, LORENZO UHRICH, P.3, PALMA, A.J.1, GÓMEZ-LÓPEZ, P.J.2, CARVAJAL, M.A.1
*1. ECSENS, DEPARTMENT OF ELECTRONICS AND COMPUTER TECHNOLOGY, UNIVERSITY OF GRANADA, 2. SKIINGLAB, DEPARTMENT OF PHYSICAL AND SPORT EDUCATION, UNIVERSITY OF GRANADA, 3. KUSTOM SKIS S.L, MADRID, SPAIN*

INTRODUCTION: Nowadays all the sports are introducing new technologies to improve the technique or to avoid injuries. In alpine skiing for example, information about acceleration, angles and times is essential to evaluate each turn as well as the overall performance of the skiers. This information can be obtained using an Inertial Measurement Unit (IMU) attached to the ski [1,2].
Our research group have developed and validated in a ski simulator previously an inertial system [3]. This system includes a sensor board per ski based on the 9DoF Razor IMU (SparkFun Electronics, Niwot, CO, USA). Therefore, the aim of this work was development a smart ski with the system embedded.
METHODS: DEVELOPED PROTOTYPE:

In the current work, a smart ski prototype with the electronic embedded has been developed. The electronic consisted of an IMU, pre-processing electronics, a Bluetooth module, and a rechargeable power supply. It is inserted into the ski during the fabrication process, carried out in collaboration with a ski manufacturer (Kustom Skis, Spain). All the elements were placed under the ski boots bindings, therefore, are protected from water to prevent damages in the system. A button and three LEDs were included as user interface as well as an USB connector to recharge the battery and reprogramme the board, which is the unique visible part of the electronic system.
RESULTS: Our first instrumented skis pair has been developed successfully, and the preliminary results obtained in the tests carried out in the indoor ski slope are promising. Alpine skiing runs were conducted in an indoor ski slope (Madrid SnowZone, Spain). The system has been working over 3 hours without any problems reporting the kinematics variables continuous.
CONCLUSION: The current work is focus on the development of a smartphone application to improve usability of the system and provide immediate feedback to the users. In conclusion, this system with the APP would help coaches and skiers to achieve faster and better training results in real conditions.
ACKNOWLEDGMENTS:
This work was partly supported by Consejo Superior de Deportes through projects Sensor for Sport Monitoring and Sensor Sport Lab, "Redes de Investigación en Ciencias del Deporte" years 2021 and 2022, and European Regional Development Funds (ERDF). Thanks also to Kustom Skis for allowing the prototype ski manufacturing at their facility.

### VALIDITY OF SKIN TEMPERATURE AND ELECTROCARDIOGRAM USING VITALPROBE WEARABLE DEVICE

VIEDMA, A., WADHI, T., SAVLA, R., PATANKAR, Y., PANERU, K., LUBIAK, S., TAMULEVICIUS, N.
*UNIVERSITY OF TAMPA*

INTRODUCTION: Vital signs such as heart rate, heart rate variability (i.e., the variation between beats), and body temperature are key baseline measures for an individual's health and fitness status (1). A novel chest-based wearable device, VitalProbe (2020) [VP], provides continuous data on vital signs including the aforementioned parameters. These vital signs help monitor physical fitness, fatigability and possibly early predictors of illnesses. However, this information is only as useful as its accuracy. Therefore, the aim of the study is to validate VP for vital signs monitoring including R-R intervals and skin temperature.
METHODS: Twenty individuals (Age: 31.9±12.4 years; Females:Males: 12:8; BMI: 23.3±5.5 Body Fat %: 20.46±8.6 %) participated in the study. During the supine measurements, participants were concurrently connected to a 12-lead ECG and VP. VP was attached to the participants via a customized adhesive gel-pad placed on the participants sternum, just above the xiphoid process. The device measured skin temperature and single-lead ECG. The R-R intervals (RRI) between the ECG and VP were compared for a 30-second window while the participants were lying down. Skin temperature was measured for 5 minutes at an interval of 1 sample/minute. Mean ± standard deviation and mean average error (MAE) and confidence interval of the error (CI) is presented for all the vitals. Additionally, paired t-test and intra-class correlation (ICC) were run for each datapoint from VP and the criterion devices.
RESULTS: A total of 565 heart beats were collected from the supine measurements, with both ECG and VP producing similar results for RRI (ECG:0.961±0.117s;VP:0.968±0.118s;p-value:0.282; ICC:0.957;MAE:0.007±0.034s). A total of 100 samples were collected for skin temperature, and both the devices output similar results (Thermistor:33.51±0.657ºC;VP:33.46±0.797 ºC;p-value:0.587; ICC:0.359; MAE:0.056±0.828 ºC).
CONCLUSION: Collected data from the study provided similar measures for both parameters. RRI measured by VP showed no significant differences compared with the ECG. Furthermore, skin temperature measurements were also similar to the thermistor. These results have practical implications in clinical settings for detecting abnormalities for both body temperature and RRI. Thus, such a device could help in managing the risk of morbidity and mortality and improving the quality of life for the individual. Further research needs to look at the performance of this device for longer periods.

### FAIR STARTS FOR ALL: EXPLORING MULTISENSORY REACTION TIMES IN DEAF AND HEARING POPULATIONS TO DEVELOP A NOVEL ATHLETICS STANDARDISED STARTING SYSTEM.

STEELE, E.
*BANGOR UNIVERSITY*

INTRODUCTION: At present in Deaf sport, no standardised starting system exists that allows for fair and equal competition between Deaf and hearing athletes. Typically, Deaf athletes are required to compete alongside hearing athletes with variable starting systems. Whilst using alternative stimuli such as lights or vibrating armbands supports the inclusion of Deaf athletes to compete alongside hearing athletes, the opportunities for fast reaction times (RTs) - an integral part of a fast start in the 100m sprint - are not equitable. Subsequently Deaf athletes, who are not eligible to compete in the Paralympic pathway can become marginalized. To enhance the equality for Deaf athletes in sport, an interdisciplinary approach focusing on both the empirical and sociocultural requirements of a standardised starting system is necessitated. A series of studies investigating sensory RT differences (auditory, visual, haptic, and bimodal stimuli) across Deaf and hearing populations will inform the optimal sensory conditions that create the smallest discrepancies in RT across populations.
METHODS: The rationale behind Study 1 was to determine the optimal stimulus effector location for haptic RTs. As such, we investigated RTs at different effector locations (unilateral hands, both hands and both legs) in Deaf and hearing populations. The aim of Study 2 was to investigate multisensory RTs (unimodal and bimodal) between Deaf and hearing populations. Both experiments required participants to perform a rapid arm movement towards a target upon stimulus presentation on a manipulandum.

RESULTS: Study 1 results highlight that adopting bimodal stimuli at a high-set compatible location i.e. both hands, promote significantly faster RTs than other effector locations. Preliminary findings from Study 2 indicate that bimodal auditory-visual stimuli promote significantly faster RTs than other unimodal and bimodal conditions along with no significant difference between populations.
CONCLUSION: Findings so far support existing stimulus effector location RT literature (1) and create an interesting parallel between the benefits of bimodal stimuli in hearing populations (2) and visual facilitation effects in Deaf populations (3) and RT discrepancies. Future research includes focus groups and interviews to address opportunities, systemic barriers and marginalisation experienced by Deaf athletes at different stages of the participation and performance pathways to inform policy and societal change to enhance equality and inclusivity for Deaf athletes. Adopting this interdisciplinary, evidence-based approach will allow a holistic and comprehensive overview and understanding of the empirical and sociocultural requirements of a starting system to accelerate accessibility and opportunity for Deaf athletes to participate in all sport.

**EFFECTS OF THE NIKE ZOOMX VAPORFLY NEXT%2 SHOES ON INTERVAL TRAINING PERFORMANCE.**

RODRIGO-CARRANZA, V.1, CASTELLANOS-SALAMANCA, M.1, RODRÍGUEZ-BARBERO, S.1, GONZÁLEZ-RAVÉ, J.M.1, GONZÁLEZ-MOHÍNO, F.1,2

*1UNIVERSITY OF CASTILLA-LA MANCHA, SPORT TRAINING LAB, TOLEDO, SPAIN. 2 FACULTAD DE CIENCIAS DE LA VIDA Y DE LA NATURALEZA, UNIVERSIDAD NEBRIJA, MADRID, SPAIN. 3 DEPARTMENT OF PHYSICAL EDUCATION AND S*

INTRODUCTION: In 2017, the "Breaking2" project (an event aimed to run the first marathon under 2 h) introduced a new advanced shoe technology, the Nike ZoomX Vaporfly (VPF). This type of footwear changed the footwear design conception by using a curved carbon-fibre plate inserted into a very light midsole composed of a novel compliant and resilient ZoomX foam. It has been shown that this model improves running performance by improving running economy (1). However, the effect of this type of footwear during training is unknown. Therefore, the purpose of this study was to analyse the influence of VPF shoes on interval training performance and neuromuscular fatigue.
METHODS: Eleven trained distance runners (mean ± SD: age 32.91 ± 7.83 years, weight 69.29 ± 7.26 kg, height 172.73 ± 5.68 cm) completed an interval training (5x 1000m with 1 min 30s of recovery) with two different conditions (Nike VPF and control condition [the own competition's shoe without carbon fiber plate]) separated by 7 days. Subjects performed a countermovement jump (CMJ) pre and post training session.
RESULTS: Subjects ran 1.84 % (3.64s, $p \leq 0.05$, partial $\eta 2 = 0.47$) faster with VPF shoes (197.30 ± 13.06s) compared to the control condition (200.90 ± 13.67s). Moreover, the Bonferroni post-hoc showed that there was a significant increase (5.2s, $p \leq 0.05$) between the first and fourth repetition in the control condition, without differences in the VPF condition. Fatigue index (%) was higher in the control condition (2.62%) than the VPF (1.98%). There was no significant difference between the CMJ heigh loss in VPF (1.35 ± 1.88cm) and control (1.98 ± 1.47cm) conditions ($p = 0.21$, partial $\eta 2 = 0.16$).
CONCLUSION: The results suggest that the use of VPF shoes allows display a slightly more constant pace (less fatigue index) and faster average time than control condition. In addition, neuromuscular fatigue assessed with the CMJ height loss appeared to be lower in the VPF although without significant differences. This type of footwear aids running performance around ~1% (2) mainly influencing on metatarsal–phalangeal and ankle joint mechanics (3) increasing stride length and contact time (1). These alterations could influence in the increasing of running speed and to delay fatigue (more constant pace) during interval training.

**A DIGITAL RUNNING COACH FOR GUIDED RUNNING-STYLE EXPLORATION AND FEEDBACK IS BOTH TECHNOLOGICALLY AND CONCEPTUALLY FEASIBLE**

NIJS, A., ROERDINK, M., BEEK, P.J.

*VRIJE UNIVERSITEIT AMSTERDAM*

INTRODUCTION: In recent years, the development of wearable systems and their use by runners has taken a leap forward. Among these, instrumented wireless earbuds form a promising emerging technology, for which we are developing a digital running coach, which guides runners through various running styles based on the principle of learning through exploration [1]. Different runners exhibit different running styles at a certain speed, which according to the dual-axis model [2] can be comprehensively described using just two variables: 1) cadence and 2) duty factor (reflecting the stance-to-flight-time ratio). The envisioned digital running coach will 1) drive runners through different running styles by modulating the cadence (through acoustic pacing) and/or duty factor (through instructions about stance time or flight time) and 2) provide feedback about the performed running styles by parameterizing cadence and duty factor from earbud data. The aim of this study is to examine the technological and conceptual feasibility of such a digital running coach.
METHODS: To assess the technological feasibility of the digital running coach, we analysed the reliability and concurrent validity for cadence and duty factor variables derived from earbud data [3]. As regards its conceptual feasibility, we compared and analysed the effectiveness of various forms of acoustic pacing [4,5] and different verbal instructions to modulate these variables.
RESULTS: Cadence and duty factor can both be reliably and validly derived from instrumented wireless earbuds [3]. Cadence can be modulated best with step-based acoustic pacing [4], without adversely affecting the impact force [5]. Duty factor can be modulated with verbal instructions about changing stance time as well as flight time.
CONCLUSION: We conclude that the envisioned digital running coach, providing runners feedback about their running style and guiding them through different running styles, is technologically and conceptually feasible. That is, the earbud data can be used to parameterize the key running variables of the dual-axis model [3] while acoustic pacing and verbal duty-factor instructions are effective in modulating runners' cadence and duty factor, respectively [4,5]. Based on these findings, we created a guided exploration protocol which instructs runners to explore the different running styles of the dual-axis model. This protocol is currently evaluated in both lab (to examine its effect on running kinetics and kinematics) and field studies (to examine the feasibility of running-style exploration). In addition, we are imple-

menting the running-style instructions, as well as feedback about the effect of such instructions for modulating running styles, in the instrumented wireless earbuds to create the first iteration of the digital running coach.

### EFFECTIVENESS OF A MUSCLE LOAD FEEDBACK APPLICATION FOR STRENGTH TRAINING ATHLETES IN IMPROVING TRAINING SESSION MUSCLE LOAD BALANCE

NOTEBOOM, L.1, NIJS, A.1, BEEK, P.1, VAN DER HELM, F.2, HOOZEMANS, M.1

*1.FACULTY OF BEHAVIORAL AND MOVEMENT SCIENCES, VRIJE UNIVERSITEIT AMSTERDAM, THE NETHERLANDS, 2.DEPARTMENT OF BIOMECHANICAL ENGINEERING, DELFT UNIVERSITY OF TECHNOLOGY, THE NETHERLANDS*

INTRODUCTION: Strength training (ST) athletes are at risk for injuries, especially at their muscles and tendons (59% of all injuries) [1]. While the exact causes of these injuries remain largely unknown, the most common reason mentioned by strength training athletes is overload [1]. Muscle overload injuries could be the result of an excessive overall training intensity or the result of typically observed imbalanced strength training routines, which overload certain muscle groups while neglecting others [2]. Muscle overload and imbalances in training sessions may be prevented if strength training athletes are more aware of their personal muscle load during their workout. Therefore, the objective of this study was to assess if a muscle load feedback application could aid ST participants in achieving a more balanced muscle load during their workouts.
METHODS: Thirty healthy participants were randomly allocated over three groups: control, 'partial feedback' and 'full feedback'. The one-repetition maximum (1RM) of all participants was estimated for 18 exercises [3]. Subsequently, all participants performed eight ST sessions, wherein they were instructed to perform eight exercises of their choice from the 18 preselected exercises, while attempting to load all muscles evenly. Performed exercises, sets, repetitions, and weights were tracked by the Gymstory sensor and app [4]. Based on these data combined with the 1RM's and anatomical knowledge of primary and secondary muscle contributions per exercise, the cumulative, individual muscle load of participants was estimated. The feedback groups received a visualization of this estimation as a muscle load body map after each exercise in the app, while the control group did not. The 'full feedback' group additionally received a list with suggestions for next exercises, targeting muscles that had not or little been loaded. The muscle load standard deviation (STD) per session was used as indicator of muscle load balance (a lower STD meant a more balanced load distribution over all muscles) and compared between groups and workouts using Generalized Estimation Equations.
RESULTS: The 'full feedback' group had a significantly lower muscle load STD compared to the control group ($p<0.001$) and the 'partial feedback' group ($p=0.038$). There was no significant effect of workout number or interaction.
CONCLUSION: ST athletes who receive feedback including a personalized muscle body map and next exercise suggestions can achieve a more balanced (estimated) muscle load in their workout. This application can provide ST athletes with more insight into their individual muscle load and may potentially aid in preventing muscle overload injuries. Future research should focus on improving the accuracy of the muscle load feedback by measuring actual muscle loads on-site instead of using anatomical estimations.

### CONSUMER VIRTUAL REALITY: FROM ENTERTAINMENT TO MOTION ANALYTICS

NOCENT, O.

*UNIVERSITÉ DE REIMS CHAMPAGNE ARDENNE*

INTRODUCTION: After the release of autonomous virtual reality headsets such as Meta Oculus Quest or HTC Vive Focus in the recent years, immersion technologies have become more affordable. With the announced rise of the metaverse, Virtual Reality (VR) will be a game changer within the entertainment industry but not only. Indeed, many VR applications are dedicated to physical activity, addressing sports like boxing, fencing, climb or fitness. The potential, in terms of motion analytics, has been underinvestigated knowing that the headset and the two hand controllers provide 6-axis positional data at a 60Hz frequency at least. Coupled with an external depth camera, 3D positions of skeleton joints can be agregated to the realtime data flow. With an appropriate software architecture, consumer virtual reality could move from pure entertainment to a flexible platform for motion analytics.
METHODS: In order to develop an open and device-agnostic software platform for motion analytics in virtual reality, we chose to embrass the open standards defined by the World Wide Web Consortium (W3C) such as WebSockets and WebXR. Acting as the back-end component, a Node.js application serves VR applications as web applications based the open source framework A-Frame. As a consequence, any device running a web browser (desktop computer, mobile phone, VR headsets) can launch such VR applications. The same server-side application, acts also as a WebSockets server enabling realtime communication between clients (devices playing the VR application) and other software components. This functionality allows, for instance, broadcasting data over the World Wide Web (WWW) for wireless monitoring and recording positional data for realtime or offline motion analytics.
RESULTS: We developed a fencing test application to validate the whole infrastructure. With the VR headset on, the user sees a virtual foil in place of his controller. He must hit several targets that appear randomly in the virtual environement. The time to reach each target is sent with positional data over the WWW. A desktop web browser connected to the same server is able to stream the VR content thanks to the broadcasted data flow. Plus, another web interface is able to draw charts to visualize motion analytics.
CONCLUSION: Following the massive adoption of virtual reality on a consumer level, we developed a software architecture relying on open standards defined by the W3C to move this technology from entertainment to motion analytics with a device-agnostic approach. This is the guaranty to deploy this solution on a large scale without any restrictions coming from manufacturers. The positional data, underinvestigated for the moment, could provide relevant information in terms of motion analytics.

**SOFT-TISSUE VIBRATIONS IN RESPONSE TO IMPACT FORCE CHARACTERISTICS IN RUNNING**

PLAY, M.C., GIANDOLINI, M., MILLET, G.Y., ROSSI, J.

*UNIV LYON, UJM-SAINT-ETIENNE*

INTRODUCTION: Ground reaction forces (GRF) are input signals that initiate soft-tissue vibrations (STV) in the lower limb soft-tissue compartment (1,2). GRF and STV can be modified by changing midsole hardness (3,4). Whether GRF parameters are closely linked with STV remains unknown. This study aimed at (i) investigating the effects of midsole hardness on GRF and STV and (ii) determining potential relationships between GRF and STV variables. It was hypothesized that lower inputs signals would lead to less STV.
METHODS: After 10 minutes of warm-up, three midsole hardness conditions were tested (Asker-C 40, Asker-C 55 and Asker-C 65, hereinafter called 'soft', 'medium' and 'hard', respectively). 123 subjects (51 females, 65.4 ± 9.7 kg, 171 ± 8 cm) ran at their preferred running speed (8.93 ± 5.14 km·h-1) on a motorized treadmill for 8.5 minutes in each condition. GRF and STV of the gastrocnemius medialis were collected at minute 8. Ten consecutive steps per shoe condition were analysed to extract variables of interest. Vertical loading rate and impact peak were extracted to GRF. Peak to peak amplitude and damping, defined as the decay of the initial vibration power over time (5), were calculated to characterize STV. Effects of midsole hardness were examined using Friedman analysis ($p<0.05$) including partial eta square calculation ($\eta$). Simple linear regressions with Spearman coefficient calculation ($r_s$) were performed to determine significant relationships between GRF and STV variables ($p<0.05$).
RESULTS: In hard condition, damping and vibration amplitude were respectively greater by 6.7% ($p<0,001$; $\eta=0.069$) and 9% ($p<0,001$; $\eta=0.121$) than medium and soft shoes. In hard condition, loading rate was 3.4 % higher ($p=0.010$; $\eta=0.038$) and impact peak significantly lower by 2.8% ($p=0.009$; $\eta=0.083$). For all conditions, vibration amplitude was correlated with loading rate ($r_s=0.24$, $p=0.008$) and impact peak ($r_s=0.35$, $p<0.001$). Neither the loading rate nor the impact peak were correlated with damping.
CONCLUSION: Midsole hardness affects both GRF and STV variables. At foot strike, lower loading rate and impact peak result in a smaller muscle vibration amplitude. The absence of significant relationships between GRF and damping suggests damping as an adaptation strategy to minimize STV. These results have methodological implications for the stress quantification and the understanding of the underlying adaptation mechanisms in running.

**VALIDITY OF HEART RATE AND RESPIRATION RATE USING VITALPROBE WEARABLE DEVICE**

SAVLA, R., WADHI, T., VIEDMA, A., CHETTIAR, E., PANERU, K., TAMULEVICIUS, N.

*UNIVERSITY OF TAMPA*

INTRODUCTION: Physiological markers measured both at rest as well as during physical activity give a comprehensive overview of the individual's physical health (1,2). VitalProbe (2020) [VP] is a novel chest-based wearable device that allows for continuous measurement of physical activity, heart rate and respiration rate. These vital signs not only help monitor physical fitness status, but possibly be early predictors of illnesses. The purpose of the study is to validate VP for vital signs monitoring of heart rate and respiratory rate.
METHODS: Twenty participants (Age: 31.9±12.4 years; Females:Males: 12:8; BMI: 23.3±5.5 Body Fat %: 20.46±8.6 % ) participated in the current study. Participants wore a polar HR monitor along with VP, while connected to a metabolic cart (MET-C). VP was attached to the participants via a customized adhesive gel-pad placed on the participants sternum, just above the xiphoid process. ECG-derived respiration rate (RR) and heart rate (HR) were compared against the criterion devices for a 3-minute window, with samples averaged every 15 seconds. Mean ± standard deviation, confidence interval (CI) and mean average error (MAE) was presented for all the vitals. Additionally, paired t-test and intraclass correlation (ICC) were run for each datapoint from VP and the criterion devices.
RESULTS: During the seated test, 320 samples were collected for each of HR and RR, with results for HR being similar between two devices. The Polar measured 75.78±15.44 beats/min whereas the VP measured 77.33±17.40 beats/min, showing no significant difference between the two (p-value:0.650) with ICC:0.758. The MAE seen was 1.548±11.66 beats/min (CI: 0.283 to 2.814).
However the RR was significantly different between MET-C and VP. The MET-C measured 15.80±5.713 breaths/min while VP measured 18.36±4.656 breaths/min, showing a significant difference (p-value:<0.001) with ICC:0.304. The MAE seen was 0.263±6.533 breaths/min (CI: 1.947 to 3.293).
CONCLUSION: Based on the results the VP showed no significant difference in the readings measured for HR (beats per minute) using the polar device,while the RR showed significant difference in the measure. The validity of the VP helps in strategizing exercise prescription intensities for both athletic and non-athletic populations, by giving objective measure for heart rate. However, respiration rate from VP is not currently viable to use by practitioners. Additionally, further research needs to look at the performance of this device for longer periods.

**INFLUENCE OF THE CURRENT SCORE ON THE FINAL RESULT IN JUDO FIGHTS**

MOUSSA, I.

*INSTITUT NATIONAL DU SPORT ET DE LEXPERTISE DE LA PERFORMANCE*

INTRODUCTION: In order to further the analysis of judo match and quantify competitive demands, it is important to estimate the influence of some match parameters [1], [2]. The purpose of the study was to develop a technical-tactical model of judo match in order to determine the probability of the outcome based on any given score throughout the match duration.
METHODS: We collected and tagged 1,291 male and female judo matches from the 2017 international judo circuit. We analyzed 13,055 combat sequences with 81 different score combinations. In order to determine the probability of a fight's outcome from the score, we

used a statistical analysis based on the multi-state model derived from the Markov process. A transition matrix provided an overview of the overall evolution of the 81 states in which a match could exist.
RESULTS: The probability of completing a match increases as the score and time progress. After two penalties, there is a 62% probability that the match will end in the next state. The probability of winning through the different mechanisms changes as the scores progress over time, at 0-0 it is through ippon (26%) while at 2-0 it is through a difference in points at the end of time (41%).
CONCLUSION: These initial results of the fighting patterns within competitions can help analysts and coaches understand and improve athletes tactical performance. Further analysis with additional co-variates (weight categories, round of competition, etc..) is necessary to better understand the evolution of specific match.

### CP-PN01 Strength, stiffness and power of muscle

#### MUSCLE ARCHITECTURE AND SPRINT PERFORMANCE: ROLE OF MUSCLE SIZE

MARTIN-RODRIGUEZ, S., GALVAN-ALVAREZ, V., ARTEAGA-ORTIZ, R., CALBET, J.A.L., SANCHIS-MOYSI, J.
*UNIVERSITY OF LAS PALMAS DE GRAN CANARIA*

INTRODUCTION: Muscle architectural features (MAF) have been reported to be determinants of sprint performance (SP). Nevertheless, previous studies are based on a small number of subjects and muscles, generally limited to males. Part of the differences in muscle architecture between subjects could be explained by differences in muscle mass, which is known to play a crucial role in SP. Therefore, this study aimed to determine if muscle architecture has an independent influence on SP after accounting for muscle mass in males and females. We hypothesized that some MAF unrelated to muscle size would impact SP differentially in males and females.
METHODS: Muscle architectural features of rectus femoris (RF), vastus lateralis (VL), vastus medialis (VM), biceps femoris (BF), semitendinosus (ST), medial and lateral heads of the gastrocnemius (GAM and GAL) muscles, and patellar and Achilles tendon thickness were assessed by ultrasonography (Philips CX50, Netherlands) in 110 volunteers (65 males and 46 females (age:23±3 and 23±3 yo, VO2max:45±6 and 39±6 ml/kg/min). Body composition (DXA) and SP (isokinetic 30-s Wingate test at 80 RPMs, WT) were assessed. Mean (Wmean) and peak (instantaneous, Wpeaki; and 1-s averages, Wpeak1-s) power outputs were recorded in the WT. Statistics: ANCOVA, bivariate correlations and multiple linear regression.
RESULTS: Although males developed a higher Wpeaki, Wpeak1-s, and Wmean than females in absolute values, these were similar when expressed per lower extremities lean mass (LLM) (Wpeaki: 54±9 and 55±7, Wpeak1-s: 43±6 and 44±5, and Wmean: 31±4 and 31±4, W/kg LLM) (all $p>0.17$). In males and females, Wpeaki, Wpeak1-s, and Wmean in absolute values were associated with the muscle thickness of RF, VL, VM, BF, ST, GAL, and GAM ($r=0.37$-$0.66$), the pennation angles and fascicle lengths of the same muscles ($r=0.2$-$0.4$) and the cross-sectional area (CSA) of the Achilles ($r=0.65$-$0.70$) and patellar tendons ($r=0.42$-$0.52$). Multiple regression analysis showed that the Achilles tendon CSA, VL and GAL thickness, and GAL pennation angle had the highest predictive value for Wpeak1-s ($R2=0.75$, $p<0.001$). When normalized to the LLM, Wmean per LLM could be predicted from VL thickness, the fascicle length of GAL and VL ($R2=0.22$, $p<0.05$).
CONCLUSION: The present findings show that when differences in muscle size are accounted for, the impacts of muscle architectural features and sex on sprint performance are minimal, leaving muscle volume as the main variable determining sprint performance during exercise on the cycle ergometer. Nevertheless, the combination of VL thickness, VL fascicle length and GAL fascicle length could explain up to 22% of the variability in LLM normalized Wmean but does not contribute to explaining the variability in peak power output. The novelty of this study resides in the large sample size (n=110) and the measurement of multiple muscles and tendons in males and females, making predictive models consistent.
Grants: DEP2017-86409-C2-1-P .

#### PASSIVE MUSCLE STIFFNESS IS ACUTELY DECREASED BY ECCENTRIC EXERCISE AT LONG MUSCLE LENGTHS WITH A LONG DURATION

KAWAMA, R., HOJO, T., WAKAHARA, T.
*DOSHISHA UNIVERSITY*

INTRODUCTION: Passive muscle stiffness has been reported to be acutely increased by resistance exercise (1). Meanwhile, our pilot study showed that muscle stiffness acutely decreased after eccentric-only exercise with a wide range of motion. However, the magnitude of the decrease in the stiffness was not large (−7.2 kPa). It was shown that the muscle stiffness was greatly decreased after stretching exercise at long muscle lengths with a long duration (2). Therefore, eccentric-only resistance exercise with a combination of long muscle lengths and a long duration may largely decrease muscle stiffness. This study aimed to investigate acute changes in passive stiffness of the individual hamstring muscles after eccentric-only resistance exercise with different combinations of muscle lengths and exercise durations.
METHODS: Thirteen healthy young male participants performed three sessions of eccentric-only exercises that comprised of stiff-leg deadlift with different muscle lengths (0–50% [short] or 50–100% [long] of maximal range of motion of deadlift) and repetition durations (2 s [short] or 5 s [long]) on separate days. The sessions were 1) short muscle lengths with a short duration (SS), 2) long muscle lengths with a short duration (LS), and 3) long muscle lengths with a long duration (LL). In each session, the participants performed three sets of 10 repetitions of the deadlift with a load of 60% of their body mass. The shear modulus of the individual hamstring muscles was measured using shear wave elastography before and 3, 30, and 60 min after each session. Time-course changes in the shear moduli were analyzed using the Friedman and Wilcoxon signed-rank tests.
RESULTS: In LL, the shear modulus of the semimembranosus (SM) was significantly lower at 3 min post-exercise (129.8 ± 22.7 kPa) than at pre-exercise (140.5 ± 19.1 kPa, $p < 0.01$); however the modulus at 30 and 60 min post-exercise was not significantly different from that at pre-exercise. No significant differences were observed in the shear modulus of SM at any time point in SS or LS. There were no significant differences in the shear moduli of the biceps femoris long head and semitendinosus between pre-exercise and 3 min post-exercise in any session.
CONCLUSION: This study showed a decrease in the shear modulus of SM after LL, but not after SS or LS. These results suggest that eccentric-only resistance exercise with a combination of long muscle lengths and long duration effectively decrease the stiffness of a specific

muscle. This result may be related to the architectural characteristics of SM (i.e., the shortest fascicles among the hamstrings [3]). Further studies are needed to clarify whether the acute change in the stiffness of SM in our study extends to a chronic change after resistance training.

**JUMPING VS. RUNNING: EFFECTS OF EXERCISE MODALITY IN A SIX-WEEK HIGH-INTENSITY INTERVAL TRAINING ON AEROBIC CAPACITY AND NEUROMUSCULAR PERFORMANCE**

VENEGAS-CARRO, M., HERRING, J.T., KRAMER, A.

*UNIVERSITY OF KONSTANZ*

INTRODUCTION: High-intensity interval training (HIIT) has been the focus of research for some decades already. It has proven to be effective at improving endurance capacity and muscle endurance. And when compared to moderate-intensity continuous training, it possesses the additional advantage that it requires less volume and time commitment. However, its potential to improve other aspects of physical performance such as strength and power has not yet been well explored, and most research studies have used only running and cycling as exercise modalities. Therefore, this study aimed to determine the efficacy of a 6-week HIIT using jumping as the exercise modality compared to running.

METHODS: 47 participants (24 +-3 years, 172 +-9 cm, 68 +-13 kg, 22 women) were randomly allocated to one of three groups: jump training (JT), running training (RT), or control (CON). The two training groups underwent a six-week HIIT with 3 training sessions per week. Both training protocols were identical in volume, and work and rest intervals, but different in exercise modality. JT performed countermovement jumps (CMJ) as exercise modality (with two slightly different ways of execution: repositioning and continuous), and RT performed running sprints as exercise modality. Immediately after every training session, the rate of perceived exertion (RPE) was recorded for every participant. Before and after the training period, all subjects were tested for maximal isometric voluntary contractions (MVC) of knee extension (KE) and plantar flexion (PF) in custom made ergometers, as well as maximal leg power during CMJ on a force plate, and maximal aerobic capacity (VO2max) during a ramp test on a cycle ergometer.

RESULTS: Analyses of variance revealed a significant group*time interaction effect for VO2max (p=0.004), and subsequent post hoc analyses showed a significant increase only in RT (p<.001, +7.6% for RT, +2.6% for JT). Analyses of MVC revealed an effect of group*time for PF and KE (p=0.006 and p=0.007, respectively) but post hoc tests showed only a significant increase in JT for PF (p=0.02, +12.8%). No interaction effects were found for maximal power during a CMJ (p=0.72). Average RPE scores of the training sessions were significantly different between training groups (p<.001), with no significant difference between groups in those sessions that consisted of the continuous type of jumps.

CONCLUSION: Despite identical programming, the choice of exercise mode profoundly impacted the training adaptations: RT significantly increased aerobic capacity, and JT significantly increased maximal leg strength. These results underline the importance of exercise modality in physical performance adaptations. In addition, the differences in RPE between the two slightly different jump training sessions suggest that not only exercise modality, but also subtle differences in how the exercise is performed can play a role.

**THE ROLE OF HAEMOGLOBIN MASS AND BLOOD VOLUME ON CRITICAL POWER IN ATHLETES**

MARINARI, G., INGLIS, E.C., RASICA, L., MURIAS, J.M., IANNETTA, D.

*UNIVERSITY OF CALGARY*

INTRODUCTION: The amount of haemoglobin (Hbmass) and the total volume of blood (BV) are important factors contributing to O2 delivery capacity to the muscle. Indeed, both Hbmass and BV are typically reported to positively and strongly correlate with the maximal rate of oxygen consumption ([dot]VO2max) during exercise 1. However, the association between Hbmass and BV with other important indices of endurance performance, such as critical power (CP), has yet to be explored. Therefore, the aim of this study was to investigate the association between Hbmass and BV with CP in a group of young athletes.

METHODS: Seventeen young males (n = 13) and females (n = 4) provincial level speed skaters participated in this study. Dual-energy x-ray absorptiometry (DXA) was used to quantify lean body mass (LBM). [dot]VO2max was assessed through a step-incremental test (30 Watts every 2 min for males; 25 Watts every 2 min for females). CP (watts; W) was determined following three time to exhaustion trials and computed using a 2-parameter hyperbolic (CP2-hyp) model. Hbmass and BV were assessed through the carbon monoxide (CO) rebreathing technique in triplicate measurements. Pearson's correlation coefficients were calculated to assess the relationship between Hbmass and BV with [dot]VO2max and CP. Values were expressed in absolute units as well as normalized to body mass (kg) and total LBM. Significance was set at $P < 0.05$.

RESULTS: Average [dot]VO2max and CP were 58.1 ± 4.6 mL·kg-1·min-1 and 243 ± 36 W, respectively. Hbmass and BV were 846 ± 99 g and 6105 ± 607 mL, respectively, and were both strongly correlated with [dot]VO2max (L·min-1) (r=0.91, P<0.001; r=0.75, P=0.001, respectively) and with CP (W) (r=0.90, P<0.001; r=0.75, P=0.001, respectively). When normalized to body mass, Hbmass (g·kg-1) remained strongly correlated with [dot]VO2max (mL·kg-1·min-1) and CP (W·kg-1) (r=0.76, P<0.001; r=0.77, P<0.001, respectively), whereas BV (mL·kg-1) did not (r=0.31, P=0.232; r=0.39, P=0.126, respectively). Similarly, when normalized to LBM, Hbmass (g·kg-1-LBM) was strongly correlated with [dot]VO2max (mL·kg-1·min-1-LBM) and CP (W·kg-1-LBM) (r=0.67, P=0.003; r=0.65, P=0.004, respectively), but BV (mL·kg-1-LBM) was not (r=0.29, P=0.256; r=0.21, P=0.410, respectively).

CONCLUSION: The novel finding of this study was that, in addition to the expected strong association between Hbmass and BV with [dot]VO2max, Hbmass and BV were also strongly associated with CP. However, when [dot]VO2max and CP were normalized to body mass or LBM, Hbmass but not BV, remained strongly correlated to CP. Thus, while both Hbmass and BV are important haematological underpinnings of the maximal aerobic capacity, only the former seems to contribute to determine CP. This finding highlights the critical role of O2 blood carrying capacity for endurance performance.

### THE VALIDITY AND RELIABILITY OF THE JUMP HEIGHT MEASURED WITH THE POLAR VANTAGE V2 SPORTS WATCH

BARZYK, P., PELTONEN, J., GRUBER, M.

*UNIVERSITY OF KONSTANZ: UNIVERSITAT KONSTANZ*

INTRODUCTION: Reduced muscle power of the lower extremities has been shown to be a major risk factor for injuries and numerous diseases (Powers et al., 2016). In this context, the jump height of a countermovement jump (CMJ) represents a valid and simple measure for testing the muscle power of the leg extensor muscles (Markovic et al., 2004). The evaluation and interpretation of performance data in-field and in a real environment using inertial measurement units (IMU) built into sports watches is becoming increasingly popular. The purpose of the present study was to assess the validity and reliability of the jump height measured by the Polar Vantage V2 sports watch in comparison to a gold-standard force plate measurement.
METHODS: Fifteen physically active participants (8 males and 7 females), age 20–42 years performed six sets of three CMJs over a two-day testing period. The participants wore the Polar Vantage V2 sport watch (Polar Electro Oy, Kempele, Finland) whilst performing the jumps on two force plates (AMTI, Watertown, Massachusetts, United States). Jump height was calculated with the data extracted from the watch and the force data provided by the force plates. To assess validity and left-right reliability of the results for the jump height measured by the Vantage V2 we calculated Pearson's r correlation coefficients as well as the coefficient of variation (CV). Intraclass correlation coefficient (ICC) was calculated to test day to day test-retest reliability of the "leg recovery test".
RESULTS: Mean jump height was 30±7 cm measured by the AMTI force plate and 30±7 cm, measured by the Polar Vantage V2, respectively. Pearson's r showed a very good correlation between the jump height measured by the force plates and with the Polar sports watch. The jump height measured by the Vantage V2 showed a good test-retest (day-day) reliability and a high correlation between the measurement whilst wearing the watch on the left arm with the measurement whilst wearing the watch on the right arm.
CONCLUSION: The present study has shown valid and reliable data for measuring vertical jump height with the Vantage V2 sports watch. The Polar Vantage V2 provides an easy-to-perform jump test that can be used in future studies to measure jump height in the field when laboratory-based measurements are not available. This opens new possibilities for intervention studies focusing on strength and performance of the lower extremities.

### THE INFLUENCE OF TRUNK INCLINATION ON THE COUNTERMOVEMENT JUMP TAKE-OFF VELOCITY IN OLDER WOMEN

DI ROCCO, F.1, PAPALE, O.1, CAPRANICA, L.2, PICERNO, P.3, FUSCO, A.1, CORTIS, C.1

*1 UNIVERSITY OF CASSINO AND LAZIO MERIDIONALE, CASSINO, ITALY; 2 UNIVERSITY OF ROME FORO ITALICO, ROME, ITALY; 3 UNIVERSITÀ TELEMATICA "E-CAMPUS", 22060 NOVEDRATE, ITALY*

INTRODUCTION: The physiological age-related functional ability decrements in older adults are more evident during high velocity coordinated movements (1) such as vertical jumps. The Countermovement Jump (CMJ) test is one of the most commonly used protocols to evaluate maximal vertical jump height and overall lower limbs power in older adults. It has been suggested that due to forward trunk inclination in the CMJ take-off, knee extension is delayed to avoid forward rotation of the body and subsequent loss of balance throughout the completion of the take-off phase (2). Therefore, forward trunk inclination at the CMJ take-off might influence subsequent take-off velocity, thus having an impact on the estimation of maximal jump height and lower limbs power. This study aimed at investigating the influence of trunk inclination on the CMJ take-off velocity in older women.
METHODS: Sixteen old women (age: 73±6.6 yrs; body mass: 57.1±7.2 kg; height 160±0.0 cm; BMI 23.0±3.2 kg/m2) were assessed during CMJ testing session. During the execution, take-off velocity and forward trunk inclination were recorded by a wearable inertial measurement unit (Sensorize, Rome, Italy) positioned on the trunk at L5 level (3). A polynomial least square fit with the highest adjusted $R^2$ was selected for the assessment of nonlinear relationship between trunk inclination performance and Take-Off Velocity at the jump. Root mean square error (RMSE) was also calculated. Significance level was set at P-value of 0.05.
RESULTS: A very strong significant (P=0.0001) 2nd order curvilinear relationship ($R^2$=0.96; RMSE=0.03) between trunk inclination (10.1±7.9°) and take-off velocity (1.1±0.2 m/s) was found. To clarify the relationship between take-off velocity and forward trunk inclination, the following equation was developed: take-off velocity = - 0.0032(trunk inclination2) + 0.0839(trunk inclination) + 0.7115
CONCLUSION: The correct kinematic execution of jumps has been mainly defined by the relative angular joint motion of the hip, knee and ankle, and muscle moments patterns (2). Accordingly, in older women, the forward trunk inclination influences the correct execution of the CMJ and take-off velocity, and consequently the estimation of maximal jump height. For these reasons, to maximize take-off velocity, it was identified that forward trunk inclination should range between 8° and 18°.

### PHYSICAL PREPARATION OF A WORLD-CLASS LIGHTWEIGHT MEN DOUBLE SCULLS TEAM FOR THE TOKYO 2020 OLYMPICS

COLOSIO, A.L., CAEN, K., LIEVENS, M., BOURGOIS, G., BOURGOIS, J.G., BOONE, J.

*UNIVERSITY OF GHENT*

INTRODUCTION: This research was designed to analyze the physical profile and training program of a world-class lightweight double sculls rowing crew for the Tokyo 2020 Olympics.
METHODS: A case study in which both rowers performed physical testing in November 2020 and April 2021 (anthropometrics, incremental rowing test and power profiling). The training program (38 weeks) in the building up to the Olympics was analyzed providing insight into training characteristics (volume; contribution of rowing, alternative, and strength training; training intensity distribution (TID)). The entire period was split into three phases: preparation period (PP:18 weeks), race period 1 (RP1:11 weeks) and race period 2 (RP2:9 weeks), and training characteristics were compared.
RESULTS: In the April 2021 testing, Rower A (height: 1.89m, weight: 74.6kg, fat percentage: 4.4%) had a VO2peak of 5.8L.min-1 (77.8mL.min-1.kg-1) and a peak power output of 491W. Rower B (height: 1.82m, weight: 70.6kg, fat percentage: 7.8%) had a VO2peak of

5.5L.min-1 (77.9mL.min-1.kg-1) and a peak power output of 482W. The mean weekly training volume was 14h47min ± 4h5min, of which 58.5±14.6% consisted of rowing, 13.4±6.8% strength training, and 28.1±12.6% alternative training. TID of rowing (power output) was 94.1±2.6% zone 1, 3.1±2.2 zone 2, and 2.8±2.6% zone 3. The contribution of zone 1 decreased (p=0.042) between PP (95.9±2.3%) and RP2 (92.0±2.6%), whereas the contribution of zone 3 increased from PP (1.1±1.2%) to RP1 (3.8±2.6%, p=0.044) and RP2 (5.2±2.4%, p=0.009). CONCLUSION: The crew combined a high volume of rowing, alternative and strength training in a pyramidal TID that shifted towards more polarized during the race periods.

**IS IT TRAINING VOLUME A CRITICAL VARIABLE DETERMINING THE ADAPTATIONS TO STRENGTH TRAINING?**

PÁEZ MALDONADO, J., CASTILLO CANO, C., SÁNCHEZ VALDEPEÑAS, J., CORNEJO DAZA, P., RODILES GUERRERO, L., ORTEGA BECERRA, M., PAREJA BLANCO, F.

*UNIVERSIDAD PABLO DE OLAVIDE*

INTRODUCTION: Resistance training (RT) is recognized as the mosteffective method to improve muscular strength. Manipulation of different RT variables (e.g. exercises, relative intensity, volume, rest interval, among others) characterizes the type and magnitude of the stimulus and, consequently, the physiological adaptations to RT (1). Regarding RT volume, recent research has compared 4 different velocity loss (VL)thresholds(VL0 vs. VL10 vs. VL20 vs. VL40) using the same relative load (from 70 to 85% one-repetition maximum [1RM]) over 8 weeks in the full-squat (SQ) exercise. Training with low VL magnitudes (VL20-VL10) induced greater strength and jump gains than training with higher VL (VL40).However, using VL as independent variables rises the problem that RT programs differ in volume and level of fatigue induced during the set. By contrast, research analyzing different volumes has also accumulated distinct levels of fatigue (3). Therefore, the aim of this study was to investigate the effect of three RT programs with different volume, but trying to isolate the effect of fatigue, on the evolution of the 1RM strength in the SQ exercise in each training session
METHODS: Thirty-six resistance-trained men were randomized in three RT interventions: low (LOW), moderate (MOD), and high (HIG) volume. The three groups trained twice a week (training sessions being 48–72 h apart) for 8 weeksthe SQ exercise, usingrelative intensities-from 70% to 85% 1RM and only one set was conducted per session. The only difference between groups was the volume accumulated by each group: LOW performed only three repetitions per session with every load; MOD performed 12, 10, 8, and 6 repetitions with 70%, 75%, 80%, and 85% 1RM, respectively; and HIG performed 24, 21, 18, and 15 repetitions with70%, 75%, 80%, and 85% 1RM, respectively. To isolate the effect of RT volume, that is trying to minimize the fatigue accumulation during the training session, 10 seconds of rest were introduced between repetitions when the difference in the mean propulsive velocity (MPV) between the best repetition and the successive repetitions was higher than 0.03 m•s-1. If the difference was higher than 0.06 m•s-1regarding the best repetition, 10 extra-seconds rest between repetitions were added. The evolution of 1RM strength throughout the training program was analyzed.
RESULTS: There was a significant “time” effect (p<0.001), but no significant “protocol x time” interactions (p=0.570) were observed. MOD showed significant 1RM improvements from session 2, while LOW attained significant enhancements from session 5, and HIG showed significant gains from session 8. Moreover, MOD showed significantly greater 1RM values than the other groups in some sessions (e.g.session 2, 6, and 11)
CONCLUSION: The three groups showed improvements in RM strength, however, a moderate volume resulted in faster and similar or even greater strength increases.

### CP-PN02 Hypoxia / Oxygenation

**MODULATION OF ANTIOXIDANT ENZYMES BY ACUTE EXERCISE IN HUMAN SKELETAL MUSCLE IN NORMOXIA AND SEVERE HYPOXIA: ROLE OF METABOLITES AND PO2**

GARCIA-GONZALEZ, E.1, GALLEGO-SELLES, A.1, GALVAN-ALVAREZ, V.1, MARTINEZ-CANTON, M.1, SANTANA, A.2, DORADO-GARCIA, C.1, MORALES-ALAMO, D.1, CALBET, J.A.L.1, MARTIN-RINCON, M.1

*1 DEPARTMENT OF PHYSICAL EDUCATION AND RESEARCH INSTITUTE OF BIOMEDICAL AND HEALTH SCIENCES , UNIVERSITY OF LAS PALMAS DE GRAN CANARIA, LAS PALMAS DE GRAN CANARIA, SPAIN. 2 DEP. OF PHYSICAL E*

INTRODUCTION: Intense exercise increases RONS in skeletal muscle, an effect exacerbated in hypoxia (Hyp), upregulating gene expression of antioxidant enzymes. However, the acute effects of exercise on protein levels of antioxidant enzymes and their molecular regulatory mechanisms remain largely unknown in human skeletal muscle (HSM). Previously, we showed NFkB-signaling activation by incremental exercise to exhaustion (IE), and animal and cell studies have shown that NFkB induces the expression of antioxidant enzymes, but whether this is the case in HSM remains to be elucidated. CaMKII has been implicated in NFkB regulation, particularly via deltaD isoform phosphorylation, a mechanism untested in HSM. Thus, we aim to determine the role of metabolite build-up and low tissue PO2 during IE on CaMKII activation and its downstream antioxidant enzymes. We hypothesized an upregulation of CaMKII and some antioxidants enzymes with a more marked response in Hyp.
METHODS: Eleven active men performed IE in normoxia (Nx) and Hyp (PIO2=73mmHg). Immediately after IE, circulation of one leg was instantaneously occluded (300mmHg). Muscle biopsies from vastus lateralis were taken before (PRE), 10s (POST, occluded leg) and 60s after IE from the occluded (OC1M) and non-occluded (nOC1M) legs simultaneously, and femoral vein blood drawn. Protein expression (WB) and muscle metabolites were measured. Statistics: ANOVA and linear mixed model.
RESULTS: At POST, muscle lactate augmented 25% in OC1M. PCr was reduced 94 and 48% in OC1M and nOC1M, respectively (P<0.05), regardless of PIO2. Femoral vein PO2 was 21.1 (Nx) and 10.6mmHg at exhaustion (Hyp). Glutathione reductase (GR) increased ~2-fold after IE (P=0.002) regardless of FIO2, being 52% lower in nOC1M. Trx1 descended ~15% (P<0.05), while Gpx1 and TrxR1 were unchanged after IE. Thr287 phosphorylation of CaMKII isoforms BetaM, DeltaA and Gamma increased ~1.6 and ~1.7-fold, while DeltaD increased 2.0 and 2.5-fold at POST and OC1M, respectively (P<0.05), regardless of PIO2. Phosphorylation levels of all isoforms returned towards PRE levels in nOC1M. A positive linear association was observed between pThr287CaMKIIdeltaD and pIKK, NFkBp105, NFkBp65+p50 and GR (all R2>0.74).

CONCLUSION: This research indicates that IE selectively upregulates the expression of antioxidant enzymes in HSM, and it does so to a similar extent in Nx and Hyp. These findings support a CaMKII-dependent activation of the exercise-induced upregulation of antioxidant enzymes in HSM. The specific regulation of antioxidant enzymes likely reflects the nature and cellular compartmentalization of RONS production. Metabolite recovery and reoxygenation for 1min at exhaustion downregulate CaMKII isoforms´activation and GR, suggesting that low PO2 and/or a high metabolite build-up are essential to trigger RONS-sensitive signalling. Our data support a mechanistic link between CaMKIIdeltaD isoform activation and NFkB-mediated upregulation of the antioxidant system, particularly GR.

**OVERNIGHT AND EARLY-MORNING PERIPHERAL OXYGENATION ARE NOT EQUAL DURING ASCENT TO ALTITUDE.**

JOYCE, K.E.1, ASHDOWN, K.2, LEWIS, C.T.3, BRADLEY, C.1, LETCHFORD, A.4, LUCAS, R.A.I.1, MALEIN, W.5, THOMAS, O.6, BRADWELL, A.R.1, LUCAS, S.J.E.1

*1. UNIVERSITY OF BIRMINGHAM; 2. UNIVERSITY OF CHICHESTER; 3. YSBYTY GWYNEDD; 4. GREYSLEYDALE HEALTHCARE CENTRE; 5. NINEWELLS HOSPITAL; 6. ROYAL GWENT HOSPITAL.*

INTRODUCTION: Acute mountain sickness (AMS) plagues many individuals ascending to high altitude each year. Clinical presentation of AMS can be evaluated using Lake Louise Scores (LLS), albeit the criteria are highly subjective. Oxygen saturation has therefore been investigated as a more objective marker; however, results have been inconclusive with methodologies varying greatly between studies. The purpose of this study was to compare arterial(ised) oxygen saturation (SaO2) with peripheral oxygenation (SpO2) measurements collected in the morning and overnight during ascent to 4,800 m.
METHODS: Peripheral oxygenation was measured continuously (1 Hz) overnight (nSpO2) and momentarily (~60 to 90 seconds, i.e., until measurement stabilised) each morning (mSpO2) using portable oximeters (3150 Model, WristOx, Nonin Medical). Arterial(ised) oxygenation was analysed from blood collected from the earlobe using the iSTAT blood gas analyser (Abbott Laboratories). Comparisons between SaO2 and nSpO2 or mSpO2, as well as nSpO2 vs mSpO2 were facilitated using Bland-Altman (B-A) plots (bias and 95% limits of agreement, LOAs) and mixed-effects analysis. All statistical tests were two-tailed with significance set to $p < 0.05$.
RESULTS: Bias (–2.04 ± 4.40%) and 95% LOAs (–10.67 to 6.59%) for nSpO2 vs SaO2 were lower than those for mSpO2 vs SaO2 (bias: –5.56 ± 5.56% and 95% LOAs: –16.45 to 5.34). The x-intercept of the best fit line plotted from B-A data for SaO2 vs nSpO2 (91.3% [CIs: 88.5 to 95.8%]) was lower than that for SaO2 vs mSpO2 (96.5% [94.2 to 99.9%]), indicating that nSpO2 was more consistent with SaO2 at lower levels of oxygenation compared to mSpO2.
CONCLUSION: During ascent to altitude, nSpO2 rather than mSpO2 was more consistent with SaO2, indicating that mSpO2 may overestimate oxygenation and underestimate the degree of desaturation exhibited overnight. Notwithstanding the ease and practicality of mSpO2, further investigation of nSpO2 is warranted, particularly, in relation the onset and progression of AMS.

**PHYSIOLOGICAL DIFFERENCES BETWEEN A TRAINING MASK AND AN ALTITUDE SIMULATION MASK DURING SUBMAXIMAL LOADING**

ABS, S.1, CLIJSEN, R.1,2,3, FREITAG, L.1, HERTEN, M.1, HOHENAUER, E.1,2,3,4

*1 THIM UNIVERSITY OF APPLIED SCIENCES, CH; 2 UNIVERSITY OF APPLIED SCIENCES AND ARTS OF SOUTHERN SWITZERLAND, CH; 3 VRIJE UNIVERSITEIT BRUSSEL, BEL; 4 UNIVERSITY OF FRIBOURG, CH*

INTRODUCTION: Altitude/hypoxic training offers the chance to improve athletic performance. In sports and athletic training, training masks are often sold as altitude masks, promising comparable effects. However, the potential benefits haven't been hardly proven so far [1][2]. Therefore, this pilot study aimed to investigate the physiological differences between wearing a training mask and an altitude mask during submaximal exercise.
METHODS: In this randomized crossover pilot-study, n=6 healthy, recreational active women (22.0±3.0 years old, 57.6±10.2 kg, 162.0±6.9 cm) performed the modified Harvard step protocol under three different conditions, separated by 2 weeks: In the training mask condition (TM), participants wore a mask (phantom athletics, AT). In the altitude mask condition (AM), participants wore a mask and were exposed to normobaric hypoxia (FiO2: 14.4 %, cloud9, sportingedge, UK). In the control condition (CM), participants wore a mask that allowed normal breathing and were exposed to normoxia (FiO2: 20.9 %). After acclimatization, baseline measurements were conducted after which, the participants performed the step-protocol and rested afterwards in a seated position for 15 min, where the follow-up measurements were conducted. The following parameters were analyzed to evaluate potential differences over the entire time period.
Capillary oxygen saturation (SpO2), muscle tissue oxygenation index (mTOI) of the quadriceps femoris muscle and heart rate (HR) were assessed to investigate the physiological changes. Ratings of perceived exertion (RPE) and dyspnea (DYS) were investigated to objectify the subjective ratings.
RESULTS: SpO2 was lower in AM (SpO2: 89.1±4.3 %) compared to TM (ΔSpO2: 6.9±2.3 %) lower in AM compared to CM (ΔSpO2: 6.8±1.9 %; both p≤.005). There was no difference between TM (SpO2: 96.1±2.1 %) and CM (SpO2: 98.9±2.5 %). The study revealed that there are no differences between the conditions for mTOI (AM: 66.7±4.3 %, TM: 70.4±3.4 %, CM: 68.4±4.0 %, p=0.06). Heart rate significantly differed between groups (p<0.001) with the highest values in AM (127±26 bpm) followed by CM (121±22 bpm) and TM (117±24 bpm). There were no differences between conditions at any specific time point for RPE and DYS (all p>0.05). The TM and CM groups did not differ significantly in any variable.
CONCLUSION: The present study shows that the SpO2 reductions and HR increases are significantly pronounced in the AM condition compared to the TM and CM condition. There were no differences between conditions for mTOI and perceptual measures. This study demonstrates, that the physiological impact of AM is higher compared to TM for SpO2 and HR.

**EFFECTS OF ENDURANCE EXERCISE UNDER NORMOBARIC HYPOXIC CONDITION ON INTESTINAL CELL DAMAGE AND GASTRIC EMPTYING RATE.**

NOMURA, S., SUMI, D., NAGATSUKA, H., GOTO, K.

*RITSUMEIKAN UNIVERSITY*

INTRODUCTION: The importance of quick nutrition intake during post-exercise is widely accepted among athletes (1). While endurance exercise attenuates transiently digestive and absorptive function (2,3,4), changes in these variables following endurance exercise in hypoxia remain unknown. Two previous studies (5,6) presented that endurance exercise in hypoxia resulted in a greater level of exercise-induced intestinal cell damage compared to the exercise in normoxia under the same absolute intensity. However, the comparison using the same relative intensity between hypoxia and normoxia has not been conducted. Therefore, the purpose of the present study was to compare the intestinal cell damage and the gastric emptying rate following endurance exercise between “hypoxia” and “normoxia“ under at the same relative intensity.
METHODS: A randomized, single-blind crossover design was selected. Eleven active males (age, 23±0.4 years; weight, 66.4±1.8 kg; height, 174±1 cm; body fat, 14.2±0.9 %) completed this study. Participants initially evaluated maximal running velocity (vMax) during incremental running test under hypoxia (FIO2 : 14.5%) and normoxia (FIO2 : 20.9%). Then, they conducted two trials on different days, consisting of 60 min run on a treadmill at 70% of vMax while inspiring either hypoxia (FIO2 : 14.5%; HYP) or normoxia (FIO2 : 20.9%; NOR). Venous blood samples were collected to evaluate plasma intestinal-fatty acid binding protein (I-FABP) as an indication of exercise-induced intestinal cell damage. The gastric emptying rate was also determined using 13C-sodium acetate breath test.
RESULTS: Running velocities at vMax and 70% vMax were significantly lower in HYP compared to NOR ($P<0.0001$). Relative change in plasma I-FABP concentration did not differ significantly between two trials ($P=0.96$). However, maximum 13C excretion time (an indication of gastric emptying rate) was significantly delayed in HYP trial ($P=0.01$).
CONCLUSION: Endurance exercise in normobaric hypoxia delayed gastric emptying rate compared to the exercise in normoxia under the same relative exercise intensity. However, hypoxic exposure during endurance exercise did not affect exercise-induced intestinal cell damage.

**PHYSIOLOGICAL AND PERFORMANCE RESPONSES TO REPEATED WINGATE SPRINTS WITH 2.5- OR 4.5-MIN RECOVERIES UNDER ACUTE HYPOXIA**

TAKEI, N., MURAKI, R., HATTA, H.

*THE UNIVERSITY OF TOKYO*

INTRODUCTION: Repeated Wingate sprints (RW), a popular form of sprint interval training, is a promising training strategy in normoxic conditions (Gibala et al., 2012). RW training under hypoxia can increase physiological adaptation (Puype et al., 2013), but whether it can improve exercise performance or not is controversial (Warnier et al., 2020). This uncertain performance outcome by RW under hypoxia is possibly due to long rest intervals, leading to a small hypoxic stimulus (Takei et al., 2020). Therefore, adjustment to shorter rest intervals is a possible option to increase hypoxic stimulus. In this study, we compared physiological and performance responses between RW with 2.5- and 4.5-min recovery in acute hypoxia.
METHODS: In this study, hypoxic training sessions (April to July 2021) in a university athletics club were recorded and analyzed. Eight university athletics sprinters (4 male and 4 female athletes) participated in the hypoxic training sessions. The hypoxic condition was generated by environmental chamber as normobaric hypoxia (15% O2). On training day, athletes performed one out of the two RW (5×30-s cycle sprints) with 2.5- (RW-2.5) or 4.5-min (RW-4.5) recovery in randomized order. SpO2 and heart rate were recorded immediately after each sprint. Mean power outputs (MPO) were recorded by cycle ergometer for each sprint.
RESULTS: During the experimental period, total of 90 hypoxic training sessions (11.3±6.1 sessions per athlete) were performed. SpO2 and MPO significantly decreased in RW-2.5 sessions compared to RW-4.5 ($p<0.01$ and 0.05, respectively). There was no significant difference in heart rate between RW-2.5 and RW-4.5 in either sprint repetition ($p=0.68$) or rest interval ($p=0.58$).
CONCLUSION: In this study, adjustment to shorter rest intervals (4.5- to 2.5-min) for RW training led to increased hypoxic stimulus (lower SpO2) and larger power outputs decrement. On the other hand, there were no effects of recovery duration on heart rate responses. Therefore, hypoxic RW with short rest intervals, compared to long rest intervals, is a possible option to increase hypoxic stimulus (e.g., increased HIF-related adaptations) with the same cardiovascular and less mechanical stress.

**AEROBIC FITNESS, BUT NOT AGE AND SEX, DETERMINES THE LEVELS OF ANTIOXIDANT ENZYMES AND ITS MAIN UPSTREAM REGULATORY TRANSCRIPTION FACTORS NRF2/KEAP1 IN HUMAN SKELETAL MUSCLE**

GALVAN, V., GALLEGO, A., MARTINEZ, M., GARCIA, E., GELABERT, M., LARSEN, S., DOLHMANN, T., SØNDERGAARD, S., PEREZ, M., PONCE, J., LOSA, J., DANIELSEN, J., MARTIN, S., MORALES, D., HOLMBERG, H.C.

(co-authors: BOUSHEL, R., HALLEN, J., HELGE, J., MARTIN, M., CALBET, J.A.
INTRODUCTION: Ageing, sedentarism and chronic inflammation are associated with increased oxidative stress (OS), which promotes endothelial dysfunction, hypertension, insulin resistance and cancer. Increased OS in human skeletal muscle (HSM) has been reported in COPD and diabetic patients and after immobilization. It has been suggested that regular exercise enhances the antioxidant capacity of skeletal muscles. Nevertheless, no attempt has been made to determine if higher aerobic fitness associates with increased expression of antioxidant enzymes (AE) and its regulatory transcription factor in HSM. Theoretically, oestrogens could contribute to the greater life span of females via reducing OS and sex differences have been reported at the transcriptomic level. Thus, the aim was to determine the basal

protein expression of key AE in HSM from 189 volunteers and to ascertain if VO2max and sex explain the observed variation. We hypothesize that a greater VO2max and female sex would be associated with higher expression of AE
METHODS: Skeletal muscle biopsies from the m. vastus lateralis obtained from 120 men (age:31±10yo, weight:91±18 kg, Fat%:29±9, BMI:29±5; VO2max:38±10 ml/kg/min) and 69 women (age: 33±11yo, weight: 82±17kg, Fat%: 43±8; BMI: 30±6; VO2max: 28±7 ml/kg/min) were analysed to assess protein expression (WB) and myosin heavy chain composition. VO2max (ergospirometry) and body composition (DXA) were determined. Statistics: ANCOVA, bivariate correlations and multiple linear regression with interaction
RESULTS: Women had higher fat % and lower VO2max than men even when expressed per kg of lower extremities lean mass (VO2max/LLM). Protein levels of NRF2, pSer40NRF2, Keap1 and NRF2/Keap1 ratio were similar in both sexes, even after accounting for sex differences in VO2max/LLM (all p>0.20). Protein levels of the AE Catalase, Glutathione Reductase (GR), SOD1 and SOD2 were similar in both sex after accounting for differences in VO2max/LLM. VO2max/LLM was positively associated with protein levels of SOD2 (r=0.55,p<0.001), NRF2 (r=0.21,p=0.003) and Keap1 (r=0.30,p<0.001). NRF2/Keap1 ratio was positively associated with the protein levels of GR (r=0.38,p<0.001) and Catalase (r=0.65, p<0.001). Multiple regression analysis showed that SOD2 is the AE more strongly associated with VO2max
CONCLUSION: These findings suggest that NRF2/Keap1 signalling likely plays a role in the regulation of the basal levels of several AE in HSM. Previous studies with lower sample sizes have shown temporary increases of AE (mostly SOD2) with training, with few reporting increased resting levels of SOD2. Our data suggest that at the population level, higher aerobic fitness associates with increased basal expression of muscle AE, which may contribute better metabolic health of subjects with higher VO2max. Aerobic fitness is a main determinant of the antioxidant capacity of HSM via mechanisms likely involving NRF2/Keap1/SOD2, GR and Catalase.

### DIFFERENCES IN MUSCLE OXIDATIVE CAPACITY BETWEEN YOUNG AND ELDERLY: A COMPARISON BETWEEN NEAR INFRARED SPECTROSCOPY AND HIGH-RESOLUTION RESPIROMETRY.

NERI, M., PILOTTO, A., COLOSIO, M., GATTI, M., CREA, E., BROCCA, L., PELLEGRINO, M.A., BOTTINELLI, R., PORCELLI, S.
*UNIVERSITY OF PAVIA*

INTRODUCTION: Ageing is characterized by a progressive functional decline associated with substantial reduction in peak oxygen consumption (V'O2peak). In addition to reduced O2 supply to skeletal muscle, impairments in muscle oxidative metabolism and mitochondrial function are two of the hallmarks of ageing [1]. Muscle oxidative capacity is typically estimated "ex-vivo" using high-resolution respirometry (HRR) from permeabilized myofibers obtained from muscle biopsies, and "in-vivo" by 31-phospate magnetic resonance spectroscopy. Recently, near infrared spectroscopy (NIRS) has been demonstrated effective in measuring non-invasively muscle oxidative capacity in young subjects with different training status [2], subjects undergoing to bed-rest [3] and patients [4]. The aim of this study was to evaluate whether NIRS technique is capable of detecting differences in muscle oxidative capacity between young and elderly comparing results with HRR data.
METHODS: Eleven elderly (E, age:68±5 ys) and ten young (Y, age:23±2 ys) participants visited the laboratory in two different occasions. Each subject performed an incremental exercise test on a cycle ergometer up to exhaustion to determine V'O2peak. Muscle oxidative capacity of vastus lateralis (VL) was estimated by NIRS as muscle oxygen consumption (mVO2) recovery rate constant (k) obtained by changes in tissue saturation index during intermittent occlusions of femoral artery [5]. Muscle biopsies were collected from VL and HRR measurements were performed in saponin-permeabilized muscle fibers using saturating substrates for complexes I+II combined (CI+II).
RESULTS: V'O2peak was lower in E compared to Y (24.6±3.7 vs 34.6±5.0 ml/min/kg; p<0,001). k for mVO2 was slower in E than Y (1.79±0.56 vs 2.47±0.74min-1; p=0.028). O2 flux for CI+II in maximal ADP-activated state of oxidative phosphorylation (OXPHOS) was lower in E than Y (35.42±13.72 vs 51.00±4.43pmol*s-1*mg-1; p=0,004). V'O2peak correlated to k and O2 flux for CI+II OXPHOS (r=0.55 and r=0.63, respectively; all p<0.015). A correlation was also found between k and O2 flux for CI+II OXPHOS (r=0.58, p=0.014).
CONCLUSION: Elderly showed a reduced exercise tolerance compared to young subjects which was at least partially attributable to an impairment in the muscle oxidative capacity as demonstrated by both "in-vivo" and "ex-vivo" data. The present results demonstrate NIRS technique to be an effective non-invasive approach to detect differences in muscle oxidative capacity between young and elderly people.

### HIITING AGEING WHERE IT HURTS: HIGH INTENSITY INTERVAL TRAINING AS A COUNTERMEASURE TO THE HALLMARKS OF HUMAN AGEING

HAYES, L.D.
*UNIVERSITY OF THE WEST OF SCOTLAND*

INTRODUCTION: The aim of the present investigation was to investigate whether 6 weeks high intensity interval training (HIIT) would affect biochemical hallmarks of ageing in older men. A secondary aim was to establish whether lifelong exercisers (LEX) exhibited a younger phenotype than sedentary older males (SED).
METHODS: Twenty-two males (62±2 years) comprised the SED group and 17 males (60±5 years) were enrolled as LEX. Individuals were tested at enrolment (phase A), following 6 weeks' preconditioning (SED) or maintenance of habitual training (LEX; phase B), and post-HIIT (6 x 30 s sprints at 40% peak power, once every five days; phase C). Blood draws were conducted at rest at the same time of day.
RESULTS: No difference between groups was observed for total testosterone or free testosterone throughout (P>0.05). Total testosterone increased in SED following preconditioning (P=0.007) and remained elevated post-HIIT compared to enrolment (P<0.001). Free testosterone in SED was greater post-HIIT than at enrolment (P=0.023). Total testosterone in LEX was unchanged throughout (P>0.05) but there was a small increase in free testosterone following HIIT (P=0.05). IGF-I was greater in LEX compared to SED at baseline (P=0.007), but not after preconditioning or post-HIIT (P>0.05). IGF-I increased in SED post-HIIT compared to baseline (P=0.002) and compared to preconditioning (P=0.005). LEX experienced no change in IGF-I throughout the study (P>0.05). Insulin was lower in LEX compared to SED at all phases (P<0.05). SED and LEX insulin was unchanged throughout (P>0.05). Glucose was not significantly different between groups at any phase (P>0.05). SED glucose was unchanged by preconditioning (P=0.598) but decreased following HIIT which was remained lower than enrol-

ment (both P<0.05). LEX glucose was unchanged throughout (P>0.05). IL-6 was significantly lower in LEX compared to SED at all phases (P<0.05). SED IL-6 decreased following preconditioning (P=0.001), without further change post-HIIT (P>0.05). However, SED IL-6 was significantly lower post-HIIT compared to enrolment (P=0.001). LEX experienced no change in IL-6 throughout (P>0.05). Homocysteine was not different between LEX and SED throughout (P>0.05). The only change within-groups occurred in LEX, whereby homocysteine was greater post-HIIT compared to enrolment (P=0.023). C-reactive protein (CRP) was significantly lower in LEX compared to SED throughout (P<0.05), and neither group experienced a change in CRP (P>0.05).
CONCLUSION: These data suggest that lifelong exercise promotes a younger phenotype compared to sedentarism (E.g. greater IGF-I, lower insulin, lower proinflammatory cytokines). Yet, some hallmarks of ageing can be attenuated with short-term HIIT. For example, post-HIIT free testosterone increased in both groups, whilst in SED IGF-I increased, and glucose and proinflammatory cytokines decreased.

**FERTILE IMPAIRMENT AFTER TREKKING AT HIGH ALTITUDE: A PROOF OF MECHANISMS ON REDOX AND METABOLIC CHANGES IN SPERM**

VERRATTI, V.1, MRAKIC-SPOSTA, S.2, FUSI, J.3, SABOVIC, I.4, FRANZONI, F.3, PIETRANGELO, T.5, BONDI, D.5, DALL'ACQUA, S.6, DANIELE, S.7, GAROLLA, A.4

*1DEPARTMENT OF PSYCHOLOGICAL, HEALTH AND TERRITORIAL SCIENCES, UNIVERSITY "G. D'ANNUNZIO" OF CHIETI-PESCARA, ITALY; 2INSTITUTE OF CLINICAL PHYSIOLOGY, NATIONAL RESEARCH COUNCIL (IFC-CNR), MILAN, ITALY*

INTRODUCTION: Many authors described the negative and reversible effects of high-altitude hypoxic exposure on animal and human fertility in terms of sperm concentration, function and biochemical alterations. In this line of research, the aim of this study was to evaluate the acute and chronic effects of high-altitude exposure on classical seminological parameters together with redox status and membrane composition in a group of Italian travellers.
METHODS: Five males, all healthy Italian lowlanders not accustomed to the altitude, were evaluated in response to a 19 days-trekking "Kanchenjunga Exploration & Physiology" through low, moderate and high altitudes. Participants completed a circuit of 300 Km distance, with over 16,000 meters of difference in altitude, covering an average daily walk of 6 hours. Sperm samples were collected before (Pre), 10 days after (Post) and 60-70 days after (Follow-up) the end of the expedition. Sperm concentration, cholesterol and oxysterols membrane content, and redox status by TOSCA and by EPR methods were measured. The blood content of hormones was determined using the immuno-chemiluminescence assay in the ADVIA Centaur XP Immunoassay System. Thyroid function – free triiodothyronine (FT3), free thyroxine (FT4), thyroid-stimulating hormone (TSH), the hypothalamus pituitary-gonadal axis – total testosterone, follicle-stimulating hormone (FSH), luteinizing hormone (LH), estradiol, and the prolactin cortisol pathways were assayed as well.
RESULTS: Hypoxic trek led to significant reduction in sperm concentration ($p < 0.001$, $\eta 2p = 0.91$, $\omega 2p = 0.88$), with a reduction from Pre to Post (71.33±38.81 to 60.65±34.63 ×106/ml, $p = 0.025$) and a further reduction at Follow-up (to 37.13±39.17 × 106/ml, $p < 0.001$ compared to Pre). Spermatic volume was significantly affected by the hypoxic trek ($p = .001$, $\eta 2p = 0.75$, $\omega 2p = 0.70$), with a significant reduction from Pre to Post (2.86±0.75 to 1.68±0.49 ml, $p = 0.001$) and a partial recovery at Follow up (to 2.46±0.45 ml, $p = 0.013$). Moreover, subjects had an increase in ROS production, and a decrease of antioxidant capacity at Post with a partial recovery at Follow-up analysis. Overall, the key result concerning the endocrine system was the impairment of the Hypothalamic-hypophyseal axis, which affect the functioning of sexual hormones significantly.
CONCLUSION: An uncontrolled ROS production, rather than a compromised antioxidant activity, was likely the cause of impaired fertility, triggered by damage to sperm quality. The reduction in fertility status observed in this study could have an evolutionary Darwinian explanation: limiting reproduction due to the "adaptive disadvantage" in terms of survival and reproduction offered by exposure to high altitude hypoxia combined with daily low to medium intensity exercise.

**MONTE ROSA EXPLORATION & PHYSIOLOGY 2021: RESULTS AND META-RESULTS TO MAKE FIELD RESEARCH FLOURISH**

BONDI, D.1, SANTANGELO, C.1, PIGNATELLI, P.1,2, BONDI, D.3, LOBEFALO, L.1, CIAMPINI, F.1, BONAN, S.1, PAGLIA, G.1, RAPAGNANI, A.4, PIETRANGELO, T.1, FULLE, S.1, VERRATTI, V.1

*1 UNIVERSITY OF CHIETI, 2 SAPIENZA UNIVERSITY OF ROME, 3 UNIVERSITY OF URBINO, 4 UNIVERSITY OF PADOVA*

INTRODUCTION: INTRODUCTION: Traveling at high altitude has become popular and altitude expeditions represent valuable ecological models to evaluate the human response to the combined stressors of physical exercise and hypobaric hypoxia [1]. Involving learners, researchers, and enthusiasts in such field research may constitute an intriguing paradigm for fostering multidisciplinary research and providing original education tools.
METHODS: The multidisciplinary "Monte Rosa Exploration & Physiology" project has been carried out involving a group of scholars, student, and mountain enthusiasts (15 participants, 8 males and 7 females, most of them familiar with mountain hiking, but unfamiliar with high altitude exposure) who all trekked up to the European highest mountain hut and were actively engaged in the design and/or conduction of scientific tests. Meteorological data were collected with the mini weather station MeteoTracker [2]. Vital signs of blood pressure (BP), peripheral saturation (SpO 2 ), resting heart rate (HR), waist circumference, and weight were acquired at the lowest (1,191 m) and highest (4,554 m) point. Acute mountain sickness (AMS) was verified with the Lake Louise AMS score [3].
RESULTS: All the participants successfully completed the trek encountering a range of temperature from –3.5 to 31.3 °C and of humidity from to 36 to 95%. Among the vital signs, the greatest percentage difference was found for HR (from 67.9 ± 13.0 to 88.5 ± 11.6 bpm, $p<0.001$, d unb =1.35) and similarly increases were found at high altitude in all the metrics of BP, while SpO 2 decreased (from 98.5 ± 0.8 to 84.1 ± 3.1 %, $p<0.001$, d unb =4.14). AMS was diagnosed in 6 participants. Waist circumference and weight were both reduced at high altitude, although very slightly (mean difference of 1.47 cm, $p=0.032$, d unb =0.58 and 0.62 kg, $p=0.014$, d unb =0.69, respectively). As meta-results, scholars confirmed the exchange of research interests, students moved their first steps into field research, and enthusiasts experienced research up close.
CONCLUSION: Students and scholars experienced and verified in the field the expected physiological response due to hypoxic stress, the likely physical over-stress and the possible emergence of mountain sickness. Participants were moved by the different purposes for taking part in the expedition, and their exchange of ideas and interests nurtured the research possibilities and the expedition itself. Moving motivated stakeholders to altitude field research, mixing several research lines, taking advantage of technological advancements, structuring a medically adequate ascent plan (and having a bit of luck) as in the present successful trial can foster multidisciplinary research and scientific education while providing novel opportunities for public engagement.

### CP-AP13 Endurance performance

#### DO THE BEST ENDURANCE ATHLETES HAVE THE HIGHEST LACTATE THRESHOLD MEASURED AS %VO2MAX (LT%)?

STØA, E.M.1, GJERLØW, L.E.1, RØNNESTAD, B.R.2, JOHANSEN, J.M., HELGERUD, J.3, SUNDE, A.1, STØREN, Ø.1

*1 UNIVERSITY OF SOUTH-EASTERN NORWAY, 2 INLAND NORWAY UNIVERSITY OF APPLIED SCIENCES, 3 NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY*

INTRODUCTION: LT expressed relative to absolute work output, e.g. as watt (LTW) among cyclists, show positive correlation with performance level (1). In contrast, the importance of LT expressed as %VO2max (LT%) in endurance sports has been unclear. Elite athletes are expected to have higher LT% than non-elite athletes (2), and data from cyclists imply differences between elite and regional athletes (3). On the other hand, another study in a small cohort of cyclists did not find a correlation between LT% and performance (1). The aim of the study was to assess whether there are differences in LT% between a large cohort of endurance athletes representing three different sports at the elite, national and regional levels.
METHODS: LT and VO2max data were collected from 292 athletes in three different endurance sports (75 long-distance runners, 95 cross-country skiers and 122 cyclists). LT was defined as the warm up [La−]b value (i.e., measured after the lowest running velocity) + 2.3 mmol · L −1, using the Arkray Lactate Pro LT-1710 analyzer. Performance level was divided into elite (N=71), national (N=158) and regional (N=63), based on history of competition level. A General Linear Model (GLM) with Tukey's post hoc test was performed to detect possible differences in VO2max and LT% between the three groups divided by competition level. A p-value ‹ 0.05 was accepted as statistically significant.
RESULTS: In total, the average VO2max among elite, national and regional athletes were 71.1 ± 6.5, 64.2 ± 8.0 and 58.1 ± 6.4 mL·kg-1·min-1 respectively, with significant differences between the three groups (p‹0.01). However, LT% were 79±6, 80±7 and 80±7 % respectively, with no significant differences between either of the three groups. In the order elite, national and regional level, VO2max results for males were 72.1±6.1, 68.0±7.1 and 60.6±5.5 mL·kg-1·min-1 respectively, with significant differences between all groups (p‹0.01). VO2max results for females were 64.8±5.2, 58.2±5.1 and 55.4±6.2 mL·kg-1·min-1 respectively, with significant differences between all groups (p‹0.01). LT% results for men were 77.9±6.3, 79.0±6.8 and 78.9±7.4% respectively, with no significant differences between groups. LT% results for women were 84.4±4.7, 82.6±5.4 and 81.9±6.7% respectively, with no significant differences between groups.
CONCLUSION: This study showed that LT% was similar between elite, national and regional endurance athletes, and therefore supports studies indicating that LT% is not a performance determining variable in endurance sports.

#### PREDICTING THE RATE OF FATIGUE DURING SKIING ON A SKI TREADMILL BASED ON ERGOSPIROMETRIC DATA

KRANZINGER, S.1, KRANZINGER, C.1, SNYDER, C.2,3, STÖGGL, T.2,3

*1 SALZBURG RESEARCH FORSCHUNGSGESELLSCHAFT MBH, 2 RED BULL ATHLETE PERFORMANCE CENTER, 3 UNIVERSITY OF SALZBURG*

INTRODUCTION: Explaining the rate of fatigue (ROF) [1] during skiing is of high interest to prevent injuries [2]. Former studies explained the ROF via blood lactate [3,4] or heart rate [3]. In order to derive the ROF without directly measuring it during skiing, we apply a Random Forest to predict the ROF as a function of features obtained from ergospirometric data.
METHODS: For the analysis we used data of three female and six male junior ski racers (age: avg = 13.2, sd = 0.4; height: avg = 157.8 cm, sd = 7.7; weight: avg = 45.9 kg, sd = 7.9). The experiment took place on a ski treadmill where participants were asked to ski as long as they were able to maintain a certain turning frequency (1.2 Hz). Participants rated their ROF every two minutes on a Likert scale from 0 (not at all fatigued) to 10 (total fatigue and exhaustion) [1]. For classification purposes, we grouped the ROF into three groups: mild fatigue (ROF: 0-3), moderate fatigue (ROF: 4-7) and severe fatigue (ROF: 8-10). To calculate features that would explain these three groups, we took the mean value of a respective feature 30 seconds before the ROF was assessed in a given time window. We collected 40 variables to use for feature selection [5], resulting in seven variables for the final analysis that were most important for predicting the ROF: Breathing rate, energy expenditure per kg, inspiratory tidal volume, carbohydrate oxidation (kcal/day), oxygen uptake per kg, METS and dead space to tidal volume ratio. For the tuning of the hyperparameters, we performed a 10-fold cross-validation. To split the data into test and training data, we applied a leave-one-subject-out cross validation, resulting in eight test data sets.
RESULTS: The mean accuracy of the eight test data sets was 47.9% (sd = 0.29) with a mean Cohens Kappa of 0.16 (sd = 0.29). The results varied greatly depending on the participant used as the test data set, ranging from 0.04 to 93.3% in terms of accuracy and 0 to 0.87 in terms of Cohens Kappa.
CONCLUSION: The results of this pilot study are promising for certain participants. We note that it is possible to use features based on ergospirometric data to predict the ROF for certain participants in the study. However, more data are needed to increase the performance of the proposed approach. For example, with more data, clustering approaches could be used to identify groups for which ROF prediction models could be applied separately. In addition, it would be interesting to include data from a wider variety of sources - i.e. kinetic and kinematic sources.

**FACING THE ANAEROBIC THRESHOLD – A FACIAL ELECTROMYOGRAPHY APPROACH FOR PHYSIOLOGICAL THRESHOLDS IDENTIFICATION DURING AEROBIC EXERCISE TESTING**

KETKO, I.1,2, IBRAHIM, R.2, HANEIN, Y.2, SCHEINOWITZ, M.2,3

*1 IDF MEDICAL CORPS; 2 FACULTY OF ENGINEERING, TEL-AVIV UNIVERSITY, ISRAEL; 3 FACULTY OF MEDICINE, TEL-AVIV UNIVERSITY, ISRAEL.*

INTRODUCTION: Non-invasive, real-time monitoring of athletes' fatigue during exercise is crucial for performance enhancement and to avoid over-training and exercise-related injuries. Facial expressions quantification through facial surface electromyography (sEMG) have a great potential in fatigue evaluation and in quantifying fatigue related outcomes. Yet, despite increased interest and the great potential [1,2], this topic has not been widely studied, apparently due to a technical gap in sEMG technology that does not allow convenient and accurate measurement especially during dynamic exercise. Recently, a novel sensor of multiarray electrodes was introduced. The sensor was already used for long term recording in freely behaving humans [3] and for emotional affect sensing [4] and demonstrated the ability to measure "masked" smiles, and to detect diverse facial expressions for emotional affect recordings. In the current study we measured and analyzed facial muscle activity in response to the anaerobic threshold during a graded exercise test.
METHODS: 5 young, healthy, and recreationally active participants (2 females) performed an incremental cycling exercise test consisting of 3 min stages, below the lactic-acid based threshold, and increasing resistance every 1 min until exhaustion. Facial sEMG which was applied on the participant's left side of the face, covering the forehead, zygomatic, buccal, nasal, and labial regions by 16 embedded electrodes was recorded continuously throughout the exercise test. Blood lactate and heart rate were documented at each exercise stage. The envelope root mean square (eRMS) of the facial EMG signal at natural-expression, recorded from each electrode, was calculated, and then averaged for each stage, including during a 3 min recovery period. sEMG data was then transformed into heatmaps and correlated with exercise intensities. Paired T-test and Pearson's correlation coefficients were used to analyze differences between eRMS and facial expressions.
RESULTS: Average eRMS (obtained from 5 subjects X 16 electrodes each) showed a stepwise increase with exercise intensity, reaching a maximal value of 2.12±1.03 [μV], versus 1.22±0.437 [μV] for light intensity ($p<0.05$). After reaching maximal value, a gradual and significant decrease in eRMS values was measured during the recovery period: 1.09±0.601 [μV] versus the maximal value, $p<0.05$. eRMS values were highly correlated with blood lactate and exercise intensity ($r=0.975$, $p<0.05$).
CONCLUSION: Our novel multiarray sEMG electrodes is highly stabilized during dynamic exercise. In addition, facial expressions are correlated with exercise intensity and can predict the anaerobic threshold. This technology may be used under various exercise protocols to further understand the role of facial expressions during exercise.

**COMPARISON OF THE CARDIO-RESPIRATORY RESPONSE DURING DEEP WATER RUNNING TRAINING VS INDOOR CYCLING TRAINING IN HEALTHY ATHLETIC SUBJECTS**

CARPENTIER, M., DUCHÊNE, A., FAORO, V.

*UNIVERSITÉ LIBRE DE BRUXELLES - ULB*

INTRODUCTION: Running sports often lead to lower limb mechanical injuries, such as ligament rupture or cartilage wear. During the recovery phases, it is often advised to practice unloaded sports such as indoor cycling (IC), to maintain a good physical condition with limited mechanical stresses1. However, despite these recommendations, the injured athletes often lose cardio-pulmonary capacity and suffer from physical deconditioning when returning to the field. Therefore, we studied an alternative training that can be proposed: deep water running (DWR). DWR has previously been showed to reduce low-limb overload, improve muscle strength2 and balance3, while water resistance forces the subject to exert greater force than moving in air4. We therefore compared the cardio-pulmonary parameters during two types of continuous trainings: DWR and IC.
METHODS: Eight active healthy subjects were enrolled in the study; 23±3 yo, 50% women, maximal oxygen consumption (VO2max) measured during a cyclo-ergometric cardio-pulmonary exercise test (CPET) of 42±5 ml/min/kg. All subjects performed randomly a DWR and an IC continuous training session, with a minimum 24h between both sessions. Training sessions consisted of a 5-minutes warm-up at 80% of HR at first ventilatory threshold (VT1), followed by 10 minutes training at 100% HR at VT1, 2 minutes rest and again 10 minutes at 100% HR at VT1. For the DWR session, subjects wore a flotation belt (Nabaji) and two "pool noodles" below their arms, to maintain their head and shoulders above water. Heart rate (HR), gas exchange and ventilation (VE) were measured continuously during CPET and DWR/IC training sessions with lactate levels measured 30s after exercise. Oxygen consumption (VO2), VE and lactate during DWR and IC training were compared, with VO2 and VE averaged during the last minute of the training session.
RESULTS: At same HR, VO2 was significantly ($p=0.0002$) higher during DWR (40±7 ml/min/kg; 97±15% of VO2max) as compared to IC training (29±5 ml/min/kg; 69±13% of VO2max). At same HR, VE was significantly ($p=0.0016$) higher during DWR (81±20 L/min, 67±18% of VE max) as compared to IC training (55±18 L/min, 45±11% of VE max). However, lactate did not significantly differ between DWR (3.9±1.6 mmol/L; 43±22% of lactate max) and IC training (2.9±2.3 mmol/L; 33±30% of lactate max).
CONCLUSION: The present results showed that when training is calibrated by HR, the VO2 and VE are higher during DWR compared to IC. This might be related to smoothened chronotropic response in a context of lower limb hydrostatic compression increasing venous return and stroke volume. Regarding the fact that DWR training is less stressful for lower limb joints and can adequately stimulate the cardio-respiratory system, DWR can be proposed as an appropriate training for injured patients in recovery.

**IMPACT OF ECCENTRIC EXERCISE-INDUCED MUSCLE DAMAGE ON ENDURANCE PERFORMANCE AND RUNNING BIOMECHANICS.**

HODY, S., BURY, T., CROISIER, J.L., SCHWARTZ, C.

*UNIVERSITY OF LIEGE*

INTRODUCTION: The occurrence of exercise-induced muscle damage (EIMD) can affect the running pattern and endurance performance. However, the EIMD-induced changes in biomechanical and physiologic parameters remain poorly understood. The aim of this study was to

examine the effects of a single isokinetic eccentric (ECC) exercise and ensuing Delayed-Onset Muscle Soreness on running biomechanics, muscle activity and physiologic measures during an exhaustive endurance run performed 48h later.
METHODS: Fourteen healthy, moderately active men completed two treadmill running tests (at 85% maximal aerobic speed) until exhaustion, with a week interval between both tests. The subject's running kinematics (using a 3D motion system), heart rate, pulmonary gas exchange, muscle activity and perceived exertion were recorded during both endurance tests (ETs). Forty-eight hours before the second test (ET2), participants were submitted to a bilateral isokinetic eccentric (ECC) protocol on the knee extensors. Indirect markers of EIMD were assessed before and 48h after the ECC exercise.
RESULTS: The ECC protocol induced EIMD as indicated by a significant increase in plasma CK (x12.52 ±33.15%), muscle pain (4.53±2.73a.u), a significant reduction in maximal isometric contraction (-19.54±14.75%) and in vertical jump performance (-17.94±17.19%, p<0.01). The running time to exhaustion was shorter (-29.30±24.10%, p<0.05) while the perceived exertion was higher (-10.1±s6.86%) for ET2 (with EIMD) compared to ET1 (p<0.01). The physiological data showed no significant difference between both ETs, except for the lactate level and heart rate measured at the end of the run which appeared significantly lower at ET2 (p<0.05). A higher step frequency (2.56±2.32%) coupled with a decrease in stride length (-2.51±2.4%) was observed during ET2 compared to ET1 (p<0.05). Articular amplitudes showed no significant differences between ETs although changes in the running pattern (i.e., vertical pelvis oscillation) were identified from the start to the end of both ETs (p<0.05). The electromyography data revealed increased muscle activity of the knee extensors during stance phase during ET2 but it did not reach significance.
CONCLUSION: Our data suggest that the knee extensors EIMD altered the running biomechanics and endurance performance without significative changes of the physiological parameters. Further investigations are required to explore whether the EIMD-induced biomechanical modifications are the result of pain perception or impaired muscle function.

## CONVERSION OF VO2 TARGETS INTO EQUIVALENT LOADS FOR EXERCISE PRESCRIPTION AND TRAINING: VALIDATION OF A STRATEGY THAT ENSURES NOTHING IS LOST IN TRANSLATION

RIZZO, M., TESO, M., LOI, M., CAEN, K., BOONE, J., POGLIAGHI, S.

*UNIVERSITY OF VERONA*

INTRODUCTION: Aerobic exercise is medicine, able to induce specific health/fitness benefits in a dose-response manner. Adequate implementation of the intensity element of the exercise dose relies on the accurate conversion of oxygen consumption (V̇O2) targets, typically derived from incremental testing (RI), into an equivalent external load for a constant work rate session (CWR). We recently proposed a strategy that, by accounting for the gap between the VO2/load relationships from the RI vs. the CWR, ensures that nothing is lost in the translation between these exercise paradigms. The evaluation of accuracy and precision of the above strategy outside of the original male-only sample is the aim of this study.
METHODS: 14 adults (7 females, 25 ± 3 yrs.) performed on a cycle ergometer a RI to detect the mean response time (MRT) and V̇O2/Power output (PO) relationship in the moderate (i.e., GET and < respiratory compensation point (RCP)) domains of exercise. For each participant, a total of four intensity targets from the RI exercise paradigm (V̇O2RItarget), two GET RESULTS: V̇O2CWR elicited in the heavy was significantly higher than the moderate-intensity trials (respectively 2602±588 and 1271±389 ml·min-1, p<0.001). These intensities corresponded to 68±5 and 34±8 %V̇O2max for the heavy and moderate domain, respectively. Independent of the intensity domain (main effect of interaction p=0.230), V̇O2CWR did not significantly differ from the intended metabolic target i.e. from V̇O2RItarget (main effect of exercise paradigm p=0.590). A very strong, significant correlation was found between V̇O2CWR and V̇O2RItarget (R2 = 0.98; p < 0.001), while there was a very small, not significant bias and small imprecision between measures ((bias -9.68ml·min-1; Z-score = 0.62; precision 115.19 ml·min-1).
CONCLUSION: Our data confirm that the correction strategy proposed by Caen K., based on individual MRT and domain-specific V̇O2/PO correction coefficients derived from RI testing, maintains its accuracy and precision outside of the male-only sample used for the development of the method. This valid and time-efficient approach allows to identify the equivalent workload associated with a desired metabolic target, granting that the intensity element of the exercise dose will be appropriately implemented for training sessions in both the moderate and heavy domain of exercise.

## CUT OFF VALUE IN PREDICTION OF SUCCESS IN TRIATHLON MIXED RELAY

LEDANOIS, T.

*IRMES*

INTRODUCTION: The mixed team triathlon relay first occured in the program of the Olympic Games in Tokyo 2021. National teams of 4 triathletes compete with every athlete running the super sprint distance (300 m swim, 7km cycle and 1,5 km run) in the Women / Men / Women / Men order. Until now, only one conference paper enlight this event (Pöller, 2015) on one event race. Recent developments on WTCS relays increase the number of events and offers the possibility to analyze more races.
To determine which placements along the race lead to the podium, we investigated athletes time on every sequence of the races. As a result, it helps staffs optimizing the composition of their relay.
METHODS: The dataset come from the World Triathlon database, range from 2009 to 2021 and contains 12 280 entries for a total of 38 races and 56 national teams. International races i.e. World Championships, the World Triathlon Series Championship relay, the continental Championship and the Major Events are included. Records were divided into 4 groups according to the final ranking of the teams: "Winner" (rank 1), "Medalists" (rank 2-3), "Finalist" (rank 4-8) and "Finisher" (rank 9 & +). A transition matrix based on three discrete-time Markov processes was used to estimate the probability of winning the race, finishing on the podium (TOP3) and finishing among the TOP 8. The probabilities are estimated at each stage end of the relay without taking transition times into account, (i.e. 12 stages, 3 per athlete).
RESULTS: The results show an increase in the probabilitý of winning the race when triathletes rank first as the race progresses, starting at 28.9%. Similarly, for each group, the probabilities increase for triathlete that succeed at staying in their groups at the end of the race. For the Finisher group, we observe a strong decrease of the probability to be classified in the finalists, from the first triathlete, starting at 29,0%.
We notice that the probability to win the race increases for the first three triathletes in the swim stage, ( 6,6% at SwimLeg1 vs 17,1% at the SwimLeg2). As well as an increase in the probability of being on the podium when staying in the Top 8 until the third relay, BikeLeg1 16,3% vs BikeLeg2 18,0%.
CONCLUSION: These results highlight intrinsic specificities of the mixed triathlon relay. (i) the podium is not defined from the first relay but starting too far from the leading group condemns the team. (ii) Within a relay team, the first two triathletes seem to constitute a strategic role of placement while the last two triathletes are more likely to carry out solitary time trial type efforts. Time differences between posi-

tions, which are maintained at the beginning and then increase throughout the race, suggest that a drafting effect loss (swimming and cycling only) could lead to abrupt breaks in the probability of reaching a higher state. This study allows to optimize the order and the composition of the relays for the national staffs during the world level events.

**OCCURRENCE OF GASTROINTESTINAL SYMPTOMS DURING EXERCISE IN ATHLETIC POPULATIONS**

COLLINS, A.J., ROLLO, I., CARTER, J.M., RANDELL, R.K.

*GATORADE SPORTS SCIENCE INSTITUTE, PEPSICO R&D LIFE SCIENCES, LEICESTER, UK*

INTRODUCTION: Gastrointestinal (GI) symptoms are common in endurance athletes. Indeed, exercise induced GI distress has been reported to occur in 30-90% of distance runners (de Oliveira et al., 2014). However, there is limited data on the prevalence of GI symptoms in other sports. Therefore, the purpose of this study was to collect information on the history of GI discomfort in a wide range of athletes.
METHODS: 340 athletes (258 males; age = 26 ± 8 years, 82 females; age = 27 ± 8 years) completed a GI history and nutrition habits survey. GI symptoms were categorised into upper and lower abdominal symptoms. Athletes rated the frequency and severity of each symptom experienced during exercise. Information on food intolerances was also collected. Participants competed in a variety of sports and ranged in competitive level (recreational (14%), competitive (46%), national (25%), elite (12%) and occupational (2%)). A 5-sample proportion test was used for sports with participants N ≥ 25 (cycling, rugby union, running, soccer and triathlon) to determine associations between sport type and GI symptoms. A 2-proportion hypothesis test was used for association between gender and GI symptoms. Chi-Square associations were used to test for relationships between GI symptoms and: level of athlete, type of sport, frequency of competitions and self-reported food allergies.
RESULTS: The most common GI symptom reported was flatulence (59%). Approximately half of athletes reported “severe” symptoms of bloating (50%), urge to defecate (50%), upper abdominal cramp (48%) and nausea (48%). Males had a greater incidence of GI symptoms compared to females ($P < 0.001$). There was no association between the level of athlete and the occurrence of GI symptoms ($Z = 3.31$, $P = 0.930$). Incidence of GI symptoms differed between sport; 76% of triathletes had a history of GI symptoms compared to 48% of soccer players, 46% of runners, 38% of cyclists and 24% of rugby union players. A negative correlation was found between frequency of competitions and GI problems ($X2$ (4, $N = 329$) = 11.5, $P = 0.021$). Self-reported food allergies (not independently validated) were correlated to GI symptoms ($X2$ (1, $N = 334$) = 5.1, $P = 0.026$).
CONCLUSION: Approximately half of all athletes had experienced GI symptoms during exercise. Frequency of competition and type of sport may influence the incidence of GI symptoms. Future priorities should focus on educating athletes with strategies to reduce the frequency and severity of GI symptoms during exercise.

**CARDIOPULMONARY EXERCISE IN FINE DUST ENVIRONMENT DOES NOT ACUTELY DETERIORATE PULMONARY FUNCTION IN HEALTHY YOUNG ADULTS**

PARK, S., KIM, J., LEE, E., SON, J., HWANG, M.

*INCHEON NATIONAL UNIVERSITY*

INTRODUCTION: Air pollution is a major environment issue and attributed to 11.65% of deaths globally. Especially fine dust is one of the first-class carcinogens and related to impaired pulmonary function and inflammation. Previous studies reported that fine dust reduces pulmonary function. However, there are a handful of studies to investigate the effect of cardiopulmonary exercise on pulmonary function in fine dust environment. Therefore, the purpose of this study was to examine the effects of acute cardiopulmonary exercise on pulmonary function in young adults under high-concentration fine dust environment.
METHODS: In cross-over design, seven participants (24.6 ± 0.5 years) visited our laboratory twice in both the high particulate matter (HPM) and low particulate matter (LPM) conditions. We measured fine dust concentrations by using AM520 SidePak Personal Aerosol Monitors. Participants performed indoor treadmill running for 30 minutes at 70% of each participant’s peak heart rate. Basic pulmonary function parameters and pulmonary diffusing capacity for carbon monoxide (DLco) were measured by using Quark PFT system including a respiratory chamber before and after the exercise.
RESULTS: The average concentration of fine dust in HPM was significantly higher than that in LPM (151.0 ± 31.0 vs. 11.1 ± 2.6 μg/m3, $P < 0.001$). There were no significant changes in FVC (forced vital capacity), FEV1 (forced expiratory volume in 1 second) and FEV1/FVC, DLco, and DLco/VA (alveolar volume) after the exercise under HPM level ($P > 0.409$). Under LPM level, FEV1 was increased after exercise (4.45 ± 0.16 vs. 4.53 ± 0.17 L, $P = 0.033$), but the other basic pulmonary function and diffusing capacity measures were not changed ($P > 0.134$).
CONCLUSION: In conclusion, moderate intensity cardiopulmonary exercise under high-level fine dust environment does not negatively affect pulmonary function in young adults, but may offset its positive influence under low-level fine dust environment.

### PHYSICAL ACTIVITY, MOTOR SKILLS AND AEROBIC FITNESS IN CHILDREN WITH ADHD

LEUENBERGER, R., BRUGGISSER, F., MÜCKE, M., LUDYGA, S.

*UNIVERSITY OF BASEL*

INTRODUCTION: Although Children with Attention Deficit Hyperactivity Disorder often show fidgeting and excessive motor Behaviour, limited evidence suggests that their physical activity levels are lower in comparison to healthy peers. We investigated whether motor skills and aerobic fitness also differed between these groups, when physical activity differences were accounted for.
METHODS: Based on age, sex and socio-economic status, propensity scores were calculated and used for matching 60 children with ADHD (18 girls; mean age: 10.5 years) from the JETPAC to 60 healthy peers (21 girls; mean age 11.1 years). All participants completed an age-appropriate version of the Movement Assessment Battery for Children (2nd edition) and the Physical Work Capacity at 170 bpm Test. Additionally, they reported their physical activity using 7 day recall protocols and filled in the Family Affluence Scale.
RESULTS: In comparison to healthy controls, children with ADHD showed lower physical activity at vigorous intensity, but had similar levels of activity at moderate intensity. Analysis of variance further revealed that children with ADHD had lower scores on all subscales of the motor test battery (manual dexterity, ball handling and balance) and a reduced physical work capacity at 170 bpm. Group differences in all assessed aspects of physical fitness remained, even when vigorous physical activity was accounted for.
CONCLUSION: In addition to developmentally inappropriate levels of hyperactivity, impulsivity and inattention, children with ADHD show pronounced impairments in motor skills and aerobic fitness. These impairments do not seem to be due to a lower engagement in physical activity only. Given that motor skills and aerobic fitness both contribute to physical health and development, ADHD treatments need to be enriched by intervention components that target these aspects.

### STRENGTH TRAINING PROGRAM WITH EMPHASIS ON ECCENTRIC ACTIONS: DO THEY IMPROVE PHYSICAL PERFORMANCE IN WOMEN THE SAME WAY AS MEN?

GALIANO, C., FLORIA, P., MUÑOZ-LÓPEZ, A., SÁEZ DE VILLARRAL, E., NUÑEZ, F.J.

*PABLO DE OLAVIDE UNIVERSITY*

INTRODUCTION: Traditionally, strength coaches prescribed resistance training based on constant and concentrically oriented goals. However, most movements in the field require players to produce forces in variable and unpredictable contexts, with an emphasis on the eccentric (ECC) component. If movement repetition varies during competition, it makes sense to conduct training programs that prepare athletes for new movements that they will undergo in the future. In this sense, some studies used rotary inertial devices (RIDs) for improving physical performance and obtain an optimal transference to sports, since they offer specificity and variability in force vector application with emphasis on ECC phase of the movement. When comparing male and female subjects, both may benefit in similar ways from using RIDs during strength training. However, most of these studies have focused on strength and hypertrophy responses. Therefore, the aim of this study was to compare the effects of a RID variable and unpredictable strength training program with emphasis on ECC actions on sprint, counter-movement jump (CMJ) and change of direction (COD) performances in male and female athletes.
METHODS: Forty-two athletes (females n=21 and males n=21) volunteered for this study. The study lasted 8 weeks. During weeks 1 and 8, CMJ, 10 and 20m sprint and COD abilities were measured as pre- and post-test. The strength training program was carried out biweekly for 6 weeks (week 2 to 7), where subjects had to perform 4 sets of 7 repetitions of the half-squat exercise with an electric motor RID, which allows the use of different inertias for the concentric (CON) and ECC actions. With the aim of increasing the variability and unpredictability of the load, the subjects did not know the magnitude of the load in each set, so different inertial units (IU) loads were established randomly for each set having an average of 2:4 IU for CON:ECC, respectively, from week 1 and 2, and an average of 4:8 from week 3 to 6. In order to achieve ECC overload, the load of the ECC action was greater that the load chosen for the CON.
RESULTS: No significant time x group interaction was observed in this study. A significant main effect of time ($p < .001$; $\eta 2p = 0.424$) was observed for CMJ performance with moderate changes for both groups (ES> 0.7). No significant changes were observed for sprint and COD performances.
CONCLUSION: Male and female athletes may benefit in similar ways when using RIDs during strength training. The increased of the variability and unpredictability of the RID load during a squat exercise modifies CMJ performance, and appears no modify sprint and change of direction in women and men. Thus, it is recommended to choose exercises with similar force vectors applied in order to achieve greater training transference to sport-specific movement. In addition, the ECC overload stimulus achieved in each session allowed for greater positive magnitude of changes (ES> 0.7) on CMJ than those showed in literature for RIDs squat training.

### MONITORING PULSE PRESSURE, RATE PRESSURE PRODUCT AND MEAN ARTERIAL PRESSURE ALONG A 6-MONTH SUPERVISED PROGRAM IN PERIPHERAL ARTERY DISEASE

ABRANTES, C.1,2, MACHADO, I.1,2, SOUSA, N.2,3, FERREIRA, J.4,5, SOUSA, P.6, MACHADO, L.6, SANTARÉM, D.1

*1.UNIVERSITY OF TRÁS-OS-MONTES E ALTO DOURO, VILA REAL; 2.CIDESD, VILA REAL; 3.ACES, SANTO TIRSO; 4.HOSPITAL DA SENHORA DA OLIVEIRA/EPE, GUIMARÃES; 5.UNIVERSITY OF MINHO, BRAGA; 6.CHTMAD, VILA REAL*

INTRODUCTION: A controlled Systolic (SBP) and diastolic blood pressure (DBP) is an important directive to risk reduction in several cardiovascular diseases. Some literature warns that the target blood pressure of 130/80 mmHg for the general population and nearly all patients with hypertension may not be optimal with regard to lower-extremity peripheral artery disease (PAD) events [1]. Related cardiovascular disease risk and arterial stiffness markers, such as the rate-pressure product (RPP), the pulse pressure (PP), as an indirect marker of arterial stiffness, and the mean arterial pressure (MAP) can potentially add relevant information to this complex disease. To a safer condition is recommended to maintain the RPP lower than 10.0 mmHg/bpm and PP below 60 mmHg in resting condition. On the other hand, the MAP must stay close to 60 mmHg to perfuse vital organs and prevent the risk of ischemia. Study aims to examine the impact of a 6-month supervised program, focus on exercise and lifestyle changes, in RPP, PP and MAP in subjects with lower-extremity peripheral artery disease.
METHODS: Nineteen male patients with PAD and claudication in stage II of Fontaine classification (age= 63.8±5.6 years; ankle-brachial index below 0.90, hypertension= 74%, diabetes=58% and smokers and past-smokers= 74%) were grouped into Walking Group (WG, n=8) and Control Group (CG, n=11). Both, the WG (supervised 40-min treadmill walking, plus 3 sets of 15 repetitions of 3 lower-limbs resistance exercises, 3 times per week) and the CG (advise to walk 40-min, 3 times per week, control risk factors and change lifestyle) were enrolled in a 6-month supervised program. SBP, DBP and heart rate (HR) were measured after 15-min in a lying rest position at 0, 3 and 6-months. The RPP was determined by SBP*HR/100, the PP was set as the difference between SBP and DBP, and the MAP, determined by DBP+1/3*(PP).

RESULTS: Repeated measures ANOVA revealed no significant differences along the intervention, neither between WG and CG in PP, RPP or MAP at 0, 3 or 6-month. In CG, PP was 70.7±16.5 and 67.4±13.8 mmHg and, in WG was 60.1±14.8 and 59.6±15.7 mmHg (0 and 6 months, respectively). In CG, RPP was 10.1±2.3 and 9.6±2.1 mmHg/bpm, and in WG 10.1±1.9 and 10.2±2.6 mmHg/bpm (0 and 6 months, respectively). The MAP in CG was 107.2±14.5 and 94.6±31.3 mmHg, and in WG was 102.3±9.2 and 82.1±44.5 mmHg (0 and 6 months, respectively).
CONCLUSION: It was concluded that the variables PP and RPP more linked to cardiovascular risk remain stable, and near the target, along the 6-months supervised program. The MAP values, indirectly linked to risk of ischemia, shown an interesting decrease in both group strategies, and the threshold related to tissue perfusion was guaranteed in patients with lower-extremity PAD.

**HIGH INTENSITY INTERVAL TRAINING AND PAIN PERCEPTION**

RANSMANN, P., TOMSCHI, F., SCHMIDT, A., BOEING-MESSING, D., HILBERG, T.

*UNIVERSITY OF WUPPERTAL*

INTRODUCTION: Exercise-induced hypoalgesia (EIH) describes the reduction of pain sensitivity following physical activity. So far, little is known about EIH resulting from high intensity interval training (HIIT). The present trial aims to elaborate the effects of a 12-minute HIIT on EIH in healthy and sportive individuals on mechanical and ischemic pain perception.
METHODS: 20 subjects (12 males and 8 females aged 26±3) enrolled in this randomized controlled crossover trail. A pre-experimental session was conducted including an incremental bicycle ergometer test up to exhaustion, in which the individual maximum heart rate (HR) was determined. Subsequently, two different interventions with at least 72 hours in between were performed, in which mechanical pain pressure thresholds were assessed at the landmarks ankle, knee, and elbow joints as well as the forehead and the sternum via a hand-held pressure algometer (PPTa). Further, using a cuff pressure device wrapped around the midportion of the gastrocnemius–soleus muscles, ischemic PPTc were examined. Pain perception was examined pre and post a 12 minutes HIIT workout, consisting of whole-body exercises or 12 minutes relaxing breathing exercise as a control session, respectively.
RESULTS: The HIIT resulted in a mean HR of 166.3±9.8 1/min equaling a relative individual maximum HR of 90.7±3.3%. Regarding PPTa, results of the three-way ANOVA ('intervention' X 'time' X 'body landmark') indicate a significant 'intervention' X 'time' effect (p=0.006). Post-hoc analyses revealed that the HIIT led to hypoalgesia at the right (p=0.007) and left ankle (p=0.040), showing an increase of the PPTa from 41.9 to 48.9 Newton (N) and 42.9 to 48.1 N, respectively. Significant differences were further observed in the right knee (p=0.001; 68.0 to 80.0 N), and at the sternum (p=0.026; 34.4 to 37.7 N), while the control session did not induce changes of the PPTa at any landmark. Considering PPTc, the results of the three-way ANOVA indicate a main effect for the factor 'time' (p=0.041) and post hoc analyses revealed a significant hypoalgesic change after the HIIT at the left calf (p=0.046; 29.7 to 31.6 kPa) and a trend towards a significant hypoalgesic change at the right calf (p=0.058 30.3 to 33.9 kPa). The control session did not induce any changes.
CONCLUSION: EIH occurred at the primarily engaged joint landmarks (PPTa at ankle and knee and also in response to the PPTc), indicating that mechanical and ischemic pain stimuli were reduced by hypoalgesic effects. These phenomena are most likely induced by local pain inhibiting mechanisms, resulting from increased blood flow given the muscle activation. Further, hypoalgesia was observed at the sternum, indicating that also centrally mediated analgesic effects might be contributing processes. No changes were observed at the forehead as well as the elbow joints, most likely due to their little engagement during the HIIT.

**WEARABLE SENSOR TECHNOLOGY TO DETECT SHOCK IMPACTS IN SPORTS: A SCOPING REVIEW**

EITZEN, I., RENBERG, J., FÆREVIK, H.

*SINTEF DIGITAL*

INTRODUCTION: The majority of existing studies using wearable sensors within the sports domain have focused on total load exposure and technique. However, numerous types of sports entail events that may be harmful from just one single impact or a limited number of impacts. To assess such events, we need to know which types of sensor technology that most accurately can detect impacts in real-life settings in different contexts. Thus, the aim of this scoping review was to map existing methods for assessments of such shock impacts using wearable sensors. We aimed to identify types of wearables used, categories of sports and activities, sensor placement, outcome measures and overall knowledge gaps.
METHODS: The protocol was drafted using the PRISMA methodology and its extensions for scoping reviews (PRISMA-ScR). To be included, papers had to report shock impacts on the whole body or specific body regions with the use of wearable sensor technology, be written in English and published between 2010-2020. Wearables were limited to sensors attached to the body, to clothing, or to equipment used by the individual. Papers were excluded if they included individuals with a functional impairment, disability, or illness, or if they focused on movement quantification, total load, movement quality or technique only. The online databases MEDLINE, SportDiscus, Scopus, PubMed, Compendex, and ISI Web of Science were searched, and the software tool Covidence used for extraction of eligible papers.
RESULTS: Thirty-four papers were included in the data material. Of these, the majority were single intervention tests validating methodology (n=20) and longitudinal/observational studies (n=11). More than 20 different types or brands of sensors were used, and 25 of the 34 included studies used additional technologies like force plates or video recordings for validation. Accelerometers was the dominant type of wearable sensor technology, interpreting peak acceleration as a proxy for impact. Three main categories of assessments were identified: foot strike in running (n=12), head impacts in invasion and team sports (n=10) and jump landings (n=6).
CONCLUSION: We identified a high proportion of validation studies up against established gold standard methods. These studies suggest that wearable sensors at present do not provide the necessary accuracy as a stand-alone method for assessments of shock impacts in the field. Caution should further be made when considering the usability of wearable sensors for different sports and movement contexts, as it is unknown whether there may be differences in accuracy and validity between different brands. This scoping review revealed a lack of consensus regarding both sensor placement and interpretation of results. Furthermore, the absence of studies assessing single shock impacts other than head impacts in different invasion and team sports, as well as the overall lack of impact assessments in demanding winter sports and track and field, is stated as considerable knowledge gaps.

### CARDIAC AUTONOMIC EFFECTS OF SUBMAXIMAL EXERCISE IN ATHLETES AFTER CONCUSSION

DELLING, A.C., COENEN, J., JAKOBSMEYER, R., REINSBERGER, C.

*PADERBORN UNIVERSITY*

INTRODUCTION: Submaximal aerobic exercise is the first step in the return-to-sport (RTS) protocol after sports-related concussion (SRC) and appears to be effective in speeding up recovery. How exercise during RTS is related to cardiac dysautonomia, a prominent and often persistent feature of SRC, remains to be elucidated. The aim of this study was to explore measures of the cardiac autonomic nervous system (cANS) in response to submaximal exercise in concussed athletes during RTS.
METHODS: Thirty athletes participated in this study. 15 SRC athletes (age: 24 ± 5, BMI: 24 ± 2) were examined during RTS (days after concussion: 2-140, number of symptoms: 1-19). SRC athletes were compared to 15 matched controls (age: 25 ± 5, BMI: 24 ± 3). All athletes performed a progressive ergometer exercise protocol until reaching 70% of their age calculated maximal heart rate (HR). cANS data were collected pre and post (±10 minutes) exercise in supine position for 5 minutes using a wrist sensor (PPG). Mean HR (mHR) and the root mean square of successive differences of RR intervals (RMSSD) were analyzed. Subjective stress levels were documented pre and post exercise using the short recovery and stress scale. Wilcoxon Signed Rank Tests were used to explore statistical significance for differences between groups (concussed vs. controls) and time (pre vs. post exercise).
RESULTS: mHR increased significantly from pre to post exercise in the SRC group (median (Mdn) = 59.34 bpm, interquartile range (IQR) = 15.54 to Mdn = 66.38 bpm, IQR = 13.11, Z = - 3.41, $p < 0.001$, r = -0.622) as well as in the control group (Mdn = 58.22 bpm, IQR = 11.75 to Mdn = 66.58 bpm, IQR = 15.42, Z = -3.41, $p < 0.001$, r = -0.622). RMSSD decreased significantly from pre to post exercise only in the SRC group (Mdn = 65.00 ms, IQR = 73.72 to Mdn = 46.68 ms, IQR = 27.48, Z = -2.73, p = 0.006, r = -0.497). The submaximal exercise parameters did not differ significantly between groups in watts achieved (Mdn = 2.02 vs. 2.17 watts/kg) or duration (Mdn = 14 vs. 14 min) of exercise. Subjective stress significantly increased for the control athletes from pre (Mdn = 3, IQR = 3) to post exercise (Mdn = 2, IQR = 4, p= 0.036, r = -0.383).
CONCLUSION: Despite similar performance parameters during a submaximal exercise test, SRC athletes revealed a significant reduction in RMSSD 10 min post exercise when compared to controls, possibly indicating an altered cardiac parasympathetic recovery after submaximal aerobic exercise. High inter- and intraindividual variability of ANS parameters, the low sample size and broad range of days post injury need to be considered when interpreting these results.

### «ATHLETE FINGERPRINTING» OF ELITE ICE HOCKEY PLAYERS AND CROSS-COUNTRY SKIERS: TOWARDS PERSONALIZED SPORTS MEDICINE

MAURER, D.

*UNIVERSITY OF BASEL*

INTRODUCTION: Elite athletes regularly experience impaired performance due to upper respiratory disease (e.g., infections, asthma). Oftentimes, illness-related training interruptions happen during intense periods, such as before or during competitions, which has a major impact on the athlete's potential success. Apart from injuries, upper respiratory symptoms are the most common reason for elite athlete's presentation at their sports physician. So far, the reasons for the high prevalence remain unclear. Here, Olink proteomics can provide a better understanding of the underlying mechanisms and help the identification of potential biomarkers of susceptibility to infections, allergic disease and asthma in elite athletes.
METHODS: We assess immunological and molecular differences in serum samples of cross-country skiers (n=14) and ice hockey players (n=21), and two control groups of amateur athletes (n=29) and non-sportive persons (n=24), by means of Olink targeted proteomics, using a proximity extension assay. Measured panels included 184 proteins involved in immune response and inflammation. Information on training (e.g., weekly hours) and medical history (e.g., asthma, allergic disease) was obtained via questionnaires.
RESULTS: A substantial number of cross-country skiers and ice hockey players either suffer from asthma (14%), allergies in general (20%), allergic rhinitis (34%) and recurrent upper respiratory infections or fever (29% and 20% respectively in intense training periods). Loss of training due to infections is reported by 43% of all elite athletes. Targeted serum analyses of 184 proteins revealed that elite ice hockey players have significantly upregulated levels of proteins involved in immune response and inflammation in comparison to cross-country skiers. Those differentially expressed proteins play key roles in innate immune response to viral infection, platelet- endothelium-leukocyte interaction, apoptosis, Th cell differentiation, lymphocyte proliferation, and TREM1, interferon and Jak-STAT signaling.
CONCLUSION: Personalized sports medicine is a newly introduced concept, now allowed by targeted proteomics. Proximity extension assay-based proteomics revealed that ice hockey players exhibit an overall pro-inflammatory profile. In comparison, amateur athletes and non-sportive controls did not show any upregulation of pro-inflammatory proteins. Cross-country skiers' profiles in general are more comparable to the latter than to elite ice hockey players. Within the groups, there are athletes with different endotypes such as pro-inflammatory, hypermetabolic, strong anti-viral and/or tissue destruction, all of which remain to be further elucidated. The impact of recent physical activity, overtraining, microbiome and exogenous exposome on inflammation- and immune response-related proteins requires further investigation.

### CARDIOPULMONARY, METABOLIC, AND MUSCULAR DEMANDS OF A WHOLE-BODY WOBBLE BOARD (ICAROS CLOUD) TRAINING

SIPPL, J., DMITRIEVA, A., VENZKE, J., PLATEN, P.

*RUHR UNIVERSITY BOCHUM*

INTRODUCTION: Training on unstable surfaces requires complex motor control mechanisms and can enhance the ability to maintain balance, improve the activation of stabilizing muscles and may be a crucial protective factor against sports injuries.1,2 However, well-known wobble boards or unstable surfaces studied so far are small and only applicable for standing exercises. We investigated the effects of a new whole-body inflatable exergaming training system with digitally guided exercises on the cardiopulmonary, metabolic, and muscular systems and training enjoyment.
METHODS: Sixteen recreational athletes (f=5/m=11, 24±1 years, 176±7 cm, 71.3±10.3 kg) absolved two identical predefined interval trainings (12 minutes, six isometric and dynamic exercises) with (ICAROS Cloud; IC) and without (Control; CON) the IC exergaming system in a randomized cross-over study design. Data of heart rate (HR), maximal lactate concentration (maxLA), energy expenditure (EE), relative perceived exertion (RPE), muscle activity measured by electromyography (EMG) and normalized to maximal voluntary contraction (MVC) of

m. rectus abdominis and m. rectus femoris, as well as acute muscle soreness (AMS), and physical activity enjoyment (PACES) were recorded. Dependent t-tests were performed for treatment comparisons. Cohens d was used to estimate the effect size.
RESULTS: No differences between treatments were detected for averaged and maximal HR, maxLA, and averaged and maximal RPE (p≥.05, respectively). Slightly higher EE during training could be shown for IC compared to CON (IC: 106.6±19.6 kcal; CON: 102.3±20.3 kcal, p=.006, d=.8). Lower AMS values occurred in IC for m. rectus abdominis (IC: 2.7±2; CON: 3.4±2, p=.029, d=.61) and m. deltoideus (IC: 2.8±1.8; CON: 4.6±1.9, p=.004, d=.85) without differences between treatments in averaged EMG values normalized for MVC (p≥.05). IC showed higher scores for positive (IC: 3.5±0.6; CON: 2.9±0.4, p<.001, d=1.23) and lower scores for negative (IC: 1.5±0.6; CON: 1.9±0.6, p=.006, d=.8) related items of PACES. 81% of the subjects preferred IC training.
CONCLUSION: Training on the newly developed ICAROS Cloud system induced comparable physical stress as identical exercises performed without IC but resulted in greater enjoyment. Hence, training in IC guided with digital devices can be recommended due to overall preferences and an increase in joy and, therefore, might induce longer lasting training adherence.

**CIRCULATING CELL-FREE DNA AS A BIOMARKER FOR INJURY PREDICTION?**

TOMASKOVIC, A.1, STOEGGL, T.2,3, BLUMKAITIS, J.2, STREPP, T.2, AGLAS, L.4, WENGER, M.4, NEUBERGER, E.1, SIMON, P.1, HALLER, N.1,2

*1 INSTITUTE FOR SPORTS SCIENCE MAINZ, 2 UNIVERSITY OF SALZBURG, AUSTRIA, 3 RED BULL ATHLETE PERFORMANCE CENTER, SALZBURG, AUSTRIA, 4 DEPARTMENT OF BIOSCIENCES, UNIVERSITY OF SALZBURG, AUSTRIA*

INTRODUCTION: Circulating cell-free DNA (cfDNA) is considered an emerging biomarker in exercise physiology. Increases during exercise depend on exercise duration and intensity [1]. Changes in cfDNA concentrations could be associated with the onset of the overtraining syndrome [2]. This case study (n=2) investigates a possible association between cfDNA levels and the incidence of overload, which prevented one participant from completing the Salzburg 10/7 HIIT study (S10/7, NCT05067426) compared to one subject who completed the study.
METHODS: S10/7 investigates the effects of a 7-day (d) high-intensity interval training (HIIT) shock microcycle. The study consists of a baseline period (b) of 9 d with time points T0 (d 1 b) and T1 (d 8 b), an intervention period of 7 d (10 HIITs: 5x4 min at 90-95% HRmax with 2.5 min rest in between, followed by a 30-min run at low intensity below the lactate threshold (LT) of 1.5 mmol/l) with time points T2 (d 2) and T3 (d 7) and a post-intervention phase of 14 d with physiological exercise testing (PET) on three time points. Case 1 (C1; m, 23 yrs., 190 cm, 87.2 kg, LT 12.5 km/h) and -2 (C2; m, 30 yrs., 166 cm, 63.5 kg, LT 14 km/h) were analyzed. Participants complete baseline measurements (blood parameters, ECG, questionnaires) at T0 and a PET at T1. At T2 and T3, participants complete two supervised HIITs in the lab, one in the morning (AM) and the second one in the afternoon (PM). Venous cfDNA levels before and immediately after exercise and chronic changes of cytokine levels at rest were analyzed in C1 and C2.
RESULTS: C1 completed the study, whereas C2 discontinued the study on d 4 of the intervention due to iliotibial band syndrome during the intervention phase. Mean cfDNA levels (in ng/ml) were 6.8 (C1) and 7.4 (C2) before and 60.4 (C1) and 220.2 (C2) after PET at T1, with fold-changes (FC) of 8.9 (C1) and 29.6 (C2), respectively. Mean cfDNA levels were 6.7 (C1) and 5.8 (C2) before and 82.5 (C1) and 300.1 (C2) after HIITs at T2, with FC of 12.6 (C1) and 51.7 (C2). IL2 levels (in pg/ml) were 2.1 (C1) and 9.6 (C2) at T0, 2.7 (C1) and 10.7 (C2) at T1 2.4 (C1) and 11.7 (C2) at T2 AM. IL6 levels were 21.6 (C1) and 75.2 (C2) at T0, 26.1 (C1) and 87.7 (C2) at T1, 23.6 (C1) and 91.5 (C2) at T2 AM.
CONCLUSION: Absolute concentrations and changes in both cfDNA and inflammatory cytokines were more pronounced in C2, who discontinued the study because of an injury. In another study with 13 participants of almost similar aerobic fitness, PET provoked on average FC of 7.4, only [1]. Future studies need to systematically analyze larger injury-specific sample to clarify if cfDNA could be a biomarker for predicting overload and injury.

### CP-BM01 Motor learning: Function of coordination networks

**A RANDOMIZED CONTROLLED STUDY TO ASSESS THE EFFECTS OF 12-WEEKS OF COORDINATIVE ACTIVITY BREAKS ON MOTOR FUNCTIONS AND BRAIN STRUCTURE OF YOUNG AND MIDDLE-AGED OFFICE WORKERS.**

SCHARF, C.1, FINK, A.2, KOSCHUTNIG, K.2, ZUSSNER, T.2, TILP, M.1

*UNIVERSITY OF GRAZ*

INTRODUCTION: Studies report a positive relationship between physical activity and cognitive functions over the entire lifespan [1]. Physical activity can also lead to changes in the brain structure [2]. However, most studies focused on the effects of aerobic and anaerobic exercise, and only a few studies investigated the influence of coordinative exercises. Therefore, we offered a coordinative activity break to the staff at the University of Graz. Besides the health promotion for the young to middle-aged adults, the project aimed to evaluate the effects of the training on brain structure and motor function.
METHODS: Seven men and 24 women (42.5±10.3 years) participated in the randomized controlled study. The nineteen participants of the intervention group (IG) performed the training, which consisted of 15 minutes of juggling and balancing tasks, two times per week for twelve weeks. Before the start of the intervention (week 0), six (week 6), and twelve (week 12) weeks after the start, we measured the balance (Y-Balance test), manual dexterity and bimanual coordination (Purdue Pegboard test), and reaction time (fall stick test). We as-

sessed the juggling performance (JP) with the 3-ball-cascade. Furthermore, we assessed changes in the gray matter (GM) volume of the brain with MRI (3T Magnetom Sykra scanner, Siemens Healthineers Erlangen, Germany) with a subgroup of the participants (n=26; IG=16, CG=9). The VBM-analysis was processed using SPM12 (Wellcome Department of Cognitive Neurology, London, v6906) and the Computational Anatomy Toolbox 12 (CAT12, r1113) under Matlab (The Mathworks, 2015). All results were FWE-corrected. We used analysis of variance, t-tests, and non-parametric tests with a significance level of 0.05 to analyze the data.
RESULTS: The JP increased significantly in the IG from week 0 (0.2±0.9) to week 6: (1.5±1.4 sec.; p<.05) and from week 6 to week 12 (3.8±4.2 sec.; p<.05), but did not change in the control group (CG). There was a significant difference in the JP between the IG and CG at week 6 (1.5±1.4 sec. vs. 0.0±0.0 sec.; p<.05) and week 12 (3.8±4.2 vs. 0.0±0.0 sec.; p<.05). GM volume significantly decreased in the precentral gyrus, middle frontal gyrus, Rolandic operculum (cluster size: kE=502; x=42, y=12, z=27), and insula (kE=247; x=46, y=9, z=4) of the right hemisphere at week 12. We did not observe any significant effects in the other parameters.
CONCLUSION: The training was associated with changes in the GM volume and with improvements in JP. We assume that the observed decrease in the GM volume indicates a reorganization of brain tissue, facilitating more automated and efficient coordination of voluntary movements and postural control. However, we found no effects on other motoric parameters. We had a physically active sample, which could be a reason for the lack of changes in the general motor functions.

### VALIDITY OF A COMPUTERIZED WOBBLE BOARD FOR FINE MOTOR SKILLS EVALUATION

DE-MAIO, M., DI-ROCCO, F., PAPALE, O., COSSENTINO, G., GALEOTTI, M., IANNUCCI, A., STALLONE, A., FUSCO, A., CORTIS, C.
*UNIVERSITY OF CASSINO AND LAZIO MERIDIONALE, ITALY*

INTRODUCTION: The evaluation of fine motor skills provides essential information about motor coordination, particularly in relation to age and clinical conditions. Several motor coordination assessments, such as the Grooved Peg Test (GPT), have been used to evaluate fine motor skills. Alongside, computerized wobble boards (WBs) have been suggested as accurate, reliable and valid tools to evaluate dynamic balance (1). Since WBs validity to assess fine motor skills has not been established, this study aimed to determine the validity of a computerized WB to assess upper limbs' fine motor skills in healthy young subjects.
METHODS: Thirteen young adults (age 26.9±3.9yrs; body mass 74.2±9.6kg; height 175±7.1cm) took part in two testing sessions, during which one WB test and one GPT were administered. The WB was connected to a laptop using a customized software, to visualize real time performances on a monitor through a motion marker (MM) and a Target Zone (TZ). During the WB test, the TZ displayed clockwise, counterclockwise, antero-posterior, medial-lateral motion patterns. For all WB tests the goal was to keep the MM within the TZ for as long as possible during the recording period. The WB test consisted of 4 different 15s trials (for each limb) with 30s recovery in between. Subjects were in a standing position, with the tested limb placed at 90° on the WB placed on a table and the monitor at eye level. The overall WB performance was represented by the sum of each condition per limb. The GPT (2) was carried out on a pegboard composed of a square table (10cmx10cm) with 25 holes arranged in a 5-by-5 grid, with varying keyhole orientation across the board and 25 pegs. Subjects were required to insert pegs into the board one at a time, completing the rows from left to right for right limb and from right to left for left limb, from top to bottom. The time recording started when subjects took the first peg and stopped when the last peg was inserted. The time to complete the GPT for each limb was recorded. Right and left limb times were averaged for each test and subsequently linear regression analysis (R2) was used to assess the relationship between WB and GPT. Root mean square error (RMSE) was also calculated. Statistical significance was set at p<0.05.
RESULTS: A very strong significant (p<0.0001) linear relationship (R2=0.85; RMSE=4.25) between WB (43.2±8.6s) and GPT (69.2±10.4s) was found. To clarify the relationship, the following equation was developed: GPT= -1.1216(WB) + 117.65.
CONCLUSION: The strong relationship between WBs and GPT indicated that WBs might be valid tools to assess fine motor skills in young adults. Considering that WBs include different motion patterns and joint range of movement, they could provide further information on fine motor skills, not only related on execution velocity and total time, particularly in patients with neurological disorder as Parkinson.

### FUNCTIONAL CONNECTIVITY OF THE BRAIN IN ACTIVE PROFESSIONAL FOOTBALL (SOCCER) PLAYERS

HAASE, F.K., FEDDERMANN-DEMONT, N., JUNGE, A., WELSCH, G., SCHUENEMANN, C., FIEHLER, J., REINSBERGER, C.
*PADERBORN UNIVERSITY*

INTRODUCTION: Long-term consequences of heading associated repetitive head impacts (RHIs) in football (soccer) are an area of scientific debate with large clinical relevance. Functional magnetic resonance imaging (fMRI) based resting-state functional connectivity (FC) in intrinsic networks of semi-professional football players revealed increased FC within the default mode network (DMN) with large exposure to RHIs, but longitudinal fMRI investigations are still sparse. We therefore aimed to determine and evaluate potential FC changes in the DMN and the salience network (SN) in relation to heading in professional football players prospectively.
METHODS: 14 active professional male football players (20.36 ± 3.34 yrs.) were included in this exploratory, longitudinal study and were scanned twice with a 3T Philips Ingenia MRI scanner between November 2017 and May 2019. Between the scans, all trainings and matches were videotaped and all performed headers were counted. Resting-state fMRI data was analyzed with the CONN functional connectivity toolbox (v.20.b) using default preprocessing and denoising steps. Smoothing was set to 6mm. T1 weighted structural MRI sequences were included for individual anatomical reconstruction of the fMRI data. A region of interest (ROI)-to-ROI approach was applied to compare the differences between the measurements while controlling for age, focusing on ROIs of the DMN and the SN. 12 ROIs with 66 connections were analyzed with non-parametric statistics (cluster-level p-FDR <0.05). Spearman correlations between total header number and significant FC changes were calculated.
RESULTS: During the observation period of 10 to 18 months (median 17.2 months) 5822 headers in total (min.: 146, max.: 943, median: 340.5) were documented. FC increased significantly within the SN (p-FDR=0.023) specifically between the right supramarginal gyrus (SMG) and the anterior cingulate cortex (p-FDR=0.050) and between the right SMG and the left rostral prefrontal cortex (p-FDR=0.02). The numbers of total headers did not correlate with any changes in FC.

CONCLUSION: This study showed explorative FC changes within the SN, a relevant intrinsic network, suggesting functional resting-state changes in football players. However, within DMN changes with increasing impact exposure were not found. Duration of the observation period or level-of-play might have contributed to these results. A missing association between heading and SN FC changes might indicate an adaptation to playing football in general rather than a specific heading effect. To test this hypothesis larger samples and a control group are needed. Future studies should also include male and female football players of various levels-of-play and player's incidence rates as the observation period of this study varied.

**CHANGES IN THE MOTOR BEHAVIOUR DURING A FAMILIARISATION PROTOCOL TO A SOFT BACK EXOSKELETON.**

FAVENNEC, A.1, FRÈRE, J.2, MORNIEUX, G.1,3

*1 UNIVERSITÉ DE LORRAINE, DEVAH, NANCY, FRANCE; 2 UNIV. GRENOBLE ALPES, CNRS, GRENOBLE INP, GIPSA-LAB, 38000 GRENOBLE, FRANCE; 3 UNIVERSITÉ DE LORRAINE, FACULTY OF SPORT SCIENCES, NANCY, FRANCE.*

INTRODUCTION: Back exoskeletons, defined as wearable structures that give an assistive torque to one or multiple joints, can prevent from low back disorders (LBD) during stoop lifting tasks (1). Results in the literature about benefits and disadvantages are inconsistent (2), possibly due to the lack of familiarisation to the use of exoskeletons (3). Thus, this study evaluated the effect of familiarisation to a back exoskeleton to define changes in the motor behaviour.
METHODS: Ten males (1.78±0.04 m, 69.9±5.8 kg, 22.3±2.4 years) performed 6 sessions of 1-h familiarisation to a CORFOR® soft back exoskeleton within 2 weeks. This familiarisation protocol consisted in several manual handling tasks and precision tasks involving trunk bending. Measurements were carried out at the beginning of the first session and at the end of each session, during which participants were asked to execute 10 repetitions of a lifting task in the sagittal plane using the stoop technique (8 kg; 15 cycles / minute). A timed precision task, involving the whole body to move a ring along a weaving metallic tube without touching it, was used to assess a performance score of the participant's ease with the exoskeleton. Prior to this CORFOR® familiarisation protocol, participants get used to stoop and precision tasks during 3 sessions of 20min. The level of muscle activity (RMS) was calculated from electromyographic (EMG) recordings of erector spinae (ES) and rectus abdominis (RA) muscles. Ellipse area of the centre of pressure displacements during the lifting task was calculated as a marker for postural stability. Back curvature was evaluated through 3D kinematics measurements yielding lumbar (LF) and thoracic (TF) flexions in the sagittal plane. A repeated measures ANOVA with Tuckey's HSD post-hoc tests were performed to assess the effect of the familiarisation protocol on the evolution of the motor behaviour.
RESULTS: Main effect of familiarisation was observed on performance score ($p<0.001$) and ellipse area ($p=0.01$). Post-hoc tests showed that sessions 3 to 6 were different ($p<0.05$) from the other sessions for these variables. There was no main effect of familiarisation on EMG RMS (ES: $p=0.63$; RA: $p=0.24$) or back curvature (LF: $p=0.12$; TF: $p=017$).
CONCLUSION: Changes in performance score and ellipse area suggested that the motor behaviour measured in the early stages of the participant's experience with the exoskeleton might not be representative of the long-term motor behaviour. This must be taken in consideration for the interpretation of the results of studies that investigated the effects of back exoskeleton without familiarisation. However, EMG and back curvature did not show any evolution across sessions. Accordingly, it seems that muscular and LBD possible benefits of the use of the exoskeleton do not change with practice.

**IMPROVEMENTS IN POSTURAL STABILITY FOLLOWING AN ONLINE CORE INTERVENTION IN OLDER ADULTS.**

ROBERTS, M., NEDOW, J., BASSOU, A., MILLER, M.B.

*CONCORDIA UNIVERSITY*

INTRODUCTION: Falls are the leading cause of hospitalizations in North America in adults aged 65 years and older, the risk of falls increasing and balance decreasing with aging. Exercise of core muscles has been shown to improve balance in older adults by improving the proprioceptive system and the strengthening of muscles involved in postural stability. However, access to exercise may be challenging as some older adults face transportation issues, inclement weather, living in remote areas, and most recently, stay-at-home pandemic regulations. Thus, online exercises are essential to reducing the obstacles to exercise participation and improving postural stability in older adults. The purpose of this study, then, was to examine the effects of an 8-week online and self-led core exercise intervention on postural stability in older adults.
METHODS: Recruited through convenience and snowball sampling, 26 older adults (73.7±5.76 years; 24F:2M), participated in this pre-to-post intervention. Inclusion criteria were adults aged 65 years and older and exclusion criteria were medical conditions for which physical activity was contraindicated. Before the start of the intervention, postural stability was assessed in the mediolateral and anteroposterior planes by recording six 30-second trials of quiet standing with eyes closed: 3 trials facing the webcam and 3 trials with the left side facing the webcam. Hip and shoulder displacement were then calculated using Kinovea, a free for download sports analysis software. The core exercise intervention consisted of three 20-minute sessions per week, over 8 weeks. One session was led online, through Zoom, by a kinesiologist and the participants were then asked to complete these same exercises at 2 other times during the week, on their own time. Modifications were offered and a chair was the only equipment necessary. The same postural stability assessment was repeated post-intervention. A non-parametric Wilcoxon signed-rank test to compare displacement pre- to post-intervention with significance set to $p < 0.05$.
RESULTS: All means indicated improved postural stability, but there were no significant differences from pre- to post-intervention in mediolateral plane displacement at the hips (pre=1.99±0.92, post=1.84±1.02; $p=0.42$) or shoulders (pre=2.26±1.26, post=1.92±1.13; $p=0.44$), nor in anteroposterior plane displacement at the shoulders (pre=3.60±1.22, post=3.23±1.39; $p=0.12$). A significant difference pre- to post-intervention in anteroposterior plane displacement at the hips was observed (pre=2.79±1.13, post=2.31±0.88; $p=0.02$).
CONCLUSION: An online and self-led core exercise intervention is safe and effective at improving anteroposterior postural stability at the hips in older adults. The use of Kinovea offers a cost-efficient method to motion analysis which can be completed online. This study suggests that online and self-led interventions are feasible in the older adult population to reduce barriers to exercise access.

### NEUROMUSCULAR CO-CONTRACTION RATIOS CAN HELP UNDERSTANDING TRUNK KINEMATICS DURING PERTURBED STANCE.

DUCHENE, Y.1, MORNIEUX, G.1,2, PETEL, A.1, PERRIN, P.P.1,2, GAUCHARD, G.C.1,2

*1 UNIVERSITÉ DE LORRAINE, DEVAH, NANCY, FRANCE ; 2 UNIVERSITÉ DE LORRAINE, FACULTY OF SPORT SCIENCES, NANCY, FRANCE.*

INTRODUCTION: During postural tasks, trunk motion relationship with neuromuscular activations have mainly been studied thanks to EMG latencies and amplitudes. However, it has been suggested that co-contractions could be a strategy to control trunk instability by stiffening the spine [1]. Hence, the main objective of the present study was to link trunk neuromuscular control thanks to co-contraction ratios with its kinematics during balance tasks.
METHODS: Thirty-six healthy male adults performed 6 trials of a postural perturbation task. Subjects stood on their left leg and faced a 550 ms support translation towards the right of 5.7 cm. Trunk angle in the frontal plane was recorded with IMUs together with EMG signals from the rectus abdominis, external obliquus and erector spinae muscles. Directed Co-Contraction Ratios (DCCR) [2] and Co-Contraction Indexes (CCI) [3] were computed. They respectively reflect the balance between left (agonists) and right (antagonists) muscles and the level of spine stiffness. Each variable was calculated over 100 ms windows, from 100 ms before ground translation (PRE) to 800 ms after. Moreover, maximal trunk amplitude was assessed. Repeated measures ANOVA between each time window and multiple linear regressions predicting trunk amplitude with DCCR and CCI were computed.
RESULTS: Lateral trunk angle increased significantly during the first 500 ms and reached its peak value (11.9±7.8°) at 571±183 ms. Between -100 ms and 100 ms, DCCR remained mainly negative (-0.35±0.44), then significantly switched to positive values (DCCR_200=0.59±0.28) until 300 ms and then were negative again. CCI increased significantly from -100 ms (CCI_PRE=336±168) to 200 ms (CCI_200=968±757) and then was stable around 1000.
DCCR predicted 39.1% of trunk lateral amplitude variance and CCI predicted 19.3% of this variance ($p<0.05$). Significant beta-coefficients were the PRE window for the DCCR model (B=-0.48) and the 300-400 ms window for DCCR (B=0.62) and CCI model (B=0.79). During PRE, an increased DCCR, in favour of lateral muscle activations, was linked with a decrease of trunk amplitude. Then, enhanced DCCR and CCI were related to a larger trunk amplitude.
CONCLUSION: The switch towards positive DCCR values indicated a larger weight for lateral muscles activation, probably increasing lateral lean during 100-300 ms window, whereas the later medial neuromuscular eccentric activation would limit trunk's lean. The CCI rise might reflect the need of stabilizing the trunk by stiffening the spine in the latest part of the perturbation.
Overall, early trunk lateral lean appeared to be the consequence of trunk muscles' actions, and was then limited by medial muscles and spine stiffness. Co-contraction ratios could therefore help understanding trunk kinematics.

### AN ANALYSIS OF LOWER EXTREMITY KINEMATICS IN RESPONSE TO PERTURBATIONS DURING RUNNING USING STATISTICAL PARAMETRIC MAPPING

KHAJOOEI, M., QUARMBY, A., KAPLICK, H., MAYER, F., ENGEL, T.

*POTSDAM UNIVERSITY*

INTRODUCTION: Investigation of human balance control strategies might help to avoid fall incidents, prevent injuries, and may characterise movement impairments, such as in neurological diseases or musculoskeletal pain conditions. However, little is known about balance strategies during running. Kinematic assessment of perturbed running continuously throughout a gait cycle can map out balance control strategies, which might be correlated with injury risk or onset. Therefore, lower extremity kinematics were analysed in response to decelerative perturbations during running using statistical parametric mapping (SPM).
METHODS: A sample of 13 asymptomatic individuals (8 females & 5 males, 28±3 years, 171±9 cm, 68±10 kg) completed an 8-minute running protocol with 30 one-sided perturbations (15 on each side) to generate decelerative disturbances. A 3D-motion capture system including 13 cameras (500Hz) was employed to record kinematic data. Joint angles of the ankle, knee, and hip in addition to stride duration, stride length and step width were calculated for leading and trailing strides for regular (RR) and perturbed running (PR). Results were analysed descriptively, followed by one-dimensional SPM of multiple paired t-tests to compare RR versus PR joint angles (MATLAB®). Spatiotemporal parameters of stride duration, stride length and step width were compared between RR and PR with paired t-tests (SPSS statistics 22) ($P<0.025$).
RESULTS: Reactively (after perturbation), perturbations caused decreased hip adduction and stride duration of the leading leg. The trailing leg reacted with reduced ankle inversion, knee and hip flexion, hip adduction, as well as an increase in stride duration and step width ($P<0.025$). In preparation for perturbations, the leading stride did not change ($P>0.025$) however, the trailing leg reduced ankle dorsiflexion, knee flexion, and hip flexion and adduction ($P<0.025$).
CONCLUSION: In summary, applied perturbations produced substantial reactive (feedback) and predictive (feedforward) responses in the lower limbs, most apparent in the trailing leg. Observed adjustments suggest an attempt of the body to keep the foot close to the ground and widen its base of support, indicated by less hip adduction and step width, to avoid a fall.

### FIELD-BASED ASSESSMENT OF LOWER AND UPPER-LIMB VISUOMOTOR REACTION TIME IN FEMALE FOOTBALL GOALKEEPERS: A PILOT STUDY

PUS, K.1,2, PESKAR, M.1,3, GIESCHE, F.4, MARUSIC, U.1,5

*1 INSTITUTE FOR KINESIOLOGY RESEARCH, SCIENCE AND RESEARCH CENTRE KOPER, SLOVENIA; 2 FACULTY OF SPORT, UNIVERSITY OF LJUBLJANA, SLOVENIA; 3 TECHNISCHE UNIVERSITÄT BERLIN, BERLIN, GERMANY*

INTRODUCTION: The ability to execute rapid motor responses to visual stimuli is a key demand for football goalkeepers (GK). While most of previous training studies focus on improving pure motor functions, interventions that address visuomotor performance of the upper and lower extremity are still scarce (Otte et al., 2020). The aims of the pilot study were to validate a self-developed field-based visuomotor reaction time test and to investigate how the test performance relates to an GK's qualities.
METHODS: Six female football GKs (21,5□4,3, national level), 5 female football forwards (24,6□4,3, national) from the two teams (domestic league), and 6 female controls (age:21□1,9) were included. Simple and choice reaction time (RT) of the upper and lower limb were assessed

with the FitLight Trainer™ system. During the visuomotor test, participants needed to respond as fast as possible to 4 sensors light stimuli in standing position. Two sensors were positioned on eye level (one arm length) and two sensors were placed on ankle height in front of the participants (each upper and lower sensor placed left and right of participants midline). For the simple RT task, the participants were responding to a single sensor at each position (n=10). For the choice RT task, a random sequence (n=12 each) was used. To test for criterion validity, visuomotor RTs were correlated with perceptual-cognitive (cognitive flexibility, working memory; Trail-Making-Test) and motor performance (agility T-Test; MTT). For GKs only, we analysed how visuomotor RTs related to the assessed GKs qualities (rated by each team coach) using an adapted questionnaire (GKs abilities and characteristics; GKAC score). To analyze potential relationships between each limb RT, Pearson correlation coefficients were calculated.
RESULTS: A strong correlation was found between a higher overall GKAC score and faster SRT of left hand (r = 0,872;p = 0,023) and the right leg (r = 0,904;p = 0,013). No significant relationship was found between RTs and standard perceptual-cognitive and motor performance (p>0.05).
CONCLUSION: Our results provide initial evidence for a potential relationship between higher playing abilities rating scores (GKAC) and faster visuomotor speed of the lower and upper limb in GKs, indicating the ecological validity of the developed RT test. Future studies with larger sample sizes are warranted to confirm our intriguing findings and to elucidate further how this or similar visuomotor tests relate to in-game performance scores, which may open up new avenues to improve performance screening and training of football GKs.

### HOW DO EXPLICIT CONTEXTUAL CUES IN VIRTUAL-REALITY AFFECT SENSORIMOTOR CONTROL IN AUTISTIC ADULTS?

ARTHUR, T.1, BROSNAN, M.2, HARRIS, D.1, BUCKINGHAM, G.1, WILSON, M.1, WILLIAMS, G.1, VINE, S.1

*1. UNIVERSITY OF EXETER; 2. UNIVERSITY OF BATH*

INTRODUCTION: Most autistic people have difficulties with controlling their bodily movements and processing sensory cues. These difficulties can limit a person's ability to perform key practical skills, while affecting how independent they are and how much physical activity they do. Recent research suggests that movement-related issues in autism could be reduced by providing individuals with explicit information about their surrounding environment. Therefore, we examined how explicit contextual cues in immersive virtual-reality affect autistic sensorimotor control.
METHODS: 22 autistic and 22 non-autistic participants completed a virtual racquetball task, in which they were required to hit normal and unexpectedly-bouncy balls using a handheld virtual-reality controller. The probability of facing each type of ball was varied unpredictably over time, in order to create volatile environmental conditions. During a cued block of trials participants received explicit visual information about the likelihood of facing each ball outcome. Conversely, non-cued trials did not contain any prior cues about likely ball bounciness.
RESULTS: When compared to a non-autistic control group, autistic individuals displayed poorer task performance, atypical gaze profiles, and more restricted swing kinematics. Although these participants showed intact predictive sensorimotor control abilities, their visuomotor control was not significantly affected by prior contextual cues in virtual-reality.
CONCLUSION: Results indicate that autistic people exhibit underlying differences in how prior information and environmental uncertainty are dynamically modulated by the brain. Our findings support the development of evidence-based programmes that make the world more stable and/or predictable for autistic people.

### PLAYING WITH A TABLE TENNIS RACKET SHORTENS YOUR PERCEIVED ARM LENGTHS

REIN, R.

*GERMAN SPORT UNIVERSITY COLOGNE*

INTRODUCTION: Many sports activities require the use of specific implements like rackets, bats and clubs. Thus, an argument can be made that tool-use is a defining characteristic in many sports. Evidence from studies in cognitive psychology suggests that specific cognitive processes support tool-use in humans including for example changes in body representations (1). Thus, these processes may affect task execution in sports as well which has important implications for training regimes and performance. Therefore, the present study seeks to explore whether bouncing with a table tennis racket triggers changes in body representation. We expected that arm lengths would increase due to the embedding of the racket into the arm body representation.
METHODS: 23 participants participated in the study in a pre-post-design. Following previous studies (2), during testing participants placed one arm inside an apparatus and subsequently indicated the perceived positions of the elbow, the wrist, and the middle finger tip using the index finger of the opposite arm whilst being blindfolded. Both arms were tested such that the non-dominant arm served as a control. After pre-testing participants bounced a ball using a table tennis racket for ten minutes with their dominant hand. Segment lengths of the forearm, the hand, and deviations from actual lengths were modelled using a linear mixed-effects model ($\alpha = 0.05$).
RESULTS: Total arm lengths decreased from pre- to post ($p < 0.01$, $d = 0.29$). Analyzing arm and forearm separately, indicated no statistical significant effects for hand but statistical significant effects for the forearm ($p < 0.05$, $d = 0.32$). No interaction effects were found indicating that effects occurred in both arms. Deviations from actual total arm length suggested that participants underestimated lengths. No differences were found between the arms but deviations increased during post testing ($p < 0.05$, $d = 0.21$). Thus, changes in body representation were found were the forearm was perceived shorter after treatment and this effect transferred from the manipulated dominant arm to the non-dominant control arm.
CONCLUSION: The results showed that using a table tennis racket alters the body representation after only ten minutes of activity. However, the changes were in the opposite direction to what was expected. The results further showed that even in the non-dominant control arm the body representation was altered which is indicative of a transfer effect. Taken together, the results suggest that changes in body representation found in other tasks involving tool-use also occur in sports. At present, it is unclear to what extent these changes are linked to performance although evidence from blind cane users suggests a correlation. Thus, further research seems warranted investigating tool-use in sports.

### CP-MH03 Exercise and training in patient populations

#### DIFFERENCES IN AEROBIC EXERCISE TRAINING-INDUCED FSTL1 EXPRESSION CHANGES IN DIFFERENT TISSUES IN OBESITY

INOUE, K.1,2, FUJIE, S.1, HORII, N.2, YAMAZAKI, H.1, UCHIDA, M.1, IEMITSU, M.1

*1> RITSUMEIKAN UNIVERSITY, 2> RESEARCH FELLOW OF JAPAN SOCIETY FOR THE PROMOTION OF SCIENCE*

INTRODUCTION: Follistatin-like 1 (FSTL1) constitutively expresses and secretes in various tissues, mainly muscles, myocardial and adipose tissues, and is involved in cardioprotection, glucose uptake, adipose thermogenesis and anti-inflammation (1-4). Therefore, it is an essential hormone for the prevention and improvement of obesity, diabetes, cardiovascular disease and aging. However, a change in secretion from several tissues in response to exercise training remains unclear. This study aimed to examine the changes in FSTL1 protein expression in response to exercise training in various tissues, such as muscles, myocardial and adipose tissues in obesity.
METHODS: Male 20-week-old obese (OLETF) rats were divided into sedentary control (OLETF-CON: N=8) and 8-week aerobic exercise training (OLETF-AT: treadmill running for 60min at 25m/min, 5days/week: N=8) groups. In addition, age-matched male LETO rats were used as a healthy sedentary control group (N=8). After the 8-week experiment, slow-twitch fiber-rich soleus muscle, fast-twitch fiber rich tibialis anterior muscle, left ventricular and epididymal fat were isolated after collection of blood. Serum, muscles, myocardium and adipose FSTL1 protein expression levels were measured by Western Blot. Soleus citrate synthase (CS) were measured as a marker of aerobic exercise training adaptation.
RESULTS: In the OLETF-CON group, serum FSTL1 levels and soleus CS activity were significantly lower than those in the LETO group ($p<0.05$). Compared with the OLETF-CON group, serum and soleus FSTL1 levels, and soleus CS activity were significantly greater in the OLETF-AT group ($p<0.05$). However, there were no significant differences in tibialis anterior muscle, myocardium and adipose FSTL1 levels among three groups. Serum FSTL1 levels were positively correlated with soleus FSTL1 levels ($p<0.05$, $r=0.462$), but not tibialis anterior muscle, myocardium and adipose FSTL1 levels.
CONCLUSION: Since the treadmill running exercise used in this study promoted the CS activity of the soleus muscle, it is considered that the slow muscle fibers are mainly recruited by the aerobic exercise training. These findings suggest that the increased FSTL1 expression of soleus muscle, which is a slow-twitch fiber-rich, may be involved in aerobic exercise training-induced increases in blood FSTL1 secretion in obesity.

#### HIGH-INTENSITY INTERVAL TRAINING IN PATIENTS WITH COPD: A FIDELITY AND TOLERABILITY STUDY

NYMAND, S., HARTMANN, J.P., RASMUSSEN, I.F., CHISTENSEN, R.H., IEPSEN, U.I., BERG, R.M.G.

*UNIVERSITY OF COPENHAGEN*

INTRODUCTION: Chronic obstructive pulmonary disease (COPD) is the third leading course of death [1]. Optimizing the recommendations for physical activity (PA) in COPD is a major target, since increased PA levels is associated with increased quality of life, reduced risk of hospitalizations and death [2]. High intensity interval training (HIIT) is time efficient and has the benefits of allowing COPD patients to complete a relative high workload sufficient to induce adaptations. Even though HIIT is widely used in pulmonary rehabilitation (PR), an optimal HIIT protocol remains as a focus of interest. This study was designed to compare long and short intervals in terms fidelity and tolerability in COPD.
METHODS: The study was a randomized cross-over trial. Ten patients diagnosed with moderate to severe COPD (58.5 ± 13.5 FEV1 %) completed the study. We compared 4x4 minutes (heart rate (HR) > 85 % of HRmax in min 3:50min) and 10 x 1 minutes (intensity at 100% of watt max) performed one week apart. To evaluate and compare the two HIIT protocols we used a predesigned model of fidelity and tolerability. The model was designed to evaluate each session in a red-amber-green system. Fidelity was accessed as adherence to training duration and training intensity measured as minutes with a HR > 85 % of HRmax for the 4 x 4 protocol and number of intervals with watt adjustment for the 10 x 1 protocol. The tolerability was assessed by a 10-point Likert scale. The lowest of the three parameters determined the overall rank of the session.
RESULTS: All participants completed the 4 x 4 protocol with a HR > 85 % in more than 3:50 minutes. One training session was reported as red and three as amber due to a low Likert scale. In the 10x1 protocol three training sessions were reported red and one amber due to both low Likert scales and adjustments to the training intensity. There was no statistical difference between protocols for either time spent with a HR>85% of HRmax or Likert scale.
CONCLUSION: Our results indicate that the 4 x 4 is more favorable in terms of fidelity in COPD. Both intervals of long and short duration are feasible in moderate to severe COPD. To find the optimal HIIT protocol in COPD the heterogeneous aspect of the disease and co-morbidities should be considered.

**EFFECTS OF SUPERVISED AEROBIC-STRENGTH TRAINING AND DIETARY INTERVENTION ON COGNITIVE PERFORMANCE IN SEDENTARY ADULTS WITH OBESITY**

SLOBODOVÁ, L.1, FORIŠEK PAULOVÁ, P.1, MINÁRIK, P.1, VADOVICOVÁ, P.1, NEMEC, M.1, AMIRI, A.1, KONRÁDY, P.1, LITVÁKOVÁ, V.1, UKROPEC, J.1, UKROPCOVÁ, B.1,2

*1: INSTITUTE OF EXPERIMENTAL ENDOCRINOLOGY, BIOMEDICAL RESEARCH CENTER SAS, BRATISLAVA, SLOVAKIA;*

INTRODUCTION: The incidence of obesity in adults is increasing markedly. Numerous studies have demonstrated that higher levels of obesity are associated with accelerated decline in cognitive performance (learning and memory). Regular physical exercise can support body weight maintenance. induce favourable changes in body composition as well as boost cognitive functions in adults. This study was aimed at examining the effects of exercise training intervention on cognitive performance in healthy adults with obesity.
METHODS: Thirteen adults underwent 3-month (age 38.6±6.2yrs; BMI 33.9±3.1 kg/m2; M7/F6) supervised aerobic-strength exercise training (two 1h strength and one 1h aerobic training sessions per week). Dietary intervention consisted of caloric restriction, food intake monitoring (caloric tables) and individualized dietary counselling once per week. The strength training targeted the major muscle groups, the initial workload was based on 15RM and 5% increase was introduced at each mesocycle. Aerobic training consisted of interval training using indoor cycling and rowing, boxing and step climbing (stepping), with a progressive increase of the interval from 5 up to 15 minutes/session. Rays auditory verbal learning test (AVLT) was performed before and after the intervention to assess cognitive performance. The learning score (learning ability), the score for delayed recall (short-term working memory) and the percentage of retention were calculated.
RESULTS: Three-month intervention induced an average weight loss of 9 kg (range 3.6 kg -14.9 kg) and increased aerobic physical fitness on average by 3.9 ml/kg/min (VO2max from 25.2±7.2 to 29.1±7.0 ml/kg/min) in adults with obesity. The cognitive performance improved in working memory (learning score 53.77±7.02 vs. 60.60±6.61; p=0.02), the delayed recall (12.00±2.38 vs. 13.83±1.03; p=0.02), but not in the percentage of retention (93.03±10.91 vs. 100.22±8.37; p=0.08) in adults with obesity. The percentage of retention was high and its variability in this population could be explained by the negative association with body weight (r=0.40; p=0.05).
CONCLUSION: Regular supervised aerobic-strength training positively affected body weight, physical fitness, and auditory learning performance in healthy adults with obesity. Here we provide evidence that regular exercise in combination with nutritional modification and caloric restriction should be recommended for individuals with obesity to boost cognitive performance.

**THE HYPOGLYCEMIC EFFECT OF EXERCISE COMBINED WITH SPIRULINA IN DIABETIC RATS: A SYSTEMATIC REVIEW AND META-ANALYSIS**

ZHONG, M.T., HUANG, J.F., WANG, J.H.

*SOUTH CHINA NORMAL UNIVERSITY*

INTRODUCTION: Diabetes mellitus (DM) is the most common chronic disease, which is predicted to affect approximately 643 million adults worldwide by 2030. Exercise has been endorsed as a key component in the management of DM, and is effective in improving glycaemic control. In addition to exercise, the functional food spirulina has been developed for DM because of excellent efficacy and no toxic side effects. Many researchers have confirmed that the hypoglycemic effect of the combination of exercise and spirulina in diabetic rats was significantly more effective than the single treatment, but some researchers have found that there is no difference. Therefore, it was still controversial in the hypoglycemic effect of exercise combined with spirulina in diabetic rats. We attempted to explore the effect and mechanism of exercise combined with spirulina in the treatment of diabetes, providing the reference for human clinical trial research and clinical treatment of diabetes.
METHODS: This study combined and analyzed the blood glucose (BG) in the combined treatment and the single treatment by systematic review and meta-analysis. The systematic review report was carried out based on the PRISMA. We conducted a literature search of PubMed, Embase, Scopus, Web of Science, Cochrane Library, Medline and CNKI for randomized controlled trials from their inception through April 2022. Two investigators independently performed literature screening, data extraction and quality evaluation., and the third researcher reviewed in case of disagreement. The quality appraisal was implemented by the SYRCLE tool. Meta-analysis was performed by Stata 16.0 software, and the outcome BG was calculated by combining the standard mean difference (SMD). Publication bias analysis was performed for BG by Egger test.
RESULTS: Four studies about exercise combined with spirulina in diabetic rats were included. A total of 156 experimental rats were included, and 52 diabetic rats were treated by exercise combined with spirulina. The included studies had a risk of bias of 8 points and low heterogeneity, as high quality literature. There was a highly significant difference in BG between combined therapy and spirulina supplementation (SMD=-0.88; 95% CI:-1.38~-0.42; P<0.01), and exercise therapy (SMD=-0.91; 95% CI:-1.37~-0.44; P<0.01), indicating that the hypoglycemic effect of exercise combined with spirulina in diabetic rats was significantly more effective than the single treatment. The Egger test indicated no publication bias between the spirulina treatment and combined treatment(t=-1.88, P>|t|=0.2013>0.05), and the exercise treatment (t=-1.90, P>|t|=0.1972>0.05).
CONCLUSION: Evidence indicated that the hypoglycemic effect of exercise combined with spirulina was more effective than either exercise or spirulina supplement. Based on the above evidence, we believed that exercise combined with spirulina improved the BG by synergistic effect of the protein expression independently.

**CIRCULATING SESTRINS AND FORCE VELOCITY PROFILING IN OLDER ADULTS WITH TYPE 2 DIABETES**

GONZÁLEZ-MARTOS, R., APARICIO-UGARRIZA, R., ALCAZAR, J., RAMIREZ-CASTILLEJO, C., REIHMANE, D., MENÉNDEZ-REY, A., GONZÁLEZ-GROSS, M., GUADALUPE-GRAU, A.

*UNIVERSIDAD DE CASTILLA LA MANCHA*

INTRODUCTION: Type 2 diabetes mellitus (T2DM) has an impact on skeletal muscle, exacerbating the negative effects of aging, such as loss of muscle mass, strength, and physical function. Stress-inducible proteins named sestrins are potential novel biomarkers of muscle function due to their ability to suppress oxidative stress and prevent muscle degeneration. Our aim was to determine the association between different force-velocity (F-V) deficit profiles with physical performance (PP), body composition (BC), and circulating sestrins in Spanish older adults with T2DM to define sestrins potential utility as biomarkers of physical functionality.
METHODS: Fifty-nine participants were classified into 3 groups according to their F-V profile based on the leg press exercise: nondeficit (NDEF=40.7%), force deficit (FDEF=28.8%), and velocity deficit (VDEF=30.5%). BC was determined by bioimpedance; physical function was evaluated through the short PP battery test (SPPB), and sestrin 1 (Sesn1) and 2 (Sesn2) were analyzed by Western Blotting. Statistical

analysis was carried out using ANOVA tests, and receiver operator characteristic (ROC) curves were plotted using the program GraphPad Prism v6.0.
RESULTS: Our findings revealed that older adults with T2DM and FDEF had a significantly lower concentration in serum Sens2 (0.60 ±0.06 a.u.) compared to NDEF (0.8±0.1 a.u.) or VDEF participants (0.77±0.07 a.u.) ($p < 0.01$). Maximal dynamic strength, arms, and legs fat-free mass were also reduced in FDEF compared to NDEF group ($p<0.05$), whereas Sens1, glycated hemoglobin (HbA1c), and fasting glucose levels were similar among all groups. ROC analysis additionally showed differences between F-V deficit groups according to Sesn2 concentrations, with a better cut-off point of 0.63 (a.u.).
CONCLUSION: These results suggest that reduced levels of sestrin 2 are associated with a progressive decrease in skeletal muscle mass, and therefore a decrease in strength and functionality.
Older adults with T2DM show different F-V profiles related to low levels of Sesn2, impaired BC and PP. Basal serum sestrin 2 levels are potential biomarkers to characterize F-V profiles and it should be taken into consideration to target exercise training in this specific population.

### THE EFFECTIVENESS OF A DIGITAL-ASSISTED GROUP REHABILITATION AFTER TOTAL HIP AND KNEE ARTHROPLASTY: A PILOT CLINICAL TRIAL

OSTERLOH, J.1, KNAACK, F.1, PORTWICH, R.2, NAWRATH, L.2, PESCHERS, J.2, EICHSTAEDT, P.3, DAROWSKI, M.1, BADER, R.1
*<1> DEPARTMENT OF ORTHOPAEDICS, ROSTOCK UNIVERSITY MEDICAL CENTER, GERMANY; <2> VITAL & PHYSIO GMBH, ROSTOCK, GERMANY; <3> E+S GESUNDE LÖSUNGEN GMBH, HAMBURG, GERMANY*

INTRODUCTION: The rising prevalence of osteoarthritis and the increasing number of total hip and knee arthroplasties [1] as well as the decreasing availability of physiotherapists [2] require new approaches for an effective postoperative rehabilitation. Digital-assisted group exercise programs can provide patients with individual rehabilitation while one therapist is able to supervise multiple patients at the same time. Therefore, the effectiveness of a novel digital-assisted individualized group therapy on functional outcomes and quality of life was evaluated in a randomized controlled pilot study. We hypothesized that the novel rehabilitation concept is more time efficient for the therapist and allows more therapy sessions for each patient resulting in better clinical outcome.
METHODS: Before total knee or hip arthroplasty surgery, 21 patients were randomly assigned to an intervention group (IG: novel digital-assisted group therapy twice a week for 30 min carried out over 6 months) or a control group (CG: postoperative standard individual therapy currently executed in Germany). Patients outcome was assessed preoperatively as well as 6 months after surgery. Quality of life (EQ-5D) as well as functional outcomes (30 Second sit to stand Test (STS), Timed up and go Test (TUG)), and gait velocity (GV) were quantified and analyzed using an analysis of covariance with baseline adjustment (ANCOVA, A1). Furthermore, additional ANCOVAs taking the number of therapy sessions into account were conducted (A2). Significance was set at $p<0.05$.
RESULTS: The IG received significantly more therapy sessions (39.09±8.10) than the CG (21.20±11.59, $p=0.001$). The ANCOVAs with baseline adjustment (A1) revealed no significant mean group differences for STS (1.03, $p=0.716$, $\eta2=0.011$), TUG (-1.83s, $p=0.262$ $\eta2=0.096$), GV (0.09m/s, $p=0.422$, $\eta2=0.050$), EQ-5D Index (19.09, $p=0.137$, $\eta2=0.162$) and EQ-5D VAS (7.70, $p=0.181$, $\eta2=0.133$). However, small to large effect sizes for the therapy-induced changes were found, indicating a tendency for greater improvements in the IG 6 months post-surgery. This tendency was also observed for the EQ-5D Index (19.39, $p=0.278$, $\eta2=0.097$) as well as the EQ-5D VAS (14.24, $p=0.093$, $\eta2=0.217$) after accounting for the different number of therapy sessions (A2).
CONCLUSION: The novel digital-assisted group rehabilitation concept allowed more therapy sessions for each individual. Effect sizes indicated that the higher training volume had positive effects on medium-term clinical outcome and quality of life after total hip and knee arthroplasty. The results point out that it is worth to conduct a larger randomized controlled trial.

### EFFICACY OF A MULTICOMPONENT CHAIR-BASED EXERCISE PROGRAM WITH COGNITIVE-MOTOR EXERCISES TO PROMOTE INDEPENDENCE IN ACTIVITIES OF DAILY LIVING FOR NURSING HOME RESIDENTS WITH MOBILITY RESTRICTIONS

CORDES, T.1, ZWINGMANN, K.2, RUDISCH, J.3, VOELCKER-REHAGE, C.3, WOLLESEN, B.4,5
*1UNIVERSITY OF VECHTA, 2CHEMNITZ UNIVERSITY OF TECHNOLOGY, 3UNIVERSITY OF MUENSTER, 4BERLIN UNIVERSITY OF TECHNOLOGY, 5UNIVERSITY OF HAMBURG*

INTRODUCTION: Nursing home residents are often characterized by dependency in activities of daily living (ADL) and severe mobility restrictions (1). Chair-based exercise (CBE) interventions may enable older people with restricted mobility to engage in physical exercise and thus promote motor and cognitive resources for ADL. So far, the type of exercises across different CBE programs differs greatly. Multicomponent exercise (e.g., a combination of strength, endurance, coordination, and task-specific training on ADL) combined with cognitive-motor exercises have shown promising results and might be advantageous compared to programs that use only one physical conditioning-component (2). However, most multicomponent exercise studies investigated independent older adults. Less is known about the efficacy of multicomponent CBE programs for those who are dependent in ADL. The aim of this study was to examine the efficacy of a multicomponent CBE program with cognitive-motor exercises to promote motor and cognitive resources for ADL for nursing home residents with severe mobility restrictions.
METHODS: A two-arm single-blinded randomized controlled trial integrated N=52 nursing home residents (81 ±11 years, 63% female) with severe restricted mobility assigned to a training or a wait list control group. Training duration was 16 weeks (twice a week; 60 minutes). Type of exercise was a multicomponent CBE program with cognitive-motor exercises. Primary outcomes to assess independence in ADL were the Barthel index and working memory (counting backwards). Statistics was performed using ANOVA for repeated measures.

RESULTS: Interaction effects of the ANOVA showed significant improvement of the intervention group over the control group in the Barthel index (F(1, 21) = 10.229, p = .003, ŋ_p^2 = .192) and working memory (F(1, 10) = 19.542, p = .001, ŋ_p^2 = .459) of the participants. The control group showed a decrease in both parameters after 16 weeks.
CONCLUSION: The multicomponent CBE program including cognitive-motor exercises is beneficial for improving independence in ADL for nursing home residents with severe restricted mobility. The results support the hypothesis that despite their high level of dependency nursing home residents can improve motor and cognitive resources to perform ADL.

**LONG-TERM EFFECTS OF HYBRID INTRADIALYTIC EXERCISE ON LEFT-VENTRICULAR FUNCTION**

GIANNAKI, C., GRIGORIOU, S., GEORGE, K., KARATZAFERI, C., ZIGOULIS, P., STEFANIDIS, I., SAKKAS, G.
*UNIVERSITY OF NICOSIA*

INTRODUCTION: Cardiovascular disease is the most common cause of death in hemodialysis (HD) patients (1). It is well known that intradialytic aerobic exercise can improve cardiovascular risk factors and reduce mortality in HD patients (2,3). The impact of other forms of exercise, such as hybrid exercise (aerobic exercise followed by resistance exercise), is not clear. The present study examined whether hybrid intradialytic exercise has a long-term benefit on left ventricular structure and function in HD patients.
METHODS: Twelve stable HD patients (10M/2F, 56±19yrs) participated in a nine-month-long hybrid intradialytic training program. Supine cycle exercise was performed three times weekly for 60 minutes each time during the first 2 hours of a HD session, using an adapted bicycle ergometer, at an intensity of 50-60% of the patient's maximal exercise capacity. Resistance exercises were performed using resistance bands and portable ankle weights and dumbbells. Echocardiographic assessment of left-ventricular structure and function was performed before, during and after the HD session at baseline and after the nine-month intervention. Left ventricular dimensions were determined from 2-dimensional guided M-Mode images, whilst left ventricular diastolic function was assessed from an apical 4-chamber view using conventional Doppler and Tissue Doppler Imaging techniques. Ejection fraction was calculated using the biplane Simpson's method.
RESULTS: All twelve HD patients completed the nine-month intervention program without any adverse effects. Ejection fraction (EF) improved significantly after nine months of hybrid exercise training compared to the baseline value (48.7±11.1 vs 58.8±6.5, p=0.046). EF measured at the end of the HD session increased from pre-HD assessment (50.0±13.4 vs 56.1±3.4, p= 0.054).
CONCLUSION: A nine-month hybrid intradialytic exercise training program resulted to a significant improvement in ejection fraction. Intradialytic hybrid exercise training was a safe and effective non-pharmacological approach to improve cardiac function in HD patients.

**UPTAKE AND UTILIZATION OF 15N-LABELLED DIETARY NITRATE BY SKELETAL MUSCLE**

KADACH, S., PARK, J.W., STOYANOV, Z., BLACK, M.I., VANHATALO, A., WALTER, P.J., CAI, H., SCHECHTER, A.N., PIKNOVA, B., JONES, A.M.
*UNIVERSITY OF EXETER*

INTRODUCTION: The nitrate (NO3-) and nitrite (NO2-) stored in skeletal muscle may be important in the maintenance of systemic nitric oxide (NO) bioavailability, especially when NO requirements are elevated such as during exercise. At any given time, skeletal muscle NO3- concentration ([NO3-]) reflects the balance between metabolism of NO3- into other nitrogen-containing species, oxidation of NO produced via nitric oxide synthases (NOS), and NO3- uptake consequent to dietary NO3- ingestion. The purpose of this study was to use a stable isotope tracer (15N-labelled NO3-) to investigate the metabolic fate of ingested NO3- through the determination of changes in NO3- concentration in skeletal muscle alongside other tissues at rest and following exercise.
METHODS: 10 healthy adults volunteered to participate in this double-blind, randomised, placebo-controlled study. Participants completed two experimental visits in which they consumed a beverage containing 12.8 mmol 15N-labelled potassium nitrate (K15NO3) or a potassium chloride placebo. Skeletal muscle (m. vastus lateralis) samples were collected at baseline, for 3 h post-supplement ingestion, and immediately following the completion of 60 maximal, unilateral contractions of the knee extensors over 5 min. All biological samples were analysed using ozone-based chemiluminescence to quantify total [NO3-] and [NO2-], and by mass spectrometry to determine the endogenous vs. exogenous origin of NO3- and NO2- (i.e., by determining the recovery of 15NO3- and 15NO2- in these tissues following the ingestion of K15NO3).
RESULTS: Neither muscle [NO3-] nor [NO2-] were altered following placebo ingestion compared to baseline. Following K15NO3 ingestion, muscle [NO3-] was elevated above baseline at both 1 h and 3 h (baseline, 35 ± 9 nmol.g-1; 1 h, 147 ± 71 nmol.g-1; 3 h, 105 ± 41 nmol.g-1; P<0.001). The majority of the increase in NO3- in muscle at 1 h was 15N-labelled (baseline: 0.9 ± 0.4 nmol.g-1; 1 h: 100 ± 63 nmol.g-1; 3 h: 50 ± 25 nmol.g-1; P<0.001). However, at 3 h, there was also an increase in skeletal muscle [NO3-] that was not 15N-labelled (baseline: 34 ± 9 nmol.g-1 vs. 3 h: 55 ± 21 nmol.g-1; P<0.05). Although there was no change in total skeletal muscle [NO2-] following the ingestion of the K15NO3 bolus, there was an increase in the contribution of 15N- labelled [NO2-] in skeletal muscle at 1 h (baseline: 0.02 ± 0.01 nmol.g-1 vs. 1 h: 0.12 ± 0.14 nmol.g-1; P<0.05), but not at 3 h, following NO3- ingestion. Exercise did not induce significant changes in total skeletal

muscle [NO3-] or [NO2-]; however there was a reduction in 15N-labelled skeletal muscle [NO3-] from pre- to post-exercise (50 ± 25 vs. 28 ± 21 nmol.g-1; P<0.05).
CONCLUSION: This study shows for the first time that skeletal muscle rapidly and robustly takes up 15N-labelled dietary NO3-. This 15N-labelled NO3- appears to be utilized to support skeletal muscle metabolic processes, such as conversion to NO2- and NO, during maximal contractions.

**ERGOGENIC EFFECT OF CAFFEINE ON 100-M SPRINT PERFORMANCE IN ATHLETICS: A FIELD TEST**

MATSUMURA, T., TOMOO, K., SUGIMOTO, T., TSUKAMOTO, H., SHINOHARA, Y., OTSUKA, M., HASHIMOTO, T.
*RITSUMEIKAN UNIVERSITY*

INTRODUCTION: Pre-exercise caffeine supplementation acutely enhances performance in various sports, both aerobic and anaerobic [Grgic et al. 2020]. To focus on athletics, the International Association of Athletics Federations (currently called World Athletics) proclaimed the effect of caffeine as an ergogenic aid to enhance sprint running performance in the consensus statement of the nutrition strategy for athletics [Burke et al. 2019; Slater et al. 2019]. However, no study has assessed the acute effect of caffeine supplementation on 100-m sprint running in athletics, and caffeine's net ergogenicity on 100-m sprint running remains unclear. We investigated the acute effects of caffeine supplementation on 100-m sprint running performance in a field test with a hypothesis that caffeine supplementation would shorten 100-m sprint time by increasing the running performance in the first 60 m.
METHODS: Thirteen male collegiate sprinters (Age: 20.6 ± 1.0 yrs; personal best 100-m sprint time: 11.18 ± 0.38 sec) were subjected to 100-m sprint running time trials (TTs) after ingestion of 6 mg･kg-1 body weight caffeine or placebo supplementation in a double-blind, counterbalanced, randomized, and crossover design. Sprint velocity was measured with a laser system, and sprint time was calculated from the data in which the effects of environmental factors that would act as confounding factors on sprint time during TTs were eliminated [Mureika, 2001; 2006]. Comparisons of the corrected 100-m sprint time were performed using a paired Student's t test. Comparisons of the corrected 60-m sprint time were performed using the Wilcoxon signed-rank test. Planned a priori comparisons between two conditions for the mean sprint velocity every 10 m were tested by a paired Student's t test. The statistical significance level was set at $P < 0.05$.
RESULTS: The corrected 100-m sprint time was significantly shortened by 0.14 sec with caffeine supplementation compared with placebo (placebo: 11.40 ± 0.39 sec, caffeine: 11.26 ± 0.33 sec, P = 0.007, d = -0.35 [-0.63 to -0.07]). The corrected sprint time up to 60 m during TTs was also significantly shorter with caffeine supplementation than with placebo (median of placebo: 7.21 sec [7.04-7.25], caffeine: 7.07 sec [6.90-7.13], P = 0.006). Furthermore, the mean sprint velocity for 0-10 and 10-20 m splits was significantly increased by caffeine supplementation (all $P < 0.05$).
CONCLUSION: Acute caffeine supplementation enhanced the corrected 100-m sprint time by improving the sprint performance in the first 60 m following more explosive acceleration in the early stage of the acceleration phase. Thus, for the first time, we directly demonstrated caffeine's ergogenicity on sprint performance in athletics.

**THE EFFECTS OF SODIUM BICARBONATE SUPPLEMENTATION ON SPRINT INTERVAL SWIMMING PERFORMANCE IN TRAINED COMPETITIVE SWIMMERS**

GOUGH, L., PRICE, M.
*BIRMINGHAM CITY UNIVERSITY*

INTRODUCTION: The use of sodium bicarbonate (NaHCO3) supplementation to improve repeated high intensity performance is recommended, however most swimming performance studies examine time trial efforts rather than repeated swims indicative of training sessions. The aim of this study therefore was to investigate the effects of sodium bicarbonate supplementation on sprint interval swimming reflective of a typical training session.
METHODS: Fourteen trained competitive swimmers (body mass: 73±8 kg) volunteered for this double blind, randomised, crossover designed study. Each participant was asked to swim 50 m (front crawl), from a competitive diving block, at their maximum effort and repeat this 8 times (Interspersed with a 50 m active recovery swim). Each exercise bout was run off a 5 min base, which left the participants with approximately 3 min passive recovery. After one familiarisation trial, this was repeated on two separate occasions whereby participants ingested either 0.3 g.kg-1 BM NaHCO3 or 0.05 g.kg-1 BM sodium chloride (placebo) 60 minutes prior to exercise. Time to complete each 50 m interval was recorded, along with blood measures for pH and bicarbonate (HCO3-) using a Radiometer (ABL9, Copenhagen, Denmark) and lactate (Lactate Pro 2, Arkray, Japan) at rest, at 60 min (post-supplementation), and post-exercise. Aggregated gastrointestinal (GI) discomfort was measured using Visual Analogue Scales (VAS) within a range of symptoms throughout each trial. Two-way repeated measures ANOVA were used to assess performance and blood measures and were conducted using a statistical software package (SPSS V28, IBM, Chicago, IL, USA). Hedges' g effect size (ES) was also calculated for pairwise comparisons between treatments and interpreted using Cohens D thresholds.
RESULTS: Performance was improved by NaHCO3 ingestion prior to the interval swimming (p=0.005, $P\eta 2$=0.301). Whilst there were no differences between sprints 1 to 4 (p>0.05), improvements were observed in sprint 5 (p=0.011; ES=0.26), 6 (p=0.014; ES=0.39), 7 (p=0.005; ES=0.6), and 8 (p=0.004; ES=0.79). Following NaHCO3 supplementation, pH was greater at 60 min (p<0.001; ES=3.23), whilst for HCO3- it was greater at 60 min (p<0.001; ES=3.23) and post-exercise (p=0.016; ES=0.53) compared to placebo. Lactate was greater following NaHCO3 supplementation post-exercise compared to placebo (17.6±4.9 vs. 14.7±3.8 mmol.l-1; p < 0.001; ES = 0.64). Aggregated GI discomfort was higher for NaHCO3 compared to placebo (21±12 vs. 3±1; p=0.021; ES=2.05).
CONCLUSION: These findings suggest NaHCO3 supplementation can improve the latter stages of sprint interval swimming performance, which is likely due to the augmentation of pH and HCO3- prior to exercise and the subsequent increase in buffering capacity. Performance improvements may be beneficial during high intensity training blocks in improving adaptation (via increasing exercise intensity training volume), however further research is warranted to investigate NaHCO3 and training responses.

**DOES ACUTE CAFFEINE INTAKE INCREASE TRAINING VOLUME DURING A RESISTANCE EXERCISE SESSION AMONG RESISTANCE-TRAINED MEN HABITUATED TO CAFFEINE?**

LATOCHA, A., KOMAREK, Z., KASZUBA, M., KRZYSZTOFIK, M., SADOWSKA-KREPA, E., DEL COSO, J., FILIP-STACHNIK, A.

*AKADEMIA WYCHOWANIA FIZYCZNEGO IM. JERZEGO KUKUCZKI W KATOWICACH*

INTRODUCTION: There is wide evidence showing the ergogenic effect of acute caffeine intake on maximal strength and power output during several forms of resistance-based exercise. Evidence also demonstrates that caffeine's ergogenicity is reduced in athletes chronically ingesting caffeine. However, there is no information about the potential effect of caffeine to enhance training volume during a resistance exercise session. The aim of this study was to explore the effect of acute caffeine intake on training volume during a session of full-body resistance exercise in individuals habituated to caffeine.
METHODS: Twelve resistance-trained men (24 ± 6 years, 83.2 ± 8.3 kg) habituated to caffeine (2.1 mg/kg/day) participated in a randomized, counterbalanced, crossover and double-blind experiment. Each participant performed two identical experimental sessions after the intake of 3 mg/kg of caffeine (CAF) or a placebo (PLAC). After 60 min for substance absorption, participants performed a resistance exercise session consisting of seven exercises: a) leg press, b) sitting leg extension, c) lying leg curls, d) lat pull-down, e) chest supported row, f) bench press g) machine overhead press. In each exercise, participants performed three sets at 70% of their one-repetition maximum (1RM) until momentary muscular failure using 4/0/x/0 tempo. Time under tension and the number of repetitions were obtained through video recording. Immediately after exercise, participants reported their rating of perceived exertion (RPE; range 6 – 20 arbitrary units (a.u.)) and muscle soreness and fatigue (on the Overall Fatigue Scale, Overall Soreness Scale, and a Soreness on Palpation Scale; range 0 – 10 a.u.) were measured before, immediately after and for the 5 days after testing.
RESULTS: There were no differences in the total number of repetitions between PLAC and CAF trials (180 ± 13 vs 184 ± 14 repetitions; $p = 0.407$) nor in the total time under tension (761 ± 70 vs 760 ± 52 s; $p = 0.971$) and RPE (13.8 ± 2.4 vs 14.6 ± 2.6 a.u.; $p = 0.289$). CAF did not modify the number of repetitions nor the total time under tension in any exercise ($p > 0.05$ for all). No significant differences were observed on the Overall Fatigue, Overall Soreness, and Soreness on Palpation before, immediately after and for the five days after testing ($p > 0.05$ for all).
CONCLUSION: These results indicate that 3 mg/kg of caffeine is not an effective dose to improve training volume during a resistance-based workout in men habituated to caffeine.

**12G OF CITRULLINE MALATE 60 MINUTES PRIOR TO EXERCISE DOSE NOT ACUTELY IMPROVE HIGH OR LOW LOAD BENCH PRESS PERFORMANCE IN EITHER MEN OR WOMEN**

NULTY, C.D., OKEEFE, O., MURRAY, C., POWER, O., COYLE, C.J.

*INSTITUTE OF TECHNOLOGY CARLOW*

INTRODUCTION: The body of research investigating the effects of citrulline malate (CM) on strength and power performance has increased substantially in recent years. After absorption, citrulline is converted arginine and then to nitric oxide (NO) promoting vasodilation and increased in blood flow to the skeletal muscle (1). This mechanism is potentially ergogenic, as it may reduce blood pressure, increase substrate and O2 delivery while facilitating clearance of metabolic by products through the urea cycle that may attenuate muscular fatigue (2). However, outcomes remain equivocal. Most RE studies have used male participants and moderate training loads, with no study to date examining the impact of load choice during resistance exercise (RE) after CM supplementation. Additionally, there is clear underrepresentation of female participants, despite data suggesting females display higher plasma nitrite levels at baseline (3) and differential physiological responses to NO promoters (4). This research aims to examine the effects of CM supplementation on resistance exercise performance at both high and low loads, and to compare these responses between the sexes.
METHODS: Nineteen resistance trained participants (n = 19; 10 male, 9 female) completed the study in a double-blind crossover design. After familiarisation, participants reported to the laboratory on two occasions separated by one week. On each occasion they consumed a taste matched beverage in a randomised order, either a 12g Citrulline Malate (CM) Solution or Placebo. Sixty minutes after consumption participants completed as many repetitions as possible at 85% and 40% one repetition maximum (1RM) respectively on the barbell bench press. Number of reps completed and peak bar velocity m.s¬-1 (Push band 2.0, Push Inc., Toronto, ON) were recorded. Two way repeated measures ANOVA were used to detect the effect of Supplementation, Sex, and Sex x Supplementation interaction on all measures at both loads. Significance was accepted at $p < 0.05$, and data are mean ± SD.
RESULTS: There were no significant effects of supplementation on repetitions completed at 85% 1RM ($F1 = 0.688$, $p = 0.419$) or 40% 1RM ($F1 = 1.267$, $p = 0.277$), nor was there a significant supplement x sex interaction at either load ($p = 0.241$; $p = 0.928$). Similarly, supplementation with 12g of CM had no significant effect on peak bar velocity during at either 85% or 40% of 1RM ($F1 = 0.688$, $p = 0.419$; $F1 = 0.685$, $p = 0.419$). However, there was a trend for PV to be lower in the female group by 0.08 ± 0.1 m.s¬-1 after CM supplementation at 85% ($F1 = 4.32$, $p = 0.054$) compared to males.
CONCLUSION: A high dose of CM does not improve upper body RE performance on sets taken to momentary muscular failure in recreational trainees. This effect appears to be regardless of light or heavy loads, with a uniform response between the sexes. The data on CM and resistance exercise performance remain mixed, and individual variability may be of larger influence than dose, sex, or load selected.

**EFFECTS OF BETA-ALANINE INGESTION ON PHYSICAL PERFORMANCE IN WELL-TRAINED TENNIS PLAYERS**

QUINTANA-MILLA, I.1, DOMÍNGUEZ, R.2, SÁNCHEZ-OLIVER, A.2, SERRANO, H.3, GUTIÉRREZ-HELLÍN, J.1, LÓPEZ-SAMANES, A.1

*1 UNIVERSIDAD FRANCISCO DE VITORIA , 2 UNIVERSIDAD DE SEVILLA , 3 ALCALA TENNIS CENTER .*

INTRODUCTION: Nutritional interventions (e.g., beta-alanine ingestion) can be capable of increasing muscle-buffering capacity and attenuating the increase in acidosis during high-intensity intermittent exercise and might increase performance in intermittent sports (e.g., soccer, tennis) (1). However, although different studies present evidence of the efficacy of beta-alanine supplementation in high-intensity efforts, the effects of beta-alanine in racket sports is barely studied. Thus, the aim of this study was to study the effects of beta-alanine supplementation (28-days) on physical tennis performance.
METHODS: Fourteen well-trained tennis players (23.28 ± 3.68 years) were randomly assigned to receive either beta-alanine (4.8 g day−1, Crown Nutrition, Spain) or placebo (fructose, 4.8 g day−1 Crown Nutrition, Spain) during 28-days in a double-blind design. Before and after the supplementation period tennis performed a neuromuscular test battery in a tennis court consisted in different test such as, counter-

movement jump, isometric handgrip strength, 10-m sprint, modified 5-0-5 agility test and repeated sprint ability. After 48 h of the realization of neuromuscular test battery, tennis players performed VO2max consumption test (i.e., treadmill).
RESULTS: Significantly greater training improvements were observed in the beta-alanine condition versus placebo group in repeated sprint ability test (p=0.042; np2 =0.12). However, no significant improvements were observed in the others physical performance parameters analysed such as countermovement jump, isometric handgrip strength, 10-m sprint, modified 5-0-5 agility test and VO2max consumption test. (p=0.246-1.000; np2 =0.00-0.04).
CONCLUSION: Beta-alanine supplementation (4.8 g day−1) during 28-days training block may improve repeated sprint ability capacity in well-trained tennis players, while no differences were reported in countermovement jump, isometric handgrip strength, 10-m sprint, modified 5-0-5 agility test and VO2max consumption test.

## COLLAGEN AND WHEY PROTEIN INGESTION DO NOT INCREASE MUSCLE CONNECTIVE TISSUE PROTEIN SYNTHESIS RATES DURING RECOVERY FROM EXERCISE IN MALE AND FEMALE RECREATIONAL ATHLETES

AUSSIEKER, T., HILKENS, L., HOLWERDA, A.M., FUCHS, C.J., SENDEN, J., SNIJDERS. T., VAN LOON, L.J.C

*MAASTRICHT UNIVERSITY*

INTRODUCTION: Resistance exercise stimulates myofibrillar and muscle connective tissue protein synthesis rates. Whey protein ingestion during post-exercise recovery further augments myofibrillar protein synthesis rates, but does not stimulate muscle connective tissue protein synthesis rates. It has been suggested that collagen protein, due to its high glycine and proline contents, may be more effective in stimulating muscle connective tissue protein synthesis rates during recovery from exercise. The objective of this study was to assess the impact of both whey and collagen protein ingestion on post-exercise myofibrillar and muscle connective tissue protein synthesis rates in male and female recreational athletes.
METHODS: In a randomized, double-blind, parallel design, 45 young male and female recreational athletes (age: 25±4 y; BMI: 24.1±2.0 kg/m2) were selected to receive primed continuous intravenous infusions with L-[ring-13C6]-phenylalanine and L-[3,5-2H2]-tyrosine. Following a single session of resistance type exercise (6 sets of the barbell squat exercise), subjects were randomly allocated to one of three groups ingesting either 30 g whey protein (WHEY, n=15), 30 g collagen protein (COLL, n=15) or a non-caloric placebo (PLA, n=15). Blood and muscle biopsy samples were collected over a subsequent 5-hour recovery period to assess myofibrillar and muscle connective tissue protein synthesis rates. Time-dependent variables were analyzed by a two-factor repeated-measures ANOVA. Non-time-dependent variables were compared between treatment groups using a one-way ANOVA. A statistical level of P<0.05 was accepted. All data are expressed as mean±SD.
RESULTS: Whey and collagen protein ingestion strongly increased circulating plasma amino acid concentrations when compared to the PLA group (P<0.05). The post-prandial rise in plasma leucine and total essential amino acid concentrations was greater in the WHEY compared with COLL group (P<0.05). In contrast, post-prandial plasma glycine, proline, and hydroxyproline concentrations increased to a greater extend in the COLL compared with WHEY group (P<0.05). Myofibrillar protein synthesis rates averaged 0.041±0.010, 0.036±0.010 and 0.032±0.007 %/h following whey, collagen, or placebo ingestion (P<0.05), respectively, with WHEY resulting in significant greater rates when compared with the PLA group (P<0.05). Muscle connective tissue protein synthesis rates did not differ between groups (WHEY: 0.072±0.019, COLL: 0.068±0.017, PLA: 0.058±0.018 %/h; P=0.09).
CONCLUSION: Ingestion of whey protein during recovery from exercise increases myofibrillar protein synthesis rates. Post-exercise collagen protein ingestion does not increase myofibrillar protein synthesis rates. Neither whey or collagen protein ingestion increase muscle connective tissue protein synthesis rates during the early stages of post-exercise recovery in male and female recreational athletes.

## LEUCINE SUPPLEMENTATION DOES NOT ATTENUATE THE DECLINE IN MUSCLE PROTEIN SYNTHESIS RATES OR PRESERVE LEG MUSCLE MASS DURING SHORT-TERM IMMOBILIZATION IN YOUNG OR OLDER ADULTS

PINCKAERS, P.J.M., CHURCHWARD-VENNE, T.A., SMEETS, J.S., MARZUCA-NASSR, G.N., GORISSEN, S.H.M., SENDEN, J.M., GIJSSEN, A.P., VAN LOON, L.J.C.

*DEPARTMENT OF HUMAN BIOLOGY, NUTRIM SCHOOL OF NUTRITION AND TRANSLATIONAL RESEARCH IN METABOLISM, MAASTRICHT UNIVERSITY MEDICAL CENTRE+, MAASTRICHT, THE NETHERLANDS*

INTRODUCTION: Muscle disuse leads to a loss of muscle mass and strength. The loss of muscle mass during disuse has been attributed to a decline in basal and post-prandial muscle protein synthesis (MPS) rates. Leucine supplementation has been suggested to stimulate post-prandial MPS rates and, as such, may represent an effective strategy to attenuate muscle disuse atrophy. The present study assessed the capacity of leucine supplementation to attenuate the loss of muscle mass and the decline in daily MPS rates during 3 days of unilateral knee immobilization in both young and older adults.
METHODS: 24 young (23±4 y) and 24 older (69±4 y) adults (male/female: 1/1) underwent 3 days of unilateral knee immobilization by means of a full leg cast with leucine (LEU) or maltodextrin (PLA) supplementation (5 g, three times daily). Prior to and directly after immobilization, quadriceps muscle cross-sectional area (CSA) was assessed by Computed Tomography and a biopsy from the m. vastus lateralis was obtained. Daily MPS rates over the 3-day immobilization period were determined by applying deuterated water. Data were analyzed with a 2-way repeated measures ANOVA, and paired and independent samples t-tests. Data are expressed as means +/- standard deviation.
RESULTS: In young adults, quadriceps muscle CSA decreased by ~1.2 % in the immobilized leg (P<0.01), with no differences between the LEU and PLA group (from 6993±1174 to 6910±1185 mm^2, and from 7330±1147 to 7241±1095 mm^2, respectively; time*treatment: P=0.92). A similar ~1.0 % decrease in quadriceps CSA was observed in the immobilized leg in older adults (P=0.02), with no differences between the LEU and PLA group (from 5753±1086 to 5679±1073 mm^2 and from 5864±1146 to 5823±1161 mm^2, respectively; time*treatment: P=0.50). In the young individuals, the decline in CSA was accompanied by a ~15 % lower MPS rate in the immobilized compared to the non-immobilized leg assessed over the 3-day intervention period (1.28±0.29 vs 1.50±0.26 %/d, respectively). The MPS rates in the immobilized leg did not differ between the LEU and PLA groups (1.29±0.24 vs 1.26±0.34 %/d, respectively; P=0.83). In the older individuals, MPS rates over the 3-day intervention period were ~23 % lower in the immobilized compared with the non-immobilized leg (1.10±0.16 vs 1.47±0.28 %/d). The MPS rates in the immobilized leg did not differ between the LEU and PLA groups (1.10±0.14 vs 1.10±0.19 %/d, respectively; P=0.90).
CONCLUSION: Free leucine supplementation (5 g, three times daily) does not attenuate the decline in MPS rates or preserve leg muscle mass during short-term immobilization in young or older individuals.

## EFFECTS OF 16/8 TIME-RESTRICTED FEEDING ON ENDURANCE EXERCISE PERFORMANCE, BODY COMPOSITION AND MARKERS OF METABOLIC HEALTH: A RANDOMIZED AND COUNTERBALANCED CROSSOVER STUDY IN HEALTHY MEN

CORREIA, J.M.1,2, PEZARAT-CORREIA, P.1,2, MINDERICO, C.2, MENDONÇA, G.V.1,2

*1 NEUROMUSCULAR RESEARCH LAB, FACULDADE DE MOTRICIDADE HUMANA, UNIVERSIDADE DE LISBOA; 2 CIPER, FACULDADE DE MOTRICIDADE HUMANA, UNIVERSIDADE DE LISBOA*

INTRODUCTION: To explore the effects of 4 weeks of time-restricted feeding (TRF) vs. regular diet on physiological indices of endurance running performance, body composition and markers of metabolic health in well-trained young men.
METHODS: Fifteen healthy males were included (age: 24.4±3.3 years, height: 175.0±0.1 cm, body mass: 75.2±11.0 kg, body mass index: 24.5±2.9 kg/m2, total cholesterol: 156.6±26.3 mg/dL, high-density lipoprotein: 53.7±8.5 mg/dL, low-density lipoprotein: 75.2±26.6 mg/dL, glycaemia: 90.1±6.9 mg/dL, peak oxygen uptake: 74.3±5.7 mL.kg fat-free mass−1.min−1). Inclusion was limited to participants with > 3 years of practice in endurance running. The order of dieting was randomized and counterbalanced, and all participants served as their own controls. Two weeks of washout separated both conditions (no specific diet or structured exercise). TRF was limited to an 8-h eating window. The non-TRF involved a customary meal pattern without any timing restrictions. Participants completed graded exercise tests and body composition scans (using dual-energy X-ray absorptiometry) at baseline and post-four weeks of each dietary intervention. Before testing, all participants were asked to fill out 4-day dietary record. Fasted blood samples were analysed for glycaemia and blood lipids. The participants were asked to follow a specific training routine in combination with each dietary intervention (3 outdoor runs x 10 km/week within the heavy domain + 3 running bouts x 1000 m within the severe domain, after each 10 km run). Two- way repeated measures ANOVAs, adjusted for baseline values as covariates, were used.
RESULTS: Energy intake was similar at baseline in both conditions (before TRF: 2311.1 ± 681.0 kcal vs. before non-TRF: 2284.9 ± 659.3 kcal, p = 0.785). We obtained a significant time x condition interaction for body mass (F = 4.97, p = 0.046; ES = 0.29). While TRF was effective in decreasing body mass (pre: 75.3 ± 11.0 vs. post: 74.8 ± 10.7 kg, p < 0.05), this was not the case for non-TRF (pre: 75.0 ± 11.1 vs. post: 75.5 ± 11.4 kg, p > 0.05). Fat mass and fat-free mass remained unchanged between time points with both interventions. Significant time main effects were obtained for the ventilatory threshold (Δ with TRF and non-TRF of ~ + 6%), absolute and fat-free mass corrected peak oxygen uptake (Δ with TRF and non-TRF of ~ + 3%) as well as for peak minute ventilation (Δ with TRF and non-TRF of ~ + 2.7%) (F = 6.8, F = 6.6 and F = 6.4, respectively; p < 0.05). Low-density lipoprotein decreased by ~ 8% after 4 weeks of TRF and non-TRF (time main effect: F = 6.8, p < 0.05).
CONCLUSION: Based on our findings, 4-weeks of TRF (with an 8-h eating window), can be used in combination with regular training to elicit body mass reductions in well-trained males. Yet, in comparison with a customary meal pattern without any timing restrictions, TRF does not offer any benefit for improving submaximal or peak exercise capacity in well-trained males.

## RESPONSE TO PROTEIN-FEEDING AFTER REPEATED BOUTS OF RESISTANCE EXERCISE DIFFERS BETWEEN MEN AND WOMEN

MALLINSON, J.E., WARDLE, S.L., O'LEARY, T., GREEVES, J.P., CEGIELSKI, J., BASS, J., BROOK, M.S., SMITH, K., WILKINSON, D.J., ATHERTON, P.J., GREENHAFF, P.L.

*UNIVERSITY OF NOTTINGHAM*

INTRODUCTION: Protein (PRO) ingestion following resistance exercise (RE) acutely increases the rate of muscle protein synthesis (MPS). This study investigated the impact of repeated bouts of RE and bolus PRO ingestion on cumulative MPS over 24h in RE trained men and women and identified any sex-based differences in responses.
METHODS: Healthy RE trained (3 times/week for at least 6 months) women (n=8: 25.9 ± 0.9 years, 23.6 ± 0.9 BMI) and men (n=8: 24.1 ± 1.1 years, 25.8 ± 0.9 BMI) were recruited into the study following written informed consent and screening. After a DXA scan, a venous blood sample was taken to allow measurement of baseline (BL) MPS over the next 24h, and participants then consumed 500ml of 70AP heavy water (D2O) over 5h. Twenty-four hours later, fasted saliva, venous blood and vastus lateralis muscle biopsy samples were obtained, and participants then performed 3 sets of 8 repetitions at 75% 1 repetition maximum (2min rest between sets) of latissimus dorsi pull down, single-leg press and chest press. Immediately post-exercise, participants ingested a drink containing 30g whey PRO. After 4h rest, saliva, venous blood and muscle biopsy samples were collected, and volunteers repeated the RE and PRO ingestion procedures. Further saliva, blood and muscle samples were obtained 4h later (8h) and the following day (24h). In addition to the whey PRO drinks, subjects consumed a controlled diet between 8h and 24h on the study day (55% carbohydrate, 30% fat and 15% PRO; men 2925 ± 98 kcal, 1.2 ± 0.1 g/kg BW PRO; women 2131 ± 109 kcal, 1.4 ± 0.1 g/kg BW PRO) and performed only the exercise prescribed. Body water and muscle protein D2O enrichment were measured to quantify the rate of MPS (1). Statistical analysis was performed using two-way repeated measures ANOVA with a Bonferroni post-hoc test. Values are mean ± SEM.
RESULTS: Overall, RE and PRO ingestion increased the rate of MPS from BL over time, but there was no gender x time interaction. Regarding this time effect, the rate of MPS increased above BL (0.068 ± 0.005 %/h) over 0-4h (0.140 ± 0.021 %/h, p<0.01), 0-8h (0.121 ± 0.012 %/h, p<0.01) and 0-24h (0.099 ± 0.011 %/h, p<0.05) in women. An increase in the rate of MPS above BL (0.058 ± 0.003 %/h) was observed in men from 0-8h (0.092 ± 0.009 %/h, p<0.05), but not 0-4h (0.092 ± 0.015 %/h) or 0-24h (0.077 ± 0.005 %/h).
CONCLUSION: Post-RE ingestion of 30g PRO increased MPS above BL following two successive bouts of exercise in RE trained men and women, and over 24h in women but not in men. This demonstrates that bolus ingestion of 2x30g PRO post-RE sustains a muscle anabolic response in RE trained women for up to 24h. The apparent blunted response in men may be explained by habituation of MPS to RE training reported in men (2).

#### RESISTANCE EXERCISE TRAINING COUNTERACTS THE ADVERSE EFFECTS OF ANDROGEN DEPRIVATION THERAPY ON BODY COMPOSITION, MUSCLE MASS, STRENGTH AND AEROBIC CAPACITY IN PROSTATE CANCER PATIENTS

HOUBEN, L.H.P., OVERKAMP, M., VAN KRAAIJ, P., TROMMELEN, J., VAN ROERMUND, J.G.H., DE VRIES, P., DE LAET, K., VAN DER MEER, S., MIKKELSEN, U.R., VERDIJK, L.B., VAN LOON, L.J.C., BEIJER, S., BEELEN, M.

*MAASTRICHT UNIVERSITY MEDICAL CENTRE+, NETHERLANDS COMPREHENSIVE CANCER ORGANISATION, TIFN.*

INTRODUCTION: Androgen deprivation therapy (ADT) is the cornerstone in the treatment of (locally) advanced prostate cancer. However, ADT results in numerous adverse effects, including an increase in fat mass, loss of muscle mass, a lower quality of life and more fatigue. We hypothesized that resistance exercise training counteracts these side effects and that protein supplementation further enhances the benefits of training.
METHODS: Sixty prostate cancer patients receiving ADT were randomly assigned to 20 weeks of supervised, progressive resistance exercise training (twice a week, 60 min) with supplementation of 31 g whey protein (EX+PRO, n=30) or placebo (EX+PLA, n=30), consumed immediately after exercise and every night before sleep. A separately recruited control group (CON; n=36) only received usual care. At baseline and after 20 weeks, body composition (dual-energy X-ray absorptiometry), leg muscle mass (quadriceps cross sectional area by computed tomography), leg press strength (1-repetition maximum; 1-RM), aerobic capacity (VO2peak), quality of life (EORTC QLQ-C30), fatigue (MFI) and habitual dietary intake (food diary) were assessed. Data were analyzed using repeated-measures ANOVA (time x treatment) followed by within-group (paired t-tests) and between-group (univariate general linear models (GLM)) analyses. For 1RM-data the %-differences over time within groups were calculated and compared between groups with univariate GLM.
RESULTS: For total fat and total lean mass, significant time x treatment interactions were found, with differences over time between EX+PLA and CON (fat mass: 0.4±2.2 vs 2.1±1.7 kg, respectively; P=0.002, lean mass: 0.6±2.0 vs -0.7±2.4 kg, respectively; P=0.053). Quadriceps cross-sectional area and 1-RM strength increased similarly in both exercise groups (EX+PLA: 2.0±3.0 cm2 and 12±14%, respectively; EX+PRO: 1.9±2.7 cm2 and 13±11%, respectively), and these improvements were significantly different from the declines observed in the CON group (-1.2±2.5 cm2 and -5±11%, respectively; P<0.001). VO2peak decreased in EX+PRO and CON (-1.5±2.3 and -3.0±2.7 mL·min-1·kg BW-1).This decline was attenuated in EX+PLA (-0.6±2.8 mL·min-1·kg BW-1) compared to CON (P<0.005). The EORTC QLQ-C30 only showed a significant decrease in perceived level of physical functioning over time, and fatigue significantly increased over time, with no differences between groups. Average habitual protein intake was >1.0 g·kg BW-1·day-1, with no changes over time or differences between groups.
CONCLUSION: Prolonged resistance exercise training counteracts the adverse effects of ADT on body composition, muscle mass, strength and aerobic capacity, with no additional benefits of protein supplementation in prostate cancer patients habitually consuming ample amounts of protein.

#### CHARACTERIZATION OF THE COMBINED EFFECTS OF EXERCISE AND IMMUNO CHEMOTHERAPY TREATMENTS ON TUMOUR GROWTH IN MC38 COLORECTAL CANCER MICE

GOUEZ, M.

*UNIVERSITÉ DE LYON*

INTRODUCTION: It is well established that physical exercise triggers several health benefits and is an important component of comprehensive health-care strategies in oncology. Previous studies have hypothesized that tumor blood flow may be modulate during exercise, which could impact the tumor microenvironment. Moreover, acute exercise, i.e., a single physical exercise bout, induces transient physiological changes resulting in tumor microenvironment modifications and possible alterations in tumor development. On the other hand, recent preclinical data have shown that moderate aerobic exercise improves tumor vascular function and increases chemotherapy efficacy in mouse models. However, the potential of exercise combined with immunotherapy as a cancer therapy remains to be elucidated. The purpose of this pre-clinical study is to assess the capacity of exercise conducted immediately prior to treatments injection to improve the efficacy of immuno-chemotherapy via modification of the tumor microenvironment. Using an orthotopic preclinical model of colon cancer, we tested the hypotheses that during exercise tumors would experience 1) decreased tissue hypoxia, 2) modulate the immune cells infiltrate that could explain the link between exercise and tumour regression and thus improved survival.
METHODS: 4 weeks mice model of colorectal cancer (MC38) will perform incremental maximal speed (MS) test and be randomly separated in 4 groups (n = 20/groups): control (CTRL), immune-chemotherapy (TRT), exercise (EXE) and combined intervention (TRT-EXE). Both TRT and TRT-EXE will receive immuno-chemotherapy (anti-PD1-1 + capecitabine + oxaliplatine) treatment 5 times per week for 1 week, moreover TRT-EXE and EXE will be submitted to 50 min of treadmill exercise at 60% MS before each treatment administration (<15 minutes). All along the protocol, tumor growth will be monitored. At D7, colon hypoxia (and tumor immune microenvironment will be measured.
RESULTS: Will be available in April 2022. Preliminary results obtained by flow cytometry show a greater decrease in tumor development in the TRT-EXE group compared to the other groups. Indeed, it seems that this is due to changes in biomarkers such as a decrease in the percentage of PD-1 expression on T cells and a decrease in the percentage of Treg on CD4+ cells. We expect that exercise improves TRT efficacy in a MC38 colorectal cancer mice model thanks a decrease of intratumoral hypoxia that can caused tumor regression for mice receiving the combination of exercise plus immuno-chemotherapy compared to TRT alone.
CONCLUSION: This study may provide insights on the combined effect of pre-treatment exercise and immuno-chemotherapy in colorectal cancer and will provide valuable information to design a randomised controlled trial with sufficient power to assess efficacy on clinically important endpoints (e.g. progression-free survival) in cancer patients eligible for immuno-chemotherapy.

**MITOCHONDRIAL RESPIRATION IN ADIPOSE AND MUSCLE TISSUE FROM PATIENTS UNDERGOING PANCREATIC SURGERY**

WIELSOE, S., SIMONSEN, C., SUNDBERG, A., BURGDORF, S.K., HANSEN, C.P., CHRISTENSEN, J., SUETTA, C., PEDERSEN B.K., NIELSEN, S., CHRISTENSEN, J.F.

*COPENHAGEN UNIVERSITY HOSPITAL, RIGSHOSPITALET, DENMARK*

INTRODUCTION: Cancer cachexia affects 80% of all pancreatic cancer patients, accounts for up to 20% of all pancreatic cancer related deaths and is associated with impaired physical performance. Increased energy expenditure and altered metabolism are hallmarks of cancer cachexia, yet the molecular mechanisms underlying these hallmarks are poorly understood. We aimed to investigate mitochondrial respiration of adipose and muscle tissue from patients undergoing pancreatic surgery as a potential early marker of cancer cachexia.
METHODS: Patients scheduled for pancreatic surgery for cancer or benign disease at Rigshospitalet, Denmark, were eligible. The patients with benign disease served as a cancer free reference group. Subcutaneous adipose tissue (SAT), visceral adipose tissue (VAT) together with muscle tissue (m. vastus lateralis) were collected during the initial part of the surgery. Mitochondrial respiration was measured by high resolution mitochondrial respirometry (Oxygraph 2k, Oroboros Instruments) performed using SUIT-protocol (Adipose tissue: leak, oxidative phosphorylation (OX), and uncoupling (UC). Muscle: Fat oxidation (FO), ATP productive (ATP), OX and UC). Prior to surgery, body composition was assessed by DXA-scan while usual gait speed and handgrip strength were used to evaluate physical performance. Differences in body composition and physical performance were analyzed using t-tests. Mitochondrial respiration was modelled using linear mixed models on log-transformed data to improve model compliance. All results are back-transformed and presented as ratios with 95% confidence intervals.
RESULTS: In total, 54 patients with pancreatic cancer (age 66±10 years, weight 77.7±16.2 kg, BMI 26.8±11.0, men 70.4%) patients and 18 patients with benign disease (age 67.7±7.7 years, weight 71.7±16.2 kg, BMI 24.7±4.7, men 38.9%) was included. Patients with pancreatic cancer had similar appendicular lean mass (+0.45kg/m2; P=0.19), fat mass (+1.58kg; P=0.59), usual gait speed (-0.3 m/s; P=0.67) and hand grip strength (+2.7 kg; P=0.30) compared to patients with benign disease. In adipose tissue we found no differences between patients with cancer and benign disease in mitochondrial respiration during leak (0.79; CI 0.51 – 1.23; P=0.30 and 0.92; CI 0.59 – 1.42; P=0.69), OX(0.76; CI 0.49–1.18; P=0.22 and 0.85; CI 0.55 – 1.33; P =0.47) or UC(0.84; CI 0.54 – 1.29; P=0.42 and 0.82; CI 0.53 – 1.27; P=0.37) for SAT and VAT, respectively. Similarly, patients with pancreatic cancer did not have increased mitochondrial respiration in muscle tissue FO (1.08; CI 0.88 – 1.33; P=0.46), ATP(1.02; CI 0.83 – 1.25; P=0.88), OX(1.05; CI 0.86–1.29; P=0.63), UC(1.07; CI 0.88–1.32; P=0.49).
CONCLUSION: The pancreatic cancer patients did not show any clinical signs of cancer cachexia at the time of the surgery compared to patients with benign pancreatic disease and there were no subclinical signs in terms of increased mitochondrial respiration in neither SAT, VAT, nor muscle tissue.

**ABSOLUTE AND RELATIVE HANDGRIP STRENGTH AS INDICATORS OF SELF-REPORTED PHYSICAL FUNCTION AND QUALITY OF LIFE IN BREAST CANCER SURVIVORS: THE EFICAN STUDY**

ESTEBAN-SIMÓN, A., DÍEZ-FERNÁNDEZ, D.M., RODRÍGUEZ-PÉREZ, M.A., CASIMIRO-ARTÉS, M.Á., ARTÉS-RODRÍGUEZ, E., CASIMIRO-ANDÚJAR, A.J., SORIANO-MALDONADO, A.

*UNIVERSITY OF ALMERÍA*

INTRODUCTION: Breast cancer (BC) is the most prevalent type of cancer in the world, with more than 2.2 million new diagnoses in 2020. BC is also the type of cancer with the highest survival rate (86% of patients surviving after 5-years). This implies that many people live long after the treatments and have to deal with their side effects. The physical function (PF) and health-related quality of life (HRQoL) of BC survivors decreases significantly, which makes important to identify markers that may be associated with a better health status and prognosis. Previous studies suggest that handgrip strength (HGS) and HGS relative to the body mass index (rHGS) are good indicators of PF and HRQoL in different populations. However, it is unknown whether this applies to BC survivors. The objective of the present study was to evaluate the association of HGS and rHGS with different PF and HRQoL variables in this population.
METHODS: Sixty female BC survivors (52.3±9.0 years) participated. Handgrip strength was assessed with a digital dynamometer, arm volume was estimated using the truncated cone formula and upper limb impairments, as well as cancer-related fatigue, depression, life satisfaction and HRQoL, were assessed using standardized questionnaires.
RESULTS: Higher levels of HGS and rHGS were associated with higher levels of HRQoL, lower cancer-related fatigue, and fewer shoulder-arm disabilities of the affected arm. However, no association of HGS or rHGS with arm volume difference, depressive symptoms or life satisfaction was found.
CONCLUSION: These results suggest that HGS and, especially, HGS relative to body mass index may be good indicators of self-reported PF and HRQoL in female BC survivors.

**EFFECT OF AN INNOVATIVE TECHNOLOGICAL SOLUTION FOR HOME-BASED RESISTANCE TRAINING ON WALKING PARAMETERS: A PRELIMINARY REPORT**

BOTTARI, A., BOCHICCHIO, G., FERRARI, L., MAIOCCHI, G., LENZI, S., TACCONI, D., SCARTON, A., POGLIAGHI, S.

*UNIVERSITY OF VERONA*

INTRODUCTION: Space-time walking gait parameters are related to health, risk of falls, independence and quality of life. These aspects are influenced by the muscle strength and power of the lower limbs. Aging affects negatively these variables, but can be counteracted by resistance training. Unfortunately, older adults have some difficulties to participate in gym program activities, that were exacerbated by the COVID-19 pandemic. Therefore, the purpose of this study was to evaluate the effects of a home-based resistance training intervention, performed using an innovative technological solution, on the main space-time parameters of walking in older adults.
METHODS: 69 healthy old subjects (35 females; 34 men, 67.1 ± 6.0 yrs) were selected and randomly divided into 2 groups: intervention (IG) (45 - F: 23; M: 22) and control (CG) (24 - F: 12; M: 12). IG received the training system (Kari®, Euleria), consisting of an inertial sensor and a tablet with dedicated software on board, for practicing exercises at home. The 3-months training program involved 12 exercises for the whole body (2-4 sets for 8-12 repetitions) performed 3 to 5 times per week. CG continued life as usual. Both groups visited the laboratory before (T0) and after 3 months (T3). In these occasions, they performed 2 trials of linear 10 m walk at self-selected speed. We used optical detection and photocell systems (Optogait® and Witty Gate®, Microgate) to collect data and speed on 4 m, cadence, stride length and double support. Compliance to the training intervention was recorded through the Kari® device and a high compliance (IGh, ≥ 3 sessions per week, # 21) and low compliance (IGl, <3 sessions per week, # 19) subgroup were created. A mixed 2-way ANOVA was used to compare results across groups (CG, IGh, IGl) and time (T0, T3).

RESULTS: While speed and double support were unaffected, there was a positive main effect of Time on stride length (increased, p<0.001) and cadence (decreased, p=0.012). The post-hoc analysis showed a significant difference between T0 and T3 in IGh (p<0.05) and CG (p<0.05) groups. Yet, there was no main effect of Group on all variables (for all variables p>0.05) and no interaction of time and group (for all variables p>0.05).
CONCLUSION: During the observation period, cadence and stride length parameters of walking gate improved in our group of healthy older adults. However, the improvement observed in the IGh was no larger than that of the CG suggesting a possible effect from an external factor. Indeed, the beginning of this study coincided with the end of the national lock down and the possibility to be engaged in spontaneous physical activities. This could have confounded the effect of the intervention protocol of our still ongoing study. A second cohort of individuals, recruited outside of the transition period that followed the epidemic, will help to isolate the effect of the training intervention from that of the return to near-normality.

### SYSTEMATIC BALANCE EXERCISE AFFECTS THE LEVEL OF SIRT1 AND SIRT3 IN OLDER ADULTS

KUBICA, J., WIECEK, M., KUSMIERCZYK, J., SZYMURA, J.

*UNIVERSITY OF PHYSICAL EDUCATION IN KRAKOW*

INTRODUCTION: Sirtuins have regulatory functions but their activity decreases with age. In young people, aerobic training have been shown to cause up-regulation of sirtuins expression. The aim of our study was to assess the impact of various forms of balance exercise (BE) on the blood concentration of selected sirtuins in older adults
METHODS: Volunteers were randomly divided into 3 groups: classic BE (CBE, n=22, age 66.64±0.63 years; body height 166.20±1.80 cm; body mass 78.55±3.07kg), virtual BE (VBE, n=16, age 65.31±0.86 years; body height 167.36±2.00 cm; body mass 79.62±2.83 kg) and control group (CON, n=22, age 66.27±0.74 years; body height 168.11±1.94 cm; body mass 78.49±3.21 kg). Classic or virtual reality BE (using Nintendo Wii) consisted of 60 min sessions, mainly of moderate intensity, performed three times per week. Venous blood samples were taken before and at the end of twelve weeks of BE. All data are expressed as mean ± SEM.
RESULTS: At baseline the level of sirtuins were similar in compared groups. In the CBE group after 12 weeks of BE the concentration of Sirt1 and Sirt3 were significantly higher than before (respectively: 2.67±0.18 ng/mL vs. 3.89±0.35 ng/mL, p < 0.001; 1.38±0.23 ng/mL vs. 2.25±0.32ng/mL, p = 0.002). Sirt1 and Sirt3 levels did not differ significantly after completion of the 12-week BE in VBT group. In the CON group, the level of sirtuins was comparable in the analyzed period of time. After 12 weeks, the level of Sirt1 was significantly higher in the CBT group than in the CON group (3.89±0.35 ng/mL vs. 2.73±0.20 ng/mL respectively, p = 0.037).
CONCLUSION: Balance exercise with moderate intensity increase blood levels of Sirt1 and Sirt3 in older adults, but the effect is dependent on form of applied exercise.
Acknowledgments: We sincerely thank the participants for their kind cooperation in this study.

### ASSOCIATION BETWEEN BARTHEL INDEX AND GRIP STRENGTH AT ADMISSION AND PROGNOSIS IN COMMUNITY-ACQUIRED PNEUMONIA: A PROSPECTIVE COHORT STUDY

RYRSØ, C.K., HEGELUND, M.H., DUNGU, A.M., FAURHOLT-JEPSEN, D., RITZ, C., KROGH-MADSEN, R., LINDEGAARD, B.

*RIGSHOSPITALET, UNIVERSITY OF COPENHAGEN*

INTRODUCTION: Functional status is a risk factor for hospitalization in patients with community-acquired pneumonia (CAP). The aim was to determine the influence of functional status on severe outcomes, including length of stay (LOS), admission to the intensive care unit (ICU), readmission, and mortality in patients with CAP.
METHODS: A prospective cohort study of 355 patients hospitalized with CAP. Functional status was assessed with the Barthel index and grip strength. The association between functional status and LOS was assessed using linear regression. The association between functional status and severe outcomes (admission to ICU, readmission, and mortality) was assessed by logistic regression.
RESULTS: Overall, 18% had a low Barthel index (<80), and 45% had a low grip strength (males <27 kg and females <16 kg). Patients with a low Barthel index had a higher risk for admission to the ICU (OR 3.6, 95% CI 1.2–10.9) and 27.9% (95% CI 2.3%–59.7%) longer LOS. Further, a low Barthel Index was associated with risk for readmission within 30, 90, and 180 days (OR 2.1-2.4, p<0.05) and mortality within 90 and 180 days (OR 4.2-5.0, p<0.05). Low grip strength was associated with an increased risk for 90 days of readmission (OR 1.6, 95% CI 1.0–2.6) and risk for mortality within 30, 90, and 180 days (OR 2.6-3.2, p<0.05).
CONCLUSION: Functional status at admission was associated with a longer LOS and increased risk for ICU admission, readmission, and mortality in patients hospitalized with CAP. Therefore, functional status should be included in the severity score of patients with CAP to identify individuals with excess risk of a poor prognosis.

### STEPS/DAY AND PEAK CADENCE MODERATE THE ASSOCIATION OF SEDENTARY TIME AND CARDIOMETABOLIC RISK IN OLDER ADULTS

COSTA, E.C., CABRAL, L.L.P., BROWNE, R.A.V., DUHAMEL, T.A., FREIRE, Y.A.

*FEDERAL UNIVERSITY OF RIO GRANDE DO NORTE, BRAZIL; UNIVERSITY OF MANITOBA, CANADA*

INTRODUCTION: Sedentary time (ST) is a risk factor for cardiometabolic diseases. There is an inverse relationship between the volume (steps/day) and intensity (peak cadence) of the ambulatory behavior and cardiometabolic disease risk in older adults. However, it is unknown whether the steps/day and peak cadence moderate the association of ST and cardiometabolic disease risk in this population. Therefore, this study investigated the moderating effect of steps/day and peak cadence in the relationship of ST and cardiometabolic disease risk in older adults.
METHODS: This cross-sectional study included 241 community-dwelling older adults (65.9 ± 4.9 years of age; 78% females). Sedentary time, steps/day and peak cadence were measured by accelerometry during seven days. Peak cadence was defined as the average of steps/min of the highest 30 min (not necessarily consecutive) for all valid days. Cardiometabolic disease risk was defined using a sex-specific continuous metabolic syndrome score (cMetS). Sedentary time was used as an explanatory variable for cMetS and steps/day and peak cadence as moderators (multiple linear regression). The Johnson-Neyman technique was used to specify the value of moderate variables at which the significant relationship between ST and cMetS disappears.

RESULTS: Both steps per day (β = -0.030, 95% CI -0.049 – -0.011; P = 0.001) and peak cadence (β = -0.004, 95% CI -0.006 – -0.001; P = 0.002) had a moderating effect in the relationship between ST and cMetS. The association of ST with cMetS disappears (p < 0.05) when step count was higher than 6,753 steps/day or peak cadence was faster than 63 steps/min.
CONCLUSION: In summary, both steps/day and peak cadence moderate the association between ST with cardiometabolic disease risk in community-dwelling older adults. A threshold of 6,753 steps/day or a peak cadence of 63 steps/min seem to offset the deleterious associations of ST with cardiometabolic risk in this population.

#### THE VALIDATION AND CALIBRATION OF RATING OF PERCEIVED EXERTION (RPE) FOR MONITORING HIGH-INTENSITY INTERVAL TRAINING (HIIT) IN ADOLESCENTS

LIU, Y., BARKER, A., WILLIAMS, C.

*UNIVERSITY OF EXETER*

INTRODUCTION: HIIT has emerged as a feasible and effective strategy to deliver vigorous intensity physical activity which is important in promoting health-related fitness in children and adolescents. However, its implementation may be hampered by the incompliance of prescribed intensity. Rating of perceived exertion (RPE) is a simple and versatile alternative to the time-consuming and expensive measurement of heart rate (HR) in quantifying HIIT intensity. No study has validated and calibrated RPE for the purpose of quantifying HIIT intensity in youth. This study aimed to validate and calibrate RPE in monitoring HIIT intensity in adolescents.
METHODS: A total of 45 healthy adolescents (16 girls, 13.0 ± 0.9 years) from previous cross-over studies were extracted retrospectively. Three groups of participants, two cycling based interval training groups (C-HIIT, 16 girls and 16 boys) and one running based interval training group (R-HIIT, 13 boys), performed 8 work intervals and 7 rest intervals (work-to-rest ratio = 75: 60s) under different intensities. Sessions were conducted on separate days and in a counterbalanced manner. RPE, HR and maximal oxygen uptake (V O2) were taken at 16 time-points (20s before each end of work and rest intervals and immediately post exercises). Within subject correlation (r) combined with Fisher's z transformation scores established the criterion validity of RPE on both HR and V O2 across the intensities and modalities. Receiver Operator Characteristic (ROC) curve analysis was performed to determine RPE cut-points across a wide range of HIIT intensity threshold: 80%, 85%, 90%, 95% and 100% HRmax and 70%, 75%, 80%, 85% and 90% V O2max.
RESULTS: Across C-HIIT and R-HIIT, RPE was significantly correlated with both HR (r = .68, p < .01) and V O2 (r = .52, p < .01). For C-HIIT, RPE and HR were largely correlated across intensities (r = .56 to .79, p < .01), while there were moderate to large correlations between RPE and V O2 (r = .47 to .63, p < .01). For R-HIIT, RPE was both largely correlated with HR and V O2 across intensities (r = .52 to .76, p < .01). The findings also showed that these correlation coefficients increased as the intensity augmented, irrespective of modality. ROC analysis indicated that the RPE cut-points could be identified for predicting HRmax (4 for 80% and 85% HRmax, 5 for 90% and 95% HRmax, and 6 for100% HRmax), while not for the V O2max threshold.
CONCLUSION: This is the first study attempting to validate and calibrate RPE as a tool to predict HRmax and( V)̇ O2max. Criterion validity has demonstrated that RPE is a valid method of quantifying intensity for HIIT interventions in adolescents and it is significantly correlated with HIIT intensity. RPE could be adopted to identify adolescents' HRmax with specific cut-points during HIIT rather than( V)̇ O2max. Future studies could use RPE as a valid and feasible tool for monitoring HRmax in order to inform more scaling up HIIT studies.

#### ESTIMATION OF ENERGY EXPENDITURE IN PROFESSIONAL CYCLISTS USING POWER DATA: VALIDATION AGAINST DOUBLY-LABELLED WATER

VAN HOOREN, B.

*MAASTRICHT UNIVERSITY*

INTRODUCTION: Accurate determination of total daily energy expenditure (TDEE) in professional cyclists is important to inform on appropriate energy intake, which in turn is required for optimal performance and injury prevention [1]. Current approaches of determining TDEE are however insufficiently accurate as they typically use basal metabolic rate (BMR) prediction equations that are developed for non-elite athletes in combination with a generic physical activity level (PAL) value to determine non-exercise energy expenditure (EE). This is combined with exercise energy expenditure (EEE) estimated from power data to determine TDEE. Knowledge about the non-exercise PAL-value and BMR equations for professional cyclists would improve the accuracy of this approach, but are currently unavailable. We therefore aimed to 1) determine the non-exercise PAL-value during training and competition based on power data in combination with a measured BMR and doubly-labelled water (DLW), and 2) compare outcomes between a multi-day cycling competition (Vuelta a España) and single-day races (Ardennes classics).
METHODS: Twenty-one male professional cyclists participated. The following parameters were measured: 1) BMR, 2) the relation between power output and EE during an incremental cycling test, 3) TDEE using DLW. The relation between power output and EE was used to determine EE during exercise (EEE). A non-exercise PAL value was obtained by subtracting BMR and EEE from TDEE. We compared the measured BMR to BMR predicted with popular equations and compared TDEE estimated with a generic approach to our approach.
RESULTS: Measured BMR was 7.9 ± 0.8 MJ/day, which was significantly higher than predicted by the Oxford equations (6.95 ± 0.5 MJ/day), but not different from the Ten Haaf [2] equation (7.87 ± 0.46 MJ/day). Mean TDEE was 31.8 ± 2.6 MJ/day and 27.3 ± 2.8 MJ/day, EEE was 21.1 ± 1.9 MJ/day and 27.8 ± 3.4 MJ/day (for only the race days), and the non-exercise PAL was 1.3 and 1.8 for the Vuelta and Ardennes classics, respectively. Non-exercise EE was estimated to be 11.51 MJ/day with the ten Haaf [2] BMR equation and a generic PAL-value of 1.45 for sedentary or light activity lifestyle [3], which overestimated non-exercise EE by 0.88 MJ/day (~3%) as compared to the measured BMR and PAL-value of 1.3 for the Vuelta.
CONCLUSION: The proposed approach can be used to get more accurate estimations of TDEE than the use of a generic PAL value in combination with BMR predictive equations developed for non-elite athletes, and is also relatively easy to implement in practice. This in turn can improve nutritional strategies in professional cyclists. A secondary finding is that TDEE is higher, while EEE and the non-exercise PAL are lower in a multi-day cycling competition compared to single-day races.

### HYPERCAPNIC WARM-UP IMPROVES THE PERFORMANCE OF THE CYCLING SPRINT INTERVAL TRAINING

DANEK, N.

*WROCLAW UNIVERSITY OF HEALTH AND SPORT SCIENCES*

INTRODUCTION: Special breathing exercises performed during the warm-up with the added respiratory dead space volume mask (ARDSv) lead to hypercapnia and stimulation of the mechanisms that lead to an increase in physical performance during a single session of cycling sprint interval training (SIT)[1]. However, to date, there is a lack of information on the use of hypercapnic warm-up in the training cycle. Therefore, we determined the effect of a 6-week experiment with the hypercapnic warm-up in SIT on the development of anaerobic capacity. This will be manifested by obtaining higher peak power output (PPO) in the Wingate test, higher hydrogen ion concentration (H+) and lactate concentration ([La-]).
METHODS: Twenty physically active men participated in the experiment. During 12 sessions of cycling sprint interval training, over a 6-week period, the experimental group (EG: n=10, age=23±2.0yr, body mass=78.2±9.8kg, body height=178±7cm, VO2max=50±5.7ml·kg-1·min-1) performed the hypercapnic warm-up (pCO2~48mmHg) with a 1200ml ARDSv mask prior to SIT. The control group (CG: n=10, age=23±2.5yr, body mass=78.5±8.6kg, body height=179±7cm, VO2max=49.9±6.1ml·kg-1·min-1), performed warm-up and SIT without the ARDSv mask. Each SIT session was preceded by a 10-min warm-up at an intensity of 60% of maximal aerobic power. The main part of the SIT consisted of 2 series of 3x10-sec "all-out" efforts with a load of 10% of the participants body mass. The recovery between efforts was 30-sec and between series was 15-min with a load of 50W. PPO, time to obtain PPO, heart rate (HR), body temperature (T), H+, [La-], and rating of perceived exertion (RPE) were analyzed before and after SIT. A two-way repeated measures ANOVA was performed to detect differences in means on endpoints. All data are expressed as mean±SEM.
RESULTS: After SIT with the hypercapnic warm-up, PPO on the Wingate test increased by 8.2% ($p<0.01$). The time to obtain PPO decreased by 0.6sec ($p<0.05$). HR in both CG and EG increased by 3beats·min-1 ($p<0.05$) and 10beats·min-1 ($p<0.01$) respectively. Body T was 0.8 °C and 1.0 °C lower after the test in EG and CG groups, respectively. [La-] and H+ were statistically significantly higher ($p<0.05$) after the 6-week SIT training only in EG group by 1.6mmol·l-1 and 9.1nmol·l-1 respectively. RPE decreased statistically significantly by 6.3%, only in EG ($p<0.01$).
CONCLUSION: Results from the present investigation suggest that six weeks of cycling sprint interval training with Warm-up with added respiratory dead space volume mask increases anaerobic performance. Hypercapnic warm-up prior to cycling SIT produces an ergogenic effect by obtaining higher PPO, [La-], H+ in the Wingate test with a lower RPE.

### BEYOND THE SECOND VENTILATORY THRESHOLD: RESPIRATORY COMPENSATION POINT AND THIRD VENTILATORY THRESHOLD.

TEALE, J.

*UNIVERSITY OF ESSEX*

INTRODUCTION: Ventilatory thresholds (VT) are commonly used to identify physiological boundaries. Recently, authors have suggested a third ventilatory threshold (VT3) is present in well trained, but not recreationally trained cyclists.(Ozkaya et al., 2021) However, it is unclear whether VT3 is an overestimation of a second ventilatory threshold (VT2) and subsequently comparable to respiratory compensation point (RCP), or indeed an independent threshold. The aims of this study were to investigate (1) time dependent change-points in respiratory parameters during an incremental cycle test to reveal whether VT3 is independent of RCP and (2) to assess the relationship between performance parameters and the presence of VT3.
METHODS: Thirty-nine cyclists performed a maximal incremental test on a cycle ergometer. VT2 and VT3 were identified via a second and third inflection point in breathing equivalents of oxygen (EQO2) and end tidal partial pressure of carbon dioxide (PETCO2), plus the first and second inflection point in the breathing equivalents of carbon dioxide (EQCO2). RCP was identified via the first inflection point in VE/VCO2. The inflection points were visually identified.
RESULTS: VT2 and RCP was identified in all participants, whereas VT3 was present in 25 participants (64.1%). Participants presenting a VT3 reported a higher peak power to weight ratio (4.7 ± 0.7 W/kg) compared to those without VT3 (4.2 ± 0.7 W/kg) ($P = 0.04$), however no significant difference was observed for peak power output (PPO) or VO2MAX between the two groups ($P=0.40$, $P=0.08$ respectively). Of the 25 participants displaying three breakpoints, power output (PO) was not different between VT2 and RCP (238.9 ± 52.4 W and 235.0 ± 54.2 W respectively) ($P=0.12$). However, PO at VT3 (310.9 ± 53.2 W) was significantly greater compared with VT2 and RCP ($P<0.001$, $P<0.001$ respectively).
CONCLUSION: It is demonstrated that the use of ventilatory equivalents and PETCO2 provide a method to determine time dependent change points in respiratory parameters. VT3 was evident in individuals who possess a higher power to weight ratio and therefore the presence of this could be dependent on trained status. Recreationally active individuals incur three identifiable phases, isotonic buffering phase, isocapnic buffering phase and hypercapnia alongside hyperventilation. However, in well trained athletes a delay between hypercapnia and hyperventilation can be identified, establishing a third threshold independent of VT2 and prior to exhaustion. Future research should look to investigate the reliability of identifying VT3 and its prevalence VT3 during other exercise modalities (running).
Ozkaya, O., Balci, G. A., As, H., & Yildiztepe, E. (2021). A new technique to analyse threshold-intensities based on time dependent change-points in the ratio of minute ventilation and end-tidal partial pressure of carbon-dioxide production. Respiratory Physiology & Neurobiology, 294, 103735.

### FACTORS AFFECTING PERFORMANCE IN WOMEN COMPETITIVE ROAD CYCLING: A SYSTEMATIC REVIEW

HERRERO-MOLLEDA, A.1, ÁLVAREZ-ÁLVAREZ, M.J.2, GARCÍA-LÓPEZ, J.1

*1.FACULTY OF PHYSICAL ACTIVITY AND SPORTS SCIENCES, UNIVERSITY OF LEON, SPAIN 2.DEPARTMENT OF NURSING AND PHYSIOTHERAPY, UNIVERSITY OF LEON, SPAIN*

INTRODUCTION: Women cycling has grown in popularity in the last couple of years. Since the introduction of the Women's World Tour in 2016, the quality of performances of riders and competitions has increased [1]. However, although the factors affecting women's road

cycling performance may be different from those affecting men, the number of studies carried out on this topic is still scarce. Therefore, the main purpose of this systematic review is to analyze the studies focused on factors affecting performance in women competitive road cycling.
METHODS: A systematic review following PRISMA guidelines [2] was conducted, using the terms performance AND bicycle OR bike OR cyclists OR cyclists' OR cyclist AND women OR female OR womens OR woman in five different databases (Pubmed, Medline, Sportdiscus, Scopus and Google Scholar). After the duplicates were removed, titles and abstracts were screened against the inclusion criteria (i.e., primary studies, 1990-present, written in any language that could be translated into Spanish or English, and full text available). Finally, a full-text review was carried out to verify that the study participants were a minimum of five elite competitive or competitive recreational women between the ages of 15 and 50.
RESULTS: A total of 1630 studies were retrieved from this search, resulting in 1065 studies after duplicates were removed. 277 studies remained after the title and abstract screening, and of these, 55 studies were finally selected after the full-text review. The selected studies were classified into 7 different factors affecting performance (i.e., physiology, nutrition, training, competition, biomechanics, psychology, and sociology) according to their main purposes. The majority of the studies focused on nutrition (24.6%), followed by physiology (31.6%) and training (22.8%). Six studies analyzed competition (10.5%), four focused on psychology (7%), and only one study focused on biomechanics (1.8%) and sociology (1.8%).
CONCLUSION: Despite the recent growth of women's competitive road cycling, currently only 55 studies have analyzed factors affecting performance. Specifically, a lack of studies focused on the biomechanics, sociology and psychology of female cyclists has been identified. Therefore, more studies focused on women's competitive road cycling are needed to fully understand the requirements of these competitions.

**OBJECTIVATION OF CYCLING PERFORMANCE: CLASSIFICATION AND DETECTION OF ATYPICAL ATYPICAL TRAINING**

CHASSARD, T.
*INSEP*

INTRODUCTION: Quantification of training loads in cycling have been of great interest, from modelling performance or to monitoring fatigue. Our goal here is to model the internal response of cyclists to a given external load, to then detect atypical behavior, and highlight some combination of parameters, such that sleep quality, mood or RPE for instance, that promote better or worse performance.
METHODS: A 6-month follow-up was conducted with 14 athletes to collect training and fitness data. Training data include information about individual training sessions, such as heart rate (BPM), power (Watts), elevation (meters), speed (meters per sec), air temperature (Celsius) and other environmental variables.
Three methods were implemented to handle these data :
-A model using quantile regression statistical framework, to build, for each power performed by the athlete, a classic interval of heart rate expected by the athlete,
- A regression model to predict heart rate from external load data (power, elevation, temperature etc.), taking into account the temporal aspect of a training,
-Some methods to objectively classify the different type of training sessions were tried, starting with PCA and using more complex method such that building embeddings for multivariate time series.
RESULTS: The quantile regression method notifies that when the athletes (internal) cardiac response is higher than her "expected" (model-predicted) cardiac response, the athletes fitness variables, as well as some performance parameters (self-reported performance), are also below the athletes standards (underperformance). The same conclusion can be drawn with lower than expected heart rate responses, for which the athletes self-reported variables suggest that the exercise was better than usual (overperformance).
The models for predicting heart rate as a time series achieved an average accuracy of 8.57 bpm using a 5-variable nonlinear regression model.
Comparing the classification results obtained by PCA, with the annotation of workouts by domain experts, it follows that classifying workouts by type is not unfeasible.
CONCLUSION: Our different prediction models allow us to obtain an interesting first baseline according to our objectives. However, as sport performance is complex to predict, other physiological behaviors could be taken into account in order to have results closer to reality. The use of VRAE (Variational Recurrent Auto-Encoders) type models would allow us to obtain a simplified and discriminating representation of training sessions according to their type. Variations of recurrent neural networks would also allow us to take into account certain physiological phenomena such as the appearance of fatigue.

**IS RPE A GOOD BASIS FOR EXERCISE PRESCRIPTIONS IN DIFFERENT ACTIVE COHORTS?**

BIRKLBAUER, A., BIRKLBAUER, J.
*UNIVERSITY OF SALZBURG*

INTRODUCTION: Borg's ratings of perceived exertion (RPE) has often been used to measure and monitor exercise intensity. A study by Scherr et al (2013) reported its strong correlation with both heart rate (HR) and blood lactate concentration (La). This ratifies it is a valid tool for monitoring and prescribing exercise intensity. RPE is therefore commonly used in rehabilitation settings, e.g. cardiac rehabilitation, to assess the subjective perceived exertion during an incremental exercise test. Especially in rehabilitation settings but also in recreational sports, exercise requires a proper level of intensity as misclassification might lead to the absence of a beneficial or potential harm of exercise. To investigate the handling of RPE (6–20 scale) in different exercise settings, we analysed the interrelationships between RPE, HR, and La in recreational athletes (RA), people suffering from long-covid (LC) and active people suffering from heart disease (HD) as especially the last two groups should avoid levels of too high intensity.
METHODS: A total of 76 participants (29 females; aged 18-69 yrs; RA: n=31, HD: n=26, LC: n=19) performed a stepwise incremental exercise test until total exhaustion on an electromagnetically braked cycle ergometer, with the initial workload varying between 25–100 W according to their individually expected maximal capacity. Capillary blood samples were obtained from the earlobes to measure lactate concentration before and within the last 15 sec of each workload during exercise testing. RPE was assessed at the time of lactate measurements. HR was continuously measured using a standardised 12-lead surface ECG. For statistical analyses, data for La, HR and RPE were determined at the individual anaerobic threshold (IAT).
RESULTS: RPE at IAT was on average at 13.0, 95% CI [12.4, 13.6] for RA and with 11.7, 95% CI [10.9, 12.5] and 12.0, 95% CI [11.1, 12.8] marginally lower for HD (p=.014, d=0.67, BF10=3.61) and LC (p=.047, d=.60, BF10=1.53), respectively. Including all groups, data showed a

positive linear Pearson correlation with medium effects between RPE and HR (p=.033, r=.25, BF10=1.34) and La and HR (p=.027, r=.25, BF10=1.58). The only significant within group correlation referred to the positive relationship between RPE and HR (p=.012, r=.49, BF10=4.80) for HD. Bayesian correlations confirmed that there was no linear association (i.e. data were more likely to occur under H0) between RPE and La – both across and within groups (p>.597, r <±.13, BF10<0.33).
CONCLUSION: Our data support the use of RPE for exercise prescriptions as intensities between an RPE of 11–14 or an RPE of 12–14 are recommended by international guidelines. In contrast to other literature (e.g. Scherr et al.), there was no correlation between HR, La and RPE. The mismatch between La and RPE might most likely be the result of using different testing protocols which were adapted according to the individual fitness level.
Scherr et al. Eur J Appl Physiol. (2013)

**FATIGUE INDEX PREDICTION IN THE WINGATE TEST IN FEMALE CYCLIST**

ENCARNACIÓN-MARTÍNEZ, A., SENDRA-PEREZ, C., OFICAL-CASADO, F.J., PRIEGO-QUESADA, J.I.

*UNIVERSITY OF VALENCIA*

INTRODUCTION: The Wingate (WAnT) test consists in pedaling 30-seconds at maximal speed and against a constant force [1]. Different metrics related to performance can be obtained from this test such as peak power, mean power, and fatigue index (FI) [1]. The FI is used for evaluating performance during the WAnT in different sports (e.g. cycling, rugby, or football) and physical fitness condition (e.g. physically inactive or professional cyclists) [2]. This study aimed to assess which physiological parameters are related to FI of WAnT test in female cyclists.
METHODS: Eighteen female cyclists (25 ±8 years, 1.65 ±0.07 m, 59.8 ±7.2 kg and BMI 21.81 ±1.97 kg/m2) performed a protocol consisting of a twelve minutes warm-up and a WAnT test. The cyclists were instructed to avoid consuming any stimulant substances and perform exercise 24 hours before the tests. Power output (W.kg-1), normalized heart rate (%), lactate (mmol.L-1), rating perceived exertion (RPE; Borg Scale 6-20), and the muscle oxygen saturation (%SmO2) on the vastus lateralis (assessing the execution inclination; EI) [3], were measured. The test was performed with a constant load of 0.075 kg per body mass kg. Multi regression analysis model with a stepwise selection of variables was performed to assess the relationship between FI with demographic variables and the rest of the outcomes of the WAnT test.
RESULTS: Participants obtained the following values in the WAnT test: FI 38.9 ±13.1%, peak power output 9.2 ±0.9 W. kg-1, mean heart rate 84 ±6% of the maximum heart rate, lactate 6.0 ±3.4 mmol/L, RPE 17 ±2 points, and EI 0.93 ±0.47. Regression analysis obtained the following model: FI = -50.97 + RPE*4.3 + EI*15.8 (R2=0.69, p<0.001).
CONCLUSION: The main finding of this study was the great correlation of EI and FI found. Thus, we can suggest the measurement of muscle oxygen saturation for monitoring this kind of anaerobic efforts.

**THE RELATIONSHIP BETWEEN TRAINING LOAD AND TIME TRIALS IMMEDIATELY FOLLOWING DIFFERENT TRAINING SESSIONS**

VERMEIRE, K., CAEN, K., BOURGOIS, J.G., BOONE, J.

*GHENT UNIVERSITY*

INTRODUCTION: The purpose was to examine the differences in training load (TL) metrics when quantifying different training sessions, which differed in intensity and duration. Also, the relationship between these TL metrics and the acute performance decrements (APD) measured immediately after the training sessions was assessed.
METHODS: 11 male recreational cyclists performed four training sessions in a random order, immediately followed by a 3 km time trial. Before the start of the training period, participants performed the time trial twice in order to obtain a baseline performance. The difference in the average power output for the time trials following the training sessions was then expressed relatively to the best baseline performance. The training sessions were quantified using seven different TL metrics, four using heart rate as input, two using the power output and one using the rating of perceived exertion (TLRPE)
RESULTS: Training sessions were ranked differently, depending on the TL metrics used. Also within the metrics using the same input (HR, power), differences were found. TLRPE was the only metric showing a response that was consistent with the APDs found for the different training sessions. The Training Stress Score (TSS) and the individualized training impulse (iTRIMP), demonstrated similar patterns but overexpressed the intensity of the training sessions. The total work done (TWD) resulted in an overrepresentation of the duration of training.
CONCLUSION: Using different TL metrics, results in different ranking of training sessions. The way in which the intensity of training sessions is calculated, plays a key-role in the determination of the total load of a session.

**DIFFERENCES IN MUSCLE OXYGEN SATURATION AND PERCEPTUAL RESPONSES BETWEEN CYCLE, ELLIPTICAL, AND TREADMILL**

MACHADO, I.1,2, SANTARÉM, D.1, SOUSA, N.2,3, PAREDES, H.1,4, ABRANTES, C.1,2

*1.UNIVERSITY OF TRAS-OS-MONTES E ALTO DOURO, VILA REAL; 2.CIDESD, VILA REAL; 3.ACES GRANDE PORTO I-SANTO TIRSO/TROFA, SANTO TIRSO; 4.INESC TEC, HUMANISE, PORTO*

INTRODUCTION: Muscle oxygen saturation (SmO2) is the balance between muscle oxygen supply and demand measured in a local muscle, and its response to different types of training remains unclear [1]. This study aimed to identify differences between 3 types of exercise at the same cardiovascular intensity on acute SmO2 and total hemoglobin (tHb) response of vastus lateralis (VL) and gastrocnemius medialis (GM) and perceived exertion (RPE).
METHODS: Fourteen volunteer healthy participants (age=34.9±9.1 years; height=169.4±8.6 cm; body mass=69.7±9.8 kg; GM skinfold=8.2±3.4 mm; VL skinfold=15.2±5.9 mm) completed 5 minutes of constant load at 50% of heart rate reserve (%HRR) in i) Cycle ergometer - cadence of 60 rpm, average power of 107±32 W; ii) Elliptical trainer - cadence of 120 bpm, average power of 110±44 W; iii) Treadmill walking - speed of 5.8 km/h, average grade of 5±3%. An ANOVA with repeated measures and Bonferroni correction for pairwise comparison was used for data analysis.

RESULTS: At a moderate intensity of 50% of HRR, significant differences were found between exercise types in SmO2 (F[1,19]=4.47, p=0.035, η2=0.256, and F[2,26]=24.15, p<0.001, η2=0.650, in VL and GM, respectively), the minimum value of SmO2 (SmO2min) (F[2,26]=4.74, p=0.018, η2=0.267, and F[2,26]=24.66, p<0.001, η2=0.655, in VL and GM, respectively), tHb (F[2,26]=4.72, p=0.018, η2=0.266, in GM) and RPE (F[2,26]=6.77, p=0.004, η2=0.342). The average value of SmO2 in VL was lower during cycle vs treadmill (65±21% vs 79±15%, p=0.018) and in GM was lower during treadmill vs elliptical (35.6±11.7% vs 51.3±11.3%, p=0.010) and cycle (35.6±11.7% vs 65.9±11.4%, p<0.001) and in elliptical vs cycle (51.3±11.3% vs 65.9±11.4%, p=0.005). The SmO2min in VL reached during the exercise was lower in cycle vs treadmill (50.9±25.9% vs 72.8±17.8%, p=0.043) and in GM was lower in treadmill vs elliptical (26.4±10.8% vs 42.9±12.3%, p=0.010) and cycle (26.4±10.8% vs 57.6±11.1%, p<0.001) and in elliptical vs cycle (42.9±12.3% vs 57.6±11.1%, p=0.010).
The tHb in GM was higher in the treadmill compared to cycle (12.66 ± 0.44 g/dL vs 12.53 ± 0.50 g/dL, p=0.024) and elliptical (12.66±0.44 g/dL vs 12.53±0.51 g/dL, p= 0.041).
A higher RPE was found in cycle vs elliptical (13.1±1.7 vs 11.5±1.7, p=0.026) and treadmill (13.1±1.7 vs 11.5±1.7, p=0.026).
CONCLUSION: For a moderate intensity at 50% of HRR, the cycle ergometer promotes lower values on VL in both SmO2 and SmO2min and the treadmill walking promotes lower values on GM in SmO2 and SmO2min with a higher tHb value. The cycle ergometer was related to a higher perceived exertion.

#### INTER-MUSCULAR COORDINATION IN ADULTS WITH DOWN SYNDROME. A NETWORK ANALYSIS

SÁNCHEZ, A.1, GARCIA-RETORTILLO, S.2, OVIEDO, G., REY, F., MASSÓ, N.

*1 SCHOOL OF HEALTH AND SPORT SCIENCES , UNIVERSITAT DE GIRONA, SALT, SPAIN; 2KECK LABORATORY FOR NETWORK PHYSIOLOGY, DEPARTMENT OF PHYSICS, BOSTON UNIVERSITY, BOSTON, MA, UNITED STATES*

INTRODUCTION: Down Syndrome (DS) is a chromosomal disorder affecting the neuro-muscular system among others. Some of the most common alterations include muscle hypotonia and impaired inter-muscular coordination during activities of daily living. However, the mechanisms underlying cross-frequency network communication among distinct muscle fibers across muscles in DS individuals remain unknown. Accordingly, we investigate how different muscle fiber types dynamically synchronize with each other and integrate as a network across lower limb muscles during a static standing position in adults with and without DS.
METHODS: Seven adults with DS (DS group) and 10 adults without disabilities (non-DS group) performed a static standing position for 30 seconds. Electromyographic activity of 8 muscles (soleus, tibialis anterior, gastrocnemius lateralis, gastrocnemius medialis, gluteus maximus, rectus femoris, biceps femoris and semitendinosus) from the right leg was collected during the task. We first obtained 10 time series of EMG band power $\bar{S}(f)$ for each muscle, representing the dynamics of all representative EMG frequency bands. Frequencies below 40-60 Hz can be attributed to the activity of small alpha-motoneurons and related type I muscle fibers, 60-120 Hz frequencies can be associated with medium alpha-motoneurons and related type IIa fibers, and higher frequencies 170-220 Hz can be attributed to the large alpha-motoneurons and their related type IIb fibers. To investigate cross-frequency interactions among EMG frequency bands that occur as a result of synchronous modulation of their spectral amplitudes, we calculate the bivariate equal-time Pearson's cross-correlation for each pair of EMG band power $\bar{S}(f)$ time series across all lower limb muscles.
RESULTS: We identify 4 patterns of inter-muscular network interactions in the non-DS group according to the role and topology of the selected muscles — each pattern is characterized by differentiated contribution of frequency bands leading to specific link strength profiles. In contrast to the non-DS group, inter-muscular network interactions for DS group are characterized by (i) an overall significant increase of link strength across all muscles ($p < 0.05$) and (ii) a change on the link strength profiles for all observed patterns.
CONCLUSION: Adults with Down Syndrome showed overexpressed/excessive network connectivity reflecting an unfunctional/pathological state, which pushes the neuro-muscular system toward a rigid order reducing its adaptability to environmental constraints. The reported empirical findings will break new ground in the study of inter-muscular coordination and will provide new understanding of the effects of the Down Syndrome disorder on the neuro-muscular system.

#### EFFECT OF PROLONGED CROSS-LEGGED SITTING ON BIOMECHANICAL VARIABLES

YOON, S., HAN, H.

*KOREA NATIONAL SPORT UNIVERSITY*

INTRODUCTION: Previous studies have reported that maintaining a cross-legged posture more than 10 minutes lead to the creep phenomenon that temporarily delay muscle restoration due to the stretching of the gluteus muscles (1). Creep situation many have a negative effect on walking and sitting movements, which are often performed in daily life. Moreover, retaining of repetitive and continuous creep conditions can induce abnormal movement pattern such as Trendelenber signs (2 & 3). Therefore, the purpose of this study was to verify the effect of cross-legged sitting for 15 minutes on the kinematic and kinetic variables.
METHODS: Nineteen healthy male adults who had no experience of musculoskeletal injuries or surgical operations on the trunk or lower extremities within the past 6 months participated in this study (age: 28.78±4.31 yrs., height: 172.95±5.84 cm, body mass: 76.50±13.10 kg, navicular drop test; 5.8±1.7 mm). After full warm-up, each participant was asked to perform one-leg squat without loads (pre_squat) followed by the intervention (a 15 minutes cross-legged sitting). Then, the squat was asked to be performed again within 2 minutes after the intervention (post_squat). A three–dimensional motion analysis included 8 infrared camera and 2 channels EMG with sampling rate as 100Hz and 1000 Hz, respectively, was performed in this study. A paired t-test was conducted to verify the intervention effect and the statistical significance was set at $\alpha$=.05.

RESULTS: Significant increase in the maximum hip adduction(8%) and knee valgus were found in post_squat compared with those of pre_squat throughout the entire single-leg squat(p<.05). Also, significantly increased pevic height in support feet was found in post_squat compared with that of pre_squat (p< .05). Finally, post_squat revealed significantly decreased gluteus medius muscle activation compared with that of pre_squat during ascending phase of the squat (p< .05).
CONCLUSION: In this study, we found that prolonged cross-sitting may cause overuse of specific lower extremity muscles as a function of compensation movement and damage to the most vulnerable joints in the body. Therefore, it is suggested that cross-legged sitting should be avoided when sitting and light strength training for the gluteus medius or dynamic break is necessary to prevent deformation of the tissues around the pelvis and lower extremities.

**NEUROMUSCULAR TRAINING AND THE EFFECT ON LOW BACK PAIN AND POSTURAL STABILITY**

SCHÄFER, H., MARKS, N., HENS, C., PLATEN, P.

*FACULTY OF SPORT SCIENCE, RUHR-UNIVERSITÄT BOCHUM*

INTRODUCTION: The complex multicausal syndrome “low back pain” (LBP) is nowadays the leading cause of disability worldwide [1]. A reduced postural control is associated with a risk factor for LBP [2]. Coordination/stabilisation exercise programs have beneficial effects in the treatment of chronic LBP [3]. The aim of the study was to investigate the effects of a neuromuscular training on LBP and postural stability.
METHODS: 112 subjects participated 12 times 1 hour in a weekly sports course for students. 54 (f: n=45/m: n=9 22±2.9 kg/m²; 26.7±7.4 yrs) conducted a standardised neuromuscular training (called RanRücken; RR), 25 (f: n=13/m: n=12; 22.1±2.5 kg/m²; 28.6±8.1 yrs) did a general strength training (ST) for LBP prevention and 33 (f: n=26/m: n=7; 22.4±3.1 kg/m²; 24.7±6.3 yrs) participated on college courses without specific neuromuscular or LBP related training (Control Group; CG). Pre- and post-measurements (MiSpEx-Protocol [4]) include isokinetic trunk force (IsoMed 2000), countermovement jumps (CMJ) and posturography (Center of Pressure; COP left/right), both measured with Wii Boards (Nintendo, CSMi modified). In addition, the von Korff-Questionnaire was assessed (Characteristic Pain Intensity (CPI), Disability Score (DS)). Data were normal distributed. Depended t-tests and mixed ANOVA were performed. Cohens d was used to estimate the effect size.
RESULTS: Trunk force did not change for RR (n=39; Flex: p=.030, d=.07; Ext: p=.133, d=.16). Back strength did not change for CG (n=29; Ext: p=.567, d=-.04). Trunk Force improvements could be detected for CG (n=29; Flex: p=.003, d=.15) and ST (n=25; Flex: p=.012, d=.23; Ext: p=.013, d=.14). CMJ performance did not differ for all groups (RR: n=53, p=.309, d=.07; ST: n=24, p=.024, d=.19; CG: n=32, p=.414, d=-.07). There were no differences in postural stability for ST (n=25; COP l.: p=.980, d=.01; COP r.: p=.806, d=.08) and CG (n=32; COP l.: p=.165, d=.33; COP r.: p=.284, d=.30). RR improved the right leg stand stability (n=54; COP l.: p=.023, d=.25; COP r.: p=.014, d=.33). Pain intensity and pain related disability did not differ for ST (n=25; DS: p=.018, d=.40; CPI: p=.286, d=.15) and CG (n=32; DS: p=.328, d=-.47; CPI: p=.422, d=-.25). RR showed less pain and pain related disability (n=54; DS: p<.001, d=.51; CPI: p<.001, d=.45). Group comparisons revealed differences in CPI and DS for RR and ST compared to CG, but not between RR and ST.
CONCLUSION: ST has small beneficial effects on the trunk force, whereas the neuromuscular training caused low improvements in postural stability. Both interventions focused on LBP reduction and prevention, but only RR could show medium effects in LBP reduction and less pain related disability.

**WHY DECELERATION OCCUR IN THE 100-M DASH? : TIMING OF THIGH MUSCLE ACTIVITY IS A FACTOR LIMITING PERFORMANCE.**

KAKEHATA, G.

*THE UNIVERSITY OF TOKYO*

INTRODUCTION: The 100-m dash can be divided into three phases (acceleration phase, maximal speed [Max] phase, and deceleration [Dec] phase) (Ae at al. 1992). The running speed (RS) reaches maximum in the Max phase. Interestingly, the maximum RS cannot be maintained, and RS gradually decreases towards the finish (the Dec phase). What happens in the Dec phase to cause the observed decrease in RS? Previous studies demonstrated a decrease in RS in the Dec phase is inevitable even in world class sprinters, due to a decrease in step frequency (SF). Hence, to lessen the inevitable decrease in RS in the Dec phase, sprinters should maintain the SF as high as possible. In addition, we have recently demonstrated that timing of rectus femoris (RF) and biceps femoris (BF) activities influences the SF at the maximal RS (30-50 m section) (Kakehata et al. 2021). Therefore, the purpose of this study was to analyze the changes in the timing of electromyography (EMG) activity of the RF and BF in both legs, together with spatiotemporal variables (RS, SF, and step length: SL) in the Max and the Dec phases of the 100-m dash.
METHODS: Nine male track & field athletes performed the 100-m dash with maximal effort. A portable wireless data logger was attached to the subjects lower back to record EMGs. We defined the Max phase as the 50-70 m section and the Dec phase as the 80-100 m section. We calculated spatiotemporal variables (RS, SF, SL). Moreover, we also calculated onset/offset timing (%) of RF and BF in both legs using a Teager-Kaiser Energy Operator filter (e.g., ipsilateral leg RF onset is “iRF-onset”, contralateral leg BF onset is “cBF-onset”). A paired-sampled t-test was used to determine the difference between the two phases (Max vs Dec). Moreover, to analyze which muscle activity timing affects the SF decrease in the Dec phase, we examined the Pearson’s product–moment correlation between the changes in SF (Δ SF) and EMG variables (Δ EMG) from Max phase to Dec phase.
RESULTS: The decreased RS in the Dec phase ($P < 0.001$) was due to a decreased SF ($P < 0.001$). Moreover, iRF-onset ($P = 0.002$), iRF-offset ($P = 0.008$), iBF-offset ($P = 0.049$), and cBF-offset ($P = 0.017$) in the Dec phase shifted to later in the running cycle as compared with the Max

phase. Furthermore, the time difference between the swing leg RF activity (iRF-onset) and the contact leg BF activity (cBF-onset) ("Scissors1") became bigger in the Dec phase (P = 0.041). Significant negative correlations were found between ΔiRF-onset and ΔSF (P = 0.045), and between ΔiBF-offset and ΔSF (P = 0.036).
CONCLUSION: The decreased RS and SF in the Dec phase of the 100-m dash would be the delayed timing of the RF and BF activities in the same leg as well as the disturbed inter-leg muscular coordination. Moreover, a greater change in EMGs have a greater change in SF. We concluded that the timings of thigh muscle activity is a factor limiting performance in the deceleration phase of the 100-m dash.

**DOES DUAL-TASKING AFFECT THE ABILITY TO GENERATE ANTICIPATORY POSTURAL ADJUSTMENTS IN YOUNG ADULTS?**

VAZAKA, A., FRANKLIN, Z., MILLS, R.

*MANCHESTER METROPOLITAN UNIVERSITY*

INTRODUCTION: To date, little is known about the impact of additional cognitive tasks on perturbed balance and whether different types of cognitive tasks elicit different balance response mechanisms. The aim of this study was to investigate how two additional cognitive tasks (Stroop test and counting backwards task) would influence young adults' ability to generate appropriate postural responses.
METHODS: Twenty young adults (25.95 ± 2.97 years) stood eyes open, bare feet shoulder-width apart on a moving platform which was translated in the anterior-posterior direction at three different frequencies (0.1, 0.25, 0.5 Hz) and performed either a counting backwards task, a Stroop task, or no additional cognitive task. Muscle tonic activity and muscle onset latencies of the Rectus Femoris, Bicep Femoris, Tibialis Anterior, and Gastrocnemius Medialis were measured through surface electromyography (1000 Hz). The number of steps taken and cognitive errors made were also recorded.
RESULTS: Results showed no significant differences in muscle onset latencies and tonic activity between dual tasking and single tasking conditions, nor between the two dual tasking conditions. Cognitive errors were made in the counting backwards task (238 total cognitive errors across all frequencies) but not the Stroop task. A frequency effect was identified with participants showing greater tonic activity in the Rectus Femoris ($p= 0.012$), the Gastrocnemius Medialis ($p= 0.016$), and the Bicep Femoris ($p= 0.043$) at 0.5 Hz, as well as earlier muscle activation in the Tibialis Anterior, ($p< 0.001$), the Gastrocnemius Medialis, ($p< 0.001$) and the Bicep Femoris ($p< 0.001$) at 0.5 Hz compared to the other frequencies. Transition and steady state muscle onset latencies were only significantly different for the Gastrocnemius Medialis at 0.25 Hz ($p= 0.001$), possibly because the 0.1 Hz frequency was too easy to require adaptation and the 0.5 Hz frequency was large enough to trigger earlier muscle activation from transition state which was then carried to steady state.
CONCLUSION: Dual tasking did not seem to influence anticipatory postural adjustments in young adults, however perturbation intensities did. It is assumed that due to the 'threatening' nature of the 0.5 Hz perturbation, a stiffer position was adopted as seen by the increased tonic activity, and anticipatory mechanisms were triggered sooner than the other frequencies, as seen by earlier muscle activation. Since posture was unchanged between single and dual tasking, it is, suggesting suggested that participants' postural control was automated and the cognitive errors in the two mental tasks could reflect their difficulty level. Future research should explore body kinematics and centre of pressure to identify the balance strategies adopted, as well as take into account cognitive task the reaction times of the cognitive task to better understand participants' allocation of attention during perturbed balance dual tasking.

**WHOLE BODY VIBRATION PRODUCES A POSTURAL DESTABILISING EFFECT DURING A HALF-SQUAT**

TUYÀ, S., FERNÁNDEZ-VALDÉS, B., PÉREZ-CHIRINOS, C., MORRAL-YEPES, M., DEL CAMPO, L., MORAS, G.

*NATIONAL INSTITUTE OF PHYSICAL EDUCATION OF CATALONIA, UNIVERSITY OF BARCELONA*

INTRODUCTION: Scientific evidence has shown that introducing instability into strength training is beneficial for improving sport performance and injury recovery (1). However, there is limited research on the effects of whole body vibration (WBV) acting as a destabilising stimulus.
METHODS: Therefore, the aim of this study was to determine whether WBV produces postural destabilising effect during a half squat with different ballasts and rhythms measuring the movement variability through entropy. A total of 12 male athletes (age: 21.24 +- 2.35 years, height: 176.83 +- 5.80 cm, body mass: 70.63 +- 8.58 kg) performed a half-squat with weighted vest, dumbbells and a bar with the weights suspended with elastic bands, with and without WBV at 40 bpm and 60 bpm. Subjects performed one set of twelve repetitions of each situation, composed by the combination of the three factors. The movement variability was analysed by calculating the sample entropy (SampEn) of the acceleration signal recorded at the waist using an accelerometer.
RESULTS: With WBV, significant differences were found between dumbbells and weighted vest ($p<0.001$; ES: 2.87 at 40 bpm; $p<0.001$; ES: 3.17 at 60 bpm) and between the bar and weighted vest at both rhythms ($p<0.001$; ES: 3.12 at 40 bpm; $p<0.001$; ES: 2.93 at 60 bpm) and a higher SampEn was obtained at 40 bpm with all ballasts ($p<0.001$; ES of WV: 1.22; ES of D: 4.49; ES of B: 4.03). No significant differences were found without WBV.
CONCLUSION: These findings reveal that the WBV produces a destabilising effect performing half-squat with different ballasts and rhythms. In addition, a higher movement variability is achieved when the ballast is placed on the upper limbs and when performed at a slow rhythm. Our results show that the WBV can be used in combination with the appropriate ballast and rhythm for the athlete's characteristics, to progress and avoid the loss of training potential of the strength exercises or to improve muscle feedforward, which can prepare the athlete for challenging situations in sport.

**STABILITY IN PARA-SHOOTING: A MULTIMODAL APPROACH.**

PRADON, D., CARPENTIER, V.T., VILLIER, E., GENET, F.

*APHP - ISPC SYNERGIES*

INTRODUCTION: Although the questions of postural control and stability are widely studied in competitive shooting in the able-bodied, no study has quantified these aspects on Paralympic athletes [1]. While the goal of postural stability may seem similar, the approach is quite different. Indeed, in the context of para-shooting, the handicap of each athlete requires an individualized and multimodal response. We have selected 2 cases of athletes to illustrate this multimodal approach.

METHODS: For each of the athletes, we have quantified the impact of spasticity on the posture by a comparative biomechanical analysis (100hz, Motive, Optitrack) of the movement in a match situation: the performance of 10 shots at 10m (Scatt MX02) before and after intramuscular infiltration of anesthetic.
Athlete 1, international SH1 level, hemiplegic, is a specialist in pistol shooting at 10m. In his practice but also in his professional life, the athlete is disabled by an almost continuous contraction of the elevator muscles of the shoulder. This hyperactivity becomes painful in stressful situations such as important competitions. We have specifically quantified the shoulders angle in relation to the horizontal axis.
Athlete 2, international SH2 level, hemiplegic, is a specialist in 10 and 50 meters rifle shooting. As part of his practice, the athlete is disabled by dystonia of the finger flexors of the hand which allows the rifle to be held on the gallows. This dystonia presents at random during the pre-shot aiming, making the athlete apprehensive with each shot. We specifically quantified the range of the area of the polygon formed by the fingers of the hand.
RESULTS: Regarding athlete 1, we observe an increase in the angle of the shoulders (13 ° vs 18 °) which is explained by the lowering of the shoulder by 4cm (133 vs 129cm from the ground). At the shooting performance, we see an improvement: 88 points versus 82, 38 versus 34.6 mm for the stability of aiming.
Regarding athlete 2, we observe a decrease in the opening of the hand (6.1% versus 1.4%). In terms of shooting performance, we do not observe any changes in the 104 score versus 102 points, but a decrease in the stability of aiming 15.5 versus 9.2 mm. This decrease is explained by a less unstable trace due to the barrel movement suppression by the involuntary contraction of the fingers.
CONCLUSION: These two multimodal analyses (ie. the combination of anesthetic block, movement analysis, Scatt analysis and performance results) highlight the relevance of a common reflection involving the technical staff, the athlete, and the medical staff. The management of disability-related underperformance factors requires that the medical staff appropriates the performance criteria of each sport in regard to its regulatory constraints.

### PATIENTS WITH LOWER-LIMB COMPLEX REGIONAL PAIN SYNDROME RELY LESS ON PROPRIOCEPTIVE INFORMATION TO CONTROL UPRIGHT STANDING COMPARED WITH HEALTHY ADULTS

MOURAUX, D., BARBANCHON, C., BAUDRY, S.

*UNIVERSITÉ LIBRE DE BRUXELLES, RESEARCH UNIT IN APPLIED NEUROPHYSIOLOGY (LAB NEURO), FACULTY OF MOTRICITY SCIENCE (FSM)*

INTRODUCTION: Previous work reported proprioceptive impairment for patients with unilateral Complex Regional Pain Syndrome (CRPS) affecting the lower limb (1). A decrease in leg proprioception can lead to decrease the contribution of proprioception on balance control, and therefore alter postural control (2). The objective of the present study was to determine whether lower-limb CRPS decreases the reliance on proprioceptive information to control balance in upright standing.
METHODS: The displacement of the centre of pressure (CoP) was measured from a force platform during 40-s epochs in 10 patients suffering from lower-limb CRPS (49±13 yr), and 10 age- and sex-matched healthy individuals (controls). Participants maintained upright standing with eyes open (EO) and closed (EC) before and after 30 min of bilateral Achilles tendon vibration (1-mm amplitude, 80Hz frequency) in a seated position. To probe the efficacy of the vibration to alter the proprioceptive pathway (3), the maximal amplitude of the Hoffmann H-reflex (Hmax) and M wave (Mmax) were recorded in in the soleus muscle in a seated position. A maximal voluntary isometric contraction (MVC) of the ankle plantar flexor muscles of the injured leg for the CRPS group and the left one for control group was recorded with the participants seated in an ergometer.
RESULTS: The MVC torque in ankle plantar flexor was lower in the CRPS patients than in controls (72 Nm vs.114 Nm, -37%, p=0.035) and unchanged after vibration. Before vibration, CRPS patients exhibited greater CoP path length than controls in EC only (360 mm vs. 233 mm, p=0.047). CoP path length did not change after vibration in patients (360mm to 342mm, -5%, p=0.922) but increased for controls in EC condition only (233mm to 280mm, +20.5%, p=0.037). The vibration-related decrease in Hmax/Mmax ratio was similar in both groups.
CONCLUSION: The lesser postural effect of vibration in CRPS patients on balance control suggest a decreased reliance on proprioception to control balance in patients (3). In addition to the decrease in the strength of the plantar flexors, this may contribute to alter postural control in patients, especially in the absence of visual information.

### QUADRICEPS AND HAMSTRING STRENGTH PREDICTORS OF REACTIVE BOUNDING COEFFICIENT IN SPRINTERS

WASHIF, J.A.

*NATIONAL SPORTS INSTITUTE OF MALAYSIA*

INTRODUCTION: Reactive strength involves exerting force in minimal time and is often referred to as plyometrics (e.g., drop jump and bounding exercises), which is inherent in sprinting development. Recently, reactive bounding coefficient (RBC) was utilised as a measure of horizontal reactive strength to evaluate stretch-shortening cycle performance in sprinters (Washif and Kok, 2020). The relation between maximum strength (prerequisite in many sport skills) and horizontal reactive strength has not been examined. Therefore, this study investigated the relationship between maximum strength and RBC10 (10 bounds). Additionally, the relationship between RBC10 and sprint performance was computed.
METHODS: Fifteen sprinters (9 men, 6 women; 21±4 years; World Athletics score: 1009±78 points) participated in the study at the beginning of their preparation training period. One repetition-maximum (1RM) was assessed during power clean and back squat exercises (day 1), while peak force was recorded during bilateral isometric prone (0°) hamstring and Nordic (eccentric) hamstring curl exercises (day 2).

The greatest force measure (average of left and right legs) of three maximal repetitions was used for analysis. Relative measure of each exercise was determined by dividing the highest weight lifted or peak force recorded with own body mass. Sprint performance was assessed in the 60m sprint from a block start, with split times at 10m and 30m, and 20-30m and 30-60m segments were recorded (day 3). All athletes were healthy, and familiarised with testing protocols as part of their previous tests and training. Pearson's product-moment correlation (r) was used to determine the relationships between variables, and interpreted as follows: small (0.10-0.29), moderate (0.30-0.49), large (0.50-0.69), very large (0.70-0.89), nearly perfect (0.90-0.99), and perfect (1.00).
RESULTS: Very large correlation was observed between relative 1RM power clean and RBC10 (r=0.71, p=0.003). Relative 1RM back squats also appear to be largely correlated with RBC10 (r=0.60, p=0.019). Absolute values for 1RM power clean (r=0.49, p=0.06) and back squat (r=0.46, p=0.089) showed moderate correlations with RBC10. Large correlation was observed between RBC10 and the absolute (r=0.58, p=0.023) and relative (r=0.66, p=0.008) values of Nordic hamstring curls. On the other hand, 'weaker' correlations were observed in absolute (r=0.50, p=0.06) and relative (r=0.36, p=0.188) values of isometric prone hamstring exercise with RBC10. Correlations coefficient between RBC10 and sprint performance ranged from -0.62 (large) to -0.72 (very large), p<0.05.
CONCLUSION: The outcomes of the study support the importance of developing maximal strength of the knee extensor and flexor muscles to enhance speed-bounding performance. Coaches and strength and conditioning professionals are advised to appropriately (e.g., eccentric exercise for hamstrings) and sufficiently integrate maximal strength training in the annual plan in order to improve horizontal 'specific-strength' quality (i.e., speed-bounding) to subsequently enhance sprint performance.

**RESISTANCE TRAINING VERSUS PLYOMETRIC TRAINING FOR IMPROVING RUNNING ECONOMY AND RUNNING TIME TRIAL PERFORMANCE: A SYSTEMATIC REVIEW AND META-ANALYSES**

EIHARA, Y., TAKAO, K., SUGIYAMA, T., MAEO, S., TERADA, M., KANEHISA, H., ISAKA, T.

*RITSUMEIKAN UNIVERSITY*

INTRODUCTION: Running economy has a critical role in long-distance running performance. Mounting studies have adopted resistance training and plyometric training as an adjunct to endurance running training to improve running economy and running time trial performance. For long distance runners, however, it is unclear which of the two training modalities is more effective in improving running economy and the performance of run-time trials. Therefore, the present systematic review and meta-analysis aimed 1) to determine if there are different effects of resistance training vs. plyometric training as an adjunct to distance running training on running economy and running time trial performance in long-distance runners; and 2) to elucidate the effective training variables to improve these outcomes.
METHODS: Electronic databases were searched on the PubMed, Web of Science, and SPORTDiscus databases with a variety of key words relating to strength training, running economy, and long-distance running performance. Twenty-two studies fully satisfied the inclusion and exclusion criteria. Data on running economy and running time trial performance were extracted for the meta-analyses. Subgroup analyses were performed using a random-effects model with the following potential moderators: 1) based on maximal oxygen uptake; 2) age; and 3) intervention period. In addition, the studies conducting resistance training were categorized with 4) training modality (isometric or dynamic); and 5) training intensity.
RESULTS: Resistance training had a beneficial effect on running economy, and the magnitude of beneficial effect of resistance training were greater than that of plyometric training (Hedges' g = -0.29, 95% CIs [-0.45, -0.13] and g = -0.12 [-0.52, 0.27], respectively). The effect on running time trial performance was also larger in resistance training (g = -0.28 [-0.74, 0.19]) than in plyometric training (g = -0.15 [-0.43, 0.13]). Subgroup analyses indicated that resistance training over a longer duration of more than 10 weeks enhanced the magnitude of the effect size (g = -0.50 [-0.81, -0.18]). Additionally, heavy-loads (≧ 90% 1RM or ≦ 4RM) resistance training improved running economy regardless of the runners' age and training duration.
CONCLUSION: The major findings obtained from the current review were that resistance training exhibited greater improvement in running economy and running time trial performance compared with plyometric training. Subgroup analysis indicated that resistance training over 10 weeks or longer had a moderately beneficial effect on running economy, and that with heavy loads produced greater improvement in running economy regardless of the age of the runner and training duration. These results suggest that as an adjunct to endurance running training, resistance training over 10 weeks or longer and with heavy load will be more effective in improvomg running economy and running time trial performance as compared to plyometric training.

INTRODUCTION: Over the last two decades, research in sport and exercise science has shown that placebo effects can have a major impact on athletic performance. Most of these studies, however, have concentrated on the benefits of ergogenic aids. Currently, we know very little about the potential placebo effect when investigating different training configurations (e.g., exercise selection, loading, volume, frequency). Hence, we aimed to investigate whether a placebo effect is present when participants are told they get "optimal training", compared to being told they get generic "control training".
METHODS: A total of 40 athletes (male: n=31, female: n=9) completed a 10-week training intervention (age: 22±4 years, height: 183±10 cm, and body mass: 84±15 kg). Measurements included countermovement jump (CMJ), 20-meter sprint, one-repetition maximum (1RM) back-squat, a leg-press test, ultrasonography of muscle-thickness, and a questionnaire regarding expectations of the training intervention. The subjects were randomized to different training programs, with slight variation in exercises and loading schemes. To administer the placebo treatment, the participants were either told that the training program they got was individualized based on their force-velocity profile, or that they were in the control group. Meaning, on average, both groups consisted of subjects doing the same workouts, but half of them believed they did optimal individualized training (Placebo), and the other half believed they were the control group with non-optimal training (Control).
RESULTS: Placebo increased 1RM squat more than Control (Effect size [ES]: 0.88±0.76, Bayes Factor: 5.1 [BF10], p<0.05). Additionally, Placebo increased muscle-thickness compared to baseline (ES: 0.73±72, BF10: 3.0, p=0.06), whereas there were no change from baseline in

Control (ES: -0.04, BF10: 0.3, p=0.89). Placebo had slightly higher adherence (placebo: 82±18% control: 72±13%, difference: BF10: 2.0, p=0.08). Importantly, the group difference in 1RM squat was still significant after controlling for the differences in adherence (p<0.05). On average, both groups reported similar levels of expectations towards the interventions (Placebo: 5.6±0.7 Control: 5.9±1.1 [Median & quartiles]), However, the expectations were not normally distributed in Control, where the subjects in the lower quartile of Control had lower expectations towards the training intervention compared to Placebo (r=0.72 [rank-biserial coefficient of correlation], p<0.05). No significant differences between groups were observed in CMJ, 20-m sprints, or leg press power.
CONCLUSION: To the author's knowledge, this is the first training study investigating the placebo effect in response to subjects believing they get optimal training configurations vs a generic training program. The results suggest that the placebo effect may explain meaningful outcome variances in sports and exercise training interventions. More research is needed to understand the potential mediators and moderators.

**THE EFFECTS OF ACUTE SLEEP DEPRIVATION ON H-REFLEX AND V-WAVE**

GONÇALVES, A., TEODÓSIO, C., PEZARAT-CORREIA, P., VILA-CHÃ, C., MENDONÇA, G.

*UNIVERSIDADE DE LISBOA FACULDADE DE MOTRICIDADE HUMANA*

INTRODUCTION: The impact of sleep deprivation on muscular strength and power remains poorly understood. In healthy individuals, it has been suggested that the negative impact of sleep deprivation on muscle strength is aetiologically linked to disturbed neural function (1). A reduction in voluntary activation was in fact observed for knee extension exercise (using the interpolated twitch technique, ITT) following ~30 (2) and 24 hr of sleep deprivation (3). Nonetheless, the ITT cannot differentiate between supraspinal and spinal adaptations and this is an importante limitation because muscle activation depends both on the excitability of descending supraspinal pathways and spinal motoneurons (MN) (4). The mechanisms underlying neural changes to specific experimental interventions can be investigated by measuring reflex responses, namely the H-reflex and V-wave (5). The H-reflex is more sensitive to changes in presynaptic inhibition and/or motoneuron excitability and the V-wave is more sensitive to modifications in supraspinal input to the MN pool. We aimed to determine the acute effects of 24 hr of sleep deprivation on H-reflex and V-wave excitability.
METHODS: Fourteen healthy young adults (eight men, six women) were included. Participants visited the laboratory on two different occasions, without and with 24 hr of sleep deprivation. In each session, participants were tested for maximal voluntary contraction (MVC) of the plantar flexors and dorsiflexors, soleus H- and M-recruitment curves (6), and evoked V wave (7), as well as tibialis anterior/ soleus electromyographic co-activation.
RESULTS: Twenty-four hours of sleep deprivation did not affect either plantarflexion MVC or soleus electromyographic normalized amplitude ($p > .05$). Moreover, H-reflex and V-wave peak-to-peak normalized amplitude did not change with sleep deprivation ($p > .05$). Conversely, we obtained a significant increase in antagonist/agonist level of co-activation during MVC post-sleep deprivation ($6.2 \pm 5.2\%$, $p < .01$).
CONCLUSION: In conclusion, we found that H-reflex and V-wave responses are well preserved after 24 hr of sleep deprivation, revealing that descending neural drive and/or modulation in Ia afferent input remains largely unaffected under these circumstances. Yet, sleep deprivation affects motor control by exacerbating the magnitude of antagonist/agonist co-activation during forceful muscle contractions and this is novel.

**ACUTE EFFECTS OF BODY-WEIGHT SQUATS VARIATIONS ON HEART RATE, ACCELERATIONS, AND PERCEPTUAL RESPONSES**

TEIXEIRA, A.1, AMARAL, A.1, MACHADO, I.1,2, SANTARÉM, D.1, CASTRO, P.1, SAMPAIO, J.1,2, ABRANTES, C.1,2

*1 UNIVERSITY OF TRÁS-OS-MONTES E ALTO DOURO, VILA REAL, PORTUGAL; 2 RESEARCH CENTER IN SPORTS SCIENCES, HEALTH SCIENCES AND HUMAN DEVELOPMENT , VILA REAL, PORTUGAL*

INTRODUCTION: The variations in organismic and task constraints related to performing the squat exercise promote different kinematic, cardiovascular, and perceived exertions (RPE). This exploratory study aimed to compare the body acceleration, heart rate (HR), and RPE responses to performing six squat variations.
METHODS: Eight healthy adults (age 26.9±2.8 yr, body mass 74.7±7.8 kg, height 174.9±0.1 cm) were submitted to a familiarisation session, and all completed in a random order six squats for 90 sec interspersed to 5-min rest (cadence: 40-60 bpm). The squat variations were deep (shoulder wide/ dynamic/ 110º), jump (shoulder width/ 90º/ dynamic), wall-sit (shoulder width/ 90º/ isometric), uneven (shoulder wide/ 90º/ dynamic), single-leg (shoulder width/ 110º/ dynamic) and unstable (shoulder width/ 90º/ dynamic in terra-core platform). An inertial measurement unit (Blue Trident sensor, Vicon, NZ) was attached to the lumbar region [1] to capture body acceleration data generated in the anterior-posterior, medio-lateral, and vertical directions, and further used to determine the root mean squares [2]. The HR was measured using a Garmin HRM3-SS (USA) monitor strapped on mid-sternum and RPE using the Borg scale (6-20). Data were analysed using a repeated-measures ANOVA
RESULTS: Jump squat exhibited highest values of HRmean and HRlast 30 sec (143.3±19.0 bpm and 159.7±19.8 bpm, respectively), with differences been identified between jump and others, except for single-leg (HRmean = $F [5,35] = 2.904$, $p=0.027$, $\eta 2 = 0.293$, and HRlast 30 sec = $F [5,30] = 3.834$, $p=0.008$, $\eta 2=0.390$). These differences were also identified for the RPE ($0.001 \leq p \leq 0.032$). The values of mean resultant acceleration ranged from 9.78 to 10.75 m. s-2 (wall-sit CONCLUSION: Jump squat recorded higher mean values for all variables analysed. HR values as a cardiovascular variable, from lower to higher, match the general RPE (except for isometric squat) suggesting a relationship between these variables. Our current findings help to reinforce evidence-based decisions regarding the complex process of exercise prescription, by understanding better the organic responses to different constraints.

**PRESCRIBING INTENSITY IN RESISTANCE TRAINING USING RATING OF PERCEIVED EFFORT: A RANDOMIZED CONTROLLED TRIAL**

BOXMAN-ZEEVI, Y.1,2, SCHWARTZ, H.1,2, HAR-NIR, I.1,2, BORDO, N.3, HALPERIN, I.1,2

*TEL AVIV UNIVERSITY SACKLER FACULTY OF MEDICINE*

INTRODUCTION: Rating of perceived effort (RPE) scales are used to prescribe intensity in resistance training (RT) in several ways. For instance, trainees can reach a specific RPE value by modifying the number of repetitions, lifted loads, or other training variables. Given the multiple approaches of prescribing intensity using RPE and its growing popularity, we sought to compare the effects of two RPE prescription approaches on adherence rates, body composition, performance and psychological outcomes, in an online RT intervention.
METHODS: We randomly assigned 57 healthy participants without RT experience (60% females, age range: 18-45) to one of two groups that received two weekly RT sessions using a resistance-band for eight weeks. In the fixed-repetition group, participants adjusted the band resistance with the goal of completing 10 repetitions and reaching a 7-RPE on a 0-10 scale by the 10th repetition. In the open-repetition group, participants selected their preferred band resistance and completed repetitions until reaching a 7-RPE by the final repetition. We measured body composition, performance tests, and program satisfaction rates.
RESULTS: We assessed 46 participants at post-test, 24 from the fixed-repetition and 22 from the open-repetition groups. We observed non-significant and trivial differences between groups in all outcomes ($p>.05$). We then combined the pre-post change scores of the two groups. We found that adherence rates began at 89% and gradually decreased to 42%. On average, participants increased their fat-free mass [0.3 kg (95% CI: 0.1-0.6)], isometric mid-thigh pull [5.5 kg (95% CI: 0.8-10.4)], isometric knee-extension [2.2 kg (95% CI: 0.8-3.7)], and push-ups [6.3 repetitions (95% CI: 4.5-8.2)]. We observed non-significant and trivial changes in bodyweight, grip-force, and countermovement jump. Participants reported high satisfaction rates with all components of the program.
CONCLUSION: Participants in both groups improved their body composition and physical capacity to a similar extent, and reported comparable satisfaction rates with the programs they followed. Accordingly, either prescription approach can be used to deliver online RT sessions based on personal preferences and logistical constraints. However, since adherences rates declined over the course of the study, future research should test additional strategies aiming to maintain adherence rates.

**FAMILIARIZATION AND LEARNING EFFECT IN ISOKINETIC STRENGTH ASSESSMENT OF KNEE MUSCLE ACTION AMONG MALE CIRCUMPUBERTAL ADOLESCENTS**

COSTA, D.1,2,5, VALENTE-DOS-SANTOS, J.2,3, SOUSA-E-SILVA, P.1,2, MARTINHO, D.1,2, DUARTE, J.1,2, OLIVEIRA, T.2, GONÇALVES, R.S.4, TAVARES, O.4, CASTANHEIRA, J.2,4, COURTEIX, D.5, COELHO-E-SILVA, M.1,2

INTRODUCTION: Assessment of muscle strength has a large spectrum of applications in sport science. Isokinetic dynamometry is considered a valid protocol to assess knee muscle strength. When multiple repetitions are completed at a short interval, participants may evidence improvements in strength performance. This phenomenon is known as learning effect. Indeed, the number of repetitions to obtain peak torque values is not consistent in the literature. Taking into account the preceding, the current study was aimed to examine the learning effect during a 5-repetition isokinetic strength protocol composed of reciprocal actions of knee extensors (KE) and knee flexors (KF) separately for concentric (cc) and eccentric (ecc) contractions among male adolescent swimmers aged 11-12 years.
METHODS: The study was approved by the Ethics Committee (CE/FCDEF-UC/00182016). The sample was composed of 38 male swimmers aged 10.06-13.26 years. Isokinetic strength of the preferred lower limb was done using Biodex System 3 (Shirley, NY, USA) adopting an angular velocity of 60 °.s-1. The protocol started with three reciprocal concentric contractions of KE and KF for familiarization. After a 60-s interval, 5 reciprocal maximal concentric (cc) contractions were performed. Then, participants rested for 60 s and the sequence was repeated for the eccentric (ecc) contractions. Each participant completed 20 isokinetic curves for analysis (KEcc: 5, KFcc: 5, KFecc:5, KEecc:5) using Acknowledge (version 4.1, Biopac Systems, Inc.). the previous allowed the extraction of peak torque (PT).
RESULTS: The gradient for PT values was, on average, KEecc (91.0 N.m) > KEcc (67.8N.m) > KFecc (61.2 N.m) > KFcc (41.7 N.m). Intraclass correlation coefficients (ICC) tended to be smaller than 80%: KEcc (ICC=0.754), KEecc (ICC=0.724), KFcc (ICC=0.580), KFecc (0.716). The percentages of participants attaining their best score in the earliest two repetitions were less than half for the concentric contractions (KEcc: 44.7%; KFcc: 44.7%). The fifth isokinetic curve retained for analysis as the best score was as follows: KEcc (n=7), KEecc (n=1), KFcc (n=9), KFecc (n=3).
CONCLUSION: A 5-repetition protocol to assess isokinetic knee muscle actions at the angular velocity of 600.s-1 is characterized by a substantial intra-individual variation in circumpubertal swimmers. As expected, the highest PT value was not obtained in the first repetition suggesting a learning effect. In fact, the best performance was distributed over the five repetitions for both KE and KF independently of the contractions. The preceding claims for refinements in the warm-up protocol, number of repetitions for familiarization and probably an additional number of repetitions in the assessment per se (from five to six). Future study needs to examine technical error of measurement, %CV and ICC and intra-individual mean differences from PT obtained in two time-moments one week apart.

**SPORT ROCK CLIMBERS PRESENT GREATER FORCE VALUES AND SIMILAR FATIGUE DYNAMICS THAN NON-CLIMBERS IN AN ALL-OUT CRITICAL FORCE TEST**

FERRER-URIS, B., BESLIJA, F., DURDURAN, T., BUSQUETS, A.

*INSTITUT NACIONAL DEDUCACIÓ FÍSICA DE CATALUNYA , UNIVERSITAT DE BARCELONA , BARCELONA, SPAIN*

INTRODUCTION: Rock climbing requires repeated fatiguing actions from the finger flexors when progressing through a sport route. All-out critical force (CF) testing has been successfully used to assess climbers resistance to fatigue [1]. Previous evidence explored the CF and energy store component (W') parameters as indicators of the aerobic isometric work threshold and anaerobic isometric work capacity, and positively related them to climbing performance [1]. The aim of our study was to explore the force fatigue dynamics of the finger flexors during an all-out CF test while comparing climbers and non-climbers.

METHODS: Twnety advanced-to-elite climbers [2] and 16 non-climbers were recruited. A flat wooden climbing hold (20 mm deep) attached to a force gauge was used to test finger flexors all-out CF using a half-crimp grip. The all-out CF test comprised 30 maximum contractions with a work:rest ratio of 7:3 s. The filtered data (Butterworth low-pass filter, 4th order, 10 Hz cut-off frequency) from the 5 central seconds of each contraction were used to compute the contraction mean value. The mean force values were fitted with an exponential regression model and then, a bi-segmental lineal regression model was used to characterize a fast fatigue phase and a slow fatigue phase. The following variables were computed: (1) maximum mean isometric force value (MIF ); (2) the CF level as the mean of the last 6 contractions; (3) the W' as the integral above CF; (4) slopes of the fast (slope1) and (5) the slow (slope2) fatigue phases defined by the two regression lines ; and (6) the x-coordinate (repetition number, Xint) and (7) y-coordinate (Fint) of the intersection between the two regression lines. All variables except Xint were expressed as % of body weight (BW) . T-tests or U-Mann Whitney were used to test differences between climbers and non-climbers. Level of significance was set at alpha = 0.05
RESULTS: Although climbers showed significant slight differences in BW% force decrements during slope1 (2.0%) and slope2 (0.6%) than non-climbers (1.4% and 0.2%), it seems that dynamic of force-fatigue followed similar trends . On the other hand, climbers presented significant greater BW % MIF, CF, W', and Fint than non-climbers. At the same time, climbers showed a slightly latter Xint than non-climbers.
CONCLUSION: These results evidenced that sport-related adaptations allow climbers to exert greater maximum isometric forces and maintain greater forces under fatiguing conditions. The greater initial force found and the similar fatigue trend between groups causes climbers to present greater force at the end of the test (CF), larger anaerobic work capacity (W'), and a greater force value when the force depletion slows down (Fint). Characterizing slope1, slope2, and Fint along with the CF value and W', could provide further insight in climbing training-related adaptations.

## EFFECTS OF BODY-WEIGHT SQUATS VARIATIONS (ANGLES, STANCE, SURFACE, AND TYPE OF CONTRACTION) ON MUSCLE SATURATIONS AND LOCAL PERCEIVED EFFORT

AMARAL, A.1, TEIXEIRA, A.1, MACHADO, I.1,2, SANTARÉM, D.1, SAMPAIO, J.1,2, ABRANTES, C.1,2

*1 UNIVERSITY OF TRÁS-OS-MONTES E ALTO DOURO, VILA REAL, PORTUGAL; 2 RESEARCH CENTER IN SPORTS SCIENCES, HEALTH SCIENCES AND HUMAN DEVELOPMENT*

INTRODUCTION: Assessment of muscle oxygen saturation (SmO2) during exercise provides information related to local blood flow and muscular oxygenation [1]. The effects of organismic and task constraints related to body-weight squat exercise on SmO2 are still unknown. This study aimed to compare the SmO2 of the vastus lateralis (VL) and soleus (SL) muscles and local perceived exertion (RPE) during six squat variations.
METHODS: Eight healthy adults participated in this study (age 26.9±2.8 yr; body mass 74.7±7.8 kg; height 174±7 cm; BMI: 24.8±3.1 kg/m2; VL skinfold=14.2±4.8 mm; SL skinfold=12.7±3.3 mm). After a familiarisation session, participants completed in a random order 6 six squats for 90 sec interspersed to 5-min rest (cadence ranged between 40-60 bpm). The squat variations were Deep (shoulder width/ dynamic/ 110º), Jump (shoulder width/ 90º/ jump), Wall-Sit (shoulder width/ 90º/ isometric), Uneven (shoulder wide/ 90º/ dynamic), Pistol (shoulder width/ 110º/ dynamic) and Unstable (shoulder width/ 90º/ dynamic in terra-core platform). The SmO2 was measured in percentage (%) using four MOXY monitors (Fortiori Design, Hutchinson, USA) in VL and SL of both legs. Local RPE (Borg 6-20) was collected immediately after each variation [2].
RESULTS: Repeated measures ANOVA revealed differences in local RPE between exercise variations ($p<0.05$). A higher local RPE was reported during Jump and Wall squats (18.6±0.9 and 16.8±3.2, respectively). No changes in mean SmO2 were identified on right VL ($F[5.30]=1.572$, $p=0.198$, $\eta2=0.208$), neither on left VL ($F[5.35]=1.778$, $p=0.143$, $\eta2=0.203$,). Differences in right SL mean SmO2 ($F[5.30]=2.548$, $p=0.049$, $\eta2=0.298$) were seen in Deep vs Pistol. Left SL ($F[5.30]=5.026$, $p=0.002$, $\eta2=0.456$) showed significant differences ($p<0.05$) in Jump (42.77%) vs Deep (65,59%), Jump vs Uneven (67.24%) and Jump vs Pistol (65.59%); Unstable (54.54%) vs Uneven, Unstable vs Wall (65.11%); Unstable vs Pistol and Unstable vs Deep; Deep vs Pistol. No differences were identified in Uneven vs Deep, Wall vs Pistol; Jump vs Unstable. In the last 30 sec of exercise, no differences were found in right SL ($F[5.25]=2.388$, $p=0.067$, $\eta2=0.323$). In turn, in the left SL ($F[5.25]=5.411$, $p=0.002$, $\eta2=0.520$) SmO2 was lower in Unstable (49.87%) compared to Deep (60.97%), to Uneven (67.38%) and to Wall (58.22%) as in Jump (30.61%) compared to Uneven and Wall; Wall was lower than Deep.
CONCLUSION: Lower SmO2 both in VL and SL, during Jump as well higher RPE, shows higher physiological stress during this body-weight squat variation. Further studies are needed to better understand the variation effects on specific muscles.

## MUSCLE PROPERTIES DURING RAPID WEIGHT LOSING IN A PROFESSIONAL BOXER: A CASE STUDY

HIRONO, T., HOLOBAR, A., UEDA, S., MITA, Y., WATANABE, K.

*CHUKYO UNIVERSITY*

INTRODUCTION: It is important for combat athletes to understand effects of rapid changes of body weight on muscular functions. The purpose of this case study was to investigate time-course changes in muscle strength, muscle size and neural input during rapid weight losing in a professional boxer.
METHODS: One professional men boxer (26 years old) participated in two matches during measurements, welter weight (66.6kg; WW) and super welter weight (69.85kg; SWW). He needed to lose weight substantially for WW and slightly for SWW. The measurement was performed at 6 week (baseline), 3 week (Pre3wk), 2 week (Pre2wk), 1 week (Pre1wk) and 0 week (Pre0wk) before and 1 week (Post1wk) after the matches. Body composition was measured using a bioelectrical impedance spectroscopy. Maximal voluntary isometric knee extension torque was measured using a dynamometer. Cross sectional area of vastus lateralis muscle (mCSA) were evaluated using an ultrasonography. High density surface electromyography on vastus lateralis was also recorded during submaximal isometric contraction based on the

maximal strength at baseline (MVC-base) and individual motor units were identified. Motor units discharge rate was evaluated at 60-70% MVC-base during 70% MVC-base ramp-up task.
RESULTS: His baseline body weights were 70.80 kg and 71.42 kg for matches of WW and SWW, respectively. At Pre0wk, his body weight decreased to 68.75 and 71.36 kg at WW and SWW, respectively. For WW match, skeletal muscle mass and mCSA were decreased a lot from baseline to the match (36.1 to 35.8 kg and 21.1 to 20.3 cm2, respectively). On the other hand, for SWW match, skeletal muscle mass and muscle cross sectional did not decrease a lot (36.4 to 36.5 kg and 23.2 to 22.7 cm2, respectively). The number of detected motor units was 15.7±5.2 at each section. As for recruitment threshold of motor units, two-way ANOVA revealed no interaction. As for motor unit discharge rate, two-way ANOVA revealed a significant interaction between condition (WW vs SWW) and time. Post-hoc tests indicated that discharge rate in WW was significantly greater at Pre0wk (16.2±2.7 pps) than at baseline (13.5±1.6 pps), Pre3wk (12.6±2.0 pps), Pre2wk (13.3±2.1 pps) and Post1wk (13.8±2.9 pps), but not change in SWW. A correlation coefficient between motor unit discharge rate and body weight at 6 time points in WW was -0.951.
CONCLUSION: Skeletal muscle mass decreased but motor units discharge rate increased as body weight losing. It is suggested that an excitability as neural input to muscle is activated as body weight losing and muscle mass decrease to maintain the muscle strength. When considering the effects of rapid body weight losing, we should keep in mind that not only body compositions but also neural factor is adapted.

#### BASIC PSYCHOLOGICAL NEED FRUSTRATION IN GRASSROOTS YOUTH SOCCER: A MIXED-METHODS STUDY OF INTRA- AND INTERPERSONAL FACTORS

ESPESETH, V.S., JOHANSEN, B.T., SERSLAND, A., TØRRE, M., SOLSTAD, B.E.

*UNIVERSITY OF AGDER*

INTRODUCTION: Previous research has emphasized that if we are to understand the behavior of adolescents in sports, we must look at both factors in- and outside the sport context, as this can affect how young people behave toward each other in the socialization process. Additionally, studies have shown that the unique socialization processes offered by sport participation might influence adolescents' mental health negatively, thereby triggering basic psychological needs frustration. Thus, the purpose of this mixed-methods study was to investigate psychosocial factors assumed to have an influence on basic needs frustration in grassroots youth soccer.
METHODS: Young players (n=588, M.age=15.7 years; SD= ±1.4) between 14-19 years of age playing for teams in Agder county were recruited to this study. The participants completed a questionnaire including intra- and interpersonal factors. Classification and Regression Tree (CRT) analyses were used to analyze the quantitative data. CRT is referred to as the most appropriate method for analyzing complex data sets. Moreover, as part of this study, 15 girls and 11 boys participated in focus group interviews (n=6). The participants were interviewed with regards to social interactions in their teams. Thematic analysis was used to analyze the qualitative data.
RESULTS: We performed four CRT analyses (i.e., an analysis for each basic need as well as an overall analysis of the three basic needs). The results from analysis 1-2 showed that psychosomatic symptoms were strongly related to autonomy and competence frustration. The group who reported higher levels of symptoms (20% of the participants >20,000; n=120) reported a higher level of autonomy and competence frustration. In analysis 1, the results showed that those reporting high levels of psychosomatic symptoms (>20,000) reported a higher level (>1,400) of being ignored (53% of the participants; n=64). In analysis 3, perceiving to be ignored was the main explanatory variable of relatedness frustration (47% of the participants; n=282). Looking at the overall basic need frustration, analysis 4 showed that perceiving to be ignored was the main explanatory variable. Other important factors in the CRT analysis were giving autonomy support to teammates and participants' emotional stability. The qualitative findings confirmed the quantitative findings with respect to social interactions, and indicated that conflicts, inequalities, and social thriving were key factors in explaining social interactions between teammates. The qualitative findings also showed that some adolescents chose to quit playing soccer due to relatedness frustration, in connection to passive exclusionary behavior.
CONCLUSION: Our findings indicated that there were positive associations between psychosocial factors and young soccer players' basic psychological needs frustration. Indeed, frustration of the three psychological needs were mainly related to psychosomatic symptoms and perceiving to be ignored.

#### CHARACTERISTICS OF THE TEAM TEACHING SYSTEM IN PHYSICAL EDUCATION CLASSES IN JUNIOR HIGH SCHOOL SPECIAL SUPPORT CLASSES: FROM VISUALIZATION DATA OF TEACHERS AND STUDENTS' VERBAL RELATIONSHIPS

AKANE, H.1, YU, A.2, YUTO, K.1, TOSHIHIRO, N.3

*1: GRADUATE SCHOOL OF HOKKAIDO UNIVERSITY OF EDUCATION, 2: GRADUATE SCHOOL OF EDUCATION, HOKKAIDO UNIVERSITY, 3: HOKKAIDO UNIVERSITY OF EDUCATION SAPPORO*

INTRODUCTION: In special needs education in Japan, it is important to give the most accurate guidance to students who have individual educational needs. Therefore, as a mechanism for providing diverse and flexible guidance, team teaching has been introduced. Even in previous research, individualized guidance is important for team teaching in special education, and for that purpose, the ability of teachers to be involved in individual student's tasks is necessary even in group activities. Especially in physical education classes conducted in special support education, coaching by team teaching is common. However, how the team teaching in the special support education so far is done, each teachers it is not clear how they interact with students. The purpose of this study is to clarify the current situation of team teaching for physical education classes in the special support class of junior high school using visualization data of the state of cooperation between the primary teachers and sub teachers, the state between the teachers and students.
METHODS: 19 junior high school students (14 boys, 5 girls) belonging to a junior high school special support class, 2 primary teachers (PT) and 5 sub teachers (ST), a total of 7 people were targeted. The survey period covers a total of 5 hours of physical education classes conducted from early July to mid-August 2021. All the target classes were conducted by team teaching.

As a state index of the team teaching, the state of cooperation between PT and ST, the state between teachers and students were collected with a business microscope of Hitachi, Ltd, and the state of communication was analyzed at. business microscope can measure verbal communications by body movements. In addition, the contents of the teachers utterances were collected by a voice recorder and analyzed by text mining.
Results and Discussion:
As a result of the state of communication, PT and ST or ST and ST, in all the target lessons, communicated with different groups and individuals. Furthermore, there was a state of one-on-one communication. The result was the same in a class in which multiple STs participated. The result of the teachers utterances revealed that the PTs and the STs commonly used the word "Kun"(in Japanese, the honorific title that is mainly used for a man) for the students.
In team teaching in physical education classes in junior high school special support classes, the PTs and the STs each communicated with different students, suggesting that they had division of roles. In addition, the fact that they had many verbal relationships with individuals suggests that the teachers were aware of each students needs and provided individualized support and guidance during group activities in physical education classes.

**INCLUSIVE PHYSICAL EDUCATION ACCORDING TO ECOLOGICAL DYNAMICS APPROACH: THE SAT MODEL**

D'ANNA, C., COPPOLA, S., ROMANO, B., FORTE, P., VASTOLA, R.

*UNIVERSITY OF PEGASO, UNIVERSITY OF SALERNO, UNIVERSITY OF MOLISE*

Improving the quality of teaching-learning process is a key aspect for the implementation of effective learning environments able to respond to multiple educational needs.
This study aims to highlights the principles of the Systemic Approach to Teaching in Physical Education, a model to educational planning according to inclusive perspective. The theoretical model and design criteria of SATinPE is at definition stage; in the next three years a longitudinal training-research will be carry out to test the theoretical model and to define the tools.
The perspective from which this model is born, shifts the focus from the technical-performance results to processes oriented to knowledge, skills and competences. According to this perspective, in the awareness that any behavior or action directed towards a goal is the product of self-organization emerging from an interaction between constraints, at the center of the model there is individual-task-environment triad. In an integrated and at the same time systemic vision, in the class group, every individual and, therefore, every individual triad, interconnects with other individualities many complex adaptive systems interact with each other, inducing in adaptations and behavioral readjustments. For this reason, the conceptual framework of SATinPE, to complete the triad, reports a double extension of the elements to be taken into consideration in the design. A first circle highlights the principles of Chows non-linear pedagogy: representative learning design, information- perception couplings, manipulation of constraints, functional variability, external focus of attention; a second circle, from an inclusive perspective highlights the seven key points of inclusive education adapted to physical education: peer learning, adaptation of tasks, extension of proposals / exploration and discovery, emotional-motivation aspects, cognitive processes, metacognition, feedback and results.
The above design variables have been the subject of study and analysis; however, as highlighted, the variables influence each other, sometimes resulting in unpredictable and unexpected educational repercussions. The systemic approach arises from this awareness with the aim of understanding how to exploit the educational effectiveness of these complex and dynamic interconnections in a functional way.

**COMMUNICATION ANALYSIS WITH WEARABLE ACCELERATION SENSOR CONTRIBUTED TO FOR PHYSICAL EDUCATION IN JAPAN.**

MAGOME, T.

*OSAKA UNIVERSITY GRADUATE SCHOOL OF MEDICINE*

[Introduction]
Currently, analysis is being conducted using science and technology in the field of education. Among them, there are contents that must be evaluated and fed back to daily educational activities. It is physical education. Physical education is closely related to future sports activities. The role of sports is important for extending a healthy lifespan. [1] In addition, it makes sense to reduce the risk of injury during exercise to support a healthy life. [2] It is even more important to objectively evaluate these contents and make them understood by the teachers and students. In this study, we focused on communication in physical education. This is because communication skills are also an even more important aspect of future education.
[Methods]
Teacher and children attached the acceleration sensors of the 100Hz sampling to their chest and the momentum in physical education and skill training was estimated. The measurements with wearable acceleration sensor were performed for five weeks. We examined from the collected data, physical activity level of class (teacher and children) and communication level.
[Results]
In two groups divided according to the high or low of physical activity and communication level, there was a significant difference in the feature quantity (change in communications) in the volley ball motion obtained from the two types of training and playing data during the class ($p<0.05$). As a result of further detailed analysis, we were able to classify communication into two typical types. And we could derive the features on the receiving side and the talking side in the discussion activity. In this way, it became possible to analyze the level of communication and the amount and content of conversation, and it was possible to suggest the possibility of using it in classes.
[Discussion & Conclusion]
We succeeded in performance analysis of children and class statement in the game and skill trainings. Although the individual's movement had been focused on until now, the analysis of the group movement must become important because using communication would be demanded recent years. Regarding this point, it is useful that the present system for analyzing the communication level in real time can

connect a model of the future's education. In addition, it may lead to improved lessons. It also objectively shows what kind of physical activity is appropriate. Controlling the thoughts and movements of children and teachers by quantifying performance and communication using the developed method contributes to the development of education.

## EFFECTS OF THE PUPILS CONSCIOUSNESS ABOUT THEIR CLASSROOM ON PHYSICAL ACTIVITY OF PHYSICAL EDUCATION CLASS IN ELEMENTARY SCHOOL

ASANO, Y.1, KAWAMOTO, T.2, MURAKAMI, M.3, NAKAJIMA, T.4
*HOKKAIDO UNIVERSITY1, SAPPORO ELEMENTARY SCHOOL ATTACHED TO HOKKAIDO UNIVERSITY OF EDUCATION2, SAPPORO FUSHIMI ELEMENTARY SCHOOL3, HOKKAIDO UNIVERSITY OF EDUCATION SAPPORO4*

Effects of The Pupils Consciousness about Their Classroom on Physical Activity of Physical Education Class in Elementary School
Introduction
In physical education classes in Japan, pupils often learn as a group by interacting with others, and therefore, the pupils consciousness about their classroom has been considered important. For this reason, the relationship between the pupils consciousness about their classroom and physical education class has been examined in many studies. However, until now, there has been no study of the pupils consciousness about their classroom based on specific data of pupils in physical education classes. The purpose of this study is to clarify the effects of the pupils consciousness about their classroom on physical activity of physical education class in elementary school.
Methods
The subjects of the study were 61 pupils (31 boys and 30 girls), enrolled in two schools in Sapporo. The target classes were tag rugby (a minimal contact version of Rugby), volleyball, high jump, and basketball. We measured the amount of pupils physical activity with physical activity meters (OMRON HJA-750C Active style Pro). We also measured pupils consciousness about their classroom using the scale of consciousness about classroom consisting of 16 questions. The results of the analysis were categorized into two groups: high consciousness group and low consciousness group, based on the median values of group consciousness. The amount of physical activity was analyzed using two-way ANOVA.
Results
In tag rugby, the high consciousness group was significantly more active than the low consciousness group in the first period. In volleyball, the high consciousness group tended to be significantly more active than the low consciousness group in the first and fourth periods. In high jump and basketball, there were no significant differences between the high consciousness group and the low consciousness group at any time.
Discussion
The significant differences in the first period of tag rugby and volleyball may be related to the pupils attitudes toward physical education classes. Based on previous studies, the higher the pupils consciousness about their classroom, the more positive the attitude toward exercise. Therefore, it can be inferred that the high consciousness group was more active than the low consciousness group in the first period of the unit in which the trial game was set. The results for high jump and basketball may be due to the content of the learning activities. For example, in high jump, the number of times the pupils engaged was standardized, which may explain why there were no significant differences between the high consciousness group and the low consciousness group.
In summary, this study suggests that the pupils consciousness about their classroom influences the amount of physical activity during the beginning of a unit in physical education classes.

## HOW DO TEACHERS ASSESS LEARNING PREREQUISITES FOR AQUATIC EDUCATION IN LEARN-TO-SWIM PROCESSES?

FOKKEN, I., STAUB, I., VOGT, T.
*GERMAN SPORT UNIVERSITY COLOGNE*

INTRODUCTION
In order to select appropriate methods for swimming lessons, the swim-specific (motor) prerequisites of the learners must be diagnosed at a teaching series' beginning of swimming lessons. This implies a high level of diagnostic competence of teachers [1]. While the majority of studies assess diagnostic competence on the basis of the accuracy of teachers judgements [2], there's little research on how teachers compose their diagnostics. Therefore, this research addresses the question of how teachers proceed in the diagnostic process and which diagnostic tools are used to get to an assessment in swimming lessons. This study forms the basis for the implementation and evaluation of a diagnostic tool to determine swim-specific prerequisites of children in primary and secondary schools.
METHODS
(1) Qualitative, structured interviews were conducted with German teachers from different backgrounds (n=10; 80% female; aged 45.7 ±18,6%; years of professional experience 16.25 ±56,9%). The interviews were transcribed, double-coded and categorically analysed. (2) The hypotheses derived were then tested in a larger-scale quantitative online study (n=596).
RESULTS
(1) It was found that the teachers diagnostic approach is highly individualised. Different diagnostic occasions and survey instruments are chosen, which differ from each other in terms of quality criteria and usability. The predominant method used is movement observation, which is mostly carried out without or on the basis of self-assembled criteria and is only partially recorded in writing. Some teachers state that they rely mainly on their "gut instinct" when dividing the group into non-swimmers and swimmers, for example. Interviewees also state that no standardised procedure is used among their colleges. (2) The evaluation of the quantitative examination of these statements has not yet been completed at this stage.
CONCLUSION
Although the teachers surveyed in the first part of the study consider themselves to be in a position to assess the learning prerequisites of their learners with the procedures they have chosen, the majority of them expresses the need for a scientifically sound procedure for diagnostics in swimming. The findings of the subsequent quantitative online survey are hypothesised to support these identified needs. Furthermore, factors influencing the diagnostic approach, e.g. professional experience and qualification level, are to be examined in a more in-depth analysis.

## AN ANALYSIS OF THE REPRESENTATION OF A LEARN-TO-SWIM PROCESS IN CHILDREN'S BOOKS: A TRANSFER OF KNOWLEDGE TO SOCIETY?

VOGEL, M., STAUB, I., VOGT, T.
*GERMAN SPORT UNIVERSITY COLOGNE*

INTRODUCTION: Learn-to-swim is a present theme in childhood that many children's books address as milestone. With this, the genre of children's books may be seen as a transfer of knowledge to society [1]. However, the focus of learn-to-swim skills mediated may differ within books, forming the rationale of evaluating to what extent water competencies [2] are addressed in children's books. Thus, this study investigates which essential water competencies are most frequently and which are least addressed in children's books themed learn-to-swim. The aim is to investigate to what extent children's books can provide a realistic representation about the process of learn-to-swim.
METHODS: To systematically search for respective children's books, elements of the PRISMA statement [3] were used. The books were found via databases and websites (e.g. The British Library, Simon & Schuster) by means of a keyword search (including e.g. swim, learn-to-swim) and selected according to predefined inclusion criteria (e.g. British, last 20 years). After screening a total number of 625 books, 11 books were identified eligible for the analysis in this study.
RESULTS: Swimming on front, back or side was most addressed in the books (91%), followed by breath control competence (82%). The safe entry and coping with risk competence both were displayed in 64% of the books. The least addressed competencies were swimming with clothes, knowing one's own ability as well as recognizing and assisting a drowning person, each addressed in one book only (9%). Three of the overall 15 water competencies were not addressed at all (i.e. orientation competence, use of personal flotation device and knowledge of local hazards competence).
CONCLUSION: In general, the sample of books analysed does not adequately address all the essential competencies, although they are equally important in terms of a learn-to-swim process with respect to water safety [2]. The missing or least addressed competencies are as if less significant and, thus, create a distorted representation of their importance. That swimming on front, back and side was most addressed, emphasizes that swimming mostly is associated with propulsion. However, research has shown that safe behaviour in, on and around the water also requires cognitive and affective skills, such as saving others or assessing one's own ability [2], which are not covered at all. Further studies in need may add a focus regarding parent's expectations on what should be taught and learned for swimming.

## MANUAL GUIDANCE IN GYMNASTICS: APPROACHING DETERMINANTS FOR THE APPLICATION BY PHYSICAL EDUCATION TEACHERS

ROHLEDER, J., RAATZ, J., VOGT, T.
*GERMAN SPORT UNIVERSITY COLOGNE*

INTRODUCTION: In gymnastics, the manual guidance of movements is of utter importance to ensure safety within motor learning processes. Physical Education (PE) teachers are required to master this technical expertise to assist movement execution and, moreover, enable students to perform this complex task mutually. Considering the associated responsibility PE teachers take in gymnastics, the question occurs to what extend teachers are able to meet this challenge. Thus, the present study aims to reveal determinants for the application of manual guidance taking theoretical expertise and practical experience into account, hypothesising both aspects to be related to problems regarding an application in gymnastics.
METHODS: A questionnaire-based design served to address PE teachers from different school types in North Rhine-Westphalia (i.e., primary and secondary schools). Literature- and interview-based category coding identified the variables theoretical expertise and practical experience, serving a predefinition of items and creation of rating-scale tasks. Subsequent to a pre-test including qualified and trainee teachers (N=3) of different experience and expertise levels (e.g., great and low gymnastics-related affinity) in order to validate the items' suitability, the optimised questionnaire was used for data collection over three weeks (soscisurvey.de). A total of 80 qualified PE teachers and trainee teachers (female: n=39; male: n=41) completed or participated at least in parts in the questionnaire. Data processing including descriptive statistics, correlations and regression analyses was performed using SPSS (version 27.0).
RESULTS: Descriptive statistics revealed an assessed score of 4.54±0.88 for theoretical expertise (ranging from 1=layperson to 6=expert). Further, theoretical expertise and problems with manual guidance correlated ($r[64]=.57$, $p<.01$; $R2 =.33$, $p<.01$). In addition, descriptive statistics revealed an assessed score of 2.28±0.70 for practical experience within the last year (ranging from 1=never to 6=daily). Further, practical experience and problems with manual guidance correlated ($r[65] =.55$, $p<.01$; $R2 =.30$, $p<.01$).
DISCUSSION:
In line with the initial hypotheses, the present study's findings confirm reasoning that problems regarding an application of manual guidance in gymnastics may be related to theoretical expertise and practical experience. In noticing linking problems, detailed analyses considering beneficial effects of coach-related compared to sport active-related experiences suggest this to reflect possible deficits of PE teacher studies at universities (i.e., the ratio of experiences in the students' vs. the prospective teachers' role) as well as lacking continuing education for PE teachers in schools. Taking pandemic-related impacts into account, however, the findings give rise to consequently research-driven teaching concepts in order to counteract PE teachers' reservations when teaching gymnastics in school.

## PRESCHOOLERS, PARENTS AND PONIES – MILITARY TRADITIONS CHALLENGES BY PEDAGOGICAL PLAY AT SWEDISH AND NORWEGIAN RIDING SCHOOLS

THORELL PALMQUIST, G.

*THE SWEDISH NATIONAL EQUESTRIAN CENTRE / SPORT SCIENCE*

Introduction
Participation in sports has grown stronger among younger children (preschoolers). Even in riding school activities, the age limit has dropped and the previously usual seven-year limit to start riding has disappeared (Thorell et al 2016). Riding lessons have been criticized for being outdated as they are still characterized by military traditions and culture (Lundesjö Kvart, 2020). Pedagogy has now been given more space in riding school education, but there is a lack of knowledge about how this has been adapted for younger children (Rosén et al, 2021).
Aim and theoretical framework
The aim of this study is to analyze riding teachers' perceptions and experience of teaching preschool children at riding schools from a sociocultural perspective. Learning at riding schools can be characterized as a process that involves preschool children and their parents being included in a culture. Through a sociocultural perspective, the riding teachers' shape the learning environment based on the culture and the prerequisites that exist at the riding school.
Methods
In-depth interviews with 11 professional riding teachers' from Sweden and Norway have been conducted. Qualitative content analysis was used.
Results
The riding school activities for preschool children focus on basics in riding and horse knowledge. Parents are also expected to learn and participate actively as assistants. The teaching is based on the traditional education system for riding school activities, but the riding teachers' feel it is difficult to apply due to the younger childrens physical and social development. Therefore, they instead create new methods with more focus on play pedagogy and balance exercises. There are also several challenging factors to deal with. Parents expectations and different levels of knowledge, as well as safety in relation to the ponies, are common challenges based on the riding teachers experiences.
Discussion and Conclusion
From the riding teachers perspective, the learning environment emerges as an interplay between them and the preschoolers - parents - ponies and through interaction and communication, experience and knowledge are formed. It can be seen as central to the learning process and to the learning environment created within the framework of the institutional community of practice. The traditional riding lessons are challenged as teaching preschool children at riding schools requires a different form of pedagogy. Being adaptable, flexible and creative is a prerequisite for creating a developing and safe learning environment for preschool children. Skills that the riding teachers' feel they have developed through experience and not primarily acquired through previous education.

## TOWARDS RACISM-CRITICAL TEACHING COMPETENCE IN PHYSICAL EDUCATION: A CONCEPTUAL APPROACH AND PRELIMINARY RESULTS

ABEL, L., VOGT, T.

*GERMAN SPORTS UNIVERSITY COLOGNE*

Introduction
Racism is an expression of social power relations and discrimination patterns based on them [1]. These patterns exist in all areas of our society, including school-based Physical Education (PE). Therefore, the aim of this conceptual approach is to contribute to a development of teaching competences with respect to mediating racism-critical PE.
According to the initial stages of this project, findings from the first of four consecutive project phases, including participatory-reflexive evaluations, will be highlighted.
Methodology
Based on 1) a systematic literature review (i.e., elements of the PRISMA statement) aiming to categorize the contexts of racism-critical PE, 2) a qualitative and 3) a quantitative survey aiming to illuminate e.g. experiences and requirements of pupils, students, and teachers in the contexts of racism-critical PE will be conducted prior to 4) aiming to develop knowledge-based professional qualification programs for PE teachers in schools and PE teacher studies at universities.
Results
Within the systematic literature review promising international qualitative and quantitative surveys as well as theoretical reflections were found. Subsequent to exclusion (e.g. English or German language; peer-reviewed publication; PE or PE study-related), this review included a total of 64 racism-critical publications. 97% of the publications were international, while 3% had a national (German) focus. Within the 64 publications 34% had a conceptual, theoretical approach, 56% were using qualitative methods, 3% were quantitative papers and 5% used a mixed-methods approach. Furthermore, considerable differences in the approach and quality of the papers were identified. Perspectives of teachers from schools and universities, students and PE studies from various age groups were found.
Discussion
In general, it appears that there are few large-scale quantitative surveys devoted to the topic of racism-critical PE, whereas there are promising quantitative and theoretical approaches. Despite the historical responsibility of Germany to act racism-critically, publications are rather lacking. Although there is an established empirically supported German discourse on intercultural education in sports, this field only includes the racism dimension of culture. Other racism dimensions such as religion or biological characteristics have not yet been considered. Thus, the findings of this systematic literature review legitimise the urgent need to follow the project phases two to four.
All in all, the overall project wishes to make a (small) contribution to a racism-free society, which is no longer characterized by the structural discrimination of minorities. We are confident that a transparent presentation of this conceptual approach will lead to a constructive critical discourse.

#### LACTATE INGESTION PROMOTES BRAIN NEUROGENESIS IN MICE, AS LIKE EXERCISE TRAINING

HWANG, D., KIM, J., LIM, K.

*KONKUK UNIVERSITY*

INTRODUCTION: Adult hippocampal neurogenesis plays an important role in learning and memory. Therefore, promoting of the AHN is required to prevent or ameliorate the cognitive deficits. Lactate, known as just byproduct of glycolysis and primary factor of fatigue when exercise, is highlighting as a promising signaling molecule that regulates the exercise-induced adult hippocampal neurogenesis. Therefore, we hypothesized that exercise with lactate intake can augment the exercise-induced adult hippocampal neurogenesis.
METHODS: Six-week-old male ICR mice were randomly divided into four group (n = 8 per group): sedentary vehicle (VEH), sedentary with lactate intake (LAC), exercise vehicle (EXE+VEH), and exercise with lactate intake (EXE+LAC). Lactate intake groups were orally administrated 3g/kg of sodium lactate and mild-intensity exercise was conducted 5 times per week for 5 weeks. At the last week of experiment, cognitive function (spatial working memory) was evaluated by Y-maze spontaneous alternation test. After the experiment ended, neurogenesis (Ki67, neural stem cell proliferation marker; DCX, marker of differentiation to immature neurons) and the relevant factors (FNDC5, BDNF, PGC1α VEGFA, HCAR1, and MCT1/2) were evaluated respectively by immunohistochemistry (IHC) and by Western blot (WB) on hippocampus.
RESULTS: The number of Ki67+ cells of LAC tended to increase compared to that of VEH and the number of DCX+ cells of LAC significantly increased compared to VEH. However, there was no difference between EXE+VEH and EXE+LAC in the number of Ki67+ and DCX+ cells. Therefore, these results indicate that the mild exercise with lactate intake did not augment exercise-induced AHN although the mild exercise and lactate promoted the adult hippocampal neurogenesis respectively. The number of arms entered did not differ among all groups. Nevertheless, the alternation of EXE+LAC was significantly higher than that of EXE+VEH and LAC. There was no difference between VEH and LAC or EXE+VEH. As a result, the performance of spontaneous alternation behavior was solely promoted by the exercise with lactate intake. Notably, the hippocampal FNDC5 protein expression of EXE+LAC was significantly enhanced compared to that of EXE+VEH and the hippocampal BDNF, PGC1α, and MCT2 protein expression of EXE+LAC was higher than that of EXE+VEH by 20, 9, and 19 % respectively. Therefore, these results indicate that the mild exercise with lactate is likely to be more beneficial on promoting the relevant proteins to the exercise-induced AHN.
CONCLUSION: The study revealed the potential that the mild exercise with oral intake of lactate can be noteworthy strategy for augmenting the beneficial effects of exercise on
hippocampus.

#### GLUCOSE INGESTION BEFORE AND AFTER RESISTANCE TRAINING DOES NOT AUGMENT RIBOSOME BIOGENESIS IN YOUNG MODERATELY TRAINED ADULTS

LIAN, K., MOEN, S.C., HAMMARSTRØM, D., ELLEFSEN, S.

*INLAND NORWAY UNIVERSITY LILLEHAMMER*

INTRODUCTION: Responses to resistance training (RT) are not uniform across the population, and individuals responding poorly to RT show a blunted ability to produce novel ribosomes. Recent research further strengthens the relationship between increased rates of total RNA, a proxy marker of ribosome biogenesis, and the magnitude of RT-induced adaptations, with ribosome abundance being associated with UBF protein levels. As a response to RT, total RNA increases robustly following 8 sessions of RT, then reaches a plateau. However, 10-15% of individuals undertaking a period of RT have previously shown considerable impaired growth, with blunted accumulation of total RNA coinciding with poor adaptations to RT. Despite RT volume being a potent tool to increase beneficial RT-induced adaptations, tweaking RT modalities alone do not convert such low-responders to high-responders. Thus, other means than RT _per se_ is necessary to circumvent this discrepancy. High glucose treatment has been observed to augment rDNA transcription _in vitro_, however, its effect on RT-induced adaptations in humans remains quite unexplored.
METHODS: Sixteen healthy moderately trained participants were included and randomized to having one leg perform unilateral resistance training with glucose supplement (16) and the other with placebo (16), alternating training every other day. Participants remained overnight fasted, only receiving glucose/placebo and protein until after completion of the daily intervention. Resistance training consisted of 3 sets of 10 repetitions maximum unilateral leg press and knee extension. Micro biopsies were sampled pre (T1/T2) and post (T3/T4) the intervention, and maximal unilateral isometric and isokinetic knee extension force and torque were measured pre (T0), during (days 4, 5, 8, 9) and post (T3/T4, day 13) intervention.
RESULTS: Despite robust increases in total RNA accumulation in glucose and placebo (26 and 22%, respectively), there were no differences between supplements ($p = 0.499$). This was also evident in the expression of mature rRNA in both glucose and placebo (34-43 and 33-41%, respectively, $p > 0.05$). Further, there were no differences between supplements in maximal unilateral isometric knee extension force and isokinetic peak torque during the intervention ($p > 0.05$) and following the last session ($p > 0.05$), apart from the 60 d/s test before last RT session ($p < 0.05$).
CONCLUSION: There were no differences in glucose- compared to placebo supplement ingestion before and after five RT sessions in muscle biology markers measured as total RNA and rRNA, or markers of muscle functionality such as muscle recovery, total session volume, and training intensity in moderately trained young adults. Based on these findings, glucose supplement before and after RT does not augment RT-induced ribosome biogenesis compared to placebo supplement, nor does it affect peak torque during a five-session RT intervention, or enhance muscular recovery following a single session of RT.

## EFFECT OF LEUCINE-ENRICHED AMINO ACID SUPPLEMENTATION ON FAT METABOLISM FOLLOWING A SINGLE BOUT OF ENDURANCE EXERCISE

LIN, C., HAYASHI, N., GOTO, K.

*RITSUMEIKAN UNIVERSITY*

INTRODUCTION: Amino acid supplementations are widely accepted as a nutritional supplement among athletes and people involved in moderate physical activities (1). Branched-chain amino acid supplementations (BCAAs), which consist of leucine, isoleucine, and valine, are oxidized and used for energy production during exercise. BCAAs delay exercise-induced fatigue and enhance fat oxidation during exercise in glycogen-depleted subjects (2). Fat metabolism can be evaluated using blood variables (e.g., plasma free fatty acid, serum total ketone body and glycerol concentrations). Additionally, attention to the breath acetone level is growing to evaluate exercise-induced fat oxidation (3). However, little has been reported on the time-course changes in serum ketone body and breath acetone after endurance exercise following short-term amino acid supplementation. Therefore, the present study aimed to investigate the effects of leucine-enriched essential amino acid (LEAA) supplementation on post-exercise fat metabolism.
METHODS: Six active healthy males (22.3 ± 1.9 years, 173.7 ± 3.4 cm, 65.8 ± 12.6 kg) completed both LEAA trial and placebo trial on different days, with a randomized, double-blind, crossover design. Participants received either LEAA supplements (AA; 4.0g/time) or placebo (PLA; maltodextrin 4.0g/time), 3 times a day (every morning, at 3 pm, before bedtime) for 5 consecutive days (days 1-5), separated by at least 21-day washout period. During the days 3-5 of supplementation period, standard meals were provided. On day 6, they performed 60 min of treadmill running at 70% of maximal oxygen consumption (VO2max), followed by a 3-h rest period. Venous blood and breath samples were collected before, immediately, 1h, 2h (breath sample only) and 3 h after exercise. Serum total ketone bodies (i.e., acetone, 3-hydroxybutyric acid) and breath acetone level were evaluated to assess fat metabolism during 3h post-exercise.
RESULTS: Breath acetone level (p=0.029), serum acetone (p=0.043), 3-hydroxybutyric acid (p=0.049) concentrations increased significantly in both trials after exercise compared with baseline and immediately after exercise. However, these responses did not differ significantly between trials.
CONCLUSION: Relative changes in each variable ranged from 180% to 2562% for serum total ketone body, 124% to 759% for breath acetone level. This may be caused by individual difference in fat oxidation capacity or exercise-induced endocrine (e.g., catecholamine, growth hormone) responses. In conclusion, our results suggested that 5-days LEAA supplementation did not affect either serum ketone body concentrations or breath acetone levels following a single bout of endurance exercise in active healthy males.

## INFLUENCE OF TETRASOD® SUPPLEMENTATION ON EXERCISE-INDUCED OXIDATIVE STRESS AND SEVERE-INTENSITY EXERCISE TOLERANCE IN HEALTHY ADULTS

COCKSEDGE, S.P., MARTIN, N.R.W., FERGUSON, R.A., BISHOP, N., UNAMUNZAGA, C., INFANTE, C., BAILEY, S.J.

*LOUGHBOROUGH UNIVERSITY*

INTRODUCTION: Oral consumption of antioxidants has the potential to mitigate exercise-induced oxidative stress and improve performance [1]. TetraSOD® is a natural marine product derived from the microalgae, tetraselmis chuii, which has been reported to confer antioxidant effects via increased gene expression of NRF2 and HMOX1, and increased gene expression and enzyme activities of SOD, GPx and CAT, in a skeletal muscle cell line [2]. The purpose of this study was to assess the potential of TetraSOD® supplementation to improve antioxidant markers in human blood and primary muscle cells and severe exercise tolerance (Tlim) in healthy adults.
METHODS: Fifteen healthy, recreationally-active, males (mean ± SD, age: 24 ± 4 years, peak pulmonary oxygen uptake (V̇O2peak): 48 ± 5 ml.kg-1.min-1) ingested a daily capsule for 2-weeks in a double-blind, randomised, crossover experimental design. At least 1-week of 'washout' separated each experimental condition. Capsules contained either 25 mg (TetraSOD®25) or 75 mg (TetraSOD®75) TetraSOD® with hemicellulose crystalline as an excipient, or hemicellulose crystalline only as a placebo (PLA). After separate ramp incremental and familiarisation cycling visits, participants completed step tests to an individualised severe-intensity work rate (70%Δ) for the determination of Tlim and V̇O2 responses on days 0, 7 and 14 of supplementation. A sub-set of five participants provided a single, un-supplemented, vastus lateralis muscle biopsy for the subsequent culture of primary myoblasts and treatment with TetraSOD®. Data were analysed using two-way repeated-measures ANOVAs with statistical significance taken as $p < 0.05$.
RESULTS: Compared to baseline, Tlim was significantly greater after 14 days TetraSOD®25 supplementation (Day 0: 411 ± 82 vs. Day 14: 480 ± 124 s; $p < 0.05$), and after 7 (Day 0: 415 ± 113 vs. Day 7: 465 ± 137 s; $p < 0.05$) and 14 (504 ± 182 s; $p < 0.05$) days TetraSOD®75 supplementation. Tlim was unaffected by PLA supplementation ($p > 0.05$). V̇O2 at exhaustion was significantly greater after 14 days TetraSOD®25 supplementation (3.49 %; $p < 0.05$), but not after 14 days TetraSOD®75 or PLA supplementation ($p > 0.05$). Preliminary gene expression analyses, in leukocyte RNA isolates, revealed no change in NRF2, HMOX1, SOD, GPx or CAT ($p > 0.05$). However, IL-10, a potent anti-inflammatory cytokine, was significantly greater from Day 7 to Day 14 of TetraSOD®25 supplementation (36.81 %; $p < 0.05$).
CONCLUSION: Two weeks of TetraSOD® supplementation improved Tlim, V̇O2 at exhaustion and IL-10 gene expression in RNA isolated from leukocytes. These findings suggest an ergogenic effect of TetraSOD® supplementation and that this effect may be linked to an anti-inflammatory response.

## INVESTIGATING THE SYNERGISTIC EFFECTS OF DIETARY NITRATE AND RESVERATROL SUPPLEMENTATION ON PERIPHERAL TISSUE MITOCHONDRIAL BIOENERGETICS

HANDY, R.M., DESORMEAUX, G.J., BARBEAU, P.A., FRANGOS, S.M., HOLLOWAY, G.P.

*UNIVERSITY OF GUELPH*

INTRODUCTION: Supplementation with dietary nitrate (NIT) and resveratrol (RSV) independently enrich various aspects of mitochondrial biology in key metabolic tissues. Importantly, these compounds appear to elicit their beneficial effects via different mechanisms of action. While RSV, a potent ligand for sirtuins, initiates mitochondrial biogenesis and modulates substrate oxidation, the short half-life of nitric oxide suggests that the benefits of NIT occur quickly, likely via vasodilatory effects. Given the differing timescale and level of regulation between these compounds, we aimed to determine if supplementation with both RSV and NIT could prevent high-fat diet (HFD) associated metabolic impairments in an additive or synergistic manner.

METHODS: n=80 male C57Bl/6/N mice consumed one of four HFD variations: un-supplemented (HFD; n=20), supplemented with +RSV (172mg RSV/kg diet; n=20), +NIT (4mM sodium nitrate via drinking water; n=20), or +RSV+NIT (n=20) for eight weeks. Characterization of whole-body metabolism was established via calorimetry and intraperitoneal glucose tolerance tests. Following the intervention period, key metabolic tissues (skeletal muscle, liver, epididymal white adipose tissue; eWAT) were permeabilized to determine mitochondrial respiratory capacity, ADP-sensitivity, and $H_2O_2$ emission, or homogenized for analysis of various protein targets. Data are expressed as mean±SD. One-way ANOVA was applied to compare differences between groups, followed by a Fisher's LSD post hoc test where appropriate. Significance was assumed when $p<0.05$.
RESULTS: Within skeletal muscle, all supplements similarly increased mitochondrial ADP-sensitivity ($p<0.05$) compared to HFD, without altering mitochondrial content, respiratory capacity, or $H_2O_2$ emission. Within the liver, supplementation did not alter mitochondrial content or respiratory capacity. However, +RSV+NIT decreased hepatic lipid accumulation ($p<0.05$), in the absence of change with +RSV or +NIT, suggesting an additive effect of these compounds on liver lipid metabolism. Within eWAT, all supplements similarly reduced crown-like structure accumulation ($p<0.0001$) and adipocyte cross-sectional area (CSA; $p<0.005$), with further reductions in CSA observed with +RSV+NIT compared to +RSV. Additionally, while mitochondrial content nor respiratory capacity were altered within eWAT, all supplements reduced mitochondrial $H_2O_2$ emission ($p<0.005$), with a strong trend towards additivity following +RSV+NIT compared to +RSV ($p=0.08$). Despite these differences, +RSV+NIT did not increase whole-body fat oxidation, alter energy expenditure, or improve glucose tolerance beyond what was observed with +RSV or +NIT.
CONCLUSION: Altogether these data indicate that combined +RSV+NIT supplementation elicits additive improvements in markers of lipid/cellular metabolic homeostasis in liver and eWAT. However, these cellular changes are not sufficient to improve whole-body glucose homeostasis beyond what is observed with each compound individually.

### EFFECT OF B-GPA ON MITOCHONDRIAL OXIDATIVE PHOSPHORYLATION AFTER MUSCLE CONTRACTION

FUKAO, N.1, TAKEGAKI, J.1, OKUMURA, K.1, FUJITA, S.1

*[1]RITSUMEIKAN UNIVERSITY*

INTRODUCTION: Creatine exists in skeletal muscle as creatine or phosphocreatine（PCr）. PCr works as an energy substrate in high-intensity exercise. β-guanidinopropionic acid（β-GPA） reduces PCr content in skeletal muscle. β-GPA is a creatine-analog that inhibits creatine transport into cells. When PCr is reduced in skeletal muscle with β-GPA, AMP-activated protein kinase is activated and stimulates mitochondrial oxidative phosphorylation (1). It has been reported that resistance exercise not only increases muscle protein synthesis but also enhances mitochondrial oxidative phosphorylation (2). Therefore, β-GPA may enhance mitochondrial oxidative phosphorylation to resistance training. In the present study, we aimed to determine the effects of β-GPA intake in combination with a resistance exercise model using electrical stimulation on the expression levels of mitochondria-related proteins.
METHODS: 7-weeks old male Sprague Dawley rats (n=2,3 /group) were subjected to a resistance exercise model in which electrical stimulation (100 Hz, 10-30V) was applied to the gastrocnemius muscle. Resistance exercises were performed every 48 hours for the right gastrocnemius (3 sec of maximal isometric contraction 50 times per session) for a total of 12 sessions. During training, the maximal exerted torque (N-m) for each session was recorded. β-GPA (0.3g/kg/day) was dissolved in 1.5 ml dextrose solution (5%) and administrated by sonde for 7days prior to the 1st training session. During training, β-GPA (0.05g/kg/day) was also administered. The same amount of dextrose solution (5%) was administered in placebo group. Muscle samples were removed 48h after the last training session. The left gastrocnemius muscle was used as an internal control. Western blotting was used to measure the expression of proteins involved in mitochondrial oxidative phosphorylation (ATP5A, UQCRC2, MTCO1, SDHB, NDUF8) in each muscle.
RESULTS: Peak torque during electrical stimulation in exercise with β-GPA group was significantly decreased compared with resistance training alone group on 2,8,10, and 11th session（$P<0.05$）. The protein expression levels of ATP5A, UQCRC, and NDUF8 were increased with positive main effect of resistance training and β-GPA respectively ($P<0.05$), but no significant interaction was observed. Only a positive main effect of exercise ($P<0.05$) was observed for MTCO1 expression, and only a positive main effect of β-GPA ($P<0.01$) was observed for SDHB expression.
CONCLUSION: Combining resistance exercise with the ingestion of β-GPA was suggested to result in greater expression of proteins involved in resistance exercise-induced mitochondrial oxidative phosphorylation, although the maximal torque exerted during the training period was reduced.

### HIGH-FRUCTOSE CORN SYRUP CONTRIBUTES TO SYMPTOM DEVELOPMENT OF INSULIN RESISTANCE THROUGH WNT-SFRP5 SIGNALLING PATHWAY: PROTECTIVE EFFECT OF EXERCISE AND VANADIUM-ZINC SUPPLEMENTATION

HAMEDCHAMAN, N.

*MAZANDARAN UNIVERSITY*

INTRODUCTION: There is a close and effective interaction between health status and insulin resistance (IR), due to the High-fructose corn syrup - 55% (HFCS-55) used in daily prepared foods and soft drinks. IR clusters are related to an imbalance in pro-and anti-inflammatory adipokines such as secreted frizzled-related protein 5 (SFRP5) and wingless-type mammary tumor virus integration site family, member 5A (WNT5A). WNT5A induces an inflammatory state to induce insulin resistance and further pathologic consequences. Regarding the non-invasive and anti-inflammatory effects of exercise training and vanadium-zinc supplementation, we aimed to investigate the effects of moderate-intensity continuous training (MICT) with vanadium-zinc supplementation on the modulation of insulin resistance induced by high-fructose corn syrup (HFCS) through Wnt-Sfrp5 signaling pathway.
METHODS: 40 male Wistar rats (aged 4-6 weeks, 100-150 g) were randomly categorized into 5 groups (n = 8/groups), including (NC) Normal Control, (FC) Fructose Control, and (FCT) Fructose Continuous Training, (FS) Fructose Supplement and (FSCT) Fructose Supplement Continuous Training. The training groups implemented the MICT for 8 weeks followed by the 8 weeks of the HFCS-55 (diluted by tap water to 20%) administration as ad-libitum syrup from the beginning. MICT protocol was 12 minutes of running in the first week increasing to 52 minutes in the last week (speed ~ 20 m/min and slope ~ 15°). About 48 hours after the final training session, serum samples were taken to measure the levels of Insulin, Glucose, GPX (Glutathione Peroxidase), TOC (Total Oxidant Capacity), TAC (Total Anti-Oxidant Capacity), MDA (Malondialdehyde), SOD (Superoxide dismutase) WNT5A, and SFRP5 by chemiluminescence technique. Data were analyzed by dependent sample T-test and one-way ANOVA ($P<0.05$).

RESULTS: Regarding the results of one-way ANOVA, the main effect of 8 weeks of MICT significantly decreased the serum levels of insulin resistance (glucose and insulin), MDA, TOC, Wnt, and increased GPX, TAC, SOD, sftrp5 (P<0.05); also the main effect of Vanadium-zinc supplementation was significant only in four variable of TAC (p = 0.001), Wnt (p = 0.002), MDA (p = 0.002) and Sfrp5 (p = 0.001). MICT with Vanadium-zinc supplementation has the greatest effect on increasing anti-inflammatory responses (increased GPX, TAC, SOD, and sftrp5) and reducing inflammatory responses (MDA, TOC, Wnt).
CONCLUSION: Implementation of 8 weeks of MICT combined with Vanadium-Zinc supplementation, more efficiently alleviated insulin resistance and metabolic dysfunctions via antioxidant defenses through Wnt- sftrp5 signaling pathway in IR rats, leading to improving physiological homeostasis and higher adaptation of the biological system.

## TIME COURSE OF TOLERANCE TO THE ERGOGENIC EFFECTS OF A MODERATE DOSE OF CAFFEINE ON BENCH PRESS EXERCISE.

GIRÁLDEZ COSTAS, V., MENCHÉN-RUBIO, M., MORENO-RUIZ, C., JIMÉNEZ-ORMEÑO, E., DEL COSO, J., SALINERO, J.J., LARA, B.

*UNIVERSITY CAMILO JOSE CELA*

INTRODUCTION: Recent evidence suggests that habituation to caffeine through daily ingestion of this substance progressively reduces caffeine's ergogenic properties on endurance-based exercise. However, there is no evidence to determine if tolerance to the ergogenic benefits of caffeine is present during strength exercise. The main goal of this study was to determine the time course of tolerance to the ergogenic effects of 3mg/kg/day of caffeine on bench press exercise.
METHODS: Eight strength trained participants (men = 4; women = 4; 30 ± 7.7 yrs., 63.4 ± 11.4 kg, 169.8 ± 10.7 cm) took part in a double-blind, crossover and randomized experiment. In one phase, participants ingested 3 mg/kg/day of caffeine for 22 days, while in another phase, they ingested a placebo. Participants rested 12 days between phase. Each substance was administered 60 min before the experimental trials, except for day 11 of ingestion where exercise was performed without substance ingestion. Three times per week during each treatment, participants performed two maximal repetitions of the bench press exercise at different loads (30%, 45% 60% 75%, and 90% of 1RM). In each repetition, mean velocity during the concentric phase of the exercise was measured using a GymAware PowerTool (GYM; Kinetic Performance Technologies, Canberra, Australia). Differences between placebo and caffeine in each testing day were obtained compared with paired t tests. The significance level was set at p<0.05.
RESULTS: The effect size of caffeine ranged from 0.1 to 0.4 in the first 10 days of ingestion and it was reduced from -0.1 to 0.2 in the last days of ingestion. In addition, it was observed that the effect size was greater at medium-low loads (30 and 45% 1RM). In comparison to the placebo, the ingestion of caffeine increased mean velocity at 30% 1RM load on days 4, 6, 8, 13, 15 and 18 (p<0.05); at 45% 1RM load on days 1, 8 and 22 (p<0.03); at 60% 1RM load on days 1, 8, 13, 18, 20 and 22 (p<0.05); at 75% 1RM load on days 6 and 13 (p<0.04); and at 90% 1RM load on days 1 and 18 (p<0.04).
CONCLUSION: The daily ingestion of caffeine did not reduce the benefits of this substance on mean velocity during bench press exercise with increasing loads. Therefore, the ergogenic benefits of caffeine still persisted after 22 days of chronic ingestion.

## FLAVANOL-RICH COCOA INTAKE MITIGATES THE COMBINED NEGATIVE IMPACT OF PROLONGED COGNITIVE EFFORT AND EXERCISE ON MENTAL FATIGUE

SUZUKI, A., YONEYA, S., KOYAMA, T., YUUKI, I.W., DORA, K., HASHIMOTO, T., TSUKAMOTO, H.

*RITSUMEIKAN UNIVERSITY*

INTRODUCTION: We previously demonstrated that prolonged cognitive effort may increase the subjective intensity during aerobic exercise, possibly influencing sports performance (e.g., football) (1). Meanwhile, intake of flavanol-rich cocoa has been reported to acutely reduce cognitive load-enhanced mental fatigue (2), but it remains unknown whether high cocoa flavanol (CF; HCF) intake improves the negative impacts of prolonged continuous cognitive effort during aerobic exercise on psychophysiological factors. We aimed to examine the rating of perceived exertion (RPE), moods, and the saliva concentrations of cortisol and sIgA as the psychophysiological markers of mental stress during a 50-min aerobic exercise with cognitive effort after ingestion of HCF or Low CF (LCF).
METHODS: Fifteen healthy young men (aged 22 ± 1 yrs; VO2 peak = 47 ± 4 ml/kg/min) performed two trials [i.e., HCF (500mg) and LCF (50mg)] in a double-blind, randomized-crossover design. Both trials used a 50-min cycling exercise protocol (60% VO2 peak; 152 ± 13 W) and the prolonged cognitive effort was achieved via a 50-min Stroop task. Participants consumed either CF capsules 75-min before such interventions. Before asking RPE (Borg scale), heart rate (HR; HR monitor) was recorded during the first and final 5 minutes of 50 min exercise with cognitive effort in both trials. Moods (mental fatigue, ability to concentrate for Stroop test, motivation for Stroop test, comfort, annoyance, and arousal; visual analog scale) and the saliva cortisol and sIgA concentrations (lateral flow device) were measured before CF intake, before and immediately after exercise with cognitive effort. The data were analyzed by 2-way ANOVA (Trials × Time) when normal distribution was confirmed. If not, the data were analyzed using a Friedman test. If a significant interaction or overall effect was observed, the P-values were adjusted using Bonferroni correction for multiple comparisons using the t-test or Wilcoxon test.
RESULTS: RPE or HR elevated during both trials similarly (i.e., there was no difference between HCF and LCF, both P > 0.05). Nevertheless, the increased mental fatigue was significantly lower in HCF (median 37, IQR 8 to 86) than LCF (median 70; IQR 11 to 85; P < 0.05). The other psychological measurements and the saliva concentrations of cortisol and sIgA were not significantly different between HCF and LCF throughout the experiment (P > 0.05).
CONCLUSION: HCF intake has no effect on RPE, while the elevation of mental fatigue in response to exercise with continuous cognitive effort may be reduced by HCF intake. Probably, cognitive fatigue, but not exercise-induced fatigue, may be reduced by HCF intake given that HCF reduced cognitive effort-enhanced mental fatigue (2). Thus, HCF may be a useful strategy to mitigate cognitive fatigue in sports.

**TRAJECTORIES OF 24-H MOVEMENT GUIDELINES FROM ADOLESCENCE TO ADULTHOOD ON DEPRESSION SYMPTOMS**

GARCÍA HERMOSO, A., EZZATVAR, Y., RAMÍREZ-VÉLEZ, R., IZQUIERDO, M., LÓPEZ-GIL, J.F.

*NAVARRABIOMED*

INTRODUCTION: Previous studies looking at the 24-h movement guidelines and health indicators have primarily focused on physical health outcomes. However, little is known about its relationship to mental health indicators. To our knowledge, the association between 24-h movement guidelines with depression symptoms from adolescence to adulthood has yet to be explored.
Objective: The aim of the study was two-fold: (i) to describe change in participant' movement behavior from adolescence (12-17 years old) to adulthood (33-39 years old); and (ii) to explore the association between change in movement behavior from adolescence to adulthood and depressive symptoms at adulthood.
Study design: We analyzed data from 7,069 individuals who participated in Waves I (1994-1995) and V (2016-2018) of the National Longitudinal Study of Adolescent Health (Add Health) in the United States, a representative sample of US adolescents. Physical activity, screen time, and sleep duration were self-reported in both waves. Adults at Wave V were categorized as having depression if they had self-reported history of depression ("Has a doctor, nurse, or other health care provider ever told you that you have or had depression?") and/or any prescription medication-use for depression in the past 4 weeks. Also, adults were asked in the prior seven days how often experienced the following symptoms using the 5-item depression scale (5-item CES-D): "felt depressed", "felt sad", "felt happy" (reverse coded), "could not shake off the blues", and "felt that life was not worth living". Trajectories of meeting all the three recommendations from adolescence to adulthood were assessed as follows: (i) always meets, which consisted of individuals who met the recommendation at adolescence and adulthood; (ii) increase, which consisted of participants who did not met the recommendation at adolescence but at adulthood; (iii) decrease, which consisted of participants who met the recommendation at adolescence but not at adulthood; and (iv) never meets, which consisted of individuals who did not met the recommendation at adolescence and adulthood.
Results: 21.0% of the sample were diagnosed with depression at adulthood. Overall, 17.6% of the sample met all the three recommendations in both waves. Individuals who met all the three recommendations at adolescence and adulthood had lower odds of depression than those who did never meet recommendations (adjusted Relative Risk=0.46, 95% CI 0.22 to 0.96).
Conclusion: Our findings highlight the importance of promoting and maintaining the adherence to the 24-h movement guidelines from adolescence to adulthood to prevent mental health.

**ROLE OF FITNESS ON THE ASSOCIATIONS BETWEEN SELF-RATED HEALTH AND DEPRESSIVE SYMPTOMS IN ADULTS WITH DIAGNOSED DEPRESSION: SONRIE STUDY**

ORTEGA-GÓMEZ, S.1,2, RUIZ-MUÑOZ, M.1,2, VALMISA, E.3, ESPINOSA-NOGALES, M.M.3, CARBONELL-BAEZA, A.1,2, ESPAÑA-ROMERO, V.1,2

*1 MOVE-IT RESEARCH GROUP, UNIVERSITY OF CÁDIZ - 2 INIBICA RESEARCH UNIT, PUERTA DEL MAR UNIVERSITY HOSPITAL - 3 MENTAL HEALTH CLINICAL MANAGEMENT UNIT, PUERTO REAL UNIVERSITY HOSPITAL, CÁDIZ.*

INTRODUCTION: Depressive symptoms have been shown to be associated with self-rated health (SRH) in healthy adults and those with comorbidities (1,2). Meanwhile, improved physical fitness seems to reduce these depressive symptoms (3). We aimed to study the effect of self-rated health (SRH) as predictor of depressive symptoms. Moreover, we also examined whether any protective effect of SRH on depressive symptoms was mediated by self-reported or objective physical fitness.
METHODS: SRH was assessed in 74 adults (11 males), aged 25 to 65 years and diagnosed with mild to moderate depression, by asking their perceptions of health. Based on their ratings, participants were categorized into 3 groups [(i) excellent/very good and good, (ii) fair and (iii) poor]. Depressive symptoms were collected by the Beck Depression Inventory-II. Fitness was measured by self-reported fitness (SRF) and physical appraisal. SRF was assessed by the International Fitness Scale, and objectively measured fitness by Senior Fitness Test and handgrip test. Multiple linear regression models were used to examine associations between SRH and depressive symptoms.
RESULTS: SRH was positively and independently associated with depressive symptoms after adjustments for sex and age and SRF ($r2=0.31$, $p<0.001$). However, the association between SRH and depressive symptoms did not remain significant when additional adjustment for physical appraisal were applied ($r2=0.12$, $p>0.05$).
CONCLUSION: SRH is an independent predictor of depressive symptoms. However, the protective effect of SRH on depressive symptoms is mediated by objectively measured fitness. Objective evaluation of fitness should be considered as a useful tool to provide additional info in depressive individuals at the clinical setting.

**EFFECT OF EXERCISE INTENSITY ON MEMORY AND PSYCHOLOGICAL WELL-BEING IN YOUNG PEOPLE: INTERACTIONS WITH LACTATE AND BDNF VAL66MET POLYMORPHISM**

BALLESTER-FERRER, J.A., CARBONELL, L., PASTOR, D., CERVELLÓ, E., MOYA-RAMÓN, M.

*MIGUEL HERNANDEZ UNIVERSITY OF ELCHE*

Introduction
Currently, high-intensity interval training (HIIT) is on the rise compared to moderate-intensity (MICT) due to its benefits for health and performance. Recent studies show how physical exercise can also influence cognitive function, although the underlying mechanisms are

not clear. In this way, different explanatory hypotheses have been proposed, ranging from the cellular and molecular level, to other more macroscopic levels, such as brain or behavioural. Our study tried to include components from some of these levels, by comparing the effects of HIIT versus MICT on visuospatial memory, looking at aspects such as psychological well-being, lactate released after each session, and Brain-Derived Neurotrophic Factor (BDNF) genotype.
Methods
Twelve physically active female students participated in this study. The HIIT session, performed on a treadmill, consisted of a 3-min warm-up, four 2-min sets at 90-95% of the maximal aerobic speed (MAS) with 2-min of passive recovery between sets, and a 3-min cool down. The MICT session (60% of the MAS) had the same duration. Saliva samples were obtained from each subject to determine BDNF polymorphism (Kit Oragene, DNAGenotek, Kanata, Canada). Before and after each session we measured visuospatial memory using a digital version of the Corsi test, psychological well-being (questionnaires of affective state and subjective vitality), and blood lactate (Lactate Scout, SensLab GmbH, Leipzig, Germany). RM ANOVA and Pearsons correlation analysis were performed. Significance was set at $p < 0.05$ level.
Results
The results indicated a time and condition interaction effect on visuospatial memory, in favour of HIIT ($p=0.04$; $\eta p2 = 0.33$). Regarding well-being, there were no statistically significant differences between the two situations ($p > 0.05$). The BDNF genotype (Val/Val or met carrier) did not imply differences at the basal level nor in response to exercise. Correlational analysis showed associations ($p < 0.01$; $r = 0.73$) between visuospatial memory and post-exercise lactate release.
Discussion
Our results suggest that HIIT, through lactate mediation, would be an effective strategy against MICT to improve memory in young university students. Moreover, we studied BDNF Val66Met polymorphism as it has been identified as a possible influencing factor in cognitive function. Our findings indicate that memory levels, both at baseline and after exercise sessions, are independent of BDNF Val66Met polymorphism. Finally, we observed that there were no differences in the psychological well-being response between the two study situations of study. In this sense, our results suggest an important role for intensity in improving cognitive function with exercise, regardless of genotype and psychological well-being.

## RELATIONSHIPS BETWEEN WELLBEING AND PHYSICAL ACTIVITY, NATURE RELATEDNESS AND OUTDOOR ENVIRONMENTS IN A REPRESENTATIVE SAMPLE OF SAUDI ADULTS

ALBUJULAYA, N., STEVINSON, C.
*LOUGHBOROUGH UNIVERSITY*

INTRODUCTION: Current government strategy in Saudi Arabia includes a focus on promoting quality of life across the population with one target area being increased physical activity. Growing evidence from other parts of the world suggests that exercising in outdoor natural environments provides added value to the wellbeing and general health benefits of physical activity. This study examined the relationships between wellbeing and physical activity in a Saudi population with specific attention on outdoor exercise environments and nature relatedness.
METHODS: A nationally representative sample of Saudi adults (n = 1018; 61% male; mean age 37.0 ± 11.6) completed an online questionnaire. This included the World Health Organisation-Five Well-Being Index (WHO-5), the International Physical Activity Questionnaire - Short Form (IPAQ-SF), the 6-item Nature Relatedness Scale (NR-6) and two questions on general health and exercise environment. The relationship between wellbeing and physical activity, nature relatedness, outdoor exercise and general health were explored with Spearman's correlations and multiple linear regression analyses.
Results: Wellbeing was positively correlated with overall physical activity (rho = .304, p < .001), general health (rho = .295, p < .001), outdoor exercise (rho = .205, p < .001) and nature relatedness (rho = .329, p < .001). These variables were entered into the multiple linear regression analysis producing a significant model (F (4,839) = 68.396, p < .001) that explained 25% of the variance in wellbeing (R-square of .246). Significant independent contributions to wellbeing were demonstrated for all predictor variables: physical activity levels (beta = 0.177, p < .001), nature relatedness (beta = 0.266, p < .001), general health (beta = 0.240, p < .001) and outdoor exercise (beta = 0.111, p < .001).
Conclusion: The results support the contribution of physical activity to wellbeing in a Saudi population and suggest the added value of exercising outdoors and encouraging connectedness with the natural environment. Providing appropriate outdoor environments for exercise should be one of the government's priorities in the effort to promote physical activity and quality of life.

## LONGER SEDENTARY TIME PREDICTS A LOWER LEVEL OF ENVIRONMENTAL MASTERY AMONG UNIVERSITY STUDENTS IN JAPAN.

MURAKAMI, Y., TSUKAMOTO, H., MURAKAMI, H., YAMAURA, K., HASHIMOTO, T.
*RITSUMEIKAN UNIVERSITY*

Introduction
Health is defined as "a state of complete physical, mental, and social well-being" (1), while Japanese university students and young populations suffer from mental problems such as severe depression (2)(3). It is well known that physical activities (PA) and sedentary behavior are associated with ill-being (e.g., anxiety and depression) (4)(5). Even though some previous studies have suggested the impact of PA for better psychological well-being (PWB) (6)(7), few studies have investigated the relationship between PA levels and PWB, including six aspects of concepts (personal growth, purpose in life, self-acceptance, autonomy, environmental mastery, and positive relationship with others). Given that the aspects of PWB have shown differences in cultural values and meanings, more investigations should be conducted to advance our understanding of these relationships, particularly in Japanese (8). The purpose of the present study was to examine the relationship between PA and PWB among Japanese university students.
Methods
Thirty-one Japanese university students (21 ± 1 yr) took part in an online-based questionnaire survey created by google form. The questionnaire consists of demographic variables (age, sex, grade point average (GPA) score, and major of study), PWB (9), and international physical activity questionnaire (IPAQ). Stepwise regression was used to determine the relationships between total PA (i.e. physical activity and sedentary times) and PWB (i.e. personal growth, purpose in life, self-acceptance, autonomy, environmental mastery, positive relationship with others).
Results

There was no relationship between PA and PWB (the scores of total and in each aspect) ($p > 0.05$). Sedentary time (h/week) significantly predicted environmental mastery in negative direction ($\beta = -0.459$、$p = 0.009$), but there was no relationship between any other variables ($p > 0.05$).
Conclusion
The findings revealed that longer sedentary time predicts a lower level of environmental mastery, which is defined as “the capacity to manage effectively one’s life and surrounding world” (10). Thus, reducing sedentary behavior may have a key role to promote well-being along with minimizing ill-being (i.e. anxiety and depression) (3) among Japanese university students in modern society.

### HRV-BIOFEEDBACK TO OPTIMIZE THE EMOTIONAL STATE IN ATHLETES: BENEFITS OF VISUO-HAPTIC GUIDANCE

BOUNY, P., ARSAC, L.M., GUÉRIN, A., DESCHODT-ARSAC, V.
*UNIVERSITY OF BORDEAUX, IMS LABORATORY, CNRS, UMR 5218*

INTRODUCTION: HRV-biofeedback (HRV-BFB) is used in sports contexts to improve one’s ability to maintain a robust emotional state, whatever the circumstances [1, 2]. It is based on benefits for the brain of synchronizing vagal and sympathetic modulations of the heart rate, which improves power in bottom-up brain stimulation. For that, breathing frequency that drives vagal modulations must be guided to resonate with sympathetic modulations. Yet, the classical 0.1 Hz resonant frequency may slightly vary among individuals. It is unclear to date if achieving a perfect resonance or achieving a perfect guidance provides more benefits. The aim of the study was to evaluate the impact of visual, haptic and visuo-haptic guidance on resonant power during one HRV-BFB session.
METHODS: 53 athletes (20 males) participated to the study. They firstly watched a neutral movie during which baseline HRV, and spontaneous breathing rate (BR) were collected. Then, using a specifically designed object, emitting light and/or vibration, athletes performed a 5-min HRV-BFB session at 0.1 Hz using either visual, haptic, visuo-haptic cues, or no feedback (video). HRV and BR were collected during HRV-BFB. Anxiety and stress were assessed through questionnaires at the beginning and after the experimental procedure.
BR and Power spectral density (PSD) of HRV were obtained at baseline and during HRV-BFB. The frequency at which the highest peak was observed in the classical LF band width (0.04-0.15Hz) was calculated at baseline (F0.1).
To quantify the athlete□s ability to achieve cardiac resonance, for each guidance condition: i) spectral power at 0.1 Hz was computed as a function of total power (P0.1); ii) Refined Composite Multiscale Entropy (RCMSE) of HRV was computed as an index of signal regularity.
RESULTS: Anxiety and stress significantly decreased after HRV-BFB. Resonance was achieved in each guidance condition as indicated by BR not different from 0.1Hz with no difference among guidance condition ($F=0.21$; $p = 0.81$). Yet, a clear distinction was observed both in P0.1 and RCMSE. Post-hoc comparisons highlighted greater P0.1 ($t=2.94$; $p<.01$) and smaller RCMSE ($t=-2.79$; $p<.01$) in visuo-haptic condition when compared to visual alone. By contrast, neither the spontaneous BR nor F0.1 was correlated to P0.1, thus indicating the greater influence of guidance compared to F0.1 in this population of athletes.
CONCLUSION: While both perfect resonance and perfect guidance might help optimize BFB-HRV [3], the present study focused on optimizing the effect of biofeedback in conditions where visual and haptic cues are combined. So, implementation of new techniques of HRV-BFB including haptic cues could be used to reinforce biofeedback effect especially in sports context where emotional state management is a determining factor of performance.

### MORE LOAD LESS HARM? PERCEIVED HARMFULNESS OF DAILY ACTIVITIES IN WEIGHTLIFTERS AND POWERLIFTERS

SYRETT, J., LIEW, B.
*UNIVERSITY OF ESSEX*

Introduction.
Weightlifting (WL) and Powerlifting (PL) are popular strength-based sports, which are associated with large spinal tissue loads (1,2). Low back pain (LBP) is one of the most common disorders incurred by WL and PL (3). Fear of movement has been thought to be a risk factor for the onset and persistence of LBP (4), but this has only been investigated in the general population. Whether similar levels of fear exist in a cohort of athletes who frequently expose themselves to high and repetitive spinal loads is uncertain. In addition, the predictors of fear in people who perform WL and PL are unknown.
Methods.
Fear of movement was quantified using the Photograph Series of Daily Activities Short Electronic Version (PHODA-SeV) (scored from 0 = ‘Not harmful at all’ – 100 = ’Extremely harmful’) in a cohort of 70 WL and PL athletes (Age = 28 ± 8, Mass (kg) = 74 ± 12, Back squat (kg) = 129 ± 49). Pain intensity in the cohort was measured using the Oslo Sports Trauma Research Centre Overuse Injury Questionnaire (OSLO) (5). 13 variables were measured and included in the stepwise regression to predict fear. Independent t-test were used to compare the cohort mean PHODA-SeV score with the mean population score (PHODA-SeV = 40). A stepwise regression model was used to determine the strongest predictors of PHODA-SeV score.
Results.

PHODA-SeV scores were 19.8 (p<.001) lower than the general population score of 40. The top three predictors in the regression model were back squat (β = -.57, p<.001), age (β = -.22, p = .037), and Oslo Q4 (To what extent have you experienced LBP related to your sport in the past 7 days?) (β = 2.0, p <.001).
Discussion.
Athletes who train in WL and PL had lower fear levels compared to the general population. Similar findings have been seen within ACL recoverees (6), where modified PHODA scores were reduced in athlete's ACL recovery group compared to the sham group (6). This would suggest that regular exposure to movements deemed dangerous reduces fear of movement. Our findings were supported by our regression analysis which found greater back squat load was associated with reduced pain score. This supports previous research (6) and the suggestion that with exposure to heavier weights and dangerous movements, WL and PL athletes have reduced fear even when LBP prevalence is high (6).
Our findings suggest that repeated exposure to activities that incur high spinal load may help pain-related fear in a cohort of largely asymptomatic athletes. Whether WL and PL can be used to manage pain-free episodes to reduce risk of LBP remains to be investigated.

## LOWER INTEROCEPTIVE BODY AWARENESS PERFORMANCE IN SOLDIERS WITH HISTORY OF EXERTIONAL HEAT STOKE COMPARED TO SOLDIERS WITHOUT HISTORY

MALGOYRE, A., VERDONK, C., MELLIER, C., CHARLOT, K., TROUSSELARD, M., SAGUI, E., JOUVION, A., TARDO-DINO, P.E.
*INSTITUTE OF BIOMEDICAL MEDICAL RESEARCH FOR FRENCH ARMED FORCES*

INTRODUCTION: Exertional heatstroke (EHS) is the most serious heat illnesses that can occur during physical effort often, but not always, under environmental stress. Despite substantial progress in primary care of EHS, physiopathology is still highly unknown. Besides dysfunction in muscle's metabolism and contractility, or alteration of gut permeability causing inflammation, first intrinsic risk factor declared by 18% of patients is the level of motivation during the trial (Abriat A, et al. Mil Med 2014). Our hypothesis is that EHS might be the consequence of failure in thermoregulatory behavior related to misjudgement of exercise cost-benefit balance. We propose that EHS might result from the overvaluation of benefits, as a consequence of overmotivation to succeed, and/or the undervalued costs of effort exertion that result from low interoceptive body awareness.
METHODS: In a pilot case-control study, we compared different psychological dimensions between soldiers with history of EHS compared to paired soldiers who had experienced similar EHS risk situations. The Multidimensional Assessment of Interoceptive Awareness questionnaire measures eight facets of body awareness. The Global Motivational Scale assesses three types of intrinsic motivation, three types of extrinsic motivation, and amotivation (lack of extrinsic or intrinsic motivation). The Freiburg Mindfulness Inventory measures dispositional trait mindfulness by indexing facets of Presence and Non-judgmental acceptance. Statistical analyses were performed using Mann-Whitney nonparametric tests.
RESULTS: Cases (n=51) and controls (n=43) did not differ for age (27.80 +/- 6.38 vs. 27.30 +/- 6.48), gender (94% vs 93%) and body mass index (24.79 +/- 2.45 vs. 24.65 +/- 2.76). Five dimensions of interoceptive body awareness were significantly lower in cases compared to controls: Body listening (2.37 +/-1.10 vs. 3.05 +/- 1.10, $p \leq 0.01$), Attention regulation (3.05 +/- 0.89 vs.3.55 +/- 0.76, $p \leq 0.01$), Emotional awareness (3.44+/- 0.95 vs. 3.88 +/- 0.81, $p \leq 0.05$,), Self-regulation (2.97 +/- 1.15 vs. 3.50 +/- 0.98, $p \leq 0.05$), and Noticing (3.52 +/- 0.87 vs. 3.88 +/- 0.72, $p \leq 0.05$). Cases and controls did not differ for almost all factors of motivation. Only the factor Amotivation was significantly lower in cases compared to controls (11.43+/-4.08 vs. 14.51+/-5.59, $p \leq 0.01$ ). Cases showed lower scores for the two mindfulness dimensions, relative to controls: Presence (18.69+/-3.02 vs. 20.30+/-2.67, $p \leq 0.05$) and Acceptation (21.57 +/-3.79 vs.23.77+/-3.70, $p \leq 0.01$).
CONCLUSION: We here showed EHS soldiers may have a lower interoceptive body awareness. The risk of EHS may be increased by reduced ability to recognize body exhaustion signals. Future work are required to precise the link between processing signals of internal physiological state, pacing strategy during exercise and the potential benefit of minfdulness-based programs.

## POORER FUNCTIONAL CAPACITY IS ASSOCIATED WITH IMPAIRED COGNITIVE FUNCTION AND WELL-BEING IN OLDER ADULTS

STAVRINOU, P.S., APHAMIS, G., SAKKAS, G., GIANNAKI, C.D.
*UNIVERSITY OF NICOSIA*

INTRODUCTION: Functional and cognitive impairment are two of the most prevalent age-related conditions [1] and are important determinants of independent living [2]. An understanding of the relationship between functional capacity and cognitive function could provide insight for developing interventions to support healthy aging. The aim of this study was to examine the associations of various parameters of functional capacity with global cognition, executive function and well-being in older individuals across the spectrum of normal cognition and cognitive impairment.
METHODS: Ninety-seven older adults (age 80.6 ± 8.2 yrs; female n = 64) participated in this cross-sectional study. Measures of global cognitive function (Mini-Mental State Examination; MMSE) and executive function (symbol cancellation test) were obtained. Functional capacity was evaluated using three sit-to-stand tests (STS-5, STS-30 and STS-60), the timed–up-and-go test (TUG), the 6-min walk test (6MWT) and the handgrip strength test (HGS). For well-being, quality of life, sleep quality, daily sleepiness and fatigue levels were assessed by specific questionnaires. Data were analyzed using adjusted partial correlations (controlling for age, sex and education) to examine the relationships between variables.
RESULTS: According to their MMSE score, 41% of the participants had a normal cognitive function, whereas 35% and 24% had mild and moderate cognitive impairment respectively. Lower levels of all functional capacity parameters were associated with worst performance in cognitive and executive function tests, with the 6MWT showing the highest correlation with the MMSE ($r = 0.35$, $p = 0.001$) and the HGS with the symbol cancellation test ($r = -0.49$, $p < 0.001$). Reduced levels of functional capacity parameters were also associated with lower quality of life (all $p < 0.05$, r from 0.32 to 0.41) and higher fatigue levels (all $p < 0.05$, r from 0.23 to 0.37). Sleep quality was positively correlated with some of the functional capacity parameters (6MWT, STS-30 and STS-60; all $p < 0.05$, r from 0.23 to 0.24).

CONCLUSION: Poorer functional capacity was associated with worst cognitive performance, ultimately affecting well-being. Tailored interventions need to be implemented for maintaining functional independence and preventing cognitive impairment in older adults.

### CP-BM06 Biomechanics in lower extremities

#### EFFECTS OF STATIC BALANCE EXERCISE COMBINED WITH DIFFERENT LEVELS OF BLOOD FLOW RESTRICTION ON PHYSIOLOGICAL AND PERCEPTUAL RESPONSES AS WELL AS MOTOR PERFORMANCE FATIGUE IN YOUNG MALES AND FEMALES

BIELITZKI, R., BEHRENS, M., BEHRENDT, T., WEINREICH, A., MITTLMEIER, T., SCHEGA, L.
*OTTO VON GUERICKE UNIVERSITY*

INTRODUCTION: Blood flow restriction (BFR) can be combined with several exercise modalities (e.g., resistance and aerobic exercise) and involves the application of cuffs to the limbs to reduce arterial blood flow and block venous return in the respective extremities. The addition of BFR to low-load resistance exercise has been shown to increase physiological and perceptual responses as well as motor performance fatigue development (i.e., decrease in maximal motor performance). However, the effects of balance exercise combined with BFR on these aspects have not been investigated to date.
METHODS: Twenty-four active males and females (23.8±3.1yrs, 67.0±12.3kg, 1.7±0.1m) participated in a randomized, counterbalanced cross-over study. Subjects completed a familiarization session and three experimental conditions (SHAM, 40%, and 80% of individuals' arterial occlusion pressure (AOP)). The balance exercise consisted of standing on a BOSU ball (3 sets of 1min with 30s rest inbetween). During exercise, muscle oxygen saturation (SmO2) of the vastus lateralis and muscle activity of various leg muscles were recorded with near-infrared spectroscopy and electromyography, respectively. Effort and leg muscle pain were assessed at the end of each set (BORG 6-20 scale). Maximal squat jump height was measured before and after exercise (0,1,2,4,8min) to quantify motor performance fatigue and recovery. SmO2 and muscle activity data were normalized to SmO2 recorded at rest and muscle activity measured during MVCs, respectively. Data were analyzed with repeated measures ANOVAs (time×condition).
RESULTS: We found a time×condition interaction for SmO2 ($p<.001$, $\eta p2=.603$) with a greater drop in each set in the 80%AOP compared to the 40%AOP ($p\leq.012$) and SHAM condition ($p<.001$). A time×condition interaction was revealed for quadriceps muscle activity ($p<.001$, $\eta p2=.339$) with a significant increase from set 1 to 3 only in the 80%AOP condition ($p<.001$). There was a time×condition interaction for effort ($p<.001$, $\eta p2=.389$) and leg muscle pain perception ($p<.001$, $\eta p2=.321$) with significant increases from set 1 to 3 only in both BFR conditions ($p<.001$). A significant time×condition interaction for jump height ($p<.001$, $\eta p2=.375$) was found with significant differences in the performance decline between 80%AOP (16.4±5.2%) and the other conditions (40%AOP: 9.1±3.2%, SHAM: 5.4±3.3%) immediately after exercise ($p<.001$). Differences in recovery between 80% AOP and the other conditions were present after 1min ($p\leq0.007$), but not 2,4, and 8min after exercise.
CONCLUSION: A static balance exercise combined with a high BFR pressure (80%AOP) decreased SmO2 and increased quadriceps muscle activity, perceptual responses, as well as motor performance fatigue. However, maximal squat jump height was not different between conditions after 2min of recovery. These data collectively suggest that the balance exercises combined with a BFR pressure of 80%AOP induced a strong training stimulus without long-term impairments of maximal performance.

#### DEEPACSA – AUTOMATIC SEGMENTATION OF ANATOMICAL CROSS-SECTIONAL AREA IN ULTRASOUND IMAGES OF HUMAN LOWER LIMB MUSCLES USING DEEP LEARNING

RITSCHE, P., WIRTH, P., CRONIN, N.J., SARTO, F., NARICI, M.V., FAUDE, O., FRANCHI, M.V.
*UNIVERSITY OF BASEL*

INTRODUCTION: Muscle anatomical cross-sectional area (ACSA) characterizes muscle function and helps to classify the severity of several muscular disorders. Ultrasound is a patient friendly, fast, and cheap method of assessing muscle ACSA, but manual analysis of the images is laborious, subjective and requires thorough experience. To date, no open access and fully automated program to segment ACSA in ultrasound images is available. Here, we present DeepACSA, a deep learning approach to automatically segment ACSA in panoramic ultrasound images of the human rectus femoris (RF), vastus lateralis (VL), gastrocnemius medialis (GM) and lateralis (GL) muscles.
METHODS: We trained deep neural networks using 1772 ultrasound images of 153 participants of different age groups (9 to 36 images per participant) acquired in previous studies by three operators (n = 153 (25 females, 128 males), age = 38.2 years (13 to 78 y)). Images of the RF, VL and GM/GL were captured with three devices using EFOV ultrasonography at several muscle regions. For each muscle, we randomly divided the images into a training set (n = 1127) for the deep neural network and a validation set (n = 90). Prior to model training, images and binary area masks were augmented, normalized, and resized. Within the training data set, we applied a random 90/10% training/test data split. We trained one model for each muscle using a U-net architecture. Following model training, we measured the ACSA in all images of the validation set using DeepACSA and compared it to manual segmentation.
RESULTS: Comparing DeepACSA analysis of the RF to manual analysis resulted in intra-class correlation (ICC), mean difference and standard error of the differences (SEM) of 0.96 (95% CI 0.939,0.973), 0.31 cm2 (0.04,0.58) and 0.91 cm2 (0.47,1.36). For the VL, ICCs, mean differences and SEMs were 0.941 (0.911,0.96), 0.25 cm2 (-0.21,0.7) and 1.55 cm2 (1.13,1.96). The GM/GL muscles demonstrated ICCs, mean differences and SEMs of 0.968 (0.948,0.98), -0.01 cm2 (-0.25, 0.24) and 0.69 cm2 (0.52,0.83). Comparability was increased for all muscles when wrong predictions of the model were removed based on visual inspection of the output. Whereas the time needed to manually segment ten ultrasound images is about ten minutes, DeepACSA requires thirty seconds for automatic segmentation on a common CPU and provides comparable results.

CONCLUSION: The segmentation of DeepACSA of RF, VL and GM/GL muscles in EFOV ultrasound images yielded comparable results to manual segmentation. Therefore, the DeepACSA tool can (automatically) segment lower limb muscles in EFOV ultrasound images using deep neural networks. DeepACSA is novel, because it objectifies and accelerates the evaluation process of EFOV ACSA ultrasound images, allowing large datasets to be evaluated quickly. However, our results demonstrated that visual inspection of the output may still be necessary to optimize predictions and avoid misclassifications.

**KINETIC CHARACTERISTICS DURING THE SIDE HOP TEST IN ATHLETES WITH CHRONIC ANKLE INSTABILITY**

ONO, K.1, NOZU, S.2, YOSHIDA, T.3, TANIGAWA, S.3

*1,3. UNIVERSITY OF TSUKUBA 2. JUNTENDO UNIVERSITY*

INTRODUCTION: Chronic Ankle Instability (CAI) is a well-known sequela after an ankle sprain that often occurs in ball sports. Athletes with CAI could have some typical movement. The Side Hop Test (SHT) is a valid test to identify individuals with CAI. Some studies have reported that the SHT time was delayed in individuals with CAI compared to healthy individuals1. Although previous studies have investigated kinematic characteristics during the SHT, few studies focused on kinetic characteristics that can explain the specific movement, especially in athletes. Therefore, this study aimed to examine the differences in lower extremity kinetic characteristics during the SHT between athletes with and without CAI.
METHODS: Twenty male athletes who play football participated in the study and were divided into the healthy control group (CON) and the CAI group (CAI). The presence of CAI was determined from the Cumberland Ankle Instability Tool score. Subjects completed the SHT with one leg, putting their hands on their hips, and hopping laterally ten times. Three-dimensional coordinates were collected using ten Vicon MX+ cameras, and ground reaction forces were collected using two force platforms. The time of SHT and the net internal joint torque of the ankle, knee, and hip were calculated as outcome measures. We looked at the peak joint torque at the lateral ground contact phase of the SHT. Differences between the two groups were examined using Mann-Whitneys U test ($p < 0.05$).
RESULTS: There was no significant difference in SHT times between the two groups (CON vs. CAI; 6.00 ± 0.39 vs. 5.91 ± 0.37, Mean±SD). The CON group demonstrated greater peak flexion (0.20 ± 0.17 vs. -0.11 ± 0.17) and abduction (-3.50 ± 0.38 vs. -3.08 ± 0.27) torques of the hip joint, greater peak flexion (0.76 ± 0.26 vs. 0.34 ± 0.20) and extension (-1.52 ± 0.39 vs. -0.83 ± 0.50) torques of the knee joint, and greater peak dorsiflexion (0.31 ± 0.18 vs. 0.02 ± 0.06), plantar flexion (-3.25 ± 0.35 vs. -2.86 ± 0.34), inversion (0.71 ± 0.10 vs. 0.41 ± 0.23), and eversion (-0.32 ± 0.15 vs. -0.16 ± 0.15) torques of the ankle joint compared to the CAI group.
CONCLUSION: Although subjects with CAI showed high performance as the CON group in the SHT, they had smaller peak joint torques than the CON group. Since previous studies have reported that athletes with CAI have specific movement characteristics, it is possible that a similar trend was observed in the SHT. However, it is noteworthy that no differences in SHT times were observed, and the possibility of compensatory strategies in athletes with CAI should be investigated in the future. This study found the kinetic characteristics of subjects with CAI who perform as fast as the SHT time in healthy athletes. Thus, the differences observed in this study should be considered when using the SHT for athletes.

**SUBJECT SPECIFIC SENSITIVITY OF SEVERAL BIOMECHANICAL FEATURES TO FATIGUE DURING AN EXHAUSTIVE TREADMILL RUN**

CHALITSIOS, C.1, NIKODELIS, T.1, MAVROMMATIS, G.2, GIANNAKOS, A.2, KOLLIAS, I.1

*1BIOMECHANICS LABORATORY, DPT OF PHYSICAL EDUCATION AND SPORTS SCIENCES, ARISTOTLE UNIVERSITY OF THESSALONIKI, GR 2DPT OF PHYSICAL EDUCATION & SPORTS SCIENCE, ARISTOTLE UNIVERSITY OF THESSALONIKI, GR*

INTRODUCTION: Human movement may be similar among individuals but never identical. Movement is produced from a functional combination of the nervous, the muscular, and the skeletal system. Mechanically, the musculoskeletal system allows a relatively large but fixed number of functional degrees of freedom, whereas the neuromuscular system has predetermined branching and connections, but is highly complex and adaptable. Endurance running is a demanding and at the same time a fundamental human activity where all the above-described properties can be observed and affected as fatigue progressively accumulates. The present study examined the sensitivity of several movement features during running to exhaustion in a subject-specific setup adopting a cross-sectional design and a machine learning approach.
METHODS: Thirteen recreational runners that trained and competed regularly performed an exhaustive running protocol on an instrumented treadmill. The ventilatory threshold, established through respiratory data, was used as a reference point regarding the gradual accumulation of fatigue. A machine learning approach was adopted to analyze kinetic and kinematic data of each participant, using a random forest classifier (1) for the region pre and post the ventilatory threshold. SHapley Additive exPlanations (SHAP) analysis (2) was used to provide explanations about the models' predictions and insights about the most important variables that described each subject's technique.
RESULTS: The classification accuracy value range was from 0.853 to 0.962. The SHAP based variable importance ranked all the features according to their value for the model, to predict the state above the ventilatory threshold. Lateral flex/ext at C7 appeared to be the most important feature for prediction in 6 out of 13 participants. Also, the maximum value of rate of force development appeared first in 3 out of 13 and vertical rotation at PSIS in 2 cases, respectively. Max force value and impulse were the most important features for 1 out of 13 of the sample participants. SHAP dependence plots also showed increased vertical dispersion of predictions in stages around the ventilatory threshold, which is consistent with feature interactions.
CONCLUSION: These results suggested that each individual exhibited distinct changes in overall running mechanical parameters in predicting the fatigued state. These findings also support the efficacy of machine learning modeling approach for understanding the complexities of running gait patterns based on collecting large amount of data in a laboratory setting. Overall, the results showed that the production of work in a fatigued condition results in subject-specific changes in biomechanical running patterns, possibly to compensate and optimize the system function to account for the imposed demands based on individual movement characteristics or constraints.

### EFFECTS OF WHOLE-BODY EXHAUSTION ON SYNCHRONIZED WALKING GAIT KINETICS AND KINEMATICS ON A DOWNWARD 10˚ INCLINE

HALDER, A.

*MALMÖ UNIVERSITY*

INTRODUCTION: Walking downwards on a slope alters postural alignment to maintain equilibrium and involves an altered gait strategy to retain balance. Walking efficiency decreases with exhaustion and muscle fatigue, as the fatigue directly affects key features of the sensorimotor system, which disorganizes voluntary control of movement accuracy. Studies have shown that the effects of motor fatigue due to repetitive activities reduce human force generating capacities to a minimal level by decreasing the joint range of motion. Human often experience fatigue and become exhausted after performing laborious tasks throughout the day in many occupations including industrial and health care workers. The collective effects from prolonged standing, and a poor or awkward working position cause discomfort in the lower back, legs, and feet with an increase of overall body and local muscle fatigue (LMF) at the end of a working day.
METHODS: This biomechanics study investigated stride length (SL), stride duration (SDN), the peak values of gait ground reaction forces (GRFspeak), required coefficient of friction (RCOFpeak), joints' angles (anglepeak), angular velocity (angvelx peak), angular acceleration (angaccx peak), minimum angle (anglemin) of foot, and muscle electromyography (EMG) during the dominant leg stance phase (SP) following an exhaustive stair ascent on a stair machine. Data were collected by a three-dimensional motion capture system synchronized with EMG and force plate when walking downwards on a 10° inclined stationary walkway.
RESULTS: Although the leg muscles' EMG showed no significant results to claim local muscle fatigue (LMF) during post exhaustive downward walking, the SL was significantly ($p<.05$) shorter than pre-exhaustive. The mean vertical GRFpeak was significantly ($p\leq.01$) reduced during late stance (LS) phase, however, the antero-posterior GRFpeak was found significantly ($p\leq0.01$) higher. The RCOFpeak was significantly ($p\leq.05$) higher during the post-exhaustive walking downwards, LS phase. None of the post-exhaustive absolute foot angle peaks and mins, angvelx peaks, and angaccx peaks significantly changed in post-exhaustion walking except knee angaccx peak, which significantly ($p<.05$) increased during the LS period.
CONCLUSION: Physical exhaustion of the subjects was evidenced by the high mean lactate value of 14.4 mmol·l-1 at the end of their stair ascent at maximum speed, which was terminated by the subjects themselves due to high strain on both the cardiovascular system and legs. The end durational stair ascent electromyography results had evidenced the onset of leg's local muscle fatigue (LMF). Neither of the muscles' mean EMG AMPs during 5-25% (ES) and 75-95% (LS) periods of walking downward were significantly changed between the pre-exhaustion and post-exhaustion trials, except the tibialis anterior (TA) muscle. The constrained post exhaustive gait kinetics indicate perturbed gait and may increase the risks for fall accidents when walking downward.

### EFFECT OF TIGER-STEP WALKING ON LOWER EXTREMITIES DURING UPHILL WALKING

KANG, J.1,2, PARK, J.1,2, KIM, J.1,2, RYU, J.1,2, PARK, S.1,2, YOON, S.1,2

*1KOREA NATIONAL SPORT UNIVERSITY, SEOUL, KOREA 2BIOMECHANICS LAB & MOTION INNOVATION LAB, SEOUL, KOREA*

INTRODUCTION: The walking can be classified according to the shape of the ground where it takes place (1). Previous studies on uphill walking claim that it requires more use of lower extremity muscles since it has to lift the body higher compared to level walking (2). Recently, many media have introduced the Tiger-step style walking as an efficient method in uphill walking (3). The Tiger-step, however, is a method conceived by the experience of some climbing experts and rather than being based on scientific evidences. Therefore, the aim of this study was to investigate the effects of Tiger-step walking on the movement of the lower extremities during uphill walking.
METHODS: Twenty healthy male adults who had no experience of musculoskeletal injuries on lower extremities in the last six months(age: 26.85±3.28 yrs, height: 174.6±3.72 cm, weight: 73.65±7.48 kg) participated in this study. All subjects were asked to perform normal walking (NW), straight tiger-step walking (STW) and cross tiger-step walking (CTW) with 60% of the pre-measured preferred speed of gait at an grades of 15° in treadmill. To investigate kinematics and kinetics differences among three types of walking, a three-dimensional motion analysis was performed using eight infrared cameras(sampling rate: 100 Hz) and seven channel of EMG(sampling rate: 1,000 Hz). An one-way ANOVA with repeated measure was conducted to verify the differences among the walking styles and statistical significance set as $\alpha=.05$.
RESULTS: Both STW and CTW showed a significant increase in stance time and stride length, and significantly reduced cadence compared with those of NW. In addition CTW also showed a longer swing time than that of NW ($p<.05$). For all lower extremity joints joint range of motion, STW and CTW revealed significantly increased compared with NW ($p<.05$). Gluteus maximus, biceps femoris, medial gastrocnemius, tibialis anterior revealed significantly increased muscle activation in STW and CTW compared with NW in gait cycle and stance phase. On the other hand, in swing phase, the muscle activity of the vastus medialis, biceps femoris, tibialis anterior of both STW and CTW significantly increased compared with those of NW.
CONCLUSION: The results of this study may solve the curiosity of many recreational hikers in club by quantifying tiger-step, which had not been scientifically proven. Moreover, our study results may be thought to help develop tiger-step more efficiently in the future.

### EFFECTS OF LOAD CARRIAGE ON POSTURAL CONTROL DURING TREADMILL BASED UPHILL WALKING

MANDALIDIS, D., MEXI, A.

*NATIONAL AND KAPODISTRIAN UNIVERSITY OF ATHENS*

INTRODUCTION: Postural control refers to the mechanism based on which the central nervous system regulates the stimuli from the sensory organs in maintaining body stability. When postural control is jeopardized by changes in the intrinsic (e.g. somatosensory) and/or extrinsic stimuli (e.g. environment) body stability is challenged increasing the likelihood of injury. It is generally accepted that a condition that may affect postural control and elicit a wide range of musculoskeletal low back and limb injuries is load transfer. However, postural control may be further aggravated when a load is required to be transferred in different ways and/or on inclined surfaces. This study aimed to assess the effects of load transfer by means of a front- or a backpack on postural control during walking on inclined surfaces.
METHODS: Thirty asymptomatic, skeletal symmetric individuals aged 20-30 years participated in the study. Postural control was assessed by means of (i) the EMG activity of the neck, thoracic and lumbar extensors (NE, TE, and LE) and trunk flexors (TF) and (ii) the anteroposte-

rior and mediolateral displacement as well as the ellipse area of CoP during treadmill based uphill walking at a constant speed of 5 km/h. Participants had to walk for 10 minutes, during which the slope of the treadmill gradually increased every 2.5 minutes from 0 to 15 degrees, at 5-degree intervals, without and with carrying a front pack or a backpack equal to 15% of each individuals body weight. A device for recording physiological signals and an inertial sensor placed on the upper torso were used to assess the EMG activity of the muscles under investigation and the displacement of the CoP, respectively.
RESULTS: Significant differences between inclinations and ways of load carriage were obtained for the EMG activity of NE ($p<0.001$), TE ($p<0.001$), and LE ($p<0.001$) as well as TF ($p<0.01$). The EMG activity of the muscles tested increased as the slope increased and it was greater when the participants walk carrying a front pack compared to a backpack or no load. Similarly, the anteroposterior displacement and ellipse area of CoP was significantly increased as the slope of the treadmill's surface increased ($p<0.001$) regardless of the way used to carry the load. The greatest anteroposterior displacement and ellipse area of CoP were obtained while walking carrying a front pack as opposed to carrying a backpack or no load. The differences between inclinations and ways of load transfer for the mediolateral displacement of CoP were not significant.
CONCLUSION: Carrying a backpack remains the least provocative way of load transfer when an individual walks on a level or a sloped surface, at least as far as the EMG activity of the trunk musculature and the displacements of CoP are concerned. Carrying a front pack under the same surface conditions should be limited, as it significantly disrupts postural control predisposing an individual to injury.

**SCALING ANALYSIS OF FORCE PLATFORM RECORDS OF STANDING WITH TASKS AND INJURY**

PRCIC, I.1, BLESIC, S.1, ANICIC, Z.2, MILANOVIC, S.1, MIRKOV, D.2, KNEZEVIC, O.2

*1UNIVERSITY OF BELGRADE, INSTITUTE FOR MEDICAL RESEARCH, BELGRADE, SERBIA, 2UNIVERSITY OF BELGRADE, FACULTY OF SPORT AND PHYSICAL EDUCATION, BELGRADE, SERBIA*

INTRODUCTION: We examined long-range temporal characteristics of two force platform records of quiet standing with or without injury, and of non-injured standing with eyes closed and on one leg only. We analysed two force platform recordings to assess balance dynamics for each leg separately.
METHODS: We used the detrended fluctuation analysis (DFA) and the local and global wavelet transform spectral analysis (WTS) to quantify force platform data temporal dynamics by DFA scaling exponents and WTS characteristic peaks, and to show how those parameters change with task or injury. DFA is a variant of a conventional fluctuation analysis, adapted for the analysis of non-stationary, non-linear data, in which a fluctuation function is calculated as a root mean square variation about the constantly changing local trend instead of the record's mean. WTS was introduced to achieve signal localization and decomposition in both time and frequency and thus expand the limits of Fourier analysis by two-dimensional time and scale decomposition of any signal with functions constructed by expanding by time scale and translating along real time of a specifically chosen original wavelet function.
RESULTS: We found long-range autocorrelated behaviour in all our records, with a visible crossover in long-range dynamics, a random behaviour on small time scales and a distinct non-linearity on higher time scales. Under the changes in experimental conditions or in injury to one leg, we found that only the scaling above the crossover, on time scales from 100ms to 1s, changes. We found increase in DFA and WTS slopes after the crossover point caused by visible change of amplitude of the mid-level characteristic peaks at about 250 and 650 ms in non-injured standing on one leg only. We observed two main types of response to injury: a compensation, seen as an increase of all the characteristic modes above the crossover point that causes a shift of the position of crossover to smaller scales, and an 'underachievement', which presents as a decrease of amplitudes of the characteristic WTS peaks above the crossover region that brings about a shift of the position of crossover point to higher time scales.
CONCLUSION: Our results further corroborate claims that DFA, WTS and similar time series analysis techniques may provide new, more sensitive discriminatory analysis framework for human balance assessments. This is particularly observable in probably the most important finding of our research, that DFA2 and WTS can distinguish injury even in quiet standing.

**EFFECT OF AROUSAL STATE AND STRETCH SPEED ON ANKLE FLEXIBILITY IN INDIVIDUALS WITH DIFFERENT MAXIMUM RANGE OF MOTION**

LIMA, C.D., TAYLOR, J.L., RUAS, C.V., PINTO, M.D., BLAZEVICH, A.J.

*EDITH COWAN UNIVERSITY*

INTRODUCTION: Several theories exist regarding the physiological mechanisms that underpin joint flexibility (maximum range of motion [ROMmax] and resistance to stretch). These contrast the importance of objective measures of the mechanical properties of the joint structures and the muscle-tendon unit (MTU) with the more subjective assessment of stretch tolerance. The present study used a cross-sectional design between nine flexible female participants who trained for flexibility for several years (age 27± 5.3 yr; ht 162.2 ± 6.7 cm; mass 58.8 ± 9.8 kg) and eight non-stretch-trained females (age 26.5 ± 5.5 yr; ht 160.5 ± 6.4 cm; mass 61.1 ± 8.8 kg). Purpose: To examine the effects of stretch rate (slow 5°·s-1; and fast 30°·s-1) and state arousal (control, arousal, and relaxation) on ROMmax and joint stiffness during passive ankle dorsiflexion.
METHODS: Participants attended the laboratory twice (Session 1 = familiarisation, Session 2 = experimental). In Session 1, participants were familiarised with the stretch trials during slow and fast ankle stretching manoeuvres on an isokinetic dynamometer. In Session 2, participants performed 4 ankle stretching 'control' tests (2 slow and 2 fast). Participants then performed stretches under 6 randomised conditions (control, arousal, and relaxation at slow and fast speeds). For the arousal and relaxation conditions, participants listened to classical music that professional musicians classified as arousing or relaxing (Kuan et al., 2017). Participants pushed a button to stop the machine at their perceived ROMmax. Joint stiffness was calculated from change of torque and angle over 80 to 100% ROMmax.
RESULTS: For ROMmax, two-way ANOVA (2 groups x 6 conditions) showed no interaction, but main effects for condition ($F_{1,5} = 6.7$, $p = 0.001$) and group ($F_{1,15} = 440.1$, $p = 0.001$) . Flexible participants (55.3 ± 4.5°) demonstrated greater ROMmax than inflexible participants (38.1 ± 6.5°) ($p = 0.001$). ROMmax in the arousal-fast condition (50.1 ± 9.0°) was 5.7% greater than the control-slow condition (47.2 ± 11.4°) ($p = 0.001$). No differences in joint stiffness analysed near the end of the ROM were observed under any conditions. However, flexible participants (112.6 ± 44.7 Nm/rad) demonstrated 35.8% lower stiffness than less flexible participants (175.6 ± 77.4 Nm/rad) ($p = 0.001$).
CONCLUSION: Individuals who are flexible and flexibility trained have lower plantar flexor musculotendinous stiffness than less flexible individuals. Yet, altering an individual's psychological state by adding arousing music improved ROMmax in both flexible and less flexible individuals but only at faster, not slower, stretch speeds. Therefore, from a practical viewpoint it might be of interest to individuals to perform stretches at a little faster speed and to add arousing music to their flexibility training. Such music can improve motivation and

overall mental state and is also used in medical rehabilitation settings to manage pain and discomfort, and reduce anxiety and muscle tension.

### VALIDITY AND RELIABILITY OF 3D ULTRASOUND IMAGING TO MEASURE HAMSTRING MUSCLE AND TENDON VOLUMES

FROUIN, A.

*NANTES UNIVERSITY*

INTRODUCTION: Measuring muscle and tendon volume is important to understanding adaptations in response to immobilization, training or rehabilitation. For instance, small-sized grafts used during anterior cruciate ligament (ACL) reconstructions are highly predictive to be at risk of later risk of failure. In addition, atrophy of semitendinosus and gracilis can be observed 2 to 4 years after the ACL surgery, altering the recovery of force in these muscles (1). Therefore, quantifying architectural parameters of these muscles could be useful to identify patients at risk of small-sized grafts, and prepare accordingly using rehabilitation programs. The current gold standard to assess muscle and tendon volumes is Magnetic Resonance Imaging (MRI). However, its cost and accessibility make it prohibitive in many clinical/research settings. 3D ultrasound (US) imaging combines B-mode US imaging and 3D motion analysis of the US probe, would produce 3D images to overcome this problem (2). This study aimed to assess the reliability (test-retest) and the validity of 3D US imaging against MRI in measuring hamstring muscle and tendon volume in healthy participants.
METHODS: Thirteen healthy volunteers received two sessions of 3D US acquisitions (spaced by 24h on average) of biceps femoris long (BFlh) and short head (BFsh), semitendinosus (ST), semimembranosus (SM) and gracilis (GR) muscle , but also semitendinosus, in addition to one session of MRI.
RESULTS: The bias for 3D US ranged from -1.92 mL (-0.81%) to 1.21mL (0.97%) for muscle volume, and 0.01 mL (0.23%) and -0.03 mL (-2.58%) for tendon volume. The reliability analysis of 3D US imaging for muscle volume give intra-class correlation coefficients (ICC) from 0.98 (GR) to 1.00 (ST), and coefficients of variation (CV) from 1.13% (SM) to 3.37% (BFsh). The standard error of measurement was between 1.79 mL (GR) to 3.85 mL (BFsh), and the minimal detectable change between 4.95 mL (GR) to 10.67 mL (BFsh). For tendon volume, ICCs were 0.99, and CVs between 3.19% (STtd) and 3.43% (GRtd). The SEM were 0.06 mL (STtd) and 0.04 mL (GRtd), and MDC were 0.17 mL (STtd) and 0.10 mL (GRtd).
CONCLUSION: This study showed that 3D US, combined with the use of a gel pad, provides hamstring (Semitendinosus, Semimembranosus, Biceps femoris) and Gracilis muscle-tendon volumes with limited bias and limits of agreement when compared to MRI. In addition, a good test-retest reliability was observed for muscle and tendon volumes. These results provide opportunities for this technique to be used to assess hamstring volume (and adaptations) in exercise training and clinical settings. For that purpose, the effects of a 9-week muscular strengthening program on muscular and tendinous volume are set to be evaluated by this method. Preliminary results would be presented at the congress.

### TOWARDS A PHYSIOLOGICAL AND PHYSICAL MODEL OF SPRINT KAYAKING; A CURRENT REVIEW OF LITERATURE

DINGLEY, A., LEE, S., LUM, D., FRANKY, H., TAN, Y., FERNANDES, J.T.F.

*BRUNEL UNIVERSITY*

INTRODUCTION: In sprint kayaking, a tenth of a second can separate those who win a medal (e.g. male 200m finals at the 2020 Olympics). Therefore, practitioners need a comprehensive understanding of the variables which influence sprint kayaking performance (e.g. physiological and physical characteristics). Although studies have investigated how physiological and physical attributes may influence sprint kayaking performance, there is currently no review study conducted to draw the literature together. The aim of this study was to critically review the physiological and physical determinants of sprint kayaking performance. A secondary aim was to inform future research and provide guidelines for practitioners.
METHODS: The studies included for review were gathered according to the Preferred Reporting Items for Systematic reviews and Meta-analyses (PRISMA) guidelines (Page et al., 20211). After initial searches, twenty-five studies were included that met the inclusion criteria. In brief, these were observational studies that sought to examine the relationship between various types of physiological or physical variables and sprint kayak performance.
RESULTS: The relationship between VO2max/peak (200m r range = -0.71 to -0.86; 500m r range = -0.22 to -0.82; 1000m r range = -0.21 to -0.90) and anaerobic threshold (200m r range = -0.54 to -0.74; 500m r range = -0.52 to -0.89; 1000m r range = -0.71 to -0.83) with race performance is stronger as the race distance increased. However, the relationship between peak power, anaerobic capacity and aerobic threshold to race distance was unclear, and did not show an obvious trend. There is a plethora of literature (n = 11 studies) suggesting the importance of both upper-body pulling and pushing strength in improving sprint kayak performance and kayak ergometer power output. However, the literature concerning the relationship between lower body strength and sprint kayak performance is lacking.
CONCLUSION: The current literatures suggests that VO2max/peak and anaerobic threshold supports sprint kayak performance. Moreover, sprint kayakers should increase upper-body pulling and pushing strength and power to support their performance. Currently, the data regarding peak power, anaerobic capacity, aerobic threshold and the relationship between lower body strength on sprint kayak performance is unclear. Therefore, future studies should look to do this; in particular, work surrounding lactate threshold, transition from heavy-severe domain which is particularly lacking currently.

**EFFECTS OF AN OFFSHORE SAILING COMPETITION ON ANTHROPOMETRY, MUSCULAR PERFORMANCE, SUBJECTIVE WELLNESS AND SALIVARY CORTISOL IN PROFESSIONAL SAILORS.**

PHILIPPE, K., PAILLARD, T., MAURELLI, O., MOODY, J., PRIOUX, J.

*UNIVERSITÉ DE PAU ET DES PAYS DE LADOUR*

INTRODUCTION: Evidence regarding the impact of offshore sailing on fatigue and readiness variables is conspicuous by its absence. This study investigated the acute effects of an offshore sailing regatta on anthropometry, muscular performance, subjective recovery and salivary biomarker cortisol.
METHODS: Ten professional offshore sailors from a mixed-sex crew partook in the study (n = 10; mean ± SD; age = 32.2 ± 3.96 years; stature = 179.1 ± 7.30 cm; body mass = 84.2 ± 12.1 kg). The race involved three offshore legs over a 3-week period. Baseline measures of anthropometry, lower- and upper body muscular function, perceptions of subjective wellness and salivary cortisol were assessed 3-hours prior to competition (i.e., before the first leg). These measures were repeated within 30-min after the cessation of each event leg. During each leg, boat movements were recorded via global positioning system units.
RESULTS: There were significant reductions in lower- (ES = 0.49) and upper muscular (ES = 0.21) functions as well as in subjective wellness (ES = 1.65). Salivary cortisol levels increased (ES = 0.84).
CONCLUSION: These results demonstrate that, during an intensified period of sailing competition, fatigue will progressively increase. This may impede sailing performance by reducing physical and cognitive efficiency. Furthermore, counter movement jump, handgrip strength, perception of subjective wellness and cortisol concentration appear to be sensitive measures for monitoring fatigue and readiness in professional sailors.

**EVOLUTION OF THE BODY POSTURE IN ELITE PARA SWIMMERS AS THE EFFECT OF BODY'S EXTRINSIC ADAPTATION TO SPORT-SPECIFIC TRAINING**

GAWEL, E., ZWIERZCHOWSKA, A., ZEBROWSKA, A.

*AKADEMIA WYCHOWANIA FIZYCZNEGO IM. JERZEGO KUKUCZKI W KATOWICACH*

INTRODUCTION: The dynamic development of the professional Paralympic sport has raised the need to progressively improve competitiveness. As athletes cannot influence individual genetic predisposition, physiological adaptations seem to be a key factor that can improve athletic performance. The human body always strives to maintain the state of equilibrium and, for this purpose, it activates compensatory yet not always beneficial compensatory mechanisms. Two closely related compensatory mechanisms are important in Para athletes: intrinsic (disability) and extrinsic (athletic training) [1-2]. While the intrinsic adaptation strategy is one-sided, the extrinsic adaptation strategy affects the athletes body in two ways, i.e. (a) it can induce new musculoskeletal adaptations, and (b) it can aggravate existing adaptations . The aim of the study was to evaluate the impact of sport-specific training on the body posture of elite para swimmers.
METHODS: The study included 22 male and female elite para swimmers (age: 19.7±4.8, body mass 63.3±10.9, body height: 1.74±0.1) from the Polish national team. The assessment of the body posture was performed with a non-invasive method Medi Mouse (Idiag M360). Spinal curvatures measurements were performed in three different trunk positions in the sagittal and frontal planes and included (a) the evaluation of the current depth and mobility of thoracic and lumbar curvatures and the differences between theirs current and proper physiological values and (b) identification of the sagittal and frontal spinal curvature deviations.
RESULTS: The analysis of the body posture relative to symmetry in the habitual position in the frontal plane show postural asymmetries and a significant tendency to mild left scoliosis in the majority of para swimmers. Moreover, regardless of the disability, lumbar lordosis and pelvic inclination in the sagittal standing were significantly less defined, whereas thoracic kyphosis showed either normal or decreased values. A significant decrease in mobility of the lumbar spine was observed in all three positions, while an increase in mobility was found in hip joints during the movement of flexion and extension.
CONCLUSION: Significant deviations both in frontal and anteroposterior curvatures of the spine might be associated with body's extrinsic adaptation to swimming training. Elite level sport-specific training can affect the quality of the body posture rather than the impairment.

**A GLIMPSE OF THE DEVELOPMENTAL PATHWAY TO ELITE LEVEL SWIMMING – A MULTIDIMENSIONAL AND LONGITUDINAL ANALYSIS OF YOUTH SWIMMERS**

POST, A.K., KONING, R.H., VISSCHER, C., ELFERINK-GEMSER, M.T.

*UNIVERSITY MEDICAL CENTRE GRONINGEN, UNIVERSITY OF GRONINGEN*

INTRODUCTION: A thorough understanding of performance development and its underlying performance characteristics during an swimmers' career could facilitate the identification and development of talented swimmers. However, longitudinal studies on multidimensional performance characteristics in talented youth swimmers are scarce. Therefore, the aim of the present study is examine the development of anthropometric, physiological, technical and psychological characteristics in relation to performance level of talented youth swimmers over a 3-year period.
METHODS: We collected data on multidimensional performance characteristics and 100m freestyle swim performance of 207 talented youth swimmers (102 males, 14.9 ± 1.3 years; 105 females, 14.2 ± 1.3 years) over 3 competitive seasons between 2017 and 2020. Based on their season best performances, swimmers were assigned to the high performance level or lower performance level group. Multilevel models were created in which repeated measures (level 1) were nested within individual swimmers (level 2). The effect of the fixed variables age and current performance level on anthropometrics (body height and weight), physiological (sprint velocity and counter movement jump height), technical (stroke frequency, stroke length and stroke index) and psychological (self-regulation of learning) characteristics was tested for significance ($p<0.05$) for males and females separately.
RESULTS: Older male and female swimmers scored higher on anthropometric, physiological, technical and psychological characteristics. High-performing male and female swimmers scored higher on physiological (sprint velocity and CMJ) and psychological (reflection) charac-

teristics compared to lower-performing swimmers. High-performing males were taller and heavier than their peers whereas high-performing females outperformed their peers on technical characteristics (stroke index).
CONCLUSION: The present study emphasizes the importance of a multidimensional and longitudinal approach in talent identification and development, reporting that high-performing youth swimmers scored higher on multiple underlying performance characteristics over a 3-year period compared to their peers. Therefore, in the guidance of young talented swimmers to the top as well as in the detection of talented swimmers, more attention has to be paid to the development of anthropometrical, physiological , technical and psychological characteristics.

### RELATIVE AGE EFFECTS ON FRENCH SWIMMERS' PERFORMANCES

DIFERNAND, A., DE LAROCHELAMBERT, Q., PLA, R., ANTERO, J., TOUSSAINT, J.F., SEDEAUD, A.

*FRENCH INSTITUTE OF SPORT*

INTRODUCTION: This study aimed to identify a Relative Age Effect (RAE) among French swimmers and apply corrective adjustment procedures to better consider performance level in each category and event.
METHODS: 5,339,351 performances of French swimmers aged 10 to 18 were collected between 2000 and 2019. Birth quarters distribution was examined according to level of performance and event within each age category. A linear relationship between performance means and months within a same category provides a rebalancing coefficient allowing to rebalance the performance by considering the effect of RAE.
RESULTS: Proportion of swimmers born in the first quarter was higher than the proportion of born in the last quarter for all events and strokes ($p < 0.01$). RAE increases with the performance level. For example, in 50m Freestyle, proportion of swimmers born in the last quarter significantly decreases: 20.12% and 10.35% vs 30.61% and 46.55% in the first quarter respectively for 'All' and 'Top10%' of U13 (p-value < 0.01). Among U11 swimmers, in average, each month represents a 0.416 second gap, if interpreted in a year, it can be up to almost 5 seconds gap.
CONCLUSION: Once the rebalancing method applied, no significant differences were found between rebalanced performances and the original ones (excepted for U13). We proposed a new method to better consider a performance depending on the swimmer's birthdate for each age category and event.

### WORD CUP AND OLYMPIC GAMES ANALYSIS OF 3M AND 10M DIVING

BRATTA, C., DEMARIE, S., CORTIS, C.

*UNIVERSITY OF CASSINO AND LAZIO MERIDIONALE*

INTRODUCTION: Sex differences in world ranked performance has been suggested to follow a diminishing trend that could lead women to reach men's results, particularly in longer events (reference 1). The same trend has not been consistently reported either for short and middle-distance events, or for technical disciplines (references 2,3). Performance trend analysis could be useful to plan athlete's careers and to discriminate between men and women developmental patterns. The aim of this study was to analyze the trend of the differences in performances between male (M) and female (F) athletes in Olympic Games (OL) and World Cup (WC) from Sydney 2000 to Tokyo 2020 in 3m springboard and 10 m platform diving.
METHODS: Diving competition results were collected from the FINA official web site (reference 4). For the female (F) and male (M) medalists (OL: F=18, M=18; WC: F=15, M=15) of each event Degrees of Difficulty (DD mean, sum, and peak values), age (3m: F=24.4±0.6yrs, M=23.1±0.2yrs; 10m: F=20.1±0.6yrs, M=21.6±0.1yrs) and Total Points (TP) were analyzed. The trends of the differences between male and female were assessed as percentage (%) and slope of the regression line of the results over time (y).
RESULTS: Sex differences in 3m DD values continuously increased, particularly in Olympics (DDm from 0.16 to 0.55; DDs from 4.00 to 6.30; DDp from 0.33 to 0.77 with a peak in 2012), while the slope of differences over time in TP decreased in gold medalists (y=-4,2419) and followed a nonlinear trend in silver (y=0,1292) and bronze medalists (y=0,0121). In 10m divers the differences between men and women increased for DD mean (Gold y=0,0095; Silver y=0,0194; Bronze y=0,006) and peak (Gold y=0,0084; Silver y=0,0193; Bronze y=0,0193), while DD sum (Gold y=-0,0155; Silver y=0,102; Bronze y=0,0015) and TP (Gold y=-0,0774; Silver y=-0,5683; Bronze y=1,0428) did not show consistent trends. Age differences between sex decreased in 3m (Gold y=-0,0286; Silver y=-0,4321; Bronze y=-0,2036) and increased in 10m (Gold y=0,3036; Silver y=0,2536; Bronze y=0,179).
CONCLUSION: Sex differences in DD tends to widen, suggesting that men technical abilities develop faster than women's. The differences in TP does not present consistent trend, suggesting that the rise in DD did not guarantee men's better results. This relatively stable differences between men and women performances agrees with the trend of short and middle-distance sports (references 1,2,3). In 3m springboard diving, where more muscular power is requested, age of both sexes rises over time. In 10m platform, where more technical abilities are demanded, men's age increases while women's decreases. This could indicate that man relies more on muscular power, while women can also rely on fast rotational velocity.

### DROWNING PREVENTION FROM JAPANESE COLLEGE SWIMMING EDUCATION

TORIUMI, T.

*KEIO UNIVERSITY*

Reasons for drowning are most commonly associated with failure to stay afloat or swim to safety. Some evidence suggests that victims drown because they cannot exit the water upon reaching the water's edge.
The purpose of this paper is to explore the real and perceived capacity of young adults to safely exit the water and ascertain what safety knowledge about exiting the water is promoted.
College-aged non-sports Japanese students (N = 62) completed a pretest survey of self-estimated capacity to exit the water under varied conditions. Participants were then tested in shallow water, deep water (flush edge), and deep water with a ledge (0.30 m) when fresh, after a 5-min swim in swimwear, in clothing, and while wearing a buoyancy vest.

Participants were Japanese young adults (N = 62) with a proven swimming capacity who were enrolled in an undergraduate Bachelor of non-Sports degree programs. Of these, 40 were male (64%) and 22 were female (36%), 80% were 19–20 years of age, 17% were 21–22 years of age, and the remaining 3% were 23 years and older. Before the commencement of an aquatics education program that focused on water safety, participants completed a pretest survey that was designed to provide a measure of self-estimated water competency and estimates of their capacity to exit the water under various conditions. Practical testing of exit skills was completed during 1.5 hr aquatics sessions/1 times per week over a 3-week period during the summer term (April–July 2021) in an indoor 50 m pool (water temperature 25 °C). Appropriate lifeguard supervision and safety equipment were available at all times. Ethics clearance for the study was obtained from Keio University Ethics Committee.
All data from the completed questionnaires were double entered into Microsoft Excel and data were transferred to SPSS version 24 for statistical analysis. Descriptive statistics expressed as frequencies and percentages were used to describe or characterize all numerical variables. These included four independent variables (gender, age, ethnicity, and self-estimated swimming competency) and four dependent variables related to previous experience, knowledge, perceptions of exiting task difficulty, and actual exiting competency. Chi-square tests of independence were used to test associations between the frequencies of the influences of age, gender, and ethnicity against the perceived and actual exertion required to perform the exiting tasks.
All participants were able to exit shallow and deep water when not fatigued, after a swim when wearing clothing or a buoyancy vest, but many failed to exit deep water over a 0.30 m ledge after swimming in clothing or in a buoyancy vest. Significantly more females than males found exiting deep water difficult. Most participants (especially males) underestimated the demands of exiting deep water. The value of situational learning via exposure to exiting difficulties in simulated pool practices is discussed.

**A MULTIDISCIPLINARY APPROACH OF A 100M BACKSTROKE SOUTH AMERICAN YOUTH CHAMPIONSCHIP RECORDIST**

LARA, J.P.R., JOAQUIM, D.P., SILVA, G.V., SILVA, R.R., COSTA, C.M., PAIXÃO, D.M., VANZELLA, F.A., ABAD, C.C.C.
*REFERENCE CENTER IN SPORTS SCIENCE -SESI SP*

INTRODUCTION: One way to understand better sport performance is analyzing well-succeeded athletes. The aim of this study was to describe a multidisciplinary profile of a female young athlete who broke the 100m backstroke South American record (time = 01:02.29s).
METHODS: A junior swimming female athlete was submitted to the 10s threatened swimming test, three vertical jumping tests, Brunel Mood Scale test (BRUMS), anthropometrical and body composition measurements, multi joint range of motion, a maximal muscle strength (1-RM) for bench press, half squat and strict pull-up exercises. All tests were obtained in three experimental sessions interspersed from 24 to 48 hours, one week before the South American Youth Championship of swimming, in 2021. A logarithmic scale was applied to the variables so that a measurement unit does not interfere in the interpretation of results. The profile of the multidisciplinary athlete was drawn using the radar chart.
RESULTS: The mean and the peak force during the threatened swimming were 92.4N and 182.2N, respectively. The high vertical jumping was 32.1cm, 35.2cm, and 46.2cm for the squat jump, countermovement jump and Abalakov test, respectively. The BRUMS scale presented values of 43,45,45,62,51 and 42 points for tension, depression, race, vigor, fatigue and confusion, respectively. The sum of seven skinfolds, as proposed by ISAK, of athlete was 84.5mm; Body mass=58.3Kg, body height=1.68m; lean mass index=30.16; body fat=14.6%; and arm-span=1.73m. The 1-RM was 53Kg for bench press, 86Kg half squat, and 62.3Kg for barbell. The respective right and left range of motion was 38.3° and 40° for shoulder internal rotation; 130° and 116° for shoulder external rotation; 5° and 12° for dorsi-flexors; 70° and 70° for plantar flexors; and 6.9° and 7.5° for knee hyperextension.
CONCLUSION: The profile described in the present study is a tool for helping coaches and sports professionals to understand the variables fluctuations across the next seasons and to make better decision concerning the long-term training process during the athlete's career. Finally, this result may be used for comparison with other top elite athletes aiming to reach the best perform.

**THE ESTABLISHMENT OF THE EVALUATION INDEX SYSTEM FOR THE SLIDING EXPERIENCE OF BOBSLEIGH AND SKELETON IN GENERAL POPULATION BASED ON DELPHI METHOD**

ANQI, L., WANG, D.
*SHANGHAI UNIVERSITY OF SPORT*

INTRODUCTION: Although Chinese skeleton team won a bronze medal in the 2022 Winter Olympic Games, Bobsleigh and skeleton is still under development in China. Therefore, it is vital to promote this sport in general population for the greater involvement of this sport. The objective of this study was to establish the evaluation index system for the sliding experience of bobsleigh and skeleton based on Delphi method.
METHODS: This study used a three-round Delphi survey to reach a consensus from fifteen experts who engage in bobsleigh and skeleton. The inclusion criteria of the experts were: 1) engaged in bobsleigh and skeleton research, 2) obtained a exercise physiology Ph.D. degree, 3) national bobsleigh and skeleton athletes, 4) national team staff of bobsleigh and skeleton. The survey included four main indicators, exercise physiology indicators, sports biochemical indicators, kinematic indicators, and subjective feelings. The second and third round of survey were adjusted based on the qualitative and quantitative analysis from the previous round of feedback. The indicators' inclusion and deletion were according to 70% concentration of the experts opinions. Data were analyzed by calculating experts authority coefficient (Cr), experts opinion coordination, and indicators coefficient of variation (CV%). The calculation of each indicator's weight was (Wi) via (Analytic hierarchy process, AHP).
RESULTS: Twenty items achieved consensus and were included in the evaluation index system for the sliding experience of bobsleigh and skeleton in general population. The index system is composed of one primary indicator (evaluation indicator of bobsleigh and skeleton sliding experience), four secondary indicators (exercise physiology indicators, sports biochemical indicators, kinematic indicators, subjective feelings), and twenty tertiary indicators (heart rate, blood pressure, respiration rate; testosterone, cortisol, epinephrine, norepinephrine and dopamine, nitric oxide, leptin, blood urea; speed, acceleration speed ； displacement, fear, emotional changes, excitement, boredom, pressure release, desire to repeat experience, and understanding of the sport). The experts authority coefficient Cr=0.84, experts opinion coordination 0.292 ($\chi 2=80.318, P<0.001$), exercise physiology indicators (CV% = 16.7,Wi = 0.1210), sports biochemical indicators (CV% = 23.6,Wi = 0.0391), kinematic indicators (CV% = 24.6%, Wi = 0.1796), subjective feelings (CV% = 21.3%,Wi = 0.6603).
CONCLUSION: Four main indicators were included in the evaluation index system for the sliding experience of bobsleigh and skeleton: exercise physiology indicators, sports biochemical indicators, kinematic indicators, and subjective feelings.

**EFFECTS OF PRE- AND POST-WORKOUT ENERGY BAR SUPPLEMENTATION ON BLOOD LACTATE AND FITNESS IN TRAINED CROSSFIT INDIVIDUALS: A RANDOMIZED CROSSOVER STUDY**

LIM, B.G.

*SEOUL NATIONAL UNIVERSITY*

INTRODUCTION: The energy bar supplementations continue to gain popularity among recreationally-active people. It is apparent that intaking of proper nutrition dose indeed affect the adaptive response to exercise but it is unknown if there is a difference between consumption timing of supplement and nutrient combination. The pre- and post-workout supplementation has their own strength, combining these benefits may have a positive impact on fitness and fatigue although research is lacking in regards to these two supplementations as a pair. The purpose of this study was to investigate the effect of pre- and post-workout supplementation on changes in fitness and blood lactate level in trained CrossFit individuals.
METHODS: In this randomized cross-over study, 20 trained CrossFit individuals (11 males, 9 females) performed CrossFit workouts (squat, clean & jerk and etc.) with pre- and post-workout supplementation. Subjects completed workouts three times per week, 60 min/day for 3 weeks with 1-week washout period. All subjects had been participating in at least three CrossFit classes per week for one year. Subjects were randomly assigned into one of two groups: chocolate bar (CH, 45g, 225kcal) or an energy bar group (ES: containing protein, caffeine, taurine, and branched-chain amino acids (BCAA), 48g, 238kcal). Subjects received 2 pieces of chocolate bar or energy bar at 5 minutes before and immediately after workout for 1 week. Following a washout period of no supplements, subjects received the alternate supplement (either chocolate bar or energy bar) for another 1 week. Blood lactate level and visual analog scale (VAS) were assessed before, immediately and 30 min after workout. And fitness tests (hand grip, broad jump and sit up) were conducted at baseline and 30 min after last workout. Data were analyzed by two-way repeated measures ANOVA ($p<.05$), 95% confidence intervals, and magnitude inferences.
RESULTS: Hand grip strength ($p<.001$, 5.6%), broad jump ($p<.05$, 2.7%) and sit up ($p<.001$, 13%) were significantly increased in the ES group. Compared to CH group, there was a significant time × group interactions for blood lactate level (F 4.9; $p=.02$) in the ES group, however, VAS did not reach significance. Blood lactate level at 30min postexercise was decreased to 7.31 mmol/L, reaching a baseline level in the ES group.
CONCLUSION: Additional ingredients in the energy bar included the BCAA, taurine and caffeine. The combination of BCAA, taurine and caffeine may effectively impact on muscle contraction and lactate clearance. These results confirm previous studies that caffeine can effectively increase anaerobic power and training volume and taurine develops energy production and general resistance to fatigue. Pre- and post-workout energy bar supplementation may have a beneficial effect on blood lactate clearance and fitness in trained CrossFit individual. The combination of proprietary supplements taken may provide benefits for removing the blood lactate during high-intensity functional exercise.

**A HIGH-PROTEIN VEGAN DIET IMPROVES BLOOD-BORNE INDICES OF CARDIOMETABOLIC HEALTH BUT DOES NOT ALTER MICRONUTRIENT STATUS COMPARED WITH AN ISONITROGENOUS OMNIVOROUS DIET DURING RESISTANCE TRAINING.**

VAN DER HEIJDEN, I., WEST, S., MONTEYNE, A.J., COELHO, M.O.C., FINNIGAN, T.J.A., STEPHENS, F.B., WALL, B.T.

*UNIVERSITY OF EXETER*

INTRODUCTION: A hypercaloric high animal protein diet is often advocated to meet increased macro- and micro- nutrient demands for optimal resistance training induced adaptations; though such diets are also associated with impairments in cardiometabolic health. Equivalent resistance-training induced increases in skeletal muscle mass and strength can be achieved consuming high-protein vegan diets which have also been used to improve markers of cardiometabolic health. Vegan diets, however, are potentially lower in key micronutrients required for optimal health and adaptation during prolonged training. In the current retrospective analysis, we investigated whether a hypercaloric, high-protein vegan diet consumed during high-volume resistance-training modulates blood-borne indices of cardiometabolic health or micronutrient status compared with an isonitrogenous omnivorous control diet.
METHODS: Twenty-two healthy young adults (age: 24±1 y, BMI: 23±1 kg·m2) undertook a 10-week progressive resistance training program (5-days/week), while following a high-protein (2 g·kg bm-1·day-1), hypercaloric (~10% daily energy surplus) omnivorous (OMNI: n=12; m=6, f=6) or mycoprotein-rich vegan (VEG: n=10; m=5, f=5) diet. Fasting venous blood samples were collected weekly to assess circulating glucose, insulin, micronutrient and lipid (using quantitative and targeted NMR-based metabonomics) statuses. Two-way repeated measures ANOVAs were performed to detect differences in each parameter. A false discovery rate of 0.276 was applied for metabonomics analyses.
RESULTS: Fasting plasma glucose concentrations remained unaltered, but serum insulin concentrations increased during training in OMNI only (from pre of 12±1 to post of 14±1 mU·L-1) resulting in an increased HOMA-IR index in OMNI (from pre of 2.4±0.2 to post of 2.9±0.2; $P<0.05$) but not VEG (from pre of 2.3±0.1 to post of 2.2±0.1; $P>0.05$). Out of 165 lipid targets, 5 differentially changed between groups throughout training ($P<0.05$). Large lipid classes (e.g. total cholesterol, triglycerides, phospholipids and fatty acids) did not change throughout training, but were higher in OMNI compared with VEG ($P<0.05$). Fasting serum ferritin concentrations decreased throughout training equivalently in both groups (OMNI: from pre of 54±14 to post of 38±9 µg·L-1, VEG: from pre of 73+31 to post of 52±20 µg·L-1, $P<0.05$) while serum vitamin B12, vitamin D and calcium concentrations did not change.

CONCLUSION: A hypercaloric and high-protein, mycoprotein rich, vegan diet can be followed during high-volume resistance-training to positively influence markers of cardiometabolic health without compromising micronutrient status when compared with a more traditional omnivorous dietary strategy.

### NO DIFFERENCES BETWEEN A NOVEL PLANT-BASED PROTEIN VS. WHEY PROTEIN ON BODY COMPOSITION AND PERFORMANCE OF PROFESSIONAL AND SEMI-PROFESSIONAL FUTSAL PLAYERS

TEIXEIRA, F.J.1,2, MATIAS, C.N.1, FALEIRO, J.1, GIRO, R.1, CARVALHINHO, R.1, MONTEIRO, C.P.2, REIS, J.F.2, VALAMATOS, M.J.2, TEIXEIRA, V.H., SCHOENFELD, B.J.

*1BETTERY LIFELAB, BETTERY S.A., LISBOA, PORTUGAL; 2CIPER, FACULDADE DE MOTRICIDADE HUMANA, UNIVERSIDADE DE LISBOA, ESTRADA DA COSTA, CRUZ-QUEBRADA, PORTUGAL*

INTRODUCTION: Futsal is a demanding team sport that involves strenuous high-intensity bouts of running accelerations and decelerations along with kicking, tackling, turning, changes of direction and repeated sprinting; these demands require high strength and power of the lower limbs. Additionally, like other small-sided games, futsal requires a high level of aerobic capacity (VO2max 55.2 to 62.8 mL.kg-1.min-1).
Evidence indicates that protein supplementation enhances muscle strength and hypertrophy, while it may also play a role in muscle repair and recovery from endurance exercise, and further improve VO2max. However, to our knowledge no study has investigated the effects of protein supplementation in futsal players.
The purpose of this study was to compare the effects of a novel plant-based protein matrix and whey protein supplementation on body composition, power, and aerobic performance in trained futsal players. Given that both protein sources provided identical amounts of protein and essential amino acids, we hypothesized that changes would be similar between conditions.
METHODS: Fifty young (18-35 y) male futsal players from national level futsal clubs volunteered to participate in this 8-week study; forty participants completed the investigation. Participants were randomly assigned to one of two groups: novel plant-based protein (PB) or whey protein (WP). The final sample was comprised of both professional and semi-professional players. Players were assessed for weight (kg), height (cm) and whole-body composition [lean body mass (LBM, kg), absolute and percentage fat mass (FM, kg and %)] using Dual energy X-ray absorptiometry (DXA) according to the procedures recommended by the manufacturer.
Anaerobic power was assessed via a supramaximal cycling test – Wingate, performed on a cycle ergometer. Participants were instructed to cycle as fast as possible against a predetermined resistance (7.5% of the participant's body mass) for 30 s.
Aerobic performance was assessed via VO2max determined by a breath-by-breath gas analyzer in an incremental treadmill test. After a 3-minute warm-up at 5 km·h-1, participants began the test at 6 km·h-1 and 2% grade. Each minute the speed increased 1 km·h-1 until volitional exhaustion so that fatigue would be induced within 8-12 minutes.
RESULTS: No time or time*group interactions were observed in any of the studied variables ($p>0.05$) with only a time effect being observed regarding a FM reduction ($p<0.05$).
CONCLUSION: Our results are consistent with some, but not all studies comparing whey protein with plant-based proteins. Methodological and protein matrix differences may account for these discrepancies between studies. Our findings suggest that whey protein does not possess any unique anabolic properties over and above those of plant-based proteins when equated for the essential amino acid profile.

### BONE AND MUSCLE PROPERTIES IN HABITUAL MEAT EATERS COMPARED TO NON-MEAT EATERS: AN OMNIPLANT PILOT STUDY

PAGE, J.1, STEBBINGS, G.K.2, MURPHY, C.H.3, KILDUFF, L.P.1, WALDRON, M.1, HEFFERNAN, S.M.1

*1. SWANSEA UNIVERSITY, 2. MANCHESTER METROPOLITAN UNIVERSITY, 3. UNIVERSITY COLLEGE DUBLIN*

INTRODUCTION: Dietary patterns excluding meat consumption are becoming increasingly popular in both public and athletic populations [1]. To date, few studies have compared skeletal muscle health and performance in meat eaters (MEs) and non-meat eaters (NMEs). Early work suggests muscle size and maximal strength in recreationally active male NMEs is comparable to that of ME [2]. Further, NMEs have been shown to have lower bone mineral density (BMD) and a greater risk of fracture compared with MEs [3]; however, other studies suggest there are no differences in BMD between these diet groups [4]. The aim of this study was to use preliminary data, from the OMnivorous and Non-meat eater Integrative Physiology and NutriTion (OMNIPLaNT) study, to compare markers of bone and skeletal muscle health between MEs and NMEs (i.e. vegans and vegetarians).
METHODS: Forty-five participants were recruited, in a cross-sectional observational design, having followed their chosen dietary pattern for > two years (NMEs=6.2±5.1 years). Dietary patterns were self-reported, confirmed using three-day weighed food diaries and a food frequency questionnaire. Men (n=23 [MEs=17], age=29±10 years, height=1.79±0.08m, body mass=81.1±16.0kg) and women (n=22, [MEs=9], age=37±14 years, height=1.67±0.04m, body mass=66.3±11.8kg) were analysed separately. Dual-energy X-ray absorptiometry was used to assess whole body composition and right femoral neck (FN) bone mineral density (BMD). Muscle function was determined via hand grip strength, and vastus lateralis (VL) muscle thickness, anatomical cross-sectional area (ACSA), physiological cross-sectional area (PCSA) and muscle volume were determined using B-mode ultrasonography. Muscle quality was assessed as ultrasound-derived echo intensity of the rectus femoris. Data were analysed using analysis of covariance, controlling for physical activity (quantified via the Baecke questionnaire) and body mass index as appropriate.
RESULTS: There were no differences between MEs and NMEs for any skeletal muscle or anthropometric phenotypes, in either men or women ($P>0.05$). FN BMD was significantly lower in male NMEs compared with MEs (NMEs=0.98±0.13g/cm2 vs MEs=1.32±0.17g/cm2, $P=0.003$), but no differences were observed between groups in women (NMEs=1.01±0.12g/cm2 vs MEs=0.97±0.11g/cm2, $P=0.527$).
CONCLUSION: The current study found no difference between MEs and NMEs for any of the assessed muscle properties (VL thickness, ACSA, PCSA, muscle volume and RF EI) which is in line with existing literature. Similar to some previous findings [3], FN BMD was lower in NMEs, but only in men and not women. Whilst the small sample size is a limitation of the current study, recruitment is ongoing and comparisons between individual plant-based/plant-predominant dietary patterns will be considered in the future.

## OP-MH13 Obesity

### MUSCLE QUALITY IN PATIENTS AWAITING BARIATRIC SURGERY: THE EFIBAR PROJECT

MARTÍNEZ-ROSALES, E.1,2, HERNÁNDEZ-MARTÍNEZ, A.1,2, LÓPEZ-SÁNCHEZ, L.1,2, RODRÍGUEZ-PÉREZ, M.A.1,2, SORIANO-MALDONADO, A.1,2, ARTERO, E.1,2

*DEPARTMENT OF EDUCATION, FACULTY OF EDUCATION SCIENCES, UNIVERSITY OF ALMERÍA, ALMERÍA, SPAIN, 2 SPORT RESEARCH GROUP , CERNEP RESEARCH CENTER, UNIVERSITY OF ALMERÍA, ALMERÍA, SPAIN,*

INTRODUCTION: Greater levels of both total and visceral body fat have been found to be associated with lower levels of muscle mass, with the latter being in turn associated with physical performance impairments in individuals with obesity. Muscle quality, defined as the expression of muscle function per unit of muscle mass, is recognized as a prognostic factor to detect individuals at risk of functional incapacity. The aim of this study is to assess the muscle quality index in patients with a high obesity rate (body mass index [BMI] ≥ 35 kg/m2) awaiting bariatric surgery.
METHODS: This cross-sectional study included 80 patients awaiting bariatric surgery (58 women; mean age: 41.1 SD 9.8, mean BMI: 47.1 SD 6.8). Specific muscle power was calculated as the ratio of sit to stand power [W] (based on the 30-s chair stand test) and skeletal muscle mass (bioelectrical impedance analysis) [kg]. Specific muscle strength was calculated as the ratio between handgrip strength [kg] and skeletal muscle mass [kg]. Muscle quality was individually categorized as normal, low, or poor based on the sex and age-specific (categorized as young adults [18-44 years] and middle-aged/older adults [45-74 years]) cut-off values according to the criteria provided by Barbat-Artigas.
RESULTS: Our results show a very high prevalence of normal muscle quality (84.4%) among our participants. In middle aged adults (>44 years old) there was a significant difference in muscle quality index between men and women (p=0.049). Middle-aged men had more specific strength (p=0.002) and power (p<0.005) than middle-aged women. However, in the younger group there were any differences. Regardless of age and BMI, men presented a higher skeletal muscle mass and strength than women.
CONCLUSION: Most of our sample presented a normal muscle quality index contrary to previous findings. This difference could be due to our sample being comprised of mostly young women and the different formulas used to obtain specific power which is the most important variable when categorizing for muscle quality. Future research studies should study the role of physical activity and body fat mass in the muscle quality index of this population.

### EFFECTS OF HIGH INTENSITY INTERVAL TRAINING (HIIT) AND MODERATE INTENSITY CONTINUOUS TRAINING (MICT) ON METABOLIC AND INFLAMMATORY MARKERS IN OBESE YOUNG WOMEN

LOPES, W.A., MENDES, V.H.S., SIMÕES, C.F., OLIVEIRA, G.H., RECK, H.B., LOCATELI, J.C., COSTA, C.E., OKAWA, R.T.P.

*STATE UNIVERSITY OF MARINGA*

INTRODUCTION: Obesity is characterized by the excessive accumulation of body fat, being considered a global pandemic and a risk factor for cardiovascular diseases [1]. Excess adiposity can lead to low-grade chronic inflammation which has been considered the link between obesity and other comorbidities [1]. Both high intensity interval training (HIIT) has been and moderate intensity continuous training (MICT) have been showing similar results in reducing body mass, body fat and visceral fat [2]. However, the effects of HIIT or MICT on metabolic and inflammatory markers have not yet been clarified [3]. Therefore, we investigated the effects of HIIT and MICT on metabolic and inflammatory markers in young obese women.
METHODS: Twenty-five obese women (28.4±4.8 years) with obesity were randomized to receive 8 weeks of HIIT (4 bouts of 4 min at 85% and 95% of HRmax alternated by 3 min of active recovery at 65% and 75% of HRmax) or MICT (41 min at 65 and 75% of HRmax). Body composition, cardiorespiratory fitness, insulin resistance (HOMA-IR), glycosylated haemoglobin (HbA1c) and levels of C-reactive protein (CRP), interleukin-10 (IL-10), tumoral necrose factor-α (TNF-α) were evaluated before and after intervention. ANOVA for repeated measure was used to analyze of the data.
RESULTS: Both training modalities reduced HbA1c (HIIT: Δ=-0.12±0.16 %, p=0.008 and MICT: Δ=-0.10±0.12 %, p=0.009). Only MICT reduced CRP (-0.36±0.16 mg/L, p=0.042). There were no significant changes in insulin resistance and other inflammatory markers measured. In terms of body composition and cardiorespiratory fitness, only HIIT significantly reduced body mass (Δ=-1.95±0.54 kg, p=0.002), body mass index (Δ=-0.72±0.20 kg/m², p=0.002), % body fat (Δ=-2.91±0.66 %, p<0.001) and increased peak oxygen consumption (Δ=1.90±0.54 ml/kg/min, p=0.024).
CONCLUSION: Although HIIT is superior in improving body composition and cardiorespiratory fitness in obese women, both training protocols were favorable for improving glycemic control and only MICT improved the inflammatory state associated with obesity.

### COMPARISON OF MAXIMAL FAT OXIDATION, BODY COMPOSITION AND MAXIMUM OXYGEN CONSUMPTION VALUES AMONG HEALTHY, DIABETIC AND OVERWEIGHT/OBESE WOMEN.

GONZÁLEZ-MARISCAL, A., OPAZO, E., MARÍN-GALINDO, A., MONTES-DE-OCA, A., RAMÍREZ-JIMÉNEZ, M., CORRAL-PÉREZ, J., PÉREZ-BEY, A., VELÁZQUEZ-DÍAZ, D., REBOLLO-RAMOS, M.

*UNIVERSITY OF CADIZ*

(co-authors) Orellana Pecino, J., Ávila, L., Ponce-González, J.G., Casals, C. INTRODUCTION: Obesity and type 2 diabetes (T2D) are related to reduced maximal fat oxidation (MFO) (1) which is an important indicator of metabolic flexibility (2). Thus, the aim of this study was to compare MFO values between healthy, diabetic and overweight/obese women.

METHODS: Fifty-two women including 33 healthy women (L) (age: 21,8±2,9; BMI: 21,2±1,7) 13 overweight/obese (OWOB) (age: 28,1±5,9; BMI: 33,7±6,9) and 6 with T2D (DM) (age: 50,5±10,7; BMI: 37,4±4,6) were included in the study. An incremental stress test was performed on a cycloergometer with two consecutive stages. The first stage consisted in 3-min increments of 15-30W depending on the weight of the subject with a cadence of 60-80 rpm until RER ≥1 in order to calculate MFO Once reached, an active rest of 3-5 minutes was taken after which the second stage began with 1-min increments until exhaustion to determine the VO2max. A 1-way ANOVA was used with Bonferroni comparisons.
RESULTS: The MFO relativized by body weight (kg) showed significant differences (p=0.01; p=0.00) between the DM-L and OWOB-L groups as well as when relativized by fat mass. L women had the highest values (mean: 0.053 g/min/kg), followed by OWOB women (mean: 0.032 g/min/kg) and DM group (mean: 0.027 g/min/kg). There were no differences in absolute values.
As for VO2max/kg, there is a significant mean difference in DM-L and L-OWOB (p=0.00) with L women having the highest values (mean: 40.02ml/kg/min), followed by OWOB women (mean: 23.6ml/kg/min) and diabetics with a mean of 17.5ml/kg/min. Otherwise, in absolute values, there is a significant mean difference in DM and L (p=0.012). No statically significant differences in the rest of comparisons.
CONCLUSION: Healthy normal-weight women have higher MFO and VO2max values relative to weight than diabetic and/or obese women. Diabetic women have a significantly lower VO2max than normal-weight women in absolute values.

### OP-LAG02 Health and Fitness

#### NOT ALL SEDENTARY BEHAVIOURS CONTRIBUTE THE SAME WAY TO ADOLESCENTS COGNITIVE-ACADEMIC PERFORMANCE. THE COGNI-ACTION PROJECT.

HERNANDEZ-JAÑA, S.1, ZAVALA-CRICHTON, J.2, CRISTI-MONTERO, C.1

*1 IRYS GROUP, PHYSICAL EDUCATION SCHOOL, PONTIFICIA UNIVERSIDAD CATÓLICA DE VALPARAÍSO, CHILE; 2 FACULTY OF EDUCATION AND SOCIAL SCIENCES, UNIVERSIDAD ANDRES BELLO, CHILE.*

INTRODUCTION: Adolescence is a key life stage for development and engrain healthy behaviours. Today evidence shows that adolescents spend excessive time in sedentary behaviours that could potentially negatively affect cognitive performance and in turn, academic achievement. However, studies report heterogeneous results depending on the sedentary behaviour type analysed. Therefore, this study aimed to establish the multivariate association of different sedentary behaviours with diverse cognitive and academic achievements.
METHODS: A total of 1,296 adolescents (10–14-years-old, 50% girls) from 19 public, subsidized, and private schools of the Valparaiso region (Chile) participated in this study. Sedentary behaviours (n=8) were self reported using two different questionnaires. Cognitive performance was evaluated through eight neurocognitive tasks from the NeuroCognitive Performance Test and the academic achievement was established by asking students their general average of the last semester in language, mathematics, history, English, and science. A canonical analysis was performed to determine the association between the two sets of variables adjusting for sex, school vulnerability, maturation, body mass index, and physical activity. Moreover, the analysis accounts for the random effect of schools.
RESULTS: Our findings show a single and significant mode of covariation related to a set of sedentary behaviours and cognitive-academic achievements (rho = 0.23, p= 0.015). Overall, some adolescents' sedentary behaviours contribute negatively (i.e., sitting at class, watching TV, using cellphone and transport), while others contribute positively (i.e., sitting doing tasks, eating, playing video games, and using computers) to the association with the cognitive-academic mode. The greatest contributions for the sedentary behaviour mode were for sitting doing tasks (rho=0.13), using computers (rho=0.13), and playing video games (rho=0.11), while for the cognitive-academic mode were the processing speed cognitive task (rho = 0.12), history grade (rho = 0.11), language grade (rho = 0.09), and working memory cognitive task (rho = 0.09).
CONCLUSION: Our findings give insights into the differentiated contribution of several sedentary behaviours related to cognitive-academic achievements. Therefore, this study could suggest that not all sedent activities might be associated with detrimental adolescents' cognitive and academic achievements. Educating adolescents to manage the time they spend on seated behaviours seems to be crucial to enhance their performance at the school level.

#### MYOFASCIAL ACTIVATION AT SUSPENSION EXERCISES IN ELDERLY AND YOUNG

BONEZI, A.1, SILVA, F.2, BONA, R.1

*UNIVERSIDAD DE LA REPUBLICA URUGUAY*

INTRODUCTION: The fascia provides connections between different body structures, transmits tension between different body segments, as well as body balance [1]. Best of our knowledge we don't find researches about anterior myofascial line activation or aging effects on fascial activation. Understand the role of fascia musculoskeletal system in dynamics situations is essential [2]. Purpose: analyse the myofascial activation of superficial back line (SBL) and superficial front line (SFL) on suspension exercises in elderly and compare with young people.
METHODS: Participated 10 elderly (65±0.5 years, 165±14cm, 70.5± 9.1kg), 10 young (22.6±1.3 years, 168±18cm, 64.3±7.2kg), both groups were physically active. The subjects performed 10 cycles, divided with accelerometry, of push-up and pull-up exercises with the suspension training apparatus (like TRX).
Surface EMG with Delsys Trigno (2000Hz), at 12 different regions of myofascial continuity, at SBL: gastrocnemius lateralis (GL), biceps femoris (BF), iliac spine (EIPS), longissimum (LG), T6, splenius head (EC). At SFL: tibialis anterior (TA), rectus femoris (RF), rectus abdominis

inferior (RAI), superioris (RAS), pectoralis major sternum (PM), sternocleidomastoideus (SCM) [3]. Followed SENIAM to processing EMG data. Then RMS values were calculated in the ABS software (Analysis of Biomechanical Signal -LIBiAM). Two-way ANOVA and Tukeys post hoc were used (α=0.05). Ethics Committee approved the protocol.
RESULTS: Elderly: great values at EC (40 ± 9 mV) in SBL; TA (70 ± 10 mV) and ECM (50 ±11 mV) in SFL (p=0.0002) both for the pull-up.
Young: great values for core regions (RF, RAI, RAS, PM) in SFL (p<0.0001) during the push-up exercise.
Comparing exercises, push-up are different for all SFL of younger (p=0.002).
Interestingly, elderly (for SBL and SFL) shows smaller values for all 12 regions compared to young "fascia" group (p=0.01).
CONCLUSION: The myofascial activation was different in the elderly compared to the young. In both SFL and SBL present different behaviors between groups and exercises too. Aging decrease fascia hydration, reduces body balance, stability and probably the efficiency of force transmission [1,2]. Younger has greater activation in the core, possibly reflecting in better force transmission of the SBL and SFL. Postural muscle line, in the elderly, increases the amount of type I collagens [1]. The position of the body can generate changes in the transmission function of the fascial tissues, as seen between exercise variations. So, results suggest different patterns of postural and central regions activation and/or connectivity of the musculoskeletal fascia system for each exercise movement. The interactions between agonist, synergist, antagonist, other adjacent muscles and fascia are active components of the body system to generate movement.

**PHYSICAL TRAINING IMPROVES THE SARCOPENIA CRITERIA IN A MICE MODEL OF CHRONIC LIVER DISEASE.**

GONZÁLEZ ROJAS, A., MORALES VILLANUEVA, V., VALERO BRETÓN, M., CABELLO-VERRUGIO, C.
*UNIVERSIDAD ANDRÉS BELLO*

INTRODUCTION: Sarcopenia is one of the complications of Chronic Liver Disease (CLD), which affects the quality of life and survival of those who suffer from it, being an independent predictor of mortality. Its diagnosis is based on decreased strength, decreased muscle mass (MM), and impaired physical function (PF). For its treatment, endurance training (ET) and resistance training (RT) a non-pharmacological tool recommended based on their broad benefits. Still, there is no clarity regarding which one is more effective. In sarcopenia due to aging, RT increases MM and strength, but in sarcopenia, due to CLD, it is minimally used. The ET is commonly applied, but it has shown positive effects only on PF in patients with CLD. We, therefore, compare the effects of RT and ET on the sarcopenia criteria in a murine model of CLD.
METHODS: Forty-seven male C57BL/6J mice (20 weeks old) were separated into two groups: chow diet (control) and hepatotoxin 5-diethoxycarbonyl-1,4-dihydrocollidine (DDC) diet (CLD). Then, the animals were randomly subdivided into 1 sedentary group (SED) and exercise groups (ET and RT). Physical training was performed for 6 weeks at moderate intensity. In vivo muscle strength (MS) was assessed (Grip Strength (GF/tibia length (mm))). MM was assessed ex vivo by muscle weight (mg/ tibia length (mm))). PF was assessed by maximal running capacity on a treadmill (meters (m)). Muscle fiber's diameter was determined in cryosections (10 µm) of the TA and Soleus (SOL) stained with WGA and quantified in Image J software. Data are presented as mean ± standard deviation. Differences between groups were determined with 2-way ANOVA and Tukeys post hoc test. p= 0.05. 95% confidence interval. Approval of the Universidad Andrés Bello Bioethics Committee 015/2019.
RESULTS: RT, but not ET, prevents MS loss induced by CLD in the hind legs [RT-CLD: 8.61±1.53 GF/mm vs. SED-CLD: 6.65±0.68 GF/mm, p=0.01]. Depending on the muscle type, the decrease in MM induced by CLD is prevented by the RT and/or ET [TA: RT-CLD: 3.06±0.51 mg/mm vs SED-CLD: 2.54±0.19mg/mm; p=0.04], [Extensor digitorum longus (EDL): RT-CLD: 0.73±0.08mg/mm vs SED-CLD: 0.51±0.07mg/mm; p=0.02], [SOL: ET-CLD:0.66±0.21 mg/mm vs SED-CLD: 0.49±0.09 mg/mm; p=0.04] and [Gastrocnemius (GA) ET-CLD: 8.31±2.41mg/mm and RT-CLD: 7.91±1.27 mg/mm vs SED-CLD: 6.36±1.64 mg/mm; p<0.05]. The alteration of the PF induced by CLD is prevented by the ET [ET-CLD: 191.77±71.07 m vs. SED-CLD: 46.70±28.88 m; p<0.0001], but not by RT. Quantification of the Feret's diameter revealed TA and SOL tissue from SED-CLD has a distribution curve with a peak of 31–35µm, whereas the fibers' size distribution from ET-CLD and RT-CLD was displaced to the right with a peak in the range of 36–40 µm.
CONCLUSION: During CLD, RT prevents the loss of MS and the MM but not the PF. ET prevents PF and MM loss, but not strength. The results suggest that combined training could improve all parameters of sarcopenia secondary to CLD.

## Invited symposia

### IS-AP04 Combat sports performance optimization: physiology, testing and rapid weight loss

**COMBAT SPORTS PHYSIOLOGY**

FRANCHINI, E.
*UNIVERSITY OF SÃO PAULO*

Understanding the physiological response to the most common training modalities and competition of combat sports athletes may help to improve the prescription and monitoring of training programs. The focus of this presentation will be on the Olympic combat sports: boxing, fencing, karate, judo, taekwondo, and wrestling. Studies reporting estimates of energy systems contributions, physiological (e.g., oxygen consumption, heart rate) and metabolic (e.g., blood lactate) responses for striking (boxing, karate, and taekwondo), grappling (judo and wrestling), and arm-based (fencing) combat sports during simulated and official competition will be presented. Based on the evidence presented, specific manipulation of effort: pause ratio, total session duration, number, and duration of individual sets for combat sports-specific exercise modalities will be suggested; with the overarching aim to provide evidenced-based suggestions for appropriate training protocols.

### WEIGHT LOSS IN COMBAT SPORTS: PREVALENCE, MAGNITUDE, METHODS, PHYSIOLOGICAL AND PERFORMANCE RESPONSES

ESCOBAR-MOLINA, R.

*FACULTAD CIENCIAS DEPORTE*

Combat sports athletes are normally classified according to their body mass at competitions in what has been denominated as weight categories. These weight categories differ between combat sports, however, the upper limit of BM for each weight category is commonly separated by 10-15% intervals. The weigh-in process also varies among combat sports, with 'official weigh-ins' occurring anywhere from 16h to 3h before the competition. Despite the differences between weight categories, weigh-in processes and physiological demands of combat sports, the prevalence of weight loss prior to competition is higher than 60% in most Olympic combat sports; with weight loss of approximately half of the percentage interval between weight categories (i.e., 5% to 8%) being common. The main methods used by combat sports athletes to decrease body mass include dieting, dehydration, and exercise using heavy clothes or in hot environments. Increased dehydration and the depletion of energy stores are common consequences of such procedures and have a negative impact on aerobic and anaerobic performance when no nutritional intervention is allowed post-weigh-in. For athletes familiarized with these weight loss processes and who use specific refeeding procedures, aerobic and anaerobic performances decrements may be reduced or eliminated. However, the development of eating disorders and other health-related problems are commonly reported in these athletic groups, especially in female combat sports athletes.

### COMBAT SPORTS-SPECIFIC TESTS

MORALES, J.

*UNIVERSITAT RAMON LLULL*

Training prescription is a complex task and regular testing is considered a key element in this process. Combat sports performance is determined by different physical capacities depending on the characteristics of the competition (i.e., grappling, striking, or mixed combat sport; lighter or heavier weight categories; number and duration of matches, as well as the interval between them, in a given competition, etc.). Therefore, specific tests are needed to assess different physical capacities or to simulate the physiological demand of a combat sports match, while considering the specificity principle. In the last two decades, many combat sports-specific tests were proposed. In this lecture, the main tests, their validation process, sensibility, and applicability will be presented. Special consideration will be presented regarding the use of such tests for training prescription and monitoring.

## Oral presentations

## OP-MH06 COVID-19: Physical activity and inactivity

### CHANGES IN PHYSICAL ACTIVITY IN SWEDEN DURING COVID-19: A COMPARATIVE CROSS-SECTIONAL ANALYSIS

ANDERSSON, K., JANSSON, A., HEDENBORG, S., SVENSSON, D.

*UNIVERSITY OF MALMÖ*

Introduction
According to accumulated data, COVID-19 related restrictions can lead to considerable inactivity and sedentary lifestyles. The Swedish COVID-19 response consisted of guidelines rather than restrictions, which could possibly have a positive impact on activity levels remaining high. To investigate to which extent self-rated physical activity changed during the Swedish COVID-19 response, two cross-sectional surveys (N = 10,560) were conducted. The data constitutes the most comprehensive material on COVID-19 and physical activity extracted from Sweden. The aim is to contribute with new knowledge about general trends in physical activity during the Corona-pandemic in Sweden.
Methods
The method used is based on a quantitative cross-sectional retrospective approach. This approach makes it possible to clearly illustrate how the respondents' (N = 10,560) answers differ depending on whether the questions referred to physical activity "before COVID-19" or "during COVID-19". The data was collected on two different occasions (dataset 1 & dataset 2). Both surveys were digital questionnaires. The first dataset was distributed through social media, and The Swedish Research Council for Sport Science, whereas the second survey was distributed via e-mail. Dataset one was collected between 8 April 2020 to 14 august 2020, while dataset two was gathered from 8 December 2021 to 22 January 2021. The analysis included descriptive statistics, t-tests, correlations, and ANOVA. Cohen's guidelines were used to establish what should be considered small, medium, and large differences.
Results
Overall, the results convey that there are significant differences for many people in everyday exercise performance during COVID-19. The most striking result is that many respondents report the same amount of everyday exercise, however, less physical training, and more sedentariness. Moreover, the result shows that elderly respondents were more affected than younger people, yet younger people reported more increased time sitting down. In terms of gender, although the Cohen guidelines categorize the difference as small, women had higher scores on sedentariness and reduced physical activity.
Discussion
Both datasets reveal that patterns of physical activity have changed during COVID-19. However, contrary to what some studies conducted in Sweden have argued, within our datasets, differences across gender and age yielded only small differences. This deviates from studies that report that COVID-19 had a substantial negative impact on certain demographic groups. We conclude that respondents report less physical training regardless of demographic specificities. That elderly report less movement aligns with the outcomes of similar large-scale studies conducted in other countries. Finally, we suggest that one reason for differing results could be the use of different definitions when employing questionnaires to gain information on perceived physical activity.

## EXERCISE AS AN INTERVENTION TO MITIGATE METABOLIC CHANGES DUE TO SEDENTARISM: A RANDOMIZED CONTROLLED TRIAL DURING COVID-19 PANDEMIC

SILVA, F.M., DUARTE-MENDES, P., FERREIRA, J.P., TEIXEIRA, A.M.

*UNIVERSITY OF COIMBRA, FACULTY OF SPORT SCIENCES AND PHYSICAL EDUCATION*

INTRODUCTION: The current COVID-19 pandemic and the implemented policies have impacted people's work, recreation, levels of physical activity and sedentary behaviors (SB) [1]. Physical inactivity and SB are considered the major causal factors for obesity, insulin resistance, and type 2 diabetes development [2]. Potential strategies to overcome these negative effects include home-based exercise [3]. This study aimed to analyse the effects of a combined training program performed during the first national COVID-19 lockdown on insulin resistance markers in non-diabetic sedentary workers.
METHODS: This study was designed as a randomized, parallel-group clinical trial of 16-weeks. Thirty-one participants (48.26 ± 7.89 years old; 77.4% women, BMI: 27.83 ± 4.26 kg/m2) concluded the study; participants were randomly assigned to an exercise group (i.e., performed 16-weeks of combined training) and to a control group (i.e., did not perform any type of exercise). The combined training program (i.e., aerobic plus resistance exercise) occurred 2-3 times/week for approximately 55 min/session. Anthropometric measures (i.e., stature, body mass, waist, and hip circumferences) and fasting blood samples were taken pre and post-intervention. Fasting insulin concentration was analysed by ELISA (Crystal Chem, USA) and fasting glucose was analysed using the standard enzymatic assays (ABX Pentra, Germany). The homeostatic model assessment of insulin resistance (HOMA-IR) was calculated as (insulin [µU/L] x glucose [mg/dL] / 405). Descriptive statistics were performed for all variables. A two-way ANOVA for repeated measures was used for intra- and inter-group comparisons.
RESULTS: A significant decrease of waist ($p < 0.001$) and hip circumference ($p = 0.001$), waist-to-height ratio ($p < 0.001$) and waist-to-hip ratio ($p = 0.011$) were observed in the exercise group compared with the control group at the post-intervention. Regarding the insulin resistance markers, a significant increase of fasting glucose ($p = 0.029$) and HOMA-IR ($p = 0.010$) were observed in the control group at the post-intervention, while no significant changes were observed in the exercise group.
CONCLUSION: Our findings suggest that the participants that performed the home-based exercise program during the first pandemic-related lockdown were able to mitigate the metabolic changes associated with a sedentary lifestyle.

## DID THE COVID-19 PANDEMIC AFFECT THE SECULAR TRENDS IN MOTOR PERFORMANCE AND BODY MASS INDEX OF FIRST-GRADERS IN A SWISS URBAN AREA?

LICHTENSTEIN, E., NEBIKER, L., ROTH, R., KELLER, M., LONA, G., HAUSER, C., HANSSEN, H., FAUDE, O.

*UNIVERSITY OF BASEL*

INTRODUCTION: The reduced ability to attend leisure time sporting activities and lockdowns disabling children from attending school during the Covid-19 pandemic presents a threat to the maintenance or uptake of unstructured and structured physical activity. It may be speculated that this potential reduction in physical activity at an early age leads to a negative effect on the physical development of children. Whether the Covid-19 pandemic had a negative influence on the development trends of children in motor performance and body composition is unclear. We hypothesize, that children performed worse in 2021 and were less fit than the observed trends from 2014 to 2020 would predict.
METHODS: As part of the ongoing monitoring of childrens' motor performance tests in the first grade in the city of Basel, Switzerland, every year all first graders are tested with four motor performance tests: 20 meter shuttle run, 20 meter sprint, side hopping and balancing backwards. Also, their height and weight is measured. Children are categorized as overweight, when they are above the 90. percentile for their age and sex in BMI and as obese when above the 97. percentile. Only data of the 13 schools that were also tested in 2020 were used. Linear regression for the performance parameters and logistic regression for weight status was used to predict 2021 performance based on data from 2014 to 2020. This prediction was then compared to the performance achieved in 2021.
RESULTS: 4454 children (637 ± 23 per year) were tested from 2014 to 2020 (50.9% male, ) and 639 (50.2 % male) in 2021. The 2021 cohort outperformed the predicted values by 6.1% for shuttle run [95 % CI: 1.8; 10.4], 0.2% for 20 meter sprint [-0.6; 1.0], 6.4% for side hopping [3.7; 9.2], and 4.0% for balancing backwards [-0.5; 8.4]. Whereas the 95 % confidence intervals of the predicted and the actual data overlapped for balancing backwards and sprint performance, they did not for side hopping and shuttle run. The proportion of overweight and obese children was 47.4 % [32.6; 62.0] and 55.9 % [37.2; 74.5] higher, respectively, than was expected from the secular trends (16.4 vs 11.1% and 10.1 vs 6.5 %).
CONCLUSION: The 2021 cohort showed better performance than predicted in all motor performance parameters but sprint time, suggesting that the safety measures for combatting the Covid-19 pandemic did not limit their motor development. However, the vastly increased number of overweight and obese children is alarming. Potential reasons for this diverging findings remains speculative. It might be assumed that an increased caloric intake in combination with increased sedentary time in the already inactive and overweight children may be partly responsible for this finding. Public health interventions in this cohort should focus on maintenance or reversion of a healthy body composition.

## PHYSICAL ACTIVITY AND SEDENTARY TIME DISTRIBUTION AMONGST ADULT RESIDENTS DURING COVID-19 LOCKDOWN IN SINGAPORE- A PUBLIC HEALTH PERSPECTIVE

MUKHERJEE, S., TAN, K.J.

*NATIONAL INSTITUTE OF EDUCATION, NANYANG TECHNOLOGICAL UNIVERSITY, SINGAPORE*

INTRODUCTION: To mitigate the spread of COVID-19 in the community, home confinements, social restrictions and closure of public facilities has become a global public health strategy. Singapore imposed a lockdown called as circuit breaker movement restrictions (CBMR) during April-June 2020. While these risk mitigation measures are imperative, they may have led to unintended consequences on physical activity (PA), sedentary behavior and health. This study investigated the PA and sedentary time (ST) distribution patterns in adult residents of Singapore during the CBMR period.

METHODS: This study used a cross-sectional, retrospective design. A 44-item questionnaire was developed. The survey link was distributed via different socially popular online platforms. The questionnaire included sections to determine PA and ST distribution patterns before and during the CBMR. It also included information on sleep duration, PA preference and routine, awareness on local initiatives and perceptions on barriers toward PA during the CBMR period.
RESULTS: There was an overall decrease in PA, and a significant increase in physical inactivity and ST during this period suggesting negative lifestyle adaptations to CBMR, with the potential to adversely affect health and fitness. A greater proportion of participants reported sleeping for longer hours during the CBMR period. Respondents had high perception of proficiency in using screen-based gadgets but there was low awareness on local governmental and organizational initiatives for exercise and health promotion on various online platforms. The Singapore society seemed to prefer outdoor and facility-based exercise venues and closure of these locations was reported as the most common barrier to be physically active during the CBMR.
CONCLUSION: Reduced PA and increased ST during the CBMR reflecting negative lifestyle adaptations and may have led to an increased the risk of chronic diseases, reduced cardiorespiratory fitness, and adverse health implications. Increased sleep duration was suggestive of successful coping with fear and anxiety related to the pandemic, and consequently may have lead to physical and mental health benefits. Majority were unaware of online exercise initiatives and programs offered during the CBMR period, and >50% respondents reported never using an online resource for exercise. While Singaporean adults may be flexible with certain aspects of being physically active, they seemed less adaptive to changes in exercise type, facility, and environment.

**NEUROVEGETATIVE BP AND HR REGULATION IN SARS-COV-2 POSITIVE ELITE-ATHLETES**

DIEBOLD, K., SCHLUNCK, M., SCHIFFERDECKER, I., SCHICK, F., SCHULTE-KÖRNE, B., ZACHER, J., PREDEL, H.G.
*INSTITUTE OF CARDIOLOGY AND SPORTS MEDICINE, GERMAN SPORT UNIVERSITY COLOGNE*

INTRODUCTION: Current studies in the general population provide evidence that persisting symptoms after SARS-CoV-2 infection may relate to a dysfunction in the autonomic nervous system regarding blood pressure (BP) and heart rate (HR) regulation (1,2,3). In many studies, the measurements have been performed in resting state or with the tilt table test (TTT). In the absence of definitive data, there is ongoing uncertainty about how the autonomic nervous system adapts to physical stress in elite athletes.
The aim of the study was to evaluate the dynamics of BP and HR and physical performance during exercise test in elite athletes before and after SARS-CoV-2 infection.
METHODS: 17 German Olympic Sports Confederation athletes (15 men, 2 women; mean age 23 years ± 5) aged between 20 and 35 with laboratory-confirmed SARS-CoV-2 infection were included in this panel study, which was implemented from December 2020 to September 2021 at the Institute of Cardiology and Sports medicine of the German Sport University Cologne (DSHS). SARS-CoV-2 infection as determined by reverse transcription–polymerase chain reaction (PCR) or serum immune globulin G antibody against the SARS-CoV-2 virus. To evaluate autonomic regulation of systolic BP and HR including rate pressure-product (HR × BPsyst.) incremental exercise test was conducted as soon as possible, after initial SARS-CoV-2 infection (t0) and 16 weeks later (t1). Physical performance was determined by peak power output (Wpeak). All results were compared with existing pre-covid data (t-1) of the athletes.
RESULTS: Our analysis showed a significant increase in HR at 250 Watt (p=0.035) at t0.The mean Wpeak (t-1: 261,06 ± 64,61, t0: 257,20 ± 69,44, t1: 256,64 ± 55,38), BPsyst. and rate pressure - product (p>0.05) showed no significant difference between all time points of measurement.
CONCLUSION: In conclusion, the study indicates that the autonomic regulation of BP and HR was not critically altered by SARS-CoV-2 infection in elite athletes. Although significant increases in HR at the pre maximum intensity levels were observed 4 weeks after acute infection, no limitations in HR regulation could be identified. Further long-term research including spiroergometry data is needed to draw reliable conclusions.

### OP-AP12 Training monitoring in team sports

**A NEW TRAINING LOAD QUANTIFICATION METHOD AT SUPRA-MAXIMAL INTENSITY AND ITS APPLICATION IN INJURIES AMONG MEMBERS OF AN INTERNATIONAL VOLLEYBALL TEAM.**

BOUZIGUES, T.
*ECOLE NORMALE SUPÉRIEURE DE RENNES*

INTRODUCTION: In volleyball (VB), the quantification of the training load (TL) is based on the number of jumps (Piatti et al., 2021), however the jump height is not considered. The repetition of intense jumps is source of significant mechanical stress and promote the injury occurrence (Bahr and Bahr, 2014). To optimize jump performance and reduce the occurrence of injuries, it's necessary to monitor and quantify specifically TL in VB (Debien et al., 2018). The aims of this study were (i) to propose a new method for quantifying TL for explosive exercises, (ii) to determine the nature of the relationships between the dynamics of TL and injury occurrence and (iii) to find a limit TL in terms of jumps, above which the risk of injury occurrence become unacceptable, for optimizing the training schedule.
METHODS: This study was conducted in 11 male VB players of the French national team (age: 25.5 ± 2.9 years; size: 197.9 ± 7.3 centimeters; weight: 89.7 ± 10.6 kilograms) over a 5-month international competitive period (23 games and 37 specific training). During these sessions, a G-Vert accelerometer(Damji et al., 2021) was used to quantify TL provided by the players during each sessions. The proposed new TL quantification method is based on considering the relative intensities of the jumps according to the maximum jump height (MJH)

and the introduction of a weighting factor(Banister and Hamilton, 1985) for high-intensity exercises based on the relationship between the number of possible jumps and their intensities. The relationships between TL dynamics occurrences of injuries were assessed using a variable dose-response model of Busso (Busso, 2003). An injury score was determined based on the injury severity score (Stevenson et al., 2001).
RESULTS: A high coefficient of determination was found ($r2 = 0.94 \pm 0.14$, $p < 0.001$), indicating a strong physiological law between the intensity of the jumps and the constraints imposed. The injury risk was dependent of the dynamics of the TL ($r2 = 0.47$; mean error = 0.7%; $p < 0.001$). A number of 12 jumps at >80% of MJH during the game sessions, in addition to the 143 jumps at <80% of MJH, seems to be the daily limit not to be exceeded.
CONCLUSION: A new approach makes it possible to quantify explosive exercises and the application of the variable dose-response model offers practical advice for the conduct of the training in VB.

**RELATIONSHIP BETWEEN EXTERNAL LOAD FROM SIMULATED ICE-HOCKEY GAMES AND PHYSICAL TEST PERFORMANCE**

BYRKJEDAL, P.T.1, BJØRNSEN, T.1, LUTEBERGET, L.S.1,2, LINDBERG, K.1, IVARSSON, A.1,3, HAUKALI, E.4, SPENCER, M.1
*1. UNIVERSITY OF AGDER, 2 NORWEGIAN SCHOOL OF SPORT SCIENCES, 3 HALMSTAD UNIVERSITY, 4 STAVANGER OILERS.*

INTRODUCTION: Well-developed physical fitness is regarded as an important factor for ice hockey game performance. Hence, off- and on-ice physical performance testing is regularly performed [1]. Despite its wide application, the importance and relevance to game performance is however uncertain due to limited game characterization data. Recent developments and application of indoor tracking systems have made such physical game performance data available and is suggested as a useful method in narrowing this research gap [2]. The purpose of this study was therefore to explore the association between physical performance measures and external load variables from simulated games.
METHODS: The study was performed over two weeks and included two days of testing and four simulated games (scrimmages). During games, players wore a Local Positioning System-tracking device. Each game included three 20-min periods and two intermissions, in accordance with official regulations. However, the games were standardized to a non-stop play design, with shifts performed every 1-min. Physical performance tests included 30-m on- and off-ice sprint, countermovement jump (CMJ), standing long jump, pullups and 1-repetition maximum in bench-press and trap-bar deadlift. External load variables from simulation games included total distance, maximum velocity (max vel), distance in speed skating zones, number of sprints, PlayerLoadTM, high intensity events (HIEs), accelerations, decelerations and change of directions (CODs). Initially, 34 players participated in the simulation games and physical tests. 14 players (age: 17.8±1.1 yrs, height: 179.5±6.5 cm, body mass: 71.2±6.0 kg, n=4 defensive, n=10 Forwards) participated in all games and completed all the physical performance tests, and thus were included in the analysis.
RESULTS: Bayesian pairwise correlation analyses showed strong evidence for associations between pullups (r=0.61) as well as on-ice top speed (r=0.55) to HIEs and max vel, respectively. There was moderate evidence for an association between on-ice top speed (r=0.44), CMJ (r=0.44) and sprint speed skating distance, while there also was moderate evidence for an association between CMJ (r=0.46) and number of sprints. Furthermore, there was moderate evidence for associations between pullups (r=0.50) as well as trap-bar (r=0.45) and CODs and max-vel, respectively.
CONCLUSION: This explorative study shows that only a few of the physical performance tests were likely to have any meaningful association with external load variables from simulated games. Specifically, only 7 of 132 correlations showed evidence for associations between fitness tests and external load performance. Based on these findings, top-speed from on-ice sprint and CMJ seem to be relevant for sprinting abilities, while pullups suggest that upper body strength plays an important role in acceleration derived data, such as CODs, accelerations, and decelerations during gameplay situations.

**TIME-INTENSITY MODELS FOR INTERMITTENT SPORTS GAMES USING THE EUROPEAN HANDBALL CHAMPIONSHIP 2020 AS AN EXAMPLE: MIXED MODELS AND MORE**

SCHÄFER, R., VENZKE, J., NIEDERER, D., MANCHADO, C., PLATEN, P.
*RUHR UNIVERSITY BOCHUM*

INTRODUCTION: Training load terminology can be confusing. Parameters like the “normalized distance” are commonly used to describe the load profile in sports games. The interpretation of such parameters is not always straightforward and depends on the question asked and the data processing. Causal effect estimates are often the target, but this is even harder for observational studies (e.g., analysis of tournament data) compared to experiments. In handball, research interest was placed on positional differences and decreasing intensity over time. Our aim is to highlight methodological pitfalls when interpreting observational data from intermittent sports games and show techniques to overcome t
METHODS: The data in this example were obtained from the European Handball Championship 2020 and recorded with the Kinexon Local Positioning System (LPS). The raw data were processed to obtain summary statistics for each player in each game, which were used for statistical modelling. A three-step procedure is used to interpret the causal effects of playing position, intensity and time played: First, I discuss a simple definition of volume, time and intensity. Second, I am going to identify the underlying causal effects using a graphical causal model. Third, I discuss and compare different models to estimate causal effects for positional differences and decreasing intensity over time.
RESULTS: The terminology of “time-normalized distance” conceals the correct interpretation: It’s the average velocity and, thus, a measure of intensity by definition. A mediation model guides the regression analysis: To identify the direct effects of intensity change over time and positional differences in intensity, we must include position and time in the same regression model. Thus, the direct effect for time yields an intensity decrease of 0.21 W/kg [CI95% [0.17; 0.25] per 10 minutes played. In the same model, positional differences were observed between wings, mid backs, left and right backs and pivots. The direct effects differed substantially from the total effect, e.g. mid backs had lower intensity estimates as direct effect (8.17 CI95% [7.93; 8.41] vs. 7.85 CI95% [7.68; 8.03]). Importantly, modelling individual observations as random effect yields larger confidence intervals compared to a simple factorial (ANOVA) design, e.g. the mean standard error was 39% higher. The random slope/intercept model outperformed other models in fit parameters (information criteria, p-values).
CONCLUSION: Causal identification strategies should generally be used when interpreting observational data from sports games. Current practice is to present simple means. This can be misleading and marginalized effects should be presented according to the assumed causal

model structure. Violation of the independence assumption may lead to narrower standard errors and might thus increase the risk of false-positive results. Also, visualizing raw data and model predictions should be a standard rather than an exception.

### METABOLIC POWER AND SUCCESS IN MEN'S HANDBALL IN THE EUROPEAN CHAMPIONSHIP

VENZKE, J., SCHÄFER, R., NIEDERER, D., MANCHADO, C., PLATEN, P.

*RUHR UNIVERSITY BOCHUM*

INTRODUCTION: Strong physical performance is a fundamental part to accomplish success in professional handball. Since accelerations are a crucial part of movement in handball, it is not sufficient to evaluate total distance as volume and average velocity as intensity parameter. Metabolic power (MP) implements both acceleration and velocity and might better reflect (metabolic) demands in terms of match intensity (metabolic) in team sports. We hypothesize, that higher metabolic demands might lead to a better match outcome in top-level handball.
METHODS: 414 elite male handball players were included. During 65 matches of the EURO 2020, local positioning system data (Kinexon Precision Technologies) were collected (16.6 Hz), yielding 1853 datasets. We analyzed net playing time only with durations above 1 min. Goalkeepers and games resulting in a draw were excluded from the analysis. Average Metabolic Power (W/kg) an energy at high metabolic power (HE; >35 W/kg) per minute were processed and further used as predictors for success. We first standardized these values across the whole dataset and then calculated means and standard errors on those for each team and match. Next, a (Bayesian) logistic mixed effect measurement error was fitted with the brms package with match and team as random effects.
RESULTS: The logistic regression shows favorable tendencies for higher metabolic demands toward success (MP: 0.67 W/kg; CI95% -128|2.66; HE: 1.03 J/kg/min; CI95% -0.88|3.08). However, these results are not conclusive due to widespread credibility intervals. The metabolic power and energy at high MP in winning teams is higher on average compared to the losing teams (MP: +0.12 W/kg; SE: 0.04; T=2.9; HE: +0.01 J/kg/min; SE: >0.01; T=3.3) when the win is the outcome. A sensitivity analysis using the goal difference outcome showed fewer benefits toward higher metabolic demands.
CONCLUSION: Our study confirms that the playing intensity in winning teams is higher on average. Recent research show that wing players expend more energy at high metabolic power compared to other positions. Winger are the preferred position for fast counter-attacks which yield a high metabolic power, thus, a simple and efficient way of scoring is a big contributor to winning. For achieving success, greater involvement with the ball, more successful passes and the completion of skill-related activities might be of great importance and contribute more directly to success in comparison with match running performance.

### APPLICATION OF TACTICAL PERIODIZATION TO PRESEASON TRAINING PERIOD IN PROFESSIONAL RUGBY UNION PLAYERS

HU, X.

*UNIVERSITÉ RENNES 2- ENS RENNES*

INTRODUCTION: Tactical periodization (TP), as an alternative paradigm to periodization, gained considerable traction in recent years for strength and conditioning (S&C) coaches [1]. It considers all training factors and contains three principal acquisition training days (i.e., Strength, Endurance, and Speed days) that allow corresponding three crucial physical capacities development [1, 2]. However, no scientific research has reported the effects of three TP acquisition days during the preseason training on physiological characteristics in rugby union (RU). Therefore, this paper aims (i) to investigate the effect of 6-weeks TP preseason training on neuromuscular function performance and aerobic fitness, as well as (ii) to characterize external workload (EWL) variation of TP in professional RU players.
METHODS: Thirty-two professional RU players (25.0±4.0 years, 103.4±16.8 kg, 185.5±8.8 cm) from a team competing in the 2nd France RU division were assessed. Based on the concept of TP, the three main acquisition days were arranged following the specific needs of the team. Subjects completed lower-body neuromuscular power (countermovement jump; CMJ) and aerobic ability (Bronco) tests before and after the preseason period. EWL was monitored using wearable 10-Hz GPS (Vector X7, Catapult Sports®, Melbourne, Australia) to characterize preseason training loads by total distance (TD), high-speed running (HSR; >15 km/h), very high-speed running (VHSR; >21 km/h), sprint running (SR; >25 km/h) distance, PlayerLoad (PL), repeated high-intensity efforts (RHIE), and the number of accelerations (ACCnum; >2 m/s/s). Statistical assessments used paired sample t-tests and independent groups one-way ANOVA with post-hoc Scheffe test.
RESULTS: Throughout the preseason, there were no differences in CMJ results. In contrast, significant improvements were found in all participants' aerobic performance ($p<0.001$; effect size=0.49). During the TP training, RHIE did not differ among acquisition days. However, PL and ACCnum were higher ($p<0.001$; effect size=0.24-0.30) on Endurance day compared to Strength day. Furthermore, Endurance (3236.57±42.28 m; $p<0.001$; effect size=0.37) and Speed (3236.86±49.65 m; $p<0.001$; effect size=0.40) days reached a greater distance than Strength day (2966.00±49.84 m). The main results indicate that there were significant differences in training intensity for HSR, VHSR, and SR among three acquisition days ($p<0.001$; effect size=0.34-1.27).
CONCLUSION: These results provide S&C coaches with insight into TP effects on the physical profiles and EWL variation of RU players during the preseason period. Especially, practitioners could use EWL variation of three acquisition days to assist with physical adaptation and technical complexity at different preseason stages.

## OP-PN22 Hypoxia I

### SIX WEEKS OF STATIC APNEA TRAINING DOES NOT AFFECT HBMASS AND EXERCISE PERFORMANCE.

BOUTEN, J., DEBUSSCHERE, J., LOOTENS, L., DECLERCQ, L., VAN EENOO, P., BOONE, J., BOURGOIS, J.G.

*UNIVERSITEIT GENT*

INTRODUCTION: Acute apnea is known to induce decreases in oxyhemoglobin desaturation (SpO2) and increases in erythropoietin concentration ([EPO]). This study examined the potential of an apnea training program to induce erythropoiesis and increase hematological parameters, such as EPO, reticulocytes and hemoglobin mass (Hbmass), maximal oxygen uptake (VO2peak) and exercise performance.
METHODS: Twenty-two male subjects, naïve to breath-holding, were randomly divided into an apnea and control group. The apnea group performed a 6-week apnea training program consisting of a daily series of 5 maximal static apneas. Before and after the apnea training period, subjects visited the lab on three test days to perform 1) a ramp incremental test measuring VO2peak, 2) a CO-rebreathing protocol for Hbmass determination and a 3-km time trial, and 3) an apnea test protocol consisting of a series of 5 maximal static apneas with continuous finger SpO2 registration. Venous blood samples were drawn before and 180 minutes after the apnea test for analysis of [EPO].
RESULTS: Maximal breath-hold time improved from 118 ± 54 s before to 155 ± 53 s after six weeks of apnea training ($p < 0.001$). Minimal SpO2 reached during the apnea test protocol was 91 ± 7% before and 82 ± 7% after the apnea training period ($p < 0.001$). The apnea test protocol did not elicit an acute increase in [EPO] ($p = 0.685$) before nor after the training program. Consequently, resting [EPO] ($p = 0.170$), Hbmass ($p = 0.134$), VO2peak ($p = 0.796$) and 3km cycling time trial performance ($p = 0.509$) were not affected either.
CONCLUSION: This study was the first to provide longitudinal data on the impact of apnea training on both the hematological parameters and its effect on exercise performance. The apnea test and training protocol consisting of 5 maximal static apneas, separated by 30 second intervals, did not induce a sufficiently strong hypoxic stimulus to cause an acute increase in [EPO] in a population naïve to breath-holding. The training protocol therefore did not result in an increase in resting [EPO], Hbmass, VO2peak and performance on a 3km cycling time trial. Longer and/or more intense apnea training sessions inducing a stronger hypoxic stimulus are probably needed to obtain changes in hematological parameters and exercise performance.

### EFFECTS OF HIGH-INTENSITY, LOW-INTENSITY AND LOW-INTENSITY WITH BLOOD FLOW RESTRICTION EXERCISE TO VOLUNTARY MUSCULAR EXHAUSTION ON METABOLIC AND IONIC HOMEOSTASIS AND VENOUS VASCULAR FUNCTION IN HEAL

FRANZ, A., JI, S., LUCKMANN, S., BOEMER, T., BEITZEL, K., WAHL, P., BEHRINGER, M.

*UNIVERSITY HOSPITAL BONN*

INTRODUCTION: Training under blood flow restriction causes faster muscular fatigue than training under free flow conditions. However, the remaining issue is whether the metabolic and ionic changes of BFR exercise differ from high mechanical intensity (HI) or light intensity (LI) exercise when the exercise is performed to voluntary muscular fatigue. In addition, the effects of BFR-induced venous hypertension or HI and LI exercise on venous vascular function are still unknown. Therefore, the present project investigated metabolic and ionic alterations as well as venous function during and after BFR, HI and LI exercise to voluntary muscular exhaustion by intravascular catheter measurements.
METHODS: In a randomized cross-over design, ten healthy male subjects underwent three trials of unilateral leg extension exercise. These trials were differentiated into a high intensity (HI, 75% 1RM), low intensity (LI, 30% 1RM) and LI with BFR trial (LI-BFR). The exercise protocol consists of 4 sets to voluntary failure. The additive BFR protocol involved the proximal occlusion of the exercising thigh by a blood pressure cuff system at a pressure of 50% of the individual arterial occlusion pressure. For analysis of changes in intravascular pressures, blood gases, oximetry and electrolytes, a venous catheter (Rete venosum dorsale pedis) were placed at the exercising leg before exercise. Venous blood gases and intravascular pressures were analyzed before, during and 5 min after exercise. In order to determine the functionality of the venous system, a phlebodynamometry was performed before and after the exercise.
RESULTS: The total workload was significantly lower in the LI-BFR condition compared to LI- and HI-condition ($p < 0.05$). The peripheral venous pressure increased significantly during the exercise ($p < 0.001$), with no difference between conditions ($p = 0.33$). Additionally, there were no significant changes in venous function assessed by phlebodynamometry all forms of training ($p = 0.56$). Analyses of the BGAs showed that venous pCO2 increased significantly during the exercise ($p < 0.001$), with no difference between conditions ($p = 0.64$). At the same time, the analyses of pO2 showed a significant reduced oxygen availability for working muscle during the exercise regardless of conditions ($p < 0.001$). Regardless of conditions, venous [K+], [Na+], [La-] showed a periodic increase during exercise ($p < 0.001$) which decreased to baseline levels 5 min post exercise, respectively.
CONCLUSION: This is the first study investigating venous vascular function before and after BFR, LI and HI exercise to voluntary muscular exhaustion. Based on the obtained data, there is no acute adverse effect on venous function after BFR or HI and LI training in young male subjects. Similarly, the data from this study shows that although BFR training leads to accelerated muscle fatigue compared to LI, the metabolic and ionic changes are equivalent to HI or LI condition, when the exercise is performed to voluntary muscular exhaustion.

### CHANGING INSPIRED FRACTION OF OXYGEN AFECTS HOMEODYNAMIC RESPONSE TO CONSTANT LOAD EXERCISE

MINHALMA, R.1, BECKERT, J.2, REIS, J.F.3, MONTEIRO, C.P.3, ALVES, F.3

*1 - LABSEC-ABCRI, ESEC, UALG, FARO, PORTUGAL; 2 - CEDOC, FCM, UNL, LISBOA, PORTUGAL; 3 - CIPER, FMH, ULISBOA, LISBOA, PORTUGAL*

INTRODUCTION: Hypoxia disrupts body internal dynamics, increases energetic demand requiring a coordinated systemic network response of the body to reestablish equilibrium [1]. This study aimed to observe how the manipulation of inspired fraction of oxygen (FiO2) during constant load cycling exercise impacts internal homeodynamics.
METHODS: Twenty-seven male moderately trained X-country cyclists volunteered to perform a single-blinded constant-load exercise test in a SRM cycloergometer either with the manipulation of FiO2 (CLEST: n=20) or in normoxia (NOR: n=7). Experimental protocol included two visits to the laboratory. During the first visit an incremental stress test was performed to establish first ventilatory threshold (LV1) to prescribe exercise intensity for the CLEST, performed in the second visit. CLEST consisted of continuous exercise at a power corresponding to

80% of the LV1 in four different FiO2 plateaus (NOR: normoxia; H1: 17.3%; H2: 15.3%; H3: 13.5%) without stopping, each with a 6-minute duration. During exercise, partial arterial saturation (SPO2), cardioventilatory parameters and vastus laterallis muscle local oxygenation were monitored continuously and at the end of each plateau capillary lactate concentration ([La]) and the rating of perceived exertion (RPE) on a 20 scale. Data was analyzed by a mixed ANOVA for repeated measures with the condition as the between-subjects factor (CLEST X NOR) and hypoxia severity as the within-subjects factor (NOR x H1 x H2 x H3). Significance was set at p≤.05.
RESULTS: During the CLEST (within-subjects effect), the decrease in FiO2 induces a drop in the SPO2, an increase of ventilation (Ve), heart rate (HR), deoxygenated hemoglobin content (DEOXY-Hb) in the vastus laterallis, and carbon dioxide production (VCO2), between all plateaus (p<0.01). However, [La] only increased at H3 (p≤.05). At H3 these variables presented the follow mean values: SPO2: 75.36±15.44 %, Ve: 63.63±12.62 L.min-1, HR: 150.84±15.99 bpm, DEOXY-Hb: 46,82±13.71 µM, VCO2: 2.84±0.41 L.min-1, and [La]: 3.51±1.36 mmolL-1. On the other hand, oxygen consumption, oxygenated hemoglobin content in the vastus laterallis and respiratory exchange ratio did not change. RPE also significantly increased along CLEST, changing from a perception of light activity at the beginning to very hard at the end (NOR: 1.85±2.10; H1: 12.90±1.89; H2: 13.80±1.40; H3: 14.95±1.61, p≤.01). The NOR group showed no differences between plateaus across the duration of exercise for any of the variables studied. Between-subjects a significant effect was only observed in SPO2, Ve, HR, and DEOXY-Hb, [La-1] and RPE (p≤.05).
CONCLUSION: Reduction in the FiO2 promotes an imbalance in internal homeodynamic stability changing exercise intensity domain for the same external power. This can be important to prescribing exercise intensity for sports and health related exercise in hypoxia.

### THE OXIDATIVE-GLYCOLYTIC BALANCE INFLUENCED BY EFFORT DURATION IS KEY DURING REPEATED CYCLING SPRINTS TO EXHAUSTION IN HYPOXIA

RABERIN, A.1, ELMER, J.1, WILLIS, S.J.1, RICHARD, T.1, VERNILLO, G.2, IAIA, M.3, GIRARD, O.4, MALATESTA, D.1, MILLET, G.P.1

*UNIVERSITÉ DE LAUSANNE: UNIVERSITE DE LAUSANNE, (2) UNIVERSITY OF CALGARY, (3) UNIVERSITY OF MILAN, (4) THE UNIVERSITY OF WESTERN AUSTRALIA*

INTRODUCTION: Repeated sprint ability is a key performance determinant in team sports. Repeated sprints exercise (RSE) performed in hypoxia (RSH) induce greater performance improvement than in normoxia (1). Manipulation of effort duration and exercise-to-rest ratio influences the oxidative-glycolytic balance for energy supply. Therefore, this study aims to compare acute performance and psycho-physiological responses during RSE to exhaustion with the same exercise-to-rest ratio (1:2) but different sprint durations (5, 10 or 20 s) either in normoxia (RSN) or hypoxia (RSH; FiO2 = 0.13).
METHODS: On separate visits, 10 active participants completed in random order three RSH and three RSN sessions (5:10; 10:20 and 20:40) to exhaustion on a cycle-ergometer (Excalibur Sport, Lode). Psycho-physiological responses and vastus lateralis muscle de-reoxygenation (Oxymon, Artinis Medical Systems) were continuously recorded.
RESULTS: Number of sprints to exhaustion was lower during RSH than RSN for 5:10 (20.8 ± 8.6 vs 14.7 ± 3.4; p = 0.014) and 10:20 (13.7 ± 6.3 vs 8.8 ± 2.5; p = 0.018) but not for 20:40 (5.6 ± 1.9 vs 5.6 ± 2.5). Fatigue index was higher during RSH only for 5:10. Blood lactate concentration increased with RSE, independently of the condition, with higher values for 20:40 than 5:10 (13.1 ± 2.7 vs 11.45 ± 2.2 mmol.l-1; p = 0.027). Ratings of perceived exertion, limb discomfort and difficulty breathing did not differ among all RSE. Change in muscle total hemoglobin during sprint tended to be lower in RSH compared to RSN (p = 0.093). The normoxia-to-hypoxia decrease (%) in number of sprints to exhaustion during 5:10 was correlated with the highest power output achieved over 5 s (r2 = 0.55; p = 0.013) or 10 s (r2 = 0.53; p = 0.016) efforts.
CONCLUSION: During RSE with short sprints and short recoveries, energy supply comes mainly from phosphocreatine breakdown and O2 bound to myoglobin. Hence the resynthesis of phosphocreatine and the myoglobin reloading during recovery period depend on O2 availability, leading to an altered performance in hypoxia in such type of RSE; i.e. 5:10 and 10:20.
The correlations between the normoxia-to-hypoxia decrease in the number of sprints and the highest best mean power over 5 s or 10 s only found for 5:10 (i.e., relying more on the oxidative pathway) show that individuals with predominantly fast twitch fibers were less impacted by the decreased O2 availability than their counterparts.
Hypoxic exposure manly impacts RSE, which relies more on the oxidative pathway (5:10 and 10:20), whereas it only has a negligible influence on RSE relying more on the glycolytic pathway (20:40). The oxidative-glycolytic balance, partly influenced by the duration of sprints, is pivotal during repeated sprints in hypoxia.

### HORMONAL, IMMUNE AND NITRIC OXIDE STRESS RESPONSES TO BLOOD-FLOW RESTRICTED LOW-LOAD RESISTANCE EXERCISE VERSUS FREE-FLOW RESISTANCE EXERCISE: A SYSTEMATIC REVIEW AND META-ANALYSIS

HJORTSHOEJ, M.H., STORGAARD, C.D., JUNEJA, H., LUNDBYE-JENSEN, J., MAGNUSSON, S.P., AAGAARD, P., COUPPÉ, C.

*BISPEBJERG-FREDERIKSBERG HOSPITAL*

INTRODUCTION: Low-load blood flow restricted training (LL-BFRT) has gained increasing popularity for strength training and as a rehabilitation tool for musculoskeletal injuries as LL-BFRT can induce muscular hypertrophy and strength gains comparable to those accompanying heavy resistance exercise (HRE). Recently, LL-BFR has also demonstrated promising physiological and clinical effects in the treatment of musculoskeletal disorders such as tendon injury. Although, adaptive mechanisms are not fully understood, it has been hypothesized that increases in systemic hormones e.g., Growth Hormone (GH), immune system signaling and nitric oxide (NO) stress responses following LL-BFR may be key factors. Therefore, the aim of the present systematic review and meta-analysis was to evaluate the acute, mid-term (10-20 minutes) and long-term (30+ minutes) hormonal, immune and oxidative stress responses following LL-BFRT compared to conventional free-flow strength training in healthy adults. We hypothesized that LL-BFRT would yield similar hormonal, immunological and NO responses compared to conventional free-flow heavy resistance exercise (HRE), but would demonstrate amplified responses compared to work-matched low-load resistance exercise (LL-RE).
METHODS: A systematic literature search was conducted in PubMed, EMBASE, Cochrane CENTRAL, CINAHL and SPORTDiscus in august 2021 and a secondary updated search will be performed in April 2022. Randomized and non-randomized studies were included in the meta-analysis. The Cochrane Risk of Bias (RoB2, ROBINS) and the TESTEX were used in order to evaluate Risk of Bias and study quality. Data

extractions were based on mean change within-groups where SDchange was computed if not reported. Authors were contacted to retrieve relevant data for analysis.
RESULTS: A total of 12,191 hits were located of which, 37 articles were included by two independent researchers and the total overall TESTEX score was 7.55 out of 15. LL-BFR demonstrated an increase in acute GH responses when compared to LL-RE (SMD 0.87; CI 0.05 – 1.69) but did not differ compared to HRE (SMD -0.18; CI -1.00 – 0.64). Similar results were retrieved when LL-BFR was compared to LL-RE at mid-term time points (SMD 2.81; CI 1.13 – 4.48). LL-BFR compared to HRE produced a similar testosterone response (SMD -0.18; CI -0.75 – 0.39) in the acute stage. Analyses were also performed for IGF-1, VEGF-1, Cortisol, IL-6 and noradrenaline where LL-BFR was compared to HRE and LL-RE (data analysis awaited).
CONCLUSION: LL-BFRT seems to elicit similar hormonal, immune system and nitric oxide responses compared to HRE, while in contrast demonstrating greater physiological responses compared to LL-RE, which could explain the beneficial clinical effects in different patient populations not tolerating heavy load during rehabilitation. These results are based on a low number of studies comprising a low number of participants and therefore, interpretations should be made with caution.

#### THE ACUTE EFFECT OF EXERCISE INTENSITY ON PERIPHERAL AND CEREBRAL VASCULAR FUNCTION IN HEALTHY ADULTS

WESTON, M.E., KOEP, J.L., LESTER, A.B., BARKER, A.B., BOND, B.

*UNIVERSITY OF EXETER*

INTRODUCTION: High-intensity interval training is known to improve peripheral vascular function, and there is a growing interest in the effects of high-intensity interval exercise (HIIE) on cerebrovascular health. Since the chronic benefits of exercise are likely related to the repeated acute responses following a single bout of exercise , it is important to investigate changes in endothelial function following a single bout of exercise. However, the effect of exercise intensity on cerebrovascular function has received little investigation, and no study has compared the acute effect of exercise intensity on cerebrovascular function, and whether this mirrors changes in peripheral vascular function. The aim of this study was to explore the acute effect of exercise intensity on cerebral and peripheral vascular function in healthy young adults.
METHODS: Ten participants (7 females, 22.7 ± 3.5 years) completed four experimental conditions on separate days: high intensity interval exercise (HIIE) with intervals performed at 75% maximal oxygen uptake (V̇O2max; HIIE1), HIIE with intervals performed at 90% V̇O2max (HIIE2), continuous moderate intensity exercise (MIE) at 60% V̇O2max and a sedentary control condition (CON). All exercise conditions were completed on a cycle ergometer and matched for time (30 min) and average intensity (60% V̇O2max). Brachial artery flow-mediated dilation (FMD) and cerebrovascular reactivity (CVR) of middle cerebral artery blood velocity were measured before exercise, and one- and three hours post-exercise. CVR was assessed using transcranial Doppler ultrasonography to both hypercapnia (carbon dioxide breathing) and hypocapnia (hyperventilation).
RESULTS: FMD was significantly elevated above baseline one and three hours following both HIIE conditions ($P<0.05$), but FMD was unchanged following the MIE and CON trials ($P>0.33$). CVR to both hypercapnia and hypocapnia, and when expressed across the end-tidal CO2 range, was unchanged in all conditions, at all time points (all $P>0.14$).
CONCLUSION: This is the first study to identify that acute improvements in peripheral vascular function following high-intensity interval exercise are not mirrored in the cerebrovasculature in healthy young adults. High-intensity interval exercise completed at both 75% and 90% V̇O2max increased brachial artery flow-mediated dilation one and three hours following exercise, compared to continuous moderate intensity exercise and a sedentary control condition. By contrast, cerebrovascular reactivity was unchanged following all four conditions. These data suggest that the peripheral and cerebral vascular systems may share a different mechanism of change, which should continue to be explored in future research.

#### VASCULAR AND CARDIAC INTERACTIONS DURING LEG AND WHOLE-BODY HYPERTHERMIA: INSIGHT INTO THE PERIPHERAL AND CENTRAL MECHANISMS CONTROLLING THE HUMAN CIRCULATION

WATANABE, K.1,2, KOCH ESTEVES, N.1, STÖHR, E.J.3, GIBSON, O.R.1, AKIYAMA, K.4, WATANABE, S.1,2, GONZÁLEZ-ALONSO, J.1

*1: BRUNEL UNIVERSITY LONDON , 2: AKITA UNIVERSITY , 3: LEIBNIZ UNIVERSITY HANNOVER , 4: YODOGAWA CHRISTIAN HOSPITAL*

INTRODUCTION: As with exercise, passive whole-body hyperthermia increases cardiac output (Q) (1,2). The concomitant rise in peripheral blood flow is thought to be mechanistically linked to enhanced cardiac function and blood flow redistribution from visceral organs. Recent evidence reveals that single leg hyperthermia increases regional leg blood flow and Q equally despite no elevation in core temperature (Tc) (3). This observation supports that peripheral thermosensitive mechanisms can explain at least part of the circulatory adjustments to whole-body hyperthermia, but direct evidence for this hypothesis is still lacking. We therefore investigated the regional vascular and cardiac responses to prolonged leg and whole-body hyperthermia to gain insight into the peripheral and central mechanisms controlling the human circulation.
METHODS: Skin (Tsk), muscle (Tm) and Tc; leg, arm, head and systemic haemodynamics; left ventricular (LV) volumes, intraventricular pressure gradients (IVPG) and ventriculoarterial (VA) coupling were assessed in eight healthy males during: (i) 3 h control (CON); (ii) 3 h of one leg heating (OLH); (iii) 3 h of two legs heating (TLH); and (iv) 2.5 h of whole-body heating (WBH). A water-perfused garment was used for heating.
RESULTS: All variables remained unchanged in CON. Leg Tsk and Tm increased rapidly by 4–10°C in all heating trials, whereas Tc increased gradually up to 0.4 ± 0.2, 0.7 ± 0.2 and 2.3 ± 0.4°C in OLH, TLH and WBH, respectively (all $p < 0.05$). Leg, forearm and extracranial blood flow increased in association with the rise in local temperature while brain perfusion remained unchanged despite elevations in Tc. The increase in Q in all heating trials was associated with an augmented stroke volume, owing to either increased LV end-diastolic volume, decreased LV end-systolic volume or both, and occurred alongside an unchanged IVPG (indicative of sucking force contributing to cardiac filling), and a gradual shortening of LV ejection and filling times with increases in heart rate. In all trials, the Q response was positively correlated to

increases in limbs and head blood flow (R2 = 0.983, p < 0.001), beat volume (R2 = 0.722, p < 0.001) and VA coupling (R2 = 0.927, p < 0.001). The latter reflected increases in LV function and reductions in the net arterial load.
CONCLUSION: Local hyperthermia induces selective elevations in peripheral tissue blood flow and reductions in net arterial load, which are met by increases in cardiac function and Q. These observations support the notion that local thermosensitive mechanisms increasing limb perfusion and venous outflow to the heart play a crucial role in the control of the human circulation during hyperthermia. These findings have implications for the use of heat therapy in exercise recovery, injury rehabilitation and treatment of circulatory diseases.

## THE EFFECT OF CHRONIC PASSIVE HEATING ON VASCULAR FUNCTION AND CENTRAL HAEMODYNAMICS IN INDIVIDUALS WITH TYPE 2 DIABETES MELLITUS

JAMES, T.1, CORBETT, J.1, CUMMINGS, M.2, ALLARD, S.2, EGLIN, C.1, BELCHER, H.1, PICCOLO, D.1, TIPTON, M.1, PERISSIOU, M.1, SAYNOR, Z.1, SHEPHERD, A.1

*1 UNIVERSITY OF PORTSMOUTH, SCHOOL OF SPORT, HEALTH AND EXERCISE SCIENCE. 2 PORTSMOUTH HOSPITALS UNIVERSITY NHS TRUST.*

INTRODUCTION: Type 2 diabetes mellitus (T2DM) is a metabolic disease which can lead to macro- and microvascular impairments [1] and increased risk of cardiovascular disease [1, 2]. Chronic passive heating has the potential to act as an exercise mimetic and improve cardiovascular health [3].
METHODS: In a pre-post experimental design, seven individuals completed the study to date (a priori power calculation = 15). Participants completed two experimental visits, undertaken pre and post (<72 h) eight to ten 1 h hot water (40° C) immersions over a 14 day period. During immersions body position was adjusted to clamp deep body temperature between 38.5 and 39° C. Macrovascular function was assessed via brachial flow mediated dilation (FMD) using ultrasound; stroke volume index (SVi), cardiac output (Q), resting heart rate (RHR) were assessed via thoracic impedance; microvascular endothelial function assessed via transdermal delivery of acetylcholine (Ach) and insulin; systolic blood pressure (SBP) and diastolic blood pressure (DBP) were also recorded. Results (mean [SD]) were analysed using a paired t-test or Wilcoxon Signed Rank test for non-parametric data (significance p < 0.05, trend p <0.1) with effects sizes by Cohen's d or Rosenthal's r.
RESULTS: Interim analysis showed that brachial FMD was unchanged (pre: 7.47 (6.95) %, post: 7.48 (4.92) %, p = 1.00, d < 0.01). SVi trended downward (pre: 56.9 (16.4) mL·m-2, post: 50.8 (15.3) mL·m-2, p = 0.06, d = 0.89), while RHR (pre: 65 (14) bpm, post: 63 (13) bpm, p = 0.14, d = 0.64) and Q (pre: 7.0 (1.3) L·min-1, post: 6.1 (1.7) L·min-1, p = 0.10, d = 0.74) did not change, but had medium effect sizes. Microvascular endothelial function was unchanged but had a medium effect size with Ach (Ach max, pre: 0.67 (0.23) CVC, post: 0.86 (0.50) CVC, p = 0.46, r = 0.28; Ach AUC, pre: 1.84 (0.82) CVC, post: 3.13 (3.55) CVC, p = 0.67, r = 0.16) and insulin (insulin max, pre: 0.26 (0.24) CVC, post: 0.37 (0.31) CVC, p = 0.25, r = 0.44; insulin AUC, pre: 0.73 (0.63) CVC, post: 0.94 (1.05) CVC, p = 0.23, r = 0.45) mediated dilations. SBP (pre: 141 (12) mmHg, post: 131 (19) mmHg, p = 0.05 d = 0.92) trended downward but DBP (pre: 79 (14) mmHg, post: 77 (12) mmHg, p = 0.57, d = 0.23) was unaffected.
CONCLUSION: Interim analysis suggests chronic passive heating does not improve macro or micro vascular function in individuals with T2DM, but may improve cardiac efficiency and blood pressure.

## THE SUPPLY OF OXYGEN TO SKELETAL MUSCLE AND REGULATION OF THE MICROVASCULATURE DURING SMALL MUSCLE MASS EXERCISE IN CHRONIC OBSTRUCTIVE PULMONARY DISEASE VS. CHRONIC HEART FAILURE

HARTMANN, J.P.1,2, DAHL, R.H.3,4, NYMAND, S.B.1,5, MUNCH, G.W.1, RYRSØ, C.K.1,6, PEDERSEN, B.K.1, THANING, P.1,7, MORTENSEN, S.P.8, BERG, R.M.G.1,2,5,9, IEPSEN, U.W.1,10

*1CENTRE FOR PHYSICAL ACTIVITY RESEARCH, COPENHAGEN UNIVERSITY HOSPITAL – RIGSHOSPITALET, COPENHAGEN, DENMARK. 2DEPARTMENT OF CLINICAL PHYSIOLOGY AND NUCLEAR MEDICINE, COPENHAGEN UNIVERSITY HOSPITAL*

INTRODUCTION: We investigated muscle convective and diffusive oxygen (O2) transport in chronic obstructive pulmonary disease (COPD) compared with healthy controls (CON) and heart failure (HF) patients during one-legged knee-extensor exercise to determine disease-specific differences in peripheral determinants during exercise with a small muscle mass.
METHODS: Eight patients with moderate to severe COPD, eight patients with HF (NYHA Class II) and eight age- and sex-matched controls were studied. We measured leg blood flow (LBF) by Doppler ultrasound during submaximal one-legged knee-extensor exercise at 10 W, while sampling arteriovenous variables across the leg in all subjects during rest and exercise. The capillary oxyhemoglobin dissociation curve was reconstructed from paired femoral arterial-venous oxygen tensions (PO_2) and saturations (SO_2), which enabled the estimation of O2 parameters in the capillaries of the contracting muscle.
RESULTS: At rest COPD patients had lower PaO2 compared to the other groups (CON: 12(1); COPD: 10(1); HF: 11 (1) kPa; p<0.05). The resting capillary oxygen tension (CON: 6(0.5); COPD: 5(0.5); HF 4(1) kPa) and saturation (CON: 76(6); COPD: 69(5); HF: 65(4) %) were significantly lower in the COPD and HF patients compared to the CON group (both p<0.05). Exercising LBF increased to a similar extent in HF (2.0(0.4) L/min) compared to CON (2.3(0.3) L/min), but was lower in COPD patients (1.8(0.3) L/min)(p<0.05). Muscle O2 extraction increased in COPD and CON during exercise (p<0,05), but not in HF. Muscle O2 consumption increased during exercise in all three groups, with no differences between groups, and the blood flow conductance (DO2), defined as VO2 divided by the capillary oxygen pressure, increased similarly across all groups, but when adjusting for flow, the DO2 was unchanged in the HF group.
CONCLUSION: When cardiorespiratory limitations are minimized by small muscle mass exercise, disease-specific factors may play a role in peripheral exercise capacity in patients with COPD vs. HF. Thus, low convective O2 transport to contracting muscle seemed to predominate the exercise limitation in COPD, whereas muscle O2 diffusive capacity was blunted in HF.

**HEMODYNAMIC RESPONSE TO METABOREFLEX IN HEART FAILURE WITH REDUCED AND PRESERVED EJECTION FRACTION**

CRISAFULLI, A., PAGLIARO, P., MILIA, R., MULLIRI, G., ROBERTO, S.

*UNIVERSITY OF CAGLIARI*

INTRODUCTION: Chronic heart failure (CHF) is a syndrome characterized by reduced cardiac output (CO) with inability to meet metabolic demands of the working muscle. Ejection fraction identifies two types of CHF: with reduced (HFrEF) or with preserved ejection fraction (HFpEF). Evidence has emerged that metabolic reflex arising from skeletal muscle evokes cardiovascular adjustments during exercise, i.e., the muscle metaboreflex (MM). Hemodynamic response to MM activation is defined as a rise in mean arterial pressure (MAP) achieved by an increase in systemic vascular resistance (SVR) and/or by an increase in CO. In healthy individuals, the MM-induced increase in MAP mainly depends on CO increment, whereas in CHF SVR increments is the principal drive. The aim of the present study was to assess the cardiovascular adjustments during MM activation in both HFrEF and HFpEF patients and to compare their response to that of a control group of healthy individuals (CTL).
METHODS: Three groups of age-matched subjects were studied: 1) 12 males patients diagnosed with HFrEF; 2) 8 males patients diagnosed with HFpEF; 3) 12 healthy males (CTL). All participants underwent a general medical examination, an incremental exercise test on a cycle ergometer, and a MM activation test consisting in a post-exercise muscle ischemia (PEMI) and in a control exercise recovery (CER) session. Hemodynamic parameters were measured by impedance cardiography.
RESULTS: Statistical analysis showed no differences in heart rate (HR) or mean blood pressure (MAP) among groups. Stroke volume (SV) and CO were not significantly different between the two groups of CHF patients. However, SV and CO responses were significantly higher in the CTL than in both CHF groups. SVR response was significantly higher in the HFrEF as compared to the CTL group, while no difference was detected between the CTL and the HFpEF. MAP response to PEMI was not different among groups. Ventricular Filling Rate (VFR, a measure of diastolic function) was significantly higher in CTL group in comparison with both groups of patients. Ventricular Emptying Rate (VER, a measure of systolic function) was significantly higher in the CTL as compared to patients.
CONCLUSION: Despite the reduced capacity to enhance CO, the MAP response was not different among groups, thus indicating that in the CHF patients there is the possibility to reach an effective MAP response. This response was the consequence of an exaggerated SVR response (i.e., vasoconstriction) due to sympathetic overdrive in both groups of patients. These findings are in good agreement with previous research, which demonstrated that the MAP target during the metaboreflex is mainly achieved by a vasoconstriction-mediated rather than a flow-mediated mechanism in CHF. The SVR increase was more accentuated in the HFrEF than in the HFpEF group, and this phenomenon suggests that the cardiovascular impairment was more pronounced in the former than in the latter group.

**MIR-16-5P, MIR-19A-3P, MIR-451A, AND MIR-25-3P CARGO IN PLASMA EXTRACELLULAR VESICLES AS BIOMARKERS OF SEDENTARISM AND EXERCISE ADAPTATION**

FERNANDEZ-SANJURJO, M., PINTO-HERNÁNDEZ, P., DÁVALOS, A., DÍAZ-MARTÍNEZ, A.E., AMADORODRIGUEZ, L., TOYOS-RODRIGUEZ, C., CASTILLA-SILGADO, J., TERRADOS, N., FERNÁNDEZ-GARCÍA, B., IGLESIAS-GUTIÉRREZ, E.

*UNIVERSITY OF OVIEDO, HEALTH RESEARCH INSTITUTE OF THE PRINCIPALITY OF ASTURIAS*

INTRODUCTION: A sedentary lifestyle is a leading risk factor for global mortality. Objective measures of training status, as well as a deeper understanding of the molecular mechanisms underlying the effects of sedentarism, are indispensable. Extracellular vesicles have been validated as key players on interorgan crosstalk in response to exercise (1). The extracellular vesicles cargo comprises a variety of macromolecules, including microRNAs (miRNAs), which have been described to response to exercise(2).
Our aim was, first, to analyse the extracellular vesicle microRNA (miRNA) profile of chronically trained young male athletes, endurance and resistance, compared to their sedentary counterparts. Then, we aimed to analyse the changes in this epigenetic profile over the course of a training macrocycle in elite athletes.
METHODS: A descriptive case-control design and a prospective cohort study were carried out. 16 sedentary young men (SED, 23.2±2.9 y), 16 Olympic male endurance athletes (END, 25.1±7.0 y) and 16 male resistance athletes (RES, 22.1±5.2 y) volunteered to participate in the case-control study. For the prospective cohort study, 8 elite male athletes (26.2±3.6 y) were recruited from Olympic kayak team, a sport with both a high endurance and resistance requirement. The plasma extracellular vesicle miRNA cargo was analysed by means of Next Generation Sequencing, followed by internal and external validation using RT-qPCR. An in silico functional analysis was performed. Physiological and biochemical parameters were also determined.
RESULTS: miR-16-5p, miR-19a-3p and miR-451a were significantly upregulated in SED compared to END and RES. TUB and TENT5C genes are common validated targets of these miRNAs, with a potential role in the anti-obesity and anti-tumour effects of training. Besides, miR-25-3p was specifically down-regulated in END compared to SED. These miRNAs show an individual response in elite athletes during a macrocycle of training. Furthermore, miR-19a-3p and miR-451a correlate with maximal aerobic capacity (VO2max) and maximal heart rate (HRmax) of the athletes, respectively.
CONCLUSION: These facts highlight the potential of these microRNAs for personalised training interventions and allow for greater resolution in the description of training adaptation. As a common perspective between the two designs, low miR-451a levels correlate with lower HRmax and lower HRmax has been reported in aerobically and anaerobically trained athletes compared to their sedentary counterparts(3). To conclude, miR-16-5p, miR-19a-3p, miR-451a and miR-25-3p from extracellular vesicles provide an objective signature of sedentary lifestyle and are also able to describe an individual response to training.

### MIR-29 FAMILY IN RESPONSE TO ENDURANCE AND RESISTANCE EXERCISE IN MOUSE BRAIN TISSUE

PINTO-HERNÁNDEZ, P., FERNÁNDEZ-SANJURJO, M., TOMÁS-ZAPICO, C., GARCÍA-FERNÁNDEZ, B., IGLESIAS-GUTIÉRREZ, E.
*UNIVERSITY OF OVIEDO*

INTRODUCTION: Regular exercise before or during the preclinical stage of Alzheimers disease (AD) has been shown to have an effect as a potential adjuvant treatment to delay cognitive decline. Moreover, exercise can modify the expression of certain circulating miRNAs in humans 1 and at the brain level in animal models of the disease 2. miR-29 family, miR-29a/b1 and miR-29b2/c clusters, is decreased in the brain tissue of 30% of patients with late-onset AD. Bace1 levels on these patients have a higher expression in accordance with the down-regulation of these miRNAs. This target is the main determinant of β-amyloid peptide formation 3. Therefore, the aim of the study was to examine the effect of 4 weeks of endurance and resistance training on miR-29a, b, c and Bace1 expression in the brain of wild-type (WT) and miR-29a/b1 knock-out mouse model group (miR29KO).
METHODS: Brain areas samples were collected from 26 C57BL/6N WT and 23 C57BL/6N miR-29KO mice, divided into three groups: sedentary (WTCON; KOCON), endurance training on a treadmill (WTEND; KOEND), and resistance training on a vertical ladder (WTRES; KORES). After 2 weeks of adaption, mice were trained for 4 weeks, 5 days/week. Maximal endurance and resistance capacity test were performed before and after training. The expression of miR-29a-3p, miR-29b-3p and miR-29c-3p and Bace1 were determined in the hippocampus, striatum, cortex and cerebellum of every group.
RESULTS: KOCON had a lower level of strength, but a same endurance capacity compared to WTCON. In response to training, KORES did not improve their strength performance, but on the contrary, KOEND improved their performance as the same way as a WT did. In both sedentary groups, KOCON mice had no miR-29a-3p expression in the four brain areas studied. Interestingly, only the hippocampus and striatum showed significant differences compared to WTCON. Both types of exercise increased only miR-29b-3p expression in the hippocampus of both genotypes. However, in the WT group these data were not significant.
CONCLUSION: The miR-29a/b1 cluster plays a relevant role in adaptation in resistance training, while its absence seems to have no effect in endurance training. Interestingly, prior to exercise intervention, miR-29a-3p expression is tissue-specific in WT mice, with the cortex and cerebellum showing similar expression levels to KO mice. However, both exercise intervention, in both genotypes, increases the expression of the other cluster partner, miR-29b1-3p, which may be a compensatory response to the other miR-29b2/c cluster.

### BDNF AND C10ORF71 METHYLATION LEVELS ARE ASSOCIATED WITH HANDGRIP STRENGTH IN APPARENTLY HEALTHY SCHOOL-AGE CHILDREN AFTER A 3-MONTH INTEGRATED NEUROMUSCULAR TRAINING

VASILEVA, F.1,2, LLADO, F.R.1, FERRER, S.J.1, GONZALES, C.J.J.1, BISBE, S.A.1,3, ARONIZ, C.A.4, BADOSA, C.G.2, CASADEVALL, B.J.2, VILARRUBLA, G.A.2, PAREZ, M.B.2, BERMEJO, L.A.2, PUIG, P.A.1,5
*<1>SCHOOL OF HEALTH AND SPORT SCIENCE-UNIVERSITY OF GIRONA, <2>BIOMEDICAL RESEARCH INSTITUTE OF GIRONA, <3>BASQUET GIRONA, <4>INTERNATIONAL UNIVERSITY OF CATALONIA, <5>NEOMA-UNIVERSITY OF GIRONA*

INTRODUCTION: Integrated Neuromuscular Training (INT) is a training designed to improve physical fitness and motor competence. BDNF is a gene involved in cognitive function, associated with higher percentage of fast-twitch muscle fibers and handgrip strength in power athletes (1). C10orf71 is a gene expressed in muscle and cardiac tissue, with a role in cardiomyocyte hypertrophy and cardiovascular health (2). However, no studies have examined its connection to physical exercise. Our objectives are: 1) to assess the effects of a 3-month INT on body composition (BC), physical fitness (PF), motor competence (MC) and DNA methylation levels of BDNF and C10orf71; and 2) to test the association of BDNF and C10orf71 with BC, PF and MC before and after the INT.
METHODS: A total of 160 apparently healthy children at the age of 7-8 years were recruited from schools in Cassà de la Selva and Salt (Northeastern Spain) who underwent a 3-month INT. INT was organized in different training circuits and applied twice/week during physical education (PE) lessons. Children were evaluated before and after the INT. BC (ponderal index, fat mass, lean mass, and bone mass), PF (endurance, handgrip strength and balance) and MC were assessed at schools. Saliva samples were collected to assess DNA methylation in a subset of the same children (sample size estimated by GRANMO 7.12 program).
RESULTS: There was a significant decrease in ponderal index, increase in lean and bone mass, improvement in endurance, handgrip strength, balance and MC after the INT ($p<0.001$). Moreover, DNA methylation levels of BDNF ($p=0.021$) and C10orf71 ($p=0.028$) decreased after the INT. There was a negative association of BDNF methylation levels with handgrip strength ($p=0.035$) and balance ($p=0.024$) after the INT that was not present at baseline. Finally, there was a negative association between C10orf71 methylation levels and handgrip strength, again after the INT ($p=0.05$). All correlations were maintained after correcting for age, sex and ponderal index.
CONCLUSION: A 3-month INT during PE lessons is effective to improve BC, PF and MC, as well as to decrease DNA methylation levels of BDNF and C10orf71 in healthy school-age children, thus suggesting a potential improvement of the cognitive function and the cardiovascular health. The decrease in DNA methylation of BDNF might be induced by the increase in handgrip strength and balance after the INT, while the decrease of C10orf71 might be induced by the increase in handgrip strength.

### EFFECT OF THE MCT1 T1471A POLYMORPHISM ON THE LACTATE-LOAD RELATIONSHIP: A PILOT STUDY

BENÍTEZ, J.A., ROJO-TIRADO, M.A., GONZÁLEZ-LAMUÑO, D., AMIGO-LANZA, T., BENITO, P.J., CUPEIRO, R.
*LFE RESEARCH GROUP. FACULTY OF PHYSICAL ACTIVITY AND SPORT SCIENCES. UNIVERSIDAD POLITÉCNICA DE MADRID.*

INTRODUCTION: The membrane transport of lactate is mediated by MCTs, being MCT1 expressed in most tissues (1). This transporter seems to be affected by the T1470A SNP in the MCT1 gene (rs1049434), leading to differences in lactate levels between genotypes (2).

However, there is a lack of studies investigating lactate kinetic during an incremental effort. Thus, the purpose of this study was to analyse the influence of the MCT1 SNP on the lactate response during an incremental test a cycle ergometer in females and males.
METHODS: Twenty trained males (AA: n=10, 23.7±4.3years, 73.13±6.71kg and 177.04±5.24 cm; TT: n=10, 23.6±6.93years, 70.08±5.23kg and 177±5.78cm) and twenty-four females (AA: n=12, 18.16±6.09years, 58.4±8.03kg and 164.69±8.15cm; TT: n=12, 22.58±5.48years, 55.39±4.81kg and 161.78±5.22cm) were classified according to their genotype. Genotyping was done using real-time PCR. The incremental test (cycle ergometer) started at 75 W, increasing 35 W every 3 min until exhaustion. Capillary lactate levels were analysed using a lactate analyser (Lactate Plus, Germany) at rest, in the last thirty seconds of each step and immediately post-maximal effort. Threshold (LT) was determined via D-max method (3). Mann-Whitney U test was used to analyse differences between genetic groups. The level of significance was set at p≤ 0.05.
RESULTS: No differences between genotypes were found in the power output at the LT (Females: AA=144.09±12.65W, TT=134.77±10.96W, p=0.072; Males: AA=179.57±19.28W, TT=189.25±21.31W, p=0.436) or the position of the LT relative to peak power (Females: AA=72.48±7.18%, TT=72.95±7.59%, p=0.918; Males: AA=64.23±8.39%; TT=66.68±4.6%; p=0.631). Also, similar final lactate (Females: AA=10.95±2.47mmol/L, TT=9.78±1.52mmol/L, p=0.291; Males: AA=11.92±2.31mmol/L, TT=10.77±1.60mmol/L, p=0.105) and peak power (Females: AA=194.42±31.4W, TT=185.67±19.95W, p=0.671; Males: AA=281.50±25.82W, TT=285.00±36.89W, p=0.796) were found between genotypes.
CONCLUSION: Our results indicate that the influence of the T1470A SNP in the MCT1 gene could not be relevant in LT during an incremental test in cycle ergometer, in accordance with a previous data (4). In contrast, final lactate in males was higher in T allele carriers compared to A allele carriers after an incremental test on a rowing ergometer, without differences in females (5). Contrary to cycling, rowing involves upper and lower extremities, suggesting that a greater muscle mass involvement is needed during exercise to expose the effect of this SNP (rs1049434) during an incremental test. Moreover, the effects of the T1470A SNP in the MCT1 gene seem to be similar in both sexes.

#### ALTERATIONS IN BELLY GEARING AND RATE OF TORQUE DEVELOPMENT IN PARKINSON'S DISEASE PATIENTS

MAGRIS, R., MONTE, A., NARDELLO, F., ZAMPARO, P.
*UNIVERSITY OF VERONA*

INTRODUCTION: Although Parkinsons disease (PD) is a degenerative disorder of the central nervous system, the strength deficit of the affected limb can be partially explained by peripheral alterations (Smart et al., 2019). Recent studies demonstrated that the muscle-tendon mechanical parameters (e.g. muscle and tendon stiffness) are impaired in early-stage Parkinson's disease patients, negatively affecting their ability to produce force (Murusiak et al, MovDisord, 2011). This study aimed to investigate how muscle and tendon mechanical properties affect the ability to produce torque rapidly (e.g. rate of torque development, RTD) in PD patients.
METHODS: Seven participants with early stage PD (UPDRS<30) and seven age matched healthy controls participated to the study. They were asked to perform six maximum voluntary contractions (MVC) where the torque of the quadricep muscles, the elongation of the patellar tendon, the EMG activity and the fascicle behavior of the vastus lateralis (VL) were recorded. After that, participants performed 6 explosive contractions at the optimal knee angle. In the entire procedures a dynamometer, an EMG apparatus and an ultrasound were utilized. Maximum isometric torque, maximum EMG activity and patellar tendon stiffness (PTStiff = ΔForce/Δlength) were determined during the MVCs. RTD (Maffiuletti et al., 2016) and belly gearing (ΔBelly length/Δfascicle length) (Azizi et al., 2008) were determined in 5 different time windows before torque onset (0-25,25-50,50-75,75-100 and 100-125ms). RTD and EMG were normalized (nRTD, nEMG) for their maximum values collected during MVCs.
RESULTS: Lower nRTD values were observed in PD than in control subjects, with significant differences from 25 to 100 ms (group: P<0.05, time*group: P<0.01), whereas similar values were observed in the first and in the last time windows (0-25 and 100-125 ms). In both groups, belly gearing decreased significantly over time (time: P<0.05), whereas nEMG showed an opposite trend (time: P<0.01). PD subjects showed lower values of belly gearing (group: P<0.01, time*group: P<0.05) and nEMG when compared with control subjects in all the investigated time windows (group: P<0.01). Although PTStiff was higher in PD patients, no significant differences were observed between populations.
CONCLUSION: The observed changes in RTD could not be entirely explained by changes in the EMG signal, but also by muscle and tendon mechanical properties. The lower RTD values (from 25 to 100 ms) in PD patients are, indeed, associated with lower values of belly gearing compared to controls (the lower the belly gearing the less effective the transmission of force along the muscle-tendon unit). On the other hand, the comparable values of RTD between groups in the first-time window (0-25 ms) could be attributed to the larger (albeit not significant) values of tendon stiffness in PD subjects.

#### TEST-RETEST RELIABILITY OF CORTICOSPINAL EXCITABILITY MEASUREMENTS DURING BALANCE PERTURBATION

HU, N., AVELA, J., WALKER, S., ZHAO, S., NEVANPERÄ, S., PIIRAINEN, J.M.
*UNIVERSITY OF JYVÄSKYLÄ*

INTRODUCTION: Posterior balance perturbation evokes short- (SLR ~30-50ms), medium- (MLR ~50-60ms), and long-latency responses (LLR ~70~90ms) in soleus muscle after ankle activation and before voluntary muscle contraction. Corticospinal and spinal mechanisms could contribute differently to each response, which can be investigated using transcranial magnetic stimulation (TMS) and peripheral nerve stimulation (PNS) methods, respectively (1). Good reliability of TMS-induced motor evoked potential (MEP) and PNS-induced Hoffman-

reflex (H-reflex) responses has been shown in several tasks, such as dynamic muscle contraction and standing (2, 3). However, it is not well known how reliable TMS and PNS methods are in dynamic balance conditions. This study investigated the test-retest reliability of MEP and H-reflex amplitude from TMS and PNS delivered at different muscle response phases during balance perturbation.
METHODS: 14 subjects completed two test sessions (S1 and S2). In each session, the balance perturbation system operated at 25cm/s, accelerating at 2.5m/s2 over 30cm displacement. Single-pulse TMS at 110% active motor threshold and PNS at 5% (±2%) of maximum M-wave elicited MEPs and H-reflexes in the right leg soleus muscle at four phases after ankle activation (10ms: Onset; 40ms: SLR; 80ms: LLR; and 140ms: voluntary activation), respectively. Test-retest reliability of MEPs and H-reflex were assessed via intraclass correlation coefficients (ICC2,1) with an absolute agreement analyzed between- and within-sessions.
RESULTS: MEPs showed good to excellent test-retest reliability (ICC=0.823-0.960) between sessions, while H-reflex demonstrated moderate to good reliability (ICC=0.626-0.887). Within-session ICC of MEPs showed excellent reliability in S1 (ICC=0.927-0.983) in all phases. In S2, ICC of all MEPs was excellent (ICC=0.917-0.978) except at 80ms (ICC=0.6). Within-session reliability of H-reflex was good to excellent in both sessions (S1: ICC=0.945-0.985; S2: ICC=0.874-0.994).
CONCLUSION: TMS measurements showed acceptable test-retest reliability for both between- and within-session comparisons in different phases. The highest reliability was observed at the voluntary activation phase (140ms), indicating that MEPs are less variant during voluntary activation compared with reflex response phases. This is supported by an earlier finding of higher MEP reliability in active muscle compared to muscle at rest (3). H-reflex demonstrated lower reliability in balance perturbation tasks compared to TMS, which is also in line with previous study (3). Within-session reliability was extremely robust. In conclusion, these methods can be considered usable in measuring corticospinal excitability during future balance perturbation experiments.

### A SYSTEMATIC REVIEW AND META-ANALYSIS OF THE FOAM ROLLING TRAINING EFFECTS ON RANGE OF MOTION

KONRAD, A., NAKAMURA, M., TILP, M., DONTI, O., BEHM, D.

*KARL- FRANZENS- UNIVERSITY GRAZ*

INTRODUCTION: In the last decade foam rolling has become a popular technique in sports practice (1). A recent meta-analysis showed that a single foam rolling exercise can acutely increase the range of motion (ROM) of a joint (2). However, evidence on the training effects of foam rolling on joint ROM, is limited and inconsistent (3,4). Hence, there is a need to conduct a meta-analysis on the long-term training effects of foam rolling on ROM. Therefore, the purpose of this meta-analysis was to investigate the effects of foam rolling training interventions on joint ROM in healthy participants.
METHODS: For the main meta-analysis we applied a random-effect model, whilst subgroup analyses were performed by applying a mixed-effect model. Subgroups included comparisons of the intervention total load (i.e., time under tension; ≤ 1520s vs. > 1520s), duration (≤4 weeks vs. >4weeks), comparisons between muscles tested (e.g., hamstrings vs. quadriceps vs. triceps surae), and study designs (RCT vs. CT).
RESULTS: In total 11 studies with 46 effect sizes were included in this meta-analysis. The main meta-analysis revealed a moderate effect of foam rolling training on ROM increases in the foam rolling group compared to the control group (ES = 0.823; Z = 3.237; CI (95%) 0.325 to 1.322; p = 0.001; I2 = 72.76). Subgroup analyses showed a significant difference in the intervention duration in favor of interventions >4 weeks compared to ≤4 weeks for ROM increases (p=0.049). Moreover, a further subgroup analysis showed significant differences between the muscles tested (p=0.047). While foam rolling increased joint ROM when applied to hamstrings and quadriceps, no such increase was observed in ankle dorsiflexion ROM after triceps surae rolling.
CONCLUSION: Our meta-analysis showed that a longer duration (i.e., > 4 weeks) foam rolling intervention can increase joint ROM in young healthy participants. However, ROM increases may be muscle-and/or joint dependent as foam rolling on the triceps surae muscle did not increase ankle dorsiflexion ROM. Although not much evidence, it is assumed that altered pain perception is a possible mechanism for long-term increases in ROM after a foam rolling intervention rather than changes in soft tissue stiffness (3).

### THE ACUTE EFFECTS OF VOLUNTARY BREATHING PATTERNS ON POSTURAL CONTROL DURING WALKING

KARAGIANNAKIS, D., MANDALIDIS, D.

*NATIONAL & KAPODISTRIAN UNIVERSITY OF ATHENS*

INTRODUCTION: Breathing and postural control are reported to be both neuromuscularly and mechanically interdependent, as the use of breathing muscles during respiration affects how these muscles are used for non-breathing movements and postural control. Previous studies have reported conflicting results regarding the effects of voluntary breathing patterns on postural control during static postural tasks (Hamaoui et al., 2010; Hernandez et al., 2019). The purpose of the current study was to evaluate the acute effects of thoracic and abdominal breathing pattern on trunk muscles activation level and spatiotemporal gait parameters during walking in healthy individuals.
METHODS: Twelve healthy, physically active participants with normal spirometric values volunteered for the study. Participants were instructed to walk barefoot for 2 minutes on an instrumented treadmill at the speed of 5.0 km/h. First with involuntary/neutral breathing (NB) and then, in a randomized order, with voluntary/abdominal breathing (AB) and voluntary/thoracic breathing (TB). Respiratory inductive plethysmography was used to assess breathing pattern, and each participant received real-time feedback regarding thorax and abdomen displacement during trial and testing. The EMG activity of sternocleidomastoid (SCM), upper trapezius (UT), and erector spinae muscle at the level of 9th thoracic vertebrae (EST9) and 5th lumbar vertebrae (ESL5) was recorded simultaneously on the right side of the body during each testing condition. The EMG signal was reported as a percentage of each muscle's maximum voluntary contraction (%MVC).

RESULTS: The findings of the current study revealed that the percentage of rib cage contribution to breathing was significantly lower during AB (35.1+/-8.1%) compared to TB (74.2+/-7.5%) and NB (65.0+/-6.6%) ($p<0.001$). Thoracic breathing elicited significantly greater activity of SCM (4.5+/-2.0 %MVC) compared to AB (3.7+/-1.4 %MVC) ($p<0.05$), whereas no significant differences were detected compared to NB (4.2+/-2.4 %MVC). No significant differences were detected between NB, AB, and TB with respect to the EMG activity of UT, EST9 and ESL5. Regarding dynamic center of pressure parameters, no significant differences were detected between the 3 breathing patterns on antero/posterior and mediolateral symmetry.
CONCLUSION: Postural control during walking was not affected by the voluntary control of breathing. Although TB demonstrated increased activation of the SCM, which has been associated with breathing pattern disorders, AB does not appear to emphasize diaphragm's stabilizing function as far as trunk muscles activation level is concerned. In addition, trunk and lower limbs movements during walking appear to compensate for the respiratory induced postural perturbations caused by the voluntary breathing patterns.

### IS-SH02 Social inequalities in sports, physical activity and health – interdisciplinary and cross-cultural perspectives

#### YOUNG PEOPLE, PHYSICAL ACTIVITY AND HEALTH; INTERSECTIONS OF RACE AND SOCIAL CLASS.

DAGKAS, S.

*ST MARYS UNIVERSITY*

With the current global economic uncertainties, recession and projected increases in poverty especially amongst young Black Asian and Minority Ethnic (BAME) people, understanding how cultural dispositions toward physical activity (PA) and health shape young people's engagement is crucial. This paper will draw on social theory in an effort to explore the ways in which the culturally diverse family in cultivating young peoples dispositions towards physical activity and health. Interviews with 10 families' (n=43) explored determinants to sport and PA participation and gained further insights in the way families conceptualise sport and PA. A series of accounts of these BAME families' voices were produced using thematic analysis. The paper suggests that cultural transmissions within the family can influence pedagogical orientations and establish embodied practices. These cultural transmissions are closely related to economic, cultural and physical capital where agency within the family environment is structured through certain socioeconomic, racial and religious backgrounds that are crucial to the development of embodied dispositions, which can facilitate or constrain experiences based on place, locality, and environment. The paper suggests that a perception of BAME families as a homogeneous group is not helpful in understanding existing inequalities or health disparities. BAME young people within similar social groupings experience inequalities in various forms and levels.

#### DEALING WITH PHYSICAL ACTIVITY AND HEALTH NORMS IN SOCIALLY UNDERPRIVILEGED CONDITIONS

GRIMMINGER-SEIDENSTICKER, E.

*UNIVERSITY OF PADERBORN*

Socially underprivileged populations are more likely to experience health problems than socially privileged populations. Nevertheless, national health promotion programmes mostly neglect social conditions, and stress the importance of self-management in health questions. However, in order to tailor health education programmes to the needs and interests of socially disadvantaged populations, it is important to understand the ways they understand health in the context of their daily experience, and how they deal with the given social and environmental circumstances. Thus, we conducted a comparative study in Germany, France, Switzerland, and Italy. All study participants were living in socially disadvantaged neighbourhoods. In total, 167 children aged 7 to 11 years (mean = 8.76 years, SD = 0.68) participated in 36 focus groups; 35 parents were involved in semi-structured interviews. The results show that both, children and parents, independently of the country, repeat the simplistic health education messages like being physically active and eating healthy to avoid overweight. They focus exclusively on the individual´s responsibility. We can identify strategies of dealing with barriers and adapting the norms to their own lifestyle. So, the overemphasis on self-causation in health education programmes may have unwanted side effects evoking increased guilt in the victims of illness, and thus causing double discrimination effects for socially underprivileged populations.

#### TACKLING PHYSICAL INEQUALITIES AND INCREASING PUPILS' MOTIVATION IN PE: AN OVERVIEW OF THE BELGIAN IMPLEMENTATION OF THE OBLOMOV METHOD

CLOES, M.

*UNIVERSITY OF LIEGE*

Levels of physical fitness, motor skills and/or body image can influence dramatically pupils' motivation towards physical activity. Moreover, a lack of movement towards the development of youths' physical literacy that contributes to their involvement in an active lifestyle. This vicious circle is sometimes reinforced in PE/sports settings when the learning goals and tasks proposed to the children do not correspond to their capabilities and personal resources. Individualized approaches are recommended but teachers experience at present many difficulties to implement it. Integrating short periods of High Intensity Intermittent Training (HIIT) in theatre open scenarios represents an original approach to motivate youths who are not at ease with physical activities. The foundations of this approach refer to the motivational power of playful situations and the imaginary of the pre-adolescents. It is the core of an Erasmus+ project called OBLOMOV (https://www.oblomovproject.eu/). In Liege, two studies have been conducted to analyze youths' reactions to the scenarios that have been elaborated: (1) an unit of 10 PE lessons with 8 classes of 5th-6th graders; (2) a series of 3 afternoons proposed to overweight primary school children by the university obesity clinic. Findings confirm the potential impact of the methodology respecting the PAMIA principles (Pleasure, Achievement, Movement, Interaction, and Autonomy). Physical educators should integrate it more often in their lessons.

## OP-BM17 Paralympics

### A PRELIMINARY PROFILING OF THE PARALYMPIC POWERLIFTING ATHLETE: ANTHROPOMETRIC, NEUROMUSCULAR AND TECHNICAL CORRELATES OF PERFORMANCE

RUM, L., ROMAGNOLI, R., BORASCHI, A., LAZICH, A., SCIARRA, T., BALLETTI, N., PIACENTINI, M.F., BERGAMINI, E.

*UNIVERSITY OF ROME*

INTRODUCTION: In Paralympic sport, the evaluation of athlete's characteristics within the domain of performance-impairment relationship is the basis of classification to guarantee a fair competition [1]. At present, the scientific literature on Paralympic powerlifting is very limited and the evidence-based knowledge about such aspects is sparse. This study aims at understanding which factors (i.e., anthropometric, neuromuscular and technical) are related to performance to gain knowledge for evidence-based classification in this sport.
METHODS: Seven Paralympic powerlifters of elite international level participated in the study (disability types: 1 arthrogryposis, 2 spina bifida, 3 mono-lateral and one bilateral amputation). After a standardized warm-up, four attempts of one repetition maximum (1RM) paralympic bench press were performed and data from the best valid lift was considered for the analysis. Anthropometric measures (e.g., body mass, fat mass, sitting height, arm span, upper body segments length, breadths and circumferences, etc.) were taken before 1RM testing. Electromyographic activity during the concentric phase of the lift was bilaterally recorded in the deltoid anterior, pectoralis major, triceps, latissimus dorsi and abdominal external oblique muscles, and normalised to maximal voluntary isometric contractions. Linear displacement and velocity parameters of barbell trajectory were obtained from video analysis and extracted from both concentric and eccentric phases of the lift. Correlation analysis was performed between 1RM load corrected by the Haleczko formula and the anthropometric, neuromuscular and technical parameters, and significant strong correlates were included in a multiple regression model.
RESULTS: Among the anthropometric measures, forearm and trunk length, and wrist width were positively associated with corrected 1RM load ($r > .82$, $p < .05$). The drift of barbell real trajectory from the straight-line displacement during the eccentric phase was the only technical factor to be significantly and strongly positively correlated with corrected 1RM ($r > .77$, $p < .05$). No neuromuscular factor showed a significant correlation. Results from the multiple regression model indicated the trunk length as the main predictor of 1RM corrected value ($R= .93$, $R2= .87$, adjusted $R2= .85$, $p = .002$).
CONCLUSION: Upper body anthropometric factors appear to have the highest degree of association with Paralympic powerlifting performance compared to both neuromuscular and technical factors. Unlike the previously reported impact of lean body mass on 1RM bench press in non-disabled powerlifters [2], body composition factors seem to not play a significant role in performance outcome in Paralympic powerlifting. Although preliminary, the current findings provide a starting point for advancing evidence-based classification in this Paralympic sport.

### LONGITUDINAL FUNCTIONAL ASSESSMENT OF A TRANSFERMORAL AMPUTEE PATIENT TREATED WITH OSSEOINTEGRATION SURGERY

BRAGONZONI, L., DI PAOLO, S., ALESI, D., MIRULLA, A.I., GRUPPIONI, E., ZAFFAGNINI, S.

*UNIVERSITY OF BOLOGNA*

INTRODUCTION: The socket-type prosthesis is the treatment of election for the lower-limb transfemoral amputation. However, patients often report skin abrasions, skin sweating, lack of balance, and walking difficulties [1-2]. The osseointegration technique is an alternative treatment for amputee patients that limits the socket-related problems and provides a more physiological mechanical loading [1].
After surgery, a critical functional recovery and dedicated rehabilitation phase is required. Little functional assessment of these patients has been reported in the literature. The purpose of the present study was to provide the functional assessment of a transfemoral amputee patient before osseointegration surgery and after rehabilitation by means of wearable sensors.
METHODS: A transfemoral amputee patient (male, 47 years, time from amputation 18 years) scheduled for osseointegration surgery was enrolled. The patient was able to walk without aids and performed a gait test the day before surgery with his standard socket-type prosthesis, consisting in 10-meters walking in a hospital indoor hall, two at self-selected speed and two at the fastest speed possible. The test was repeated 3 months after surgery (after the clearance from the rehabilitation, 3M FU), and 6 months after surgery (6M FU).
A set of 15 wearable inertial sensors (Awinda, Xsens Technologies) was used to collect full body kinematics. Complete gait cycles were isolated and spatiotemporal and kinematical parameters were extracted. The differences between the amputee (AL) and the sound (SL) limb among the follow-ups were reported. One-way ANOVA with post-hoc comparisons was conducted in Spm1D ($p<0.05$).
RESULTS: Shorter step length and longer swing phase were found for the AL at pre-op, with greatest differences in the midstance. Also, hip abduction and rotation, pelvis forward tilt and obliquity, trunk forward tilt, and lateral bending on the AL were also noticed. At follow-ups, symmetry index progressively improved (1.14, 1.09, 1.06 at pre-op, 3M FU, and 6M FU, respectively). Asymmetries in hip abduction, hip rotation, and pelvis rotation decreased at follow-ups and no more trunk forward and lateral tilt were found.
CONCLUSION: The altered spatiotemporal and kinematical parameters found preoperatively were in line with the current literature [1]. After rehabilitation, the patient showed higher time spend on the AL and lesser kinematical asymmetries. The osseointegration surgery showed to progressively restore a physiological kinematics in the transfemoral amputee patient.

### PROSTHESIS STIFFNESS AFFECTS INTACT AND RESIDUAL LIMB STIFFNESS DIFFERENTLY IN A UNILATERAL TRANSTIBIAL AMPUTEE RUNNER.

PAVAILLER, S., FABRE, A., ROCHE, H.

*SALOMON SAS*

INTRODUCTION: Recent developments in the prosthetics field have helped people with lower limb amputation run by providing carbon fiber blades with spring-like properties. A spring-like behavior can also be applied to the entire leg, in a so called "spring-mass" model of

running (1). In unilateral transtibial amputee runners, the spring-mass behavior was shown to be dependent on the leg (sound vs. prosthetic) and the characteristics of the prosthesis used (2). This case study aimed at determining the effect of prosthesis stiffness on spring-mass behavior of the sound and prosthetic leg in a unilateral transtibial amputee runner.
METHODS: One male below knee amputee runner participated in this study. He used a newly developed running blade (Hopper, Hopper SAS, France) that allowed stiffness adjustment thanks to a mechanism at the stump-blade junction. Two blade stiffness conditions were compared (HIGH = 21.6 kN/m, LOW = 18.2 kN/m) while running at 11 and 13 km/h on a 15-m pathway. Measurements included ground reaction forces with 3 force plates embedded in the pathway. Centre of mass vertical displacement was derived from force data as described previously (2). 10 steps (5 per leg) were collected for each speed and blade stiffness. The vertical stiffness (Kvert) was calculated for both the sound and prosthetic leg using the equation Kvert = Fpeak/Δy with Fpeak the maximal vertical ground reaction force and Δy the maximal vertical displacement of the center of mass during ground contact. As data from only one runner were analyzed, the trends between conditions are presented using means and 95% confidence intervals (CI).
RESULTS: At 11 km/h, similar Kvert were observed in the sound and prosthetic leg for the LOW condition (47.2 CI=3.3 vs. 43.1 CI=2.6 N/body weight/m, respectively), whereas Kvert was higher in the sound leg for the HIGH condition (66.5 CI=9.8 vs. 45.7 CI=1.5 N/body weight/m). This difference in the sound leg was mainly due to a decreased Δy in the HIGH condition.
Similar results were observed at 13 km/h. Kvert in the LOW condition was unchanged between sound and prosthetic leg (54.2 CI=2.5 vs. 49.3 CI=3.7 N/body weight/m, respectively), but was higher in the sound leg for HIGH (61.1 CI=6.3 vs. 48.5 CI=2.7 vs. N/body weight/m). This difference in the sound leg was also due to a decreased Δy in the HIGH condition.
CONCLUSION: The higher Kvert in the sound limb is in line with a previous study in unilateral transtibial amputee runners (3), but was observed only in the highest running blade stiffness condition in the present study. In other words, the blade stiffness had an influence on the vertical stiffness in the sound leg only. This could be due to compensatory mechanisms in the joint stiffnesses of the sound leg as proposed previously (3). These results show that blade stiffness can serve as an adjustment variable for unilateral transtibial amputee runners.

**OVERALL ATHLETE WELL-BEING STATES IN JAPANESE ELITE ATHLETES VIA A NATIONAL SURVEY**

KINUGASA, T., NOGUCHI, Y.
*JAPAN SPORT COUNCIL*

INTRODUCTION: It appears that the optimization of athlete well-being has received considerable attention in academic and practical fields of high performance sport. The International Olympic Committee has promoted the importance of athlete well-being particularly focused on mental health (Reardon et al., 2019). Nevertheless, the literature is limited to understand the case of Japanese athletes. Therefore, the aim of this study was to conduct a fact-finding national survey of athlete well-being in Japan.
METHODS: First, a total of 100 Japanese university student-athletes (43 male, 57 female) from 17 Olympic and 7 Paralympic sports completed an online survey as a pilot study. The validity, reliability, and feasibility of the national survey were verified in the pilot study. Consequently, the validated survey was applied to Japanese elite athletes who competed at the Tokyo 2020 Olympic and Paralympic Games. The respondents were 92 Japanese elite athletes (42 male, 50 female), aged 16 to 64 years (30.8±9.4). The state of the respondents' well-being in the past 3 years was calculated on a 5-point scale (1 = very good, 2 = somewhat good, 3 = not so good, 4 = not good at all, 5 = not sure) to account for the influence of the COVID-19 widespread in 2020 in Japan.
RESULTS: Test-retest reliability of the national survey was found to be good (r = 0.7 ± 0.3) (Hopkins, 2000). The results of the national survey indicated that the overall states of athlete well-being in the Japanese elite athletes were perceived as relatively good in terms of physical, mental, educational, organizational, social, and financial aspects (Wylleman, 2019). Interestingly, there were 78 respondents (84.8%) who had someone they could talk to when they felt anxious or distressed, while 55% of the university student-athletes indicated the availability of someone whom they could approach in the pilot study. Parents (48.7%) were the most common people to talk to about their concerns and problems of well-being, followed by friends (44.9%), teammates (47.4%), and coaches (38.5%). However, many Japanese elite athletes (84.8%) mentioned that they had never received or used athlete well-being support from the national sport federations and the government due to lack of information and accessibility to the services etc. The respondents agreed that the national sport federations and the government should implement measures to enhance and support athlete well-being including consultation services, athlete education, and coach education.
CONCLUSION: Taken together, we could recommend to develop an evidence-based national system to enhance and support athlete well-being in Japan and to provide related programmes (consultation services and education etc) so as to support athlete well-being in a better way than currently available.

## Oral presentations

### OP-SH14 Youth development

**CHANGES IN THE PERCEIVED MOTIVATIONAL CLIMATE AS PREDICTORS OF ATHLETES' GOAL-DIRECTED EFFORT DURING A SEASON: MEDIATIONAL ROLE OF GOAL MOTIVES**

MARTÍNEZ-GONZÁLEZ, N., ATIENZA, F.L., DUDA, J.L., BALAGUER, I.
*UNIVERSITY OF VALENCIA*

Introduction
Self-Concordance Model (Sheldon & Elliot, 1999) emphasizes the importance of motives that underlie the goals pursued (and whether these motives are autonomous or controlled) to the effort exerted to achieve one's goals. Self Determination Theory framework points to the importance of the motivational climate that coaches create to athletes' goal regulation (Ryan & Deci, 2017). According to Duda's (2013)

multidimensional and theoretically-integrated conceptualization of the motivational climate, more or less empowering (task-involving, autonomy supportive, and socially supportive) and disempowering (ego-involving and controlling) motivational climates hold differential implications for the processes underlying goal pursuit.
Past work grounded in SDT and SCM has been primarily cross-sectional and/or didn't take into consideration the higher order empowering/disempowering climate dimensions (Martínez-González et al., 2021). Adopting a longitudinal design, the purpose of this research was to test if changes in perceived empowering and disempowering climates predicted changes in the goal-directed effort during the season through changes in autonomous and controlled goal motives.
Methods
Participants were 112 Spanish male and female athletes aged between 18 and 34 years (M = 20.90; SD = 2.79). All of them participated in university team sports and completed a package of questionnaires assessing variables of interest at the beginning and at the middle of the sport season.
Results
Path analysis showed that changes in perceptions of an empowering motivational climate positively predicted changes in autonomous goal motives, which in turn led to positive changes in goal-directed effort. Changes in the perceive disempowering climate did not predict changes in goal-directed effort through controlled nor autonomous goal motives.
Discussion
These findings are in concordance with SCM, SDT and past research, and support the positive implications of perceived empowering climates in relation to athletes' pursuit of adaptive goals when examined over time.

### IMPLEMENTING A POSITIVE YOUTH DEVELOPMENT PROGRAM TO FOSTER DECISION-MAKING IN FEMALE YOUTH VOLLEYBALL

MUÑOZ LLERENA, A.1,2, HERNÁNDEZ-HERNÁNDEZ, E.2, CABALLERO-BLANCO, P.1

*1. UNIVERSIDAD DE SEVILLA; 2. UNIVERSIDAD PABLO DE OLAVIDE DE SEVILLA*

Introduction
Decision-making is a skill that implies success in both the sports context and the daily life of people, involving four conceptions: emotional, volitional, motivational and cognitive; it is composed of three dimensions: confidence in own abilities, concern about improving decision-making and ability to overcome difficult situations in competition. Decision-making is one of the skills addressed in Positive Youth Development (PYD) programs, which are proliferating in the last decade, and specially the Teaching Personal and Social Responsibility Model (TPSR) and the Sport Education Model (SE). The aim of this study is to analyze the effect of the application of a hybrid TPSR+SE PYD program on decision-making in female youth volleyball players.
Method
A convergent mixed-method design was employed, combining phenomenological design (qualitative) and pretest-posttest design (quantitative). 15 girls (age=8.93±0.80) from a volleyball team in a subsidized school in Seville took part in the study. Qualitative data assessed players' and coach's insight of decision-making enhancement through semi-structured interviews (players) and field notes (coach); data was analyzed using NVivo 12 software. Quantitative data assessed two factors of decision-making (perceived decisional competence and commitment in decisional learning) obtained through CETD questionnaire; non-parametric tests were applied using SPSS 26.0 software. Integration of qualitative and quantitative data was carried out using a joint display.
Results
Qualitative data analysis showed positive results in the majority of the group within perceived decisional competence and commitment in decisional learning. Quantitative data analysis reported higher values in posttest when compared to pretest in both factors, although they were not significant ($p > .5$). Integration showed discrepancies between qualitative and quantitative results in both perceived decisional competence and commitment in decisional learning, with only a few congruent observations derived from some participants' interviews.
Discussion
Results showed an improvement in perceived decisional competence (more and enhanced decision-making in conflict resolution, achieving goals and sport-specific decisions) and commitment in decisional learning (autonomous goal setting and choosing the best decisions to achieve those goals) in the majority of the group; however, the lack of significance in the quantitative analysis caused discrepancies in data integration. Due to the limitation in the sample size and the possibility of suffering a satisficing process fulfilling the questionnaires due to lack of comprehension and motivation and context influence, there is more confidence in qualitative results. Considering those findings, the application of a hybridized PYD program in female youth volleyball players seems to improve decision-making skills. However, more studies are needed that use larger samples to strengthen these results.

### THE BODY CONFIDENT SPORT GUIDELINES AND THE ATHLETIC DISORDERED EATING (ADE) SCALE – AN INDIVIDUAL AND ORGANISATIONAL APPROACH TO PREVENTING DISORDERED EATING AND IMPROVING BODY IMAGE IN CURRENT AND F

BUCKLEY, G.

*BODY CONFIDENT COLLECTIVE*

Sport has an incredible capacity to improve an individual's body image, yet eating disorders remain significantly higher in current and former athletes than the general population. Eating disorder prevention work has long been seen as a potential compromise to an athlete's performance, however since the thorough developments in the Female Athlete Triad and Relative Energy Deficiency in Sport (RED-S) we can now comprehend and understand that a nourished athlete is a performing athlete. Sports science has prioritised quantitative measures of success and physiological performance, but recent scientific developments have highlighted that the relationship an athlete has with

their body can influence whether an athlete engages or quits their sport, and whether they develop confidence, self-efficacy, self-esteem and psychological wellbeing long after their sport has ceased.
This presentation introduces two new tools to the sports science and psychology field; the Athletic Disordered Eating (ADE) Scale and the Body Confident Sport Guidelines (BCSG). The ADE Scale was developed through exploratory mixed methods design using qualitative interviews, classic test theory and item response theory and is a 17-item scale that assesses current and former athletes for disordered eating and body image concern. The project found that 60% of current and former athletes have disordered eating and demonstrated a significant need for preventative support at both the individual and organisational level. The other findings of the exploratory sequential project have been translated into the BCSGs to generate 5 tangible and practice guidelines to shape culture positively so that sport is a place of body confidence, body safety and body celebration, rather than a risk factor for body dissatisfaction and eating disorder development.
The guidelines are intended to provide a benchmark of expectations to champion body confident sport and are for uptake amongst athletes, coaches, parents, supporters, sporting clubs, sports administrators and sports media. The five guidelines have been developed to address all determinants of body confidence: whether that be environmental, cultural, behavioural or social. These guidelines are intended to prevent and protect athletes from psychological and physical harm and to encourage safety, diversity and inclusion. The five guidelines include: (1) empathetic and informed body communication, (2) decentring weight and body composition importance, (3) promotion of food first principles, (4) flexible uniforms and equipment, and (5) creating safe environments.
These guidelines have been launched internationally and are currently being taken up by innumerable major sporting organisations and just as importantly at a grassroots and club level. This presentation will highlight the evidence backing the guidelines and additionally initiate important conversation about how research translation can be transformed into tangible outcomes that shape and

**THE DUAL COMMITMENT OF STUDENT ATHLETES IN LOWER SECONDARY SCHOOLS IN FINLAND**

ROMAR, J.E., KÄLLBERG, C., HUUHKA, V., KUOKKANEN, J.
*ÅBO AKADEMI UNIVERSITY*

The Finnish dual career (DC) policy can be described as state sponsored, including a centralized network of upper-secondary-level (ages 16–19 years) and tertiary-level (i.e., higher education) educational institutions that enable athletes to acquire a degree while competing in sports. The absence of national standards has hindered the provision of optimal developmental grounds for talented young athletes in lower secondary education. Consequently, the Finnish Olympic Committee introduced a lower secondary sports schools pilot project (LSSSPP) that started on a trial basis at 19 public lower secondary schools (ages 13–15 years) in 2017 and expanded in 2020 as a nationwide model open to all interested schools across the country. The national project aimed to find solutions that allowed student athletes opportunities for practice and flexibility in school-related issues in Grades 7–9.
Utilizing rich qualitative data derived from individual interviews with student athletes from grade eight (n = 15), teachers (n = 4), principals (n = 2), and nonparticipant observations (n = 7) at five schools in conjunction with the LSSSPP, the present study examined how young student athletes succeed in school and sports and in combining these two. The data was analysed using collaborative qualitative data analysis to find themes describing these student athletes. The main findings indicated that most student athletes had high ambitions and showed strong orientations in their school approaches. For some student athletes, the student and athlete roles conflicted, and they prioritized sports over educational success. A similar variation in student athletes' sport commitments was found: from having a goal to become a professional athlete to pursuing sport as a leisure activity. Student athletes in this study were in the beginning of their DC, and they needed to be recognized as a heterogeneous group with individual pathways. In all, the findings indicated the demanding nature of the dual commitment of student athletes in lower secondary sport schools. As earlier research findings mainly come from upper secondary and university students, the study responds to the Finnish Olympic committee´s need to evaluate the LSSSPP to improve DC support functions at these specialized educational institutions.
Keywords: student athlete, dual career, sport and education, qualitative methods

**THE MEANING AND SIGNIFICANCE OF NON-CLUB TALENT DEVELOPMENT ENVIRONMENTS FROM THE PERSPECTIVE OF ELITE FOOTBALL PLAYERS**

SÖDERSTRÖM, T.
*UMEÅ UNIVERSITY*

Adult football success in Sweden can, besides the training in the club, be advanced through the Swedish football associations regional (U15-17) and national (U15-U21/23) team systems or through elite sport schools at the upper secondary school. These systematic talent development environments are of central interest in this study. Research on talent development environments has had a focus on football academies and environmental success factors (e.g., Cooper, 2021; Larsen et al, 2013). However, to date, research undertaken has not in any greater extent taken into consideration non-club environments and athletes views on how useful those environments have been for their development into elite football players. Thus, in this paper the aim is to explore the meaning and significance of non-club talent development environments by scrutinizing elite football players experiences of participating in such environments and their importance for their development as football players.
The material in this study is based on interviews with 13 male and 12 female present and former elite football players between 22-35 years of age. The results showed that being selected at age 15 as one of 16 players in one of the 24 district squads (a two-year process) is, for both women and men, mostly a question of being confirmed and has little or no importance with respect to their football development. The analysis of players experiences of upper secondary elite sport schools (2-3 trainings/week) revealed a more mixed picture. Half of the men and women considered it, although they trained more hours, of little importance for their development. However, those players who have participated in elite sport schools organized by an elite club highlighted to a greater extent the importance of the school environment. The players perceived the national team activities (foremost U15-U19) as professional and serious, but since most players club environment had the same or better quality it had little significance for their development as a football player. Overall, the analysis shows that the importance of non-club environments for developing as a football player are dependent on the players background and present level (e.g., elite vs. grassroot, youth vs. senior team). In conclusion, the players stories suggest that the value of non-club talent development environments appears to be of minor importance for their path towards elite football. The essential environment for the players is the club environment.

### IS-PN04 Rethinking lactate – from metabolic 'poison' to critical metabolic signal?

#### LACTATE IN CONTEMPORARY EXERCISE SCIENCE: A PHOENIX RISEN

BROOKS, G.

*UNIVERSITY OF CALIFORNIA*

For much of the twentieth century, lactate was considered a dead-end metabolite or 'poison' causing fatigue. This idea, floated by Nobel-prize winning scientists, went unchallenged for nearly 100 years. Indeed, it is still common for some scientists to describe the main biological role of lactate as causing fatigue. Prof. Brooks was the first to challenge this paradigm and his pioneering research revolutionised thinking. Rather than being a fatigue-causing metabolite, Prof. Brooks provided the first evidence that lactate is a major metabolic intermediate that moves between cells and has important biological roles in energy substrate utilisation, cell signalling, and adaptation. Prof. Brooks will therefore open this symposium with an historical overview of how understanding of lactate and its role in exercise physiology and medicine has changed dramatically in the last three decades. He will tell the definitive story of lactate and highlight how its role in physiology has changed dramatically in the last three decades. He will describe how this "metabolic poison" is now known to shuttle between tissues and cells (i.e., the "lactate shuttle"), where it has a multitude of diverse roles such as wound healing, cancer biology, insulin secretion, management of sepsis, learning and memory, and treatment of traumatic brain injury. Hence, in contemporary biology, the role of lactate in metabolism needs to be understood and viewed as a 'phoenix risen' in contrast to the early 20th century view of lactate as a dead-end metabolite that causes fatigue.

#### LACTATE EXCHANGE BETWEEN TISSUES AND THE EFFECTS OF TRAINING

THOMAS, C.

*INSEP*

During heavy exercise, the rapid increase in the energy demand of contracting skeletal muscles is associated with an increase in glycolysis and the subsequent production and accumulation of lactate and protons. The lactate that accumulates in muscle can also be exchanged between tissues, where it serves as an important link between energy metabolism in different tissues. In the 1970s, a saturation phenomenon was observed for lactate transport from exercising human skeletal muscle to the blood compartment; it was subsequently reported that muscle lactate uptake also displayed a saturation effect. A monocarboxylate transporter (MCT) family, which mediates the 1:1 transmembrane cotransport of lactate and protons via a facilitated diffusion mechanism was first identified in red blood cells in the early 70 s by Halestrap and Denton, and later in skeletal frog muscle and cardiac myocytes. The MCT family currently comprises 14 members. MCT distribution is ubiquitous, but intracellular distribution varies among the different cell types (e.g., plasma membrane, mitochondrial membrane, peroxisome), although this distribution is not universally accepted. Lactate/proton cotransport is bidirectional, which means that these transporters facilitate lactate flux, relative to lactate concentration and the proton gradient, either into or out of the skeletal muscle, according to the cell-to-cell "lactate shuttle" first described by Prof. Brooks. This cell-to-cell lactate shuttle provides the basic framework for the understanding of lactate metabolism and exchange. Without the MCTs, lactate could not be as rapidly exchanged between tissue compartments, under conditions ranging from postprandial to sustained exercise.
In skeletal muscle, the most important and well-described isoforms are MCT1 and MCT4. During the last two decades, interest has focused on the effects of a single session of exercise and regular exercise training on the muscle content of these two isoforms. Despite limited research, it appears that both MCT1 and MCT4 belong to a class of proteins that can be rapidly altered by a single session of exercise. Further studies are needed to investigate the underlying mechanisms and to clarify the role of transcriptional regulation on the expression of these proteins in response to exercise. Such research has important implications for the design of an acute exercise stimulus to maximally increase MCT content. The content of MCT1 and MCT4 in humans can also be affected by chronic activity levels, as indicated by the results of both cross-sectional and longitudinal studies. The type of training appears to be of little importance, as few studies have not observed an increase in MCT content or lactate transport capacity following training. However, further research is still required to determine the optimal intensity and duration of a training session to promote improvements in both MCT content and lactate transport capacity, although high-intensity exercise app.

#### A NEW BIOLOGICAL ROLE FOR LACTATE AS A CRITICAL METABOLIC SIGNAL?

BISHOP, D.

*VICTORIA UNIVERSITY*

Lactate is an abundant metabolite produced through glycolysis in many cell types, including skeletal muscle, cancer cells, immune cells, and the brain. While this lactate was traditionally considered a dead-end metabolite, new findings have challenged the way scientists think about lactate. Recent evidence, using both qPCR and RNA-seq, indicates that lactate accumulation is associated with the upregulation of genes associated with metabolism, DNA repair, and inflammation. As transcription is controlled by sequence-specific transcription factors (proteins) that interact with DNA in the nucleus, this has led us to hypothesise that the molecular mechanisms by which lactate increases transcription might relate to increased DNA binding of transcription factors. In support of this, Prof. Brooks has reported that the addition of lactate to myotubes leads to an increased DNA binding of ROS-responsive transcription factors. An alternative and/or complimentary hypothesis is that lactate may also regulate gene transcription in skeletal muscle cells via chromatin modifications. Incubating cells with lactate has been shown to produce a less compact chromatin structure, which should facilitate access of transcription factors to DNA.

Some of our own research suggests this may be via reduced activity of HDAC proteins, which leads to less histone deacetylation and a more relaxed, transcriptionally permissive chromatin (in contrast, greater HDAC activity produces a more condensed, transcriptionally repressed chromatin conformation). Chromatin compactness (and hence gene expression) is also regulated in part through the chemical labelling of histones - highly alkaline proteins found in cell nuclei that package and order the DNA. The addition of chemical tags, such as acetyl and phosphate groups, reduces the positive charge of histones and disrupts electrostatic interactions between DNA and histones – leading to chromatin relaxation. A recent article in Nature reported that lactylation is a previously unknown histone modification that results in the covalent attachment of a lactate-derived lactyl group to lysine residues in the tails of histone proteins. It was also observed that an increase in lactylated histones correlated with increased gene expression in macrophages (immune cells). Thus, results from disparate studies, in different experimental models, converge to establish the hypothesis that increasing the lactate concentration decreases HDAC activity and modifies and relaxes chromatin, which facilitates the transcription of many genes. This emerging understanding of a new role for lactate is of fundamental biological importance as lactate is generated in both physiological (e.g., during exercise) and disease (e.g., cancer) contexts. In this talk, Prof. Bishop will describe pioneering work by Prof. Brooks, and newer evidence from multiple labs, different experimental models, and his own unpublished data, that lactate accumulation is associated with the upregu

## IS-BM02 Opportunities to study new features of neuromuscular physiology and mechanics by imaging…

### STANDARD FRAME RATE ULTRASOUND IMAGING CAN REVEAL DIFFERENCES BETWEEN HEALTHY MOTOR UNITS AND THOSE UNDERGOING NEURODEGENERATIVE CHANGE

HODSON-TOLE, E.

*MANCHESTER METROPOLITAN UNIVERSITY*

Motor unit (MU) remodelling and loss result from various causes, including ageing and neurodegenerative diseases such as Motor Neurone Disease (MND). An indicator of such ongoing neurogenic changes is spontaneous, intermittent, involuntary excitation and contraction of single MUs, termed fasciculation. Fasciculations are typically detected during clinical examination using intramuscular electromyography and are a diagnostic indicator for MND. They are however also visible in standard frame rate, b-mode ultrasound image sequences, where they are seen as transient, localised muscle tissue displacements. Driven by a need for sensitive biomarkers of MND disease progression, there has been increasing interest in using non-invasive ultrasound imaging and high-density surface electromyography to both diagnose and monitor changes in motor unit behaviours and characteristics related to MND. Such markers may also have application to investigating ageing-related changes to MUs to improve understanding of force decline and loss of physical ability.
Standard frame rate ultrasound imaging is widely accessible and commonly used in medical settings and physiology/biomechanical research settings. Its application to studying MU physical properties is however in its infancy and not widely exploited. In this presentation I will therefore review recently proposed quantitative image analysis approaches that provide automated, objective measures of fasciculation occurrence and MU characteristics in standard frame rate (~80 fps) b-mode ultrasound image sequences. Comparisons between computer vision-based feature tracking and learning-based foreground detection approaches will be provided. Additionally, an overview of some physical motor unit properties that can be quantified using these techniques, such as spatial (location, area) and temporal characteristics. In the second part of the presentation a comparison of physical and electromechanical properties between MUs in healthy and MND-affected muscles will be provided, based on data collected using high-density electromyography and standard frame rate B-mode ultrasound imaging. The talk will conclude by reviewing some of the challenges still to be addressed for new biomarkers of neurodegeneration to be established, and will also consider how useful these markers and standard frame rate ultrasound may be in understanding changes in MU properties associated with ageing

### ELECTRICAL AND PHYSICAL MOTOR UNIT PROPERTIES REVEALED WITH SIMULTANEOUS HIGH-DENSITY ELECTROMYOGRAPHY AND ULTRASOUND IMAGING

BOTTER, A.

*XXXX*

During a muscle contraction, myofibrils translate the neural excitation arising from spinal motoneurons into tensile forces, which are transmitted to tendons and finally, to the skeleton. Current technology allows to study this cascade of events non-invasively and from different perspectives. Surface EMG provides information about the degree of neural excitation issued to the muscle both at global level and, when detected with multiple electrodes (high-density EMG, HD-EMG), at single motor unit level. Ultrasound (US) imaging, conversely, is applied to study muscle properties both from anatomic (e.g. tissue architecture and texture) and functional (e.g. muscle contraction patterns, tissue elasticity and muscle anisotropy) perspectives. Although both techniques underwent significant advancements in the last ten years, individually they provide a partial description of the complex electromechanical phenomena leading to muscle force production. When combined, therefore, EMG and US have the potential to provide a more detailed and complete description of the events underpinning the generation of muscle force.
In this talk I will briefly introduce the challenges related to the combined acquisition of EMG and US, the way they have been addressed and the applications to the study of global muscle properties. Afterwards, I will present a method to study the electrical and physical (i.e. mechanical and anatomical) characteristics of single MUs by combining HD-EMG and US image sequences detected at high frame rate (2500 fps). The method uses individual MU firings obtained through HD-EMG decomposition to identify the corresponding region of muscle tissue displacement in the US tissue velocity sequences. The time evolution of the tissue velocity in the identified region is regarded as the MU tissue displacement velocity. The method was tested in simulated conditions and applied to experimental signals to study the local association between the amplitude distribution of single MU action potentials and the identified displacement area. We were able to identify the location of simulated MUs in the muscle cross-section with an error lower than 2mm and to reconstruct the temporal profiles of the simulated MU displacement velocities with cross correlation coefficients higher than 0.85. Multiple regression analysis of 180 experimental MUs detected during isometric contractions of the biceps brachii revealed a significant association between the identified location of MU displacement areas and the centroid of the transversal EMG amplitude distribution.

The proposed approach has the potential to enable non-invasive assessment of the electrical, anatomical, and mechanical properties of single MUs in voluntary contractions. Information obtained from this multi-modal approach, such as MU firing properties, location and territory, is required to better investigate fundamental aspects of MU and muscle function, as well as changes resulting from neurodegenerative disease.

### USING ULTRAFAST ULTRASOUND IMAGING FOR THE IDENTIFICATION OF FIRING PATTERN AND LOCATION OF SINGLE MOTOR UNITS IN VOLUNTARY CONTRACTIONS

GRÖNLUND, C.

*UMEÅ UNIVERSITY*

The central nervous system controls human locomotion by successive recruitment of motor units (MUs) in the skeletal muscles. The MU comprises a motoneuron and a bundle of innervated muscle fibers within a localized territory. Today, the function of MUs is measured and analyzed by electromyographical (EMG) methods. It provides the basis for MU analysis in diagnosing neuromuscular diseases, exercise physiology and sports, and rehabilitation medicine. The EMG records the muscle fibers' repeated electrical depolarizations following a firing pattern transmitted from the spinal cord via the motor neuron. The so-called excitation–contraction mechanism links the electrical depolarization to the thickening and shortening of the fibers (mechanical twitch). Therefore, recording and analyzing mechanical twitches may provide an alternative way to study MUs.
Non-invasive ultrasound imaging allows mechanical information from a large field of view in soft tissues such as the muscles. In skeletal muscle applications, ultrasound has mainly been used for structural imaging. For example, in diagnostics of neuromuscular disease, the quantification of muscle function in exercise physiology and sports, detection of contraction onset. High-resolution ultrafast ultrasound imaging, with a high frame rate (>1000 images per second), has been successfully applied on imaging the MUs' mechanical twitches during externally controlled electro-stimulations. However, electrical stimulation provides no information about (neural) firing pattern. Voluntary contractions are required to access this information. Our group recently proposed methods to extract the mechanical twitches of contracting MUs in ultrasound image sequences under voluntary contractions.
In this talk, we will present how spatiotemporal and deep learning methods can be used to detect firing pattern and position of single MUs in high frame rate ultrasound image sequences of voluntary contractions. We will start with discussing the need for ultrafast imaging systems as compared to clinical ultrasound systems, and that there may be work-arounds to achieve MU identification using low frame rate systems such as clinical commercial US systems. Next, we present some work on estimating the contractile properties of the individual MU twitches during voluntary contractions. Finally, we discuss the influence of the myofascial coupling and a need for authentic simulation models of the intra-muscular contraction patterns arising from the contraction of the fibres of the active MUs. This will be important to facilitate further advances of this new research field of neuromuscular imaging.

### OP-LAG03 Physical activity promotion

### FACTORS ASSOCIATED TO PHYSICAL ACTIVITY IN USERS OF NATIONAL PROGRAM OF HEALTHY HABITS AND LIFESTYLES "HEVS" OF THE MINISTRY OF SPORT IN COLOMBIA

CASTRO, C.1, GÁLVEZ, A.1, MENDOZA, D.1, TRIANA-REINA, H.R.1, RUIZ, N.2, LEANDRO, R.2, DÍAZ DEL CASTILLO, A.2, SAENZ, N.2, SERRATO, J.2, OREJARENA, J.2

*1 UNIVERSIDAD SANTO TOMÁS, BOGOTÁ, COLOMBIA 2 MINISTERIO DEL DEPORTE, BOGOTÁ, COLOMBIA*

INTRODUCTION: Obesity is considered a public health problem in the world; it is estimated that by 2025 one fifth of the population will be overweight, represented as being overweight or obese (1). In the population, the consumption of sugary drinks and processed foods has increased and physical activity has decreased, which increases excess weight (2). To counteract the above, both globally and in Colombia, good practices are carried out to promote of healthy habits and lifestyles, based on this, has created a national program led by the Colombian Ministry of Sports in conjunction with Municipal and Department of Sports entities dedicated to the healthy habits and life styles called "HEVS". This program encourages regular physical activity practices, healthy eating and smoke-free environments and performs research activities. HEVS is conducting a research to identify the performance of physical activity and associated factors across the country and those involved in the HEVS Program. METHODS: The research scope consisted of 75.086 people over 18 years of age, users of the HEVS Program who provide information at the time thy joined the program related to their physical condition such as weight, height and other lifestyle statistics. Individuals comprise 33 departments and 11 municipalities. For the statistical analysis, a hierarchical logistic regression model was carried out. The dependent variable was compliance with the physical activity recommendations (0 = does not comply, less than 150 minutes and 1 = complies, equal to or greater than 150 minutes per week). RESULTS:The users had a mean age of 44.04 ± 15.75 years, and 87.7% were women. 92.5% of users do not comply with the physical activity recommendations and exercised less than 150 minutes a week. This corresponds to 49.489 people who answered this variable. The remaining 7.5% (4.026 people) comply with the recommendation. Users grupos regulares de actividad física (realizados 3 veces por semana) reported a greater probability of complying with the recommendations (OR=2.72; 95% CI=2.36 to 3.13) que los usuarios inscritos en grupos realizados 2 veces por semana. Moreover, users in the Caribbean region, the Coffee Region, and Antioquia presented a probability greater than 2 of complying with the recommendations, compared to those who live in the Amazon, Eastern Plains or Casanare. Men were more likely than women (OR=1.2; 95% CI=1.06 to 1.4) to follow the recommendations, and consuming more than 5 or more servings between fruits and vegetables was also associated with more than 150 minutes per week of physical activity (p≤0.01). However, the variable of high blood glucose was not related to compliance with the recommendations. CONCLUSIONS:The practice of physical activity from 150 minutes a week or more is associated with the intake of more than 5 or more servings between fruits and vegetables and gender, being higher in men than in women. ## CONSTRUCTION OF A MUNICIPAL PUBLIC POLICY FOR SPORT AND PHYSICAL ACTIVITY: A SIGNIFICANT COLOMBIAN EXPERIENCE

ARIAS, A., ORDOÑEZ, N., GÓMEZ, J., CARRILLO, L., SÁNCHEZ, D., COLORADO, A., RIVERA, L., OBANDO, L., MERCHÁN, N., SEGURA, L.

*UNIVERSIDAD DE CIENCIAS APLICADAS Y AMBIENTALES UDCA / INSTITUTO MUNICIPAL DE RECREACIÓN Y DEPORTE DE CHÍA.*

Introduction
The public policy for sports and physical activity of the municipality of Chía in Colombia was built with the participation of public and private actors, guided by the Municipal Institute of Recreation and Sports of Chía and the Colombian Network Association of Schools of Sport, Physical Education and Recreation [1]. This significant experience, from the perspective of qualitative research, becomes a reference for the organizations of the sector, which must guide long-term planning processes with the active participation of the community [3].
Method
The public policy in its formulation phase was developed in five stages with a qualitative methodology: formation of working groups for interest groups (beneficiaries, representatives of organizations, dignitaries and experts), identification of problems and needs, selection of solution alternatives, definition of guidelines, discussion with stakeholders on the technical document [2]. The construction of the public policy was developed through a semi-structured interview addressed to the focus groups, validating the process with the feedback of the results.
Results
546 people participated in the process. 52.10% women and 47.90% men. 50.7% from the urban area and 20.5% from the rural area. The public policy was structured around 5 axes (coverage with equity and quality, professional suitability, culture of organizational self-management, sports infrastructure and implementation, and institutional development), which materialized in a strategic plan and an operational plan 2021 - 2032.
Discussion
The way how the public policy was built, allowed to establish guidelines, which facilitated the establishment of goals and indicators for the sector in the municipality, with the purpose of improving the quality of life of the inhabitants through the practice of sports and physical activity [4]. With this space for citizen participation, social, political and economic reality of the sector is evidenced, and contributes to the concerted design of strategic lines, to focus the action of the State at all levels, taking into account its articulation with the Sustainable Development Goals 2030 [1].

## INCIDENCE OF INSTITUTIONAL DESIGN, IN THE STATE OF GOVERNANCE OF NATIONAL SPORTS ORGANIZATIONS.

GÓMEZ, J., ARIAS, A., ORDOÑEZ, N., RAMOS, J., GUERRERO, O.

*ECCI UNIVERSITY*

INTRODUCTION: Governance is the form of government that guarantees the fundamental right to practice sport [2]. On this premise, Play the Game developed research in 15 countries. With the study completed in 2021, the National Sport Governance Observer (NSGO) index was determined, generating the following question: What is the incidence of institutional design, in the state of governance of national sports organizations (NSOs)?
METHODS: The NSGO instrument was used, composed of 4 dimensions (Transparency, democratic processes, internal control and social responsibility), 47 principles and 274 indicators. This instrument was applied by researchers to 8 NSOs from the 15 countries [1].
RESULTS: The NSGO index for the 15 countries is 40%. The NSGO index by country is: United States 53%, Canada 41%, Colombia 45%, Bosnia and Herzegovina 51%, Bulgaria 41%, Georgia 21%, Iceland 37%, Lithuania 44%, Portugal 39%, Serbia 59%, Slovenia 30%, Spain 46%, Ukraine 38%, India 27%, and Indonesia 28%. Regarding the institutional design in each country, it was found that there are two systems, one open and the other mixed; the first, typical of developed countries, such as the United States; the second, related to developing countries, Colombia case.
CONCLUSION: In the open system, inclusive policies are developed, articulating public and private education with sports programs or activities, providing opportunities in the recruitment of athletes, sports training, and participation in sports events [3]. The mixed system is mainly delimited by laws, which establish a hierarchical order for public and private sports organizations [4]. It is evident that the institutional design affects the state of the governance of the NSOs. It is also clear that open or mixed national systems adapt their private organizational structure to what is established by international sports federations and the International Olympic Committee. This situation does not occur in the national public sphere, because there is no high influence of international government agencies.

## LOWER COST OF TRANSPORT COINCIDES WITH SELF-SELECTED WALKING SPEED IN PREGNANT INDIVIDUALS

BONA, R.L.1, RACEDO, A., BEGINSKI, R., BONEZI, A., BIANCARDI, C.

*UNIVERSIDAD DE LA REPUBLICA URUGUAY*

INTRODUCTION: Pregnancy has important structural and physiological changes related to the growth of the baby [1]. These changes can alter metabolic and biomechanical parameters of pregnant individuals (PI) [2]. Changes in the body centre of mass (CM), body dimensions, and weight can influence postural aspects as well as gait pattern [3]. Thus, changes may occur in different variables such as cost of transport (C) (unit J.kg-1.m-1) [4], ventilatory efficiency, and walking speed. Aim: to compare C, VE/VCO2, self-selected walking speed (SSWS) on treadmill and on a track, at different walking speeds, of PI and a control group (CG).
METHODS: PI: n=24: n=8 in 1st trimester (T1), 12-13 wks; n=8 in 2nd trim. (T2), 26-27 wks; n=8 in 3rd trim. (T3), 35-36 wks; CG: n=8 healthy non-PI. C is energetic cost to travel a given distance. Ventilatory efficiency evaluated by the ventilatory equivalent for carbon dioxide (VE/VCO2). VO2 uptake was collected during trials of 5 min at 5 walking speeds, in randomized order (SSWS, ±40%, ±20% of SSWS) on the treadmill [5]. The SSWS was initially assessed on a track, and then tested on the treadmill. ANOVA for repeated measures was used to

compare C and VE/VCO2 for walking speed and groups. One-way ANOVA was used to compare SSWS on the track and on the treadmill. Multiple comparisons were possibly made with Tukey's post-hoc analysis (α=0.05).
RESULTS: Values of C were higher in PI compared to CG for all Ts (p=0.005; differences between Ts p=0.001). VE/VCO2 also showed higher values for PI (among Ts p<0.0001) compared to CG (p<0.0001). Differences in the SSWS (T1 0.83±0.14; T2 0.82±0.18; T3 0.85±0.18; CG 1.01±0.14 m.s-1) on the treadmill and on the track were found for all T (p<0.0001), and between PI and CG (p<0.0001).
CONCLUSION: C always showed the characteristics of "U" shape described previously [4], with higher metabolic economy at SSWS. Interestingly, VE/VCO2 showed higher values in T2 compared to T1, T3 and CG. VE/VCO2 is known to be affected by increased chemoreceptor numbers, peripheral ergoreceptor response, dead space ventilation, and muscle mass involved in exercise [2]. The feeling of greater respiratory difficulty with the increase in walking speed and due to the smaller excursion of the diaphragm by the increased abdominal volume. Our results showed that the greatest respiratory comfort (lower VE/VCO2) occurred at the highest speed performed (above SSWS). The choice of SSWS seems to be related to a greater metabolic economy and not to respiratory comfort.
After all physiological changes in T1 and T2 of pregnancy [1], T3 resulted to a certain adaptation. Lower metabolic economy is probably due to the physical alterations such as increase in body mass, displacement of the CM which could have altered the pendulum mechanism, generating displacement with less mechanical efficiency [5].

### IS-AP05 Crossing boundaries in talent development: implications at the micro, meso and macro level

#### CROSSING BOUNDARIES BY THE ATHLETE

ELFERINK-GEMSER, M.
*UNIVERSITY OF GRONINGEN, UMCG*

In order to deliver maximum performance, talented athletes repeatedly push their boundaries. Not seldom, this leads to crossing their physical and mental boundaries resulting in injuries, which can have a negative impact on their physical and mental well-being, as well as a decrease in performance development. Skills related to 'self-regulation of learning and training' are related to prevention of injury and also to successful rehabilitation. Athletes who self-regulate well, take responsibility for their own development and score better on adherence to their rehabilitation once they get injured. Successful athletes are able to apply this skill in various situations and domains: not only when they are injured but also during regular sports training and competition. In addition, they use it for school work and in combining sport and school, thereby crossing boundaries between domains. This holds for individual and team sports, male and female athletes.

#### CROSSING BOUNDARIES BETWEEN SPORTS FROM A DEVELOPMENTAL AND PERFORMANCE PERSPECTIVE

LENOIR, M.
*UNIVERSITY OF GHENT*

Traditional research on talent identification and development has primarily focused on individual characteristics matching the required performance characteristics in a particular sport. More recently, researchers have increasingly crossed boundaries between sports, resulting in more profound insights in differences as well as similarities in profiles in young and promising sports talents. The aim of this contribution is to explore the benefits of such information for a healthy development of sport participants as well as for training of the young promising athlete. A scientifically based overview is given of a) how 'different' sports can contribute to a general healthy development of the young athlete (diversification), and b) how 'similar' sports can be applied to train key characteristics in young athletes in a specialization pathway.

#### CROSSING BOUNDARIES BETWEEN DOMAINS: WHAT CAN SPORTS LEARN FROM THE CONTEXT OF SCHOOLS?

FABER, I.
*CARL VON OSSIETZKY UNIVERSITY OLDENBURG*

Talent programs have become an integral part of the sports context in Western society. These programs aim to recognize young talented athletes and support them in their development to the top. Unfortunately, in practice it is not easy to find rough diamonds and to counter disappointing results. Moreover, the sports context is a dynamic and constantly changing environment. That is why sports associations are always looking for innovative methods within their talent programs.
It is not only in the sports context that progress is being made with regard to talent programs. Particularly in education, more attention has been paid to the excellent student in recent years and various programs/approaches have been developed. There too, strategies are being sought to better recognize talented young people and to provide them with the best possible guidance in their development process. These programs/approaches have been developed in the educational context and independently of the sports context. Cross-domain peeking at the neighbours in education have pointed out new knowledge, ideas and insights for the sports context.

## Oral presentations

### OP-PN20 Hydration

#### CHALLENGING PROLONGED REHYDRATION CONCEPTS: AD-LIBITUM FLUID INTAKE, RESULTING IN CONSUMPTION OF >200% FLUID LOSS POST-EXERCISE, WAS INSUFFICIENT TO ACHIEVE EUHYDRATION 20 H AFTER INTERMITTENT RUNNING

FUNNELL, M., JUETT, L., FERRARA, R., MEARS, S., JAMES, L.

*LOUGHBOROUGH UNIVERSITY*

INTRODUCTION: The majority of rehydration research has focused on the composition, volume, and timing of rehydration drinks consumed in a prescribed manner in a short post-exercise period (0-6 h). Little is known about rehydration kinetics over longer time frames more typical of times between exercise sessions in athletes (6-24 h). This study documented 20 h rehydration from intermittent running while concealing the primary aim of the study.
METHODS: Twenty-eight male intermittent games players (age 25 ± 3 y; predicted V̇O2max 54 ± 3 mL·kg-1·min-1; training sessions·week-1 6 ± 3) were pair-matched to an exercise (EX) or rest (RE) group. Body mass, urine and blood samples were collected at 08:00, pre-intervention (09:30), post-intervention (12:00), 3 h post-intervention and 08:00 the next day, to determine hydration status. The intervention was a 110-min intermittent running session in EX (modified Loughborough Intermittent Shuttle Test) and a 110-min rest in RE, with water allowed ad-libitum in both. Subjects completed a weighed diet record and urine collection for the 24 h period.
RESULTS: Changes typical of hypohydration were apparent in EX following the intervention (body mass: EX -2.0 ± 0.5 %; RE -0.2 ± 0.3 %; serum osmolality: EX 293 ± 4 mOsm·kg·kgH2O-1; RE 287 ± 6 mOsm·kgH2O-1; P≤0.022). Water intake during the intervention (EX 704 ± 286 mL, RE 343 ± 230 mL) and in the 3 h post-intervention (EX 1081 ± 460 mL, RE 662 ± 230 mL) was greater (P≤0.004) in EX, with no difference thereafter (P=0.923), with 209 ± 97 % fluid loss in EX consumed post-exercise. Total 24 h urine output was lower in EX (EX 1697 ± 824 mL, RE 2370 ± 842 mL; P=0.039). Body mass was reduced (-0.6 ± 0.5 %; P=0.030) and urine osmolality elevated (844 ± 197 mOsm·kgH2O-1 vs 698 ± 200 mOsm·kgH2O-1; P=0.004) the following day in EX, but not RE. Sweat sodium losses were 1861 ± 647 mg during exercise in EX, but 24 h sodium intake was not different between groups (P=0.801). Total 24 h urine sodium losses were reduced in EX (EX 1557 ± 834 mg, RE 2606 ± 828 mg; P=0.003), but not enough to account for sweat losses, meaning 24 h sodium balance was lower in EX (EX -383 ± 1178 mg, RE 524 ± 726 mg; P=0.022).
CONCLUSION: Ad-libitum water intake during 110 min intermittent running produced hypohydration of ~2% body mass, and despite free access to fluids meaning ~209% of fluid loss was consumed post-exercise, a small degree of hypohydration remained 20 h post-exercise (reduced body mass and elevated urine osmolality). This might be explained by the negative sodium balance in EX over the 24 h lessening fluid retention. Although small and unlikely to impair exercise performance in isolation, any hypohydration present before a subsequent training session means significant hypohydration is more likely in that session or that more significant deficits might more easily accrue with repeated exercise.

#### SEVERE FLUID RESTRICTION FOR 24 H INCREASES A BIOMARKER OF KIDNEY INJURY IN MALES

JUETT, L.A., FUNNELL, M.P., JAMES, L.J., MEARS, S.A.

*LOUGHBOROUGH UNIVERSITY*

INTRODUCTION: Hypohydration induced by exercise exacerbates biomarkers of renal tubular injury, such as urinary kidney injury molecule-1 (uKIM-1) (1). However, the isolated effects of hypohydration (in the absence of heat stress and/or exercise) on biomarkers of renal tubular injury are not well-understood. Fluid restriction/inadequate fluid intake is common in athletes who 'make weight' in weight-category sports, as well as in settings where there is reduced availability of fluids and/ or toilet facilities. The present study investigated the effects of 24 h severe fluid restriction on biomarkers of renal tubular injury, including uKIM-1 and urinary neutrophil gelatinase-associated lipocalin (uNGAL).
METHODS: Fifteen males (age: 27 ± 5 y; BMI: 24.1 ± 3.8 kg/m2) completed two trials in a randomised order, involving either severe fluid restriction (limiting water consumption to 100 mL; HYP) or maintaining euhydration (40 mL/kg body mass water; EU) for 24 h whilst consuming a dry food diet. At baseline and 24 h post-baseline, nude body mass, blood samples and urine samples (additional urine sample at 12 h) were collected. To account for changes in urine concentration affecting urinary biomarkers of renal injury, uKIM-1 and uNGAL concentrations were corrected for urine osmolality. Data are presented as mean ± standard deviation.
RESULTS: At 24 h post-baseline, severe fluid restriction resulted in increased body mass loss (HYP: -1.52 ± 0.34%, EU: -0.24 ± 0.40%), plasma volume loss, urine osmolality, and serum osmolality (HYP: 297 ± 4 mOsm/kg, EU: 289 ± 2 mOsm/kg) compared to EU (P < 0.005). Fluid restriction increased osmolality-corrected uKIM-1 concentrations by 92 and 21% at 12 h post-baseline (HYP: 1.097 ± 0.587 ng/mOsm, EU: 0.570 ± 0.408 ng/mOsm; P < 0.001) and 24 h post-baseline (HYP: 1.932 ± 1.173 ng/mOsm, EU: 1.599 ± 1.012 ng/mOsm; P = 0.01), respectively, compared to EU. There were no trial by time interaction effects for osmolality-corrected uNGAL (P = 0.781), serum creatinine (P = 0.826) or serum uric acid (P = 0.097).
CONCLUSION: Severe fluid restriction for 24 h increased renal injury, compared to when euhydration was maintained with water ingestion. The difference between trials with regards to osmolality-corrected uKIM-1, yet lack of differences in osmolality-corrected uNGAL concentrations, suggest that the location of renal injury was the proximal tubules. The increased proximal tubular injury was likely mediated by serum hyperosmolality and subsequent increases in circulating vasopressin. The long-term consequences of an acute increase in a biomarker of proximal tubular injury and/ or repeated increases require further research.

### WHOLE-BODY AND MUSCLE-LOCALIZED BIOELECTRICAL IMPEDANCE VECTOR MIGRATION OVER A GIRO D'ITALIA PRO RACE

CEBRIÁN-PONCE, A.1, GARNACHO-CASTAÑO, M.V.2, CASTIZO-OLIER, J.3, CARRASCO-MARGINET, M.1, ESPASA-LABRADOR, J.1, NORIEGA, Z.1, IRURTIA, A.1

*1 INEFC-BARCELONA SPORTS SCIENCES RESEARCH GROUP, INSTITUT NACIONAL D'EDUCACIÓ FÍSICA DE CATALUNYA , UNIVERSITAT DE BARCELONA , BARCELONA 08038, SPAIN; 2 CAMPUS DOCENTE SANT JOAN DE DÉU.*

INTRODUCTION: Giro d'Italia is one of the most demanding multistage races included in the professional cycling Tour, in which it is difficult to intervene systematically in these group of cyclists to assess the adaptations to such intense competitions. Bioelectrical impedance vector analysis (BIVA) is a non-invasive and safe technique for assessing hydration and body composition changes [1]. The purpose of this study was to apply BIVA to assess possible hydration changes evoked over the 3 weeks of Giro d'Italia in a group of elite rink hockey players.
METHODS: 9 elite cyclists completed whole-body and muscle-localized BIVA (quadriceps, hamstrings and calves) assessments at three different checkpoints: one day before the start of Giro d'Italia 2013 (PRE), on the first resting day (MID), and on the final day of the race (POST). A tetra-polar phase-sensitive BIA at 50 kHz was used to measure height-adjusted resistance, height-adjusted reactance and phase angle. Hotelling's T2 test determined differences in the complex vector through the 95% confidence intervals. Haemoglobin, haematocrit, plasma volume and osmolality were also assessed in all three checkpoints as a hydration biomarkers. All the procedures were in accordance to the Declaration of Helsinki.
RESULTS: Whole-body BIVA reported a non-significant shortening vector migration in PRE-MID and a significant lengthening vector migration in MID-POST. In PRE-POST, there was a significant lengthening of the vector. Regarding muscle-localized BIVA, no significant vector migrations were reported neither in quadriceps nor in hamstrings. As far as calves' vector migration, there was a significant shortening of the vector in PRE-MID and a significant lengthening of the vector in MID-POST. Across PRE-POST the mean calves' vector experienced a significant shortening.
Haemoglobin and haematocrit significantly decreased in PRE-MID and significantly increased in MID-POST, but below baseline values. The dynamic of plasma volume was opposite: it significantly increases in PRE-MID and decreases in MID-POST. Considering the entire 3-week race, plasma volume values increased significantly. Osmolality increased significantly from the start to the end of the competition.
CONCLUSION: Haematological markers showed that major hydration changes were experienced in the second half of the race, a fact that was confirmed by the kinetic of whole-body and calves' vector migration. Whole-body BIVA lengthening vector indicated a global dehydration, but a possible fluid accumulation in the calves could have occurred, not like in quadriceps or hamstrings since there were none changes. Results indicate that BIVA is sensitive to assess hydration adaptations in relation to hydration biomarkers changes induced by a strenuous race.

### TIMING OF CARBOHYDRATE AND PROTEIN INTAKE AND HYDRATION STATUS OF GERMAN JUNIOR FOOTBALL PLAYERS

BRAUN, H., BAUHAUS, H., STEGEMANN, S., THEVIS, M.

*MANFRED DONIKE INSTITUTE FOR DOPING ANALYSIS, GERMAN RESEARCH CENTRE OF ELITE SPORTS, GERMAN SPORT UNIVERSITY COLOGNE*

INTRODUCTION: Recently, the UEFA expert group highlighted that nutritional support plays a key factor for junior football players and will help to optimise growth, health, performance, recovery, training adaptations and body composition (Colllins et al. 2020). Although, young players may have different nutritional needs from those of adults the expert group stated that carbohydrate (CHO) and protein (PRO) needs are similar to those of senior players and Urine specific gravity (USG) can be a useful indicator of hydration status suggesting euhydration of USG <1.020. Data on nutritional status in junior football players are still rare, therefore this observational study focus, whether academy players follow the UEFA nutrition guidelines on training and match days.
METHODS: In total, 55 male junior football players (15 ± 0,8 yrs; 176 ± 8 cm; 63,9 ± 8,6 kg) from 3 academy teams (Under 17, 16 & 15 yrs) of a German professional football club were asked to weigh and record their food and beverages consumed on five consecutive days as well as their activities. These included training days (TD1 - TD3), pre-match day (MD-1) and a match day (MD). MD Kick-Off time was between 11am-1pm. Dietary protocols were analysed based on the German food database (BLS 3.1) using Ebispro Software. On each morning, urine samples were collected and analysed for urine specific gravity (USG).
RESULTS: On TDs mean PRO 1.7 ± 0.7 g/kg/d and CHO 4.7 ± 2.1 g/kg/d intake was within the recommended guidelines. In 21% of all TDs PRO intake was <1g/kg and for CHO <3 g/kg (22%) respectively. Mean MD-1/MD PRO intake (1.6 ± 0.7 g/kg/d) and CHO intake (4.4 ± 2.0 g/kg/d) was similar to TDs. However, 78% of the players are below the recommended CHO intake (6-8g/kg/d) on MD-1. On MD pre-Match CHO Intake (<4 hrs before Kick Off) was 1.5 ± 0.8 g/kg. Depending on the team and Kick-Off time 20% - 38% of the players consumed CHO <1 g/kg. Mean total water intake (TWI) on TDs was 4.0 ± 1.8. L (63 ± 29 mL/kg) and 3.8 ± 1.9 L (60 ± 30 mL/kg) on MD-1/MD. Mean morning USG on TDs was 1.022 ± 0.008 (30% <1.020 and 32% >1.025), on MD-1 1.023 ± 0.008 (26% <1.020 and 38% >1.025) and on MD 1.023 ± 0.006 (32% <1.020 and 41% >1.025).
CONCLUSION: In the present study, PRO and CHO intake of German Junior Football Players were within the recommended guidelines on training days, but not for CHO on MD-1 and MD. A relatively high number of players have had a low CHO intake and a morning USG >1.025 before Kick-Off on MD, assuming that they were not well prepared for competition. These data suggest that young academic football players need more information regarding a sport specific diet and timing of nutrient intake during trainings days, but specifically on match day.

### A NOVEL NUTRITIONAL BLEND IMPROVES SUBJECTIVE & OBJECTIVE MEASURES OF SLEEP IN MALE AND FEMALE PARTICIPANTS: A RANDOMISED COUNTERBALANCED, REPEATED MEASURES CROSSOVER, DOUBLE BLIND DECEPTION STUDY

LANGAN-EVANS, C.1, HEARRIS, M.A.1, GALLAGHER, C.1, LONG, S.1, THOMAS, C.2, CHEUNG, W.3, HOWATSON, G.3, MOSS, A.D.1, MORTON, J.P.1

*1LIVERPOOL JOHN MOORES UNIVERSITY 2LOUGHBOROUGH UNIVERSITY 3NORTHUMBRIA UNIVERSITY*

INTRODUCTION: Nocturnal sleep is a fundamental process in aiding the recovery of several key psycho-physiological functions, yet a large majority of the global population experience some form of sleep disturbance [1, 2]. To that end, the nutritional regulation of sleep is of interest, with studies employing a range of active ingredients purported to enhance sleep qualities [3]. However, to determine the true efficacy of any intervention on measures of sleep, participants should be sufficiently blinded to monitoring of their sleeping patterns [4]. Therefore, the aim of this study was to examine the effects of a novel nutritional blend on subjective and objective assessments of sleep, whilst blinding participants to this as primary outcome measure.
METHODS: The study was a randomised, counterbalanced, repeated measures crossover, double blind deception design. Male and female participants (n = 16; age: 24 ± 3; body mass: 69.8 ± 11.6 kg; stature: 170.8 ± 9.1 cm) completed a three day free living familiarisation period, employed to establish baseline measurements for specific subjective (core consensus sleep diary & Karolinska sleepiness scale) and objective (actigraphy) nocturnal sleeping patterns, daily energy/macronutrient intakes (weighed inventory & remote food photography method), physical activity (actigraphy), and light (Lux sensor) exposure profiles, which were then replicated during the main intervention and placebo trials. Additionally, participants provided daily urine samples for assessment of targeted and untargeted metabolomes, analysed via hydrophilic liquid interaction chromatography (HILIC). Statistical comparison between the main trials was conducted via parametric paired samples t-test or non-parametric Wilcoxon tests for normally or non-normally distributed data, respectively.
RESULTS: The intervention trial resulted in a 24 min reduction in sleep onset latency ($p = 0.002$), 22 min increase in total sleep time ($p = 0.01$) and a 2.4% increase in sleep efficiency ($p = 0.03$) compared to the placebo trial. Additionally, there was a reduction in morning sleepiness ($p = 0.02$) between the intervention and placebo trials. 75% of participants remained blinded to sleep assessment as a primary outcome within the main trials and when unblinded, 56% subjectively indicated improved sleep during the intervention trial. HILIC analysis highlighted several significantly elevated metabolomes during the intervention trial inclusive of 6-Sulfatoxymelatonin and D-Serine.
CONCLUSION: Data demonstrate that within male and female participants during free living conditions, nocturnal sleep can be enhanced using a novel nutritional blend, by shortening time to fall asleep and extending time asleep, resulting in overall greater sleep efficiency. These improvements may be caused by the inclusion of the sleep enhancing ingredients tryptophan and glycine, which lead to the upregulation of key metabolites involved in the neurophysiological modulation of sleep/wake cycles.

### EXAMINATION OF AMORPHOUS CALCIUM CARBONATE ON THE INFLAMMATORY AND MUSCLE DAMAGE RESPONSE IN EXPERIENCED RESISTANCE TRAINED INDIVIDUALS.

HOFFMAN, J.R., BEN-ZEEV, T., ZAMIR, A., LEVI, C., OSTFELD, I.

*ARIEL UNIVERSITY*

INTRODUCTION: Calcium is a micronutrient that has an important role in both bone health and skeletal muscle function. Calcium supplementation is often used to achieve adequate calcium intake. Several studies have concluded that calcium supplementation is effective at enhancing bone strength, but may be more efficacious when it is combined with vitamin D. When provided by itself, the efficacy of calcium alone has been inconclusive. Part of this may be related to its formulation. The calcium found in most dietary supplements is from either carbonate and citrate salts derived from various sources including oyster shells, coral calcium, dolomite minerals, and other synthetic material and has limited absorbability. Calcium carbonate is one of the most abundant minerals in nature, having six known polymorphs. The least stable polymorph is the amorphous form, which has the greatest absorption capability. The instability of the amorphous calcium carbonate provides a highly bioavailable calcium source that enables a fast and effective transport of the mineral across the intestinal epithelium calcium carbonate. In consideration of the greater absorption capability of the amorphous calcium carbonate (ACC), and the limited research on young, active participants, the purpose of this study was to examine the effect of 3-weeks of amorphous calcium carbonate (ACC) supplementation (2000mg per day) on the recovery response to resistance exercise in trained men.
METHODS: Participants were randomly divided into a supplement (ACC; n=15) or placebo (PL; n=15) group. Following the supplementation protocol (T3) participants performed 6-sets of 10-repetitions per set in both the bench press (BP) and incline BP exercises, using 80% of their maximal strength. Participants returned 24- (T4) and 48-hours (T5) post-T3 performing 6-sets of the BP exercise only using the same loading pattern as T3.
RESULTS: Significant decreases in the number of repetitions performed ($p<0.001$), peak power ($p<0.001$) and mean power ($p=0.009$) were noted over time, but no significant interactions were observed ($p>0.05$). Magnitude-based inference analysis (MBI) indicated that the change in repetitions was possibly beneficial for ACC at T4 and likely beneficial at T5. No significant interactions were noted for general soreness ($p=0.452$), but a trend towards an interaction was observed in upper body soreness ($p=0.089$). Confidence intervals for mean percent change scores indicated significant differences between the groups at T4 and T5. MBI analysis indicated that ACC was very likely or likely to be beneficial at T4 and T5, respectively. No significant interactions were noted for interleukin (IL)-6, IL-10, tumor necrosis factor-α or creatine kinase-muscle.
CONCLUSION: ACC supplementation may have a potential beneficial effect in attenuating the decline in performance, possibly due to the carbonate component. The benefits associated with the attenuated soreness response requires further investigation.

### TART CHERRY SUPPLEMENT ENHANCES SKELETAL MUSCLE GLUTATHIONE PEROXIDASE EXPRESSION AND FUNCTIONAL RECOVERY AFTER MUSCLE DAMAGE

WANGDI, J.T., O'LEARY, M.F., KELLY, V.G., JACKMAN, S.R., TANG, J.C.Y., DUTTON, J., BOWTELL, J.L.

*QUEX INSTITUTE*

INTRODUCTION: Montmorency cherry concentrate (MCC) supplementation enhances functional recovery from exercise. However, to date, only indirect blood biomarkers provide evidence supporting the mechanistic hypotheses of antioxidant and anti-inflammatory effects. This study is the first to investigate functional recovery from exercise alongside molecular changes within the exercised muscle following MCC supplementation.
METHODS: Ten healthy males (age: 23.4±5.4 y, weight: 78.0±21.9 kg, height: 1.78±6.90 m) completed two maximal unilateral eccentric knee extension trials following MCC (20.167 mg/mL polyphenolics and 7.211 mg/mL total anthocyanins) or placebo (PLA) supplementation for 7 d prior to and 48 h following exercise. Knee extension maximum voluntary isometric contractions (MVC) was assessed before (PRE), immediately (POST), 24 and 48 h after exercise; and normalised to PRE (100%). Venous blood and vastus lateralis muscle samples were collected at each time point. Plasma phenolic acids were quantified via HRAM mass spectrometry. Intramuscular mRNA expression of SOD1 and 3, GPX1, 3, 4 and 7, Catalase, and Nrf2 were quantified and expressed as fold change from PLA baseline. Relative intramuscular protein expression of SOD1, Catalase and GPX3 were quantified via immunoblotting. All data are presented as mean±SD.
RESULTS: MCC supplementation enhanced recovery of normalized MVC compared to placebo (POST PLA 59.5±18.0% vs MCC 76.5±13.9%; 24h PLA 69.8±15.9% vs MCC 80.5±15.3%, supplement effect p=0.024). After 7d supplementation plasma hydroxybenzoic (PLA 10.27±0.85 vs MCC 11.76±2.71 mmol/L, supplement effect p=0.028), hippuric (PLA 2.14±1.13 vs MCC 6.45±3.93 mmol/L, supplement effect p=0.002) and vanillic acid (PLA 16.55±8.08 vs MCC 40.47±36.83 mmol/L, supplement effect p=0.003) concentrations were higher in MCC vs PLA group. MCC elevated muscle antioxidant gene expression: SOD3 (POST: PLA 1.84±1.94 vs MCC 4.60±3.91; 24 h: PLA 5.51±8.33 vs MCC 4.28±4.87; supplement effect p=0.038), GPX1 (POST: PLA 4.09±6.95 vs MCC 4.90±6.69; 24 h: PLA 2.36±3.58 vs MCC 3.91±7.59; interaction effect p=0.017), GPX3 (POST: PLA 2.02±2.84 vs MCC 3.52±5.81; 24 h: PLA 2.91±3.71 vs MCC 7.39±8.72; supplement effect p<0.001), GPX4 (POST: PLA 11.12±30.71 vs MCC 34.01±95.85; 24 h: PLA 6.35±16.61 vs MCC 25.52±72.12; supplement effect p=0.011), and GPX7 (POST: PLA 0.63±0.54 vs MCC 2.42±3.70; 24 h: PLA 0.68±1.22 vs MCC 1.67±2.16; supplement effect p=0.001). In addition, muscle GPX3 protein expression (POST: PLA 0.64±0.82 AU vs MCC 2.60±2.32 AU; 24 h: PLA 0.72±0.50 AU vs MCC 1.88±1.55 AU; supplement effect p=0.004), but not SOD1 or catalase, was higher after MCC vs PLA.
CONCLUSION: This study showed for the first time that MCC supplementation significantly increased expression of antioxidant genes and proteins in human skeletal muscle, in parallel with a significant increase in plasma [phenolic acids]. This study also confirmed previous findings that MCC supplementation improved functional muscle recovery from muscle damage.

### EFFECT OF CANNABIDIOL (CBD) SUPPLEMENTATION ON RECOVERY AN PERFORMANCE AFTER INTENSIVE RESISTANCE TRAINING

DIEL, P.

*DEUTSCHE SPORTHOCHSCHULE KÖLN*

INTRODUCTION: The consumption of cannabidiol (CBD) to support recovery and enhance performance has become popular among athletes. Potential anti-inflammatory and anti-oxidative properties of CBD are supposed to result in pro-regenerative effects after strength training. Therefore, we have conducted three intervention studies to investigate the effects of CBD treatment on performance and muscle recovery after resistance training.
METHODS: Three independent randomized, double-blind, placebo-controlled trials were conducted in cross-over designs. The effects of a single CBD (60mg in aquarious solution) application after intensive strength training was investigated in study 1 in advanced (n=16) and in study 2 in highly advanced resistance-trained athletes (n=8). Effects on lower body performance and muscle damage proxies (MDP) were quantified. In study 3. advanced (n=8) and highly advanced (n=10) resistance-trained athletes were treated daily with two different CBD products (60mg CBD in aquarious solution or oil/day) during a 7-day lasting intensive training week. In addition to lower body performance and MDP, bench press performance here anti-inflammatory, and anti-oxidative effects were investigated.
RESULTS: In highly advanced athletes a single CBD application reduced creatine kinase concentrations (CK) 24h after the training bout (CBD:). This was not confirmed for less advanced athletes. A small but significant effect of CBD was observed on CK (p<0.05) and myoglobin (MYO)(p<0.05) concentrations after 72h.These results are in line with previous interventions, which detected a small effect on muscle soreness via visual analog scale 24h and 72h post-exercise in well-trained athletes. Only advanced athletes showed small effect of CBD on squat performance after 72h (p<0.05). In study3 a significant increase in CK and MYO-concentration was observed in all athletes after the intense training week. In advance athletes, a significant reduction of Myo (p<0.05) and CK (p =0.07) serum concentrations could be detected in the CBD oil group. After the training week a significant decrease in countermovement jump (CMJ) in advanced (p<0.05) as well in highly advanced athletes in squat performance (p<0.05) were detected. No significant effect of CBD on these performance parameters was identified, however trends can be assumed.
CONCLUSION: The results indicate faint but significant effects of a single CBD application after strength training on MDP. Interestingly the effects correlate to the performance levels of the athletes. Similar trends could be observed after repeated treatment. Clinical parameters for liver toxicity were not affected by 7-day treatment with 60mg CBD /day. Interestingly some of these parameters respond to the intensive training which could be antagonized by CBD. In all three studies the effect of CBD administration on strength performance is inconsistent. Potential effects are faint and it may be speculated that we can distinguish between responders and non-responds. This needs to be investigated in future studies. In our training setting we also do not found evidence for anti-inflammatory or antioxidant effects of CBD.

### A COMPARISON OF ADVERTISED VERSUS ACTUAL CANNABIDIOL (CBD) CONTENT OF OILS, AQUEOUS TINCTURES, E-LIQUIDS AND DRINKS PURCHASED IN THE UK.

JOHNSON, D.A., HOGAN, M., MARRIOT, R., HEANEY, L.M., BAILEY, S.J., CLIFFORD, T., JAMES, L.J.

*LOUGHBOROUGH UNIVERSITY*

INTRODUCTION: Cannabidiol (CBD) is a phytocannabinoid uniquely available to consumers in many nations in over-the-counter products. CBD-containing products are used by both recreational exercisers and professional athletes for several purported benefits (e.g. enhance exercise-recovery, pain relief, improve sleep and reduce anxiety). Whilst analyses of CBD-containing products have identified discrepancies between advertised and actual CBD content, there is limited information regarding whether different types of CBD-containing products

vary in this regard. Such differences would have important implications for informing consumer choices. Therefore, this study assessed CBD concentrations in a range of product types.
METHODS: 63 products were purchased online within the UK from 40 brands (13 aqueous tinctures, 29 oils, 10 e-liquids and 11 drinks) and analysed for CBD concentration in a blinded fashion. Cannabinoids were extracted using isopropyl alcohol and methanol and CBD concentrations were quantified in aqueous tinctures, oils and e-liquids by high performance liquid chromatography and in drinks by gas chromatography-mass spectrometry. Percentage deviations from advertised concentrations were rank-transformed and product types compared using one-way ANOVA for unequal variance, followed by post-hoc Holm-Bonferroni corrected t-tests. Relationships between variables were examined using Spearman's ranks or Pearson's correlations.
RESULTS: Only 5/29 oils had measured concentrations within 10% of advertised (8% of all products). All other products fell >10% below advertised, except one oil that was 50% greater than advertised. Median (±interquartile range) deviation from advertised concentrations was -51.4±41.4% for aqueous tinctures, -19.0±14.5% for oils, -29.2±10.2% for e-liquids, and -65.6±36.5%, for drinks, and was less for oils vs all other product types (P<.01), less for e-liquids vs aqueous tinctures (P=.04) and drinks (P<.01), but not different between aqueous tinctures and drinks (P=.19). There was no linear relationship between product price (normalised to advertised CBD concentration) and relative discrepancy between measured and advertised CBD concentration for any product type (R<.26, P>.05).
CONCLUSION: Oils deviated least from advertised concentrations, but overall results reinforce concerns over product quality, whereby most athletes and exercisers using CBD are likely obtaining less than their target dose. As CBD doses in over-the-counter products are already lower (e.g. ~50 mg) than proven clinical doses (≥300 mg), the discrepancies highlighted in this study may contribute to the lack of perceived benefit experienced by a third of athletes using CBD, and may indicate a need for improved regulation of CBD products. Potential issues associated with consumer CBD products should be conveyed to athletes and exercisers. Deviations were independent of product price but may indicate poor manufacturing standards, or that CBD is susceptible to degradation in consumer products.

### OP-PN21 Ageing II

#### ELASTIC BAND RESISTANCE EXERCISE INCREASES MYOFIBRILLAR PROTEIN SYNTHESIS IN YOUNGER BUT NOT OLDER ADULTS, LARGELY INDEPENDENT OF ACUTE INTRACELLULAR SIGNALING

MARSHALL, R., MORGAN, P.T., SMEUNINX, B., QUINLAN, J., BROOK, M.S., ATHERTON, P.J., SMITH, K., WILKINSON, D.J., BREEN, L.

*UNIVERSITY OF BIRMINGHAM*

INTRODUCTION: Resistance exercise training (RET) attenuates age-related declines in muscle mass and strength (sarcopenia). Compared with typical machine-based RET, however, the efficacy of cost-effective, accessible elastic band RET (EB-RET) for muscle adaptive remodelling lacks supporting mechanistic evidence. EB-RET may, therefore, offer a promising and accessible RET strategy in the absence of traditional facilities.
METHODS: In a parallel study design, 8 young (YM; 24 ± 4 yrs) and 8 older (OM; 68 ± 6 yrs) males consumed an oral stable isotope tracer (D2O) combined with serial vastus lateralis muscle biopsies to measure integrated myofibrillar protein synthesis (iMyoPS) and regulatory signalling over ~48hrs prior to (habitual) and following an acute bout of EB-RET (6 x 12 repetitions at ~70% of one-repetition maximum). Daily saliva samples were obtained to monitor body water isotope enrichment via TC/EA-IRMS. Deuterated alanine incorporation into myofibrillar protein was determined via gas chromatography-pyrolysis-isotope ratio mass spectroscopy. Subsequently, the iMyoPS rates were calculated as the percentage per day [2H]-alanine via the precursor-product equation. Intracellular protein expression and phosphorylation status were determined by immunoblot. A two-way repeated-measures ANOVA was performed to detect group, time, and interaction effects. A statistical significance of $p< 0.05$ was recognised. Data are presented as mean ± SEM unless otherwise stated, with individual data points presented.
RESULTS: Habitual iMyoPS did not differ between YM and OM (1.62 ± 0.21 vs 1.43 ± 0.47%·day-1, respectively; P=0.128). There was a significant increase in iMyoPS after EB-RET in YM (2.23 ± 0.69%day-1; P=0.02), but not OM (1.75 ± 0.54%day-1; P=0.30). The Δ change in iMyoPS (%day-1) was greater in YM (0.61 ± 0.62%/day-1) vs. OM (0.32 ± 0.58%/day-1) (effect size = 0.5) but was not significantly different between groups. EB-RET increased the phosphorylation of key anabolic signalling proteins similarly in YM and OM at 1h post-exercise, including p-IRS-1Ser636/639 (YM: ~106%, OM: ~79%), p-AktSer473 (YM: ~181%, OM: ~124%), p-4EBP-1Thr37/46 (YM: ~48%, OM: ~59%), p-P70S6KThr389 (YM: ~550%, OM: ~424%) and p-RPS6Ser240/244 (YM: ~1030%, OM: ~1005%) (all P<0.05). There were no differences between YM and OM in protein expression of amino acid transporters/sensors (LAT-1, SNAT-2 & Sestrin-2) or proteolytic markers (MuRF1, Atrogin-1, Caspase-3, all P>0.05) following EB-RET.
CONCLUSION: EB-RET increased rates of iMyoPS in YM but not OM. Alterations in mTORC1 signal phosphorylation after EB-RET revealed only marginally impaired responses in OM compared with YM. Therefore, the capacity for EB-RET to support muscle mass accrual may be impaired in older age, and the manipulation of exercise variables (e.g., load, volume, time-under-tension) may be necessary to optimise muscle adaptive remodelling to EB-RET in OM.

#### GREATER MUSCLE VOLUME AND LOAD-INDUCED MYOFIBRILLAR PROTEIN SYNTHESIS, BUT POORER MUSCLE QUALITY IN OBESE VS. LEAN OLDER ADULTS

MORGAN, P.1,2, SMEUNINX, B.1,3, MARSHALL, R.1, QUINLAN, J.1, SHEPHERD, S.4, MCPHEE, J.3, NIELSEN, N.5, BREEN, L.1

*1. UNIVERSITY OF BIRMINGHAM, UK, 2. MANCHESTER METROPOLITAN UNIVERSITY, UK, 3. MONASH UNIVERSITY, AU, 4. LIVERPOOL JOHN MOORES UNIVERSITY, UK, 5. UNIVERSITY OF SOUTHERN DENMARK, DK.*

INTRODUCTION: The presence of obesity in older age may be accompanied by equivalent or even greater levels of muscle mass compared with lean age-matched individuals, despite a paradoxically impaired postprandial muscle anabolic response to amino acid provision. However, the metabolic basis through which obesity appears to protect absolute levels of muscle mass in older age are unclear, but may relate to augmented muscle anabolism during weight-bearing activity. Similarly, beyond absolute muscle mass, muscle quality is an important predictor of numerous health outcomes in older age, including function, and may be adversely affected by the presence of obesity.

METHODS: We determined the muscle anabolic response to weight-bearing activity and indices of muscle morphology, quality and function in 15 older-obese (OO; Body fat: 35.0 ± 2.9%), 10 older-lean (OL; 20.0 ± 2.8%) and 10 young-lean (YL; 13.0 ± 5.2%) adults. Rates of habitual and weight bearing-induced integrated myofibrillar protein synthesis (iMyoPS) were assessed 48h prior to and following a 45-min bout of brisk treadmill walking (~55% V̇O2max), using an oral stable isotope tracer (D2O) and serial muscle biopsy, plasma and saliva samples. iMyoPS rates were determined via gas chromatography-pyrolysis-isotope ratio mass spectroscopy. Acute intramuscular anabolic signaling was also determined post-exercise. Indices of muscle mass, quality, function, morphology and the abundance, species and sub-cellular location of intramyocellular lipids (IMCL) were determined via 3T MRI, electromyography, dynamometry, ELISA, immunofluorescence and transmission electron microscopy. Diet and physical activity were monitored/controlled throughout.
RESULTS: Relative to habitual activity, step count was higher on the day of the 45-min treadmill task in OO and OL but not YL. No differences in habitual iMyoPS were observed between groups. However, the 48h change in weight bearing-induced iMyoPS rates was greater in OO compared with YL and OL. Quadriceps muscle volume was lower in OL but not OO compared with YL. Markers of IMCL were higher/worsened, and muscle function lower, in OO compared with YL and OL, indicative of impaired muscle quality.
CONCLUSION: In summary, iMyoPS rates were elevated above 48h habitual values following intensity-matched weight-bearing activity in OO compared with YL and OL, which may explain the observed greater muscle mass in obese vs. lean age-matched individuals, likely driven by physical activity levels. Despite this, indices of muscle quality were markedly lower in OO. Indeed, whilst muscle quality was reduced in OL, this reduction was exacerbated by the presence of obesity, which might be modulated by alterations in contractile protein content and the abundance, species and/or sub-cellular location of lipids. However, the effects of obesity on muscle protein turnover across the lifespan remains to be fully elucidated, particularly in the 'oldest old' and in severely/morbidly obese individuals.

**SKELETAL MUSCLE MASS MAINTENANCE DURING A TRANSATLANTIC OCEAN ROWING RACE.**

HOLSGROVE-WEST, R.1, REVUELTA INIESTA, R.1, ABDELRAHMAN, D.2, MURTON, A.2, WALL, B.1, STEPHENS, F.1

*1 DEPARTMENT OF SPORT AND HEALTH SCIENCES, COLLEGE OF LIFE AND ENVIRONMENTAL SCIENCES, UNIVERSITY OF EXETER, UK. 2 DEPARTMENT OF SURGERY, UNIVERSITY OF TEXAS MEDICAL BRANCH, GALVESTON, TX, USA*

INTRODUCTION: Ultra-endurance transatlantic rowing represents a unique scenario of controlled and sustained elevated total energy expenditure (TEE) and intake (EI) for ~7 weeks in males and females of varying ages. Due to the nature of rowing, some muscle groups are in constant use whereas others are relatively inactive. The aim of the present study was to characterise changes in muscle thickness and architecture across a transatlantic rowing race, and to provide insight as to whether any sex or age differences exist.
METHODS: Fifty-six competitors (m=35, f=21; age 39±11 y, range 24-67 y; time at sea 46.3±6.7 d) in the 2020 and 2021 Talisker Whisky Atlantic Challenge rowed 12-18 h per day for 3000 miles. Thickness (Tm) of relatively active (vastus lateralis, vastus intermedius, biceps brachaii and rectus abdominus) and inactive (gastrocnemius, soleus, triceps) muscles were measured pre (<7 d) and post (<24 h) row using ultrasound, with fascicle length (Lf) and pennation angle (PA) also measure in gastrocnemius. Body mass was measured at the same time. TEE was assessed in the final week of the row using the 2H218O doubly labelled water technique; EI and dietary macronutrient composition was analysed from recall of all daily ration packs over this period.Two-way ANOVAs were used to determine sex differences in all parameters. Data are presented as mean±SD.
RESULTS: There was no change in Tm of vastus lateralis (-3.8±21%, P=0.07), vastus intermedius (-3.7±19%, P=0.20), biceps brachaii (-1.6±11%, P=0.20), or rectus abdominus (1.9±23%, P=0.98), whereas there was a decrease in Tm of gastrocnemius (-14.3±13%, P<0.001), soleus (-8±10%, P<0.001), and triceps (-11±11% P<0.001) in both males and females post row. Rate of atrophy in gastrocnemius was lower in older than younger men (0.16±0.2 v 0.45±0.2 %.day-1, respectively; P<0.05), but greater in older than younger females (0.68±0.4 v 0.27±0.2 %.day-1, respectively; P<0.05).There was no difference between males and females in increase in gastrocnemius Lf (3.0±11.6% v 3.8±18.0%, respectively; P=0.42) and decrease in PA (-17.4±17.7% v -13.4±24.2%, respectively; P=0.5). Males and females had a similar reduction in body mass (10.6±3.6%; P<0.0001) throughout the row. TEE/RMR was similar for males and females (2.5±0.5 v 2.8±0.5, P=0.1) as was EI/RMR (2.3±0.4 v 2.4±0.3, P=0.7). Males and females had similar CHO (43±5%, 5.7 g.kg-1, P=0.80) and fat (42±3%, 2.4 g.kg-1, P=0.35) intake, but protein intake was higher in males than females (16±2%, 2.0±0.4 vs.12±2%, 1.5±0.5 g.kg-1, respectively; P<0.01).
CONCLUSION: During prolonged rowing, despite being in a sustained negative energy balance and resultant considerable body mass loss, active muscles maintained mass. Despite dietary protein intake remaining high, inactive muscles still atrophied considerably, an effect that appeared to be diminished in older males but enhanced in older females. Physical activity appears to be a major determinant of muscle mass maintenance under conditions of extreme endurance.

**MECHANICAL EFFICIENCY AND FEMALE AGEING**

ROLDAN, A.1, MONFERRER-MARÍN, J.1, MONTEAGUDO, P.1,2, BLASCO-LAFARGA, C.1

*1 UNIVERSITY OF VALENCIA; 2 UNIVERSITY JAUME I*

INTRODUCTION: Ageing supposes an impaired maximum fat oxidation point (MFO), accompanied of a shifting down and leftward of oxidation rates curves (1). This behavior seems related to reduced muscle power at higher intensities (2), what may be associated with dropped levels of exercise efficiency with the increase of intensity in older adults. This is a limiting factor for daily living activities (3). Due to paucity of literature on efficiency with ageing, this study analyses differences on efficiency and economy up to the second ventilatory threshold comparing two age-groups of over-60 female.
METHODS: Twenty-four women performed a submaximal graded cycling test (10W every 3-min 15-s) with gas analysis by indirect calorimetry (ethics committee H105715353921). Two groups were set, considering a younger group (<65yr; 63.25±1.54y, n= 12) and an older one (>65yr; 71±4.88y, n=12). MFO was calculated, together with delta and gross efficiencies (DE% & GE%), and exercise economy (EC). Since GE% is the ratio between the external work developed and its cost, mechanical power output and metabolic power input (both in kcal·min) were determined using the mean of VO2 and RER values in the last 60s of each stage. Meanwhile, DE% was determined by the slope between metabolic power input and mechanical power output. Finally, EC (expressed in Kj·L-1) was calculated as the ratio between mean power output in the last 60s and mean steady-state oxygen uptake of each stage in the test.
RESULTS: We found differences on economy, both at the MFO intensity (<65yr; 62.64 ± 18.93 Kj·L-1 and >65yr; 43.26 ± 11.35 Kj·L-1; ECMFO p=0.01) and peak (<65yr 103.55 ± 55.13 Kj·L-1 and >65yr 59.73 ± 20.27 Kj·L-1; ECPeak p=0.02). Conversely, there were no differences on gross efficiency (p=0.17), nor regarding the delta efficiency (p=0.93).
CONCLUSION: EC confirmed age differences, pointing to higher efficiency in the younger old females. However, we failed to found age differences in any parameter of metabolic efficiency. Recently Blasco-Lafarga et al. (2) found an inverse correlation between GE% and the point of maximal carbohydrates oxidation in >60y women, so being more efficient by reducing carbohydrate oxidation would allow older

women to cope with increasing intensity whatever the age-group. Notwithstanding, efficiency maybe be related to the influence of many other factors like the cardiorespiratory, neuromuscular or biomechanical efficiencies (4). Noteworthy, future studies should look more closely to some parameters such as cadence, given that lower cadences would have greater economy compared to higher cadences (5), and we did not control for it. Larger samples are also needed.

### OP-AP19 Cycling I

#### A LONGITUDINAL STUDY ON THE INTERCHANGEABLE USE OF WHOLE-BODY AND LOCAL EXERCISE THRESHOLDS IN CYCLING

CAEN, K., BOURGOIS, J.G., STASSIJNS, E., BOONE, J.

*GHENT UNIVERSITY*

INTRODUCTION: This study longitudinally examined the interchangeable use of critical power (CP), the maximal lactate steady state (MLSS) and the respiratory compensation point (RCP) (i.e., whole-body thresholds), and breakpoints in muscle deoxygenation (m[HHb]BP) and muscle activity (iEMGBP) (i.e., local thresholds).
METHODS: Twenty-one participants were tested on two timepoints (T1 and T2) with a 4-week period (study 1: 10 women, age=27±3yr, V̇O2peak=43.2±7.3mL·min-1.kg-1) or a 12-week period (study 2: 11 men, age=25±4yr, V̇O2peak=47.7±5.9mL·min-1.kg-1) in between. The test battery included one ramp incremental test (to determine RCP, m[HHb]BP and iEMGBP) and a series of (sub)maximal constant load tests (to determine CP and MLSS). All thresholds were expressed as oxygen uptake (V̇O2) and equivalent power output (PO) for comparison.
RESULTS: None of the thresholds were significantly different in study 1 (V̇O2:P=0.143, PO:P=0.281), but differences between whole-body and local thresholds were observed in study 2 (V̇O2:P<0.001, PO:P=0.024). Whole-body thresholds showed better 4-week test-retest reliability (TEM=88-125mL·min-1 or 6-10W, ICC=0.94-0.98) than local thresholds (TEM=189-195mL·min-1 or 15-18W, ICC=0.58-0.89). All five thresholds were strongly associated at T1 and T2 (r=0.75-0.99), but their changes from T1 to T2 were mostly uncorrelated (r =-0.41-0.83).
CONCLUSION: Whole-body thresholds (CP/MLSS/RCP) showed a close and consistent coherence taking into account a 3-6%-bandwidth of typical variation. In contrast, local thresholds (m[HHb]BP/iEMGBP) were characterized by higher variability and did not consistently coincide with the whole-body thresholds. Also, we found that most thresholds evolved independently of each other over time. Together, these results do not justify the interchangeable use of whole-body and local exercise thresholds in practice.

#### EFFECT OF PEDALLING CADENCE DURING ECCENTRIC CYCLING ON MUSCULAR ACTIVATION AND PERCEIVED EXERTION

MATER, A., BOLY, A., ASSADI, H., CLOS, P., MARTIN, A., LEPERS, R.

*UNIVERSITÉ DE BOURGOGNE*

INTRODUCTION: For a given power output, changing the cycling pedalling rate alters factors such as perceived exertion, oxygen consumption or muscular activation (1). While this observation holds for traditional (i.e., concentric) cycling, no data are available for eccentric cycling (ECC), despite the fact that this exercise modality has been extensively studied in the last decade, especially in the rehabilitation field (2). Notably, the effects of ECC cycling cadence on muscular activity and perception of effort remain unknown.
METHODS: In the current investigation, twelve participants completed four sessions one week apart: 1) determination of maximal concentric aerobic power (MAP); 2) familiarization with ECC cycling at five cadences (30, 45, 60, 75, and 90 rpm); 3) and 4), ECC cycling exercise consisting of 5 min at the five different cadences at either 40 or 60% MAP. Perceived exertion (PE) was reported and the mean electromyography (EMG) root mean square was calculated over the last 30 s of exercise for the vastus lateralis and rectus femoris muscles. The optimal cadence for each parameter, minimising either PE (PECAD-OPT) or EMG (EMGCAD-OPT) was estimated using second-order polynomial regressions.
RESULTS: At both power outputs, PE and EMG showed an effect of cadence ($P < 0.001$) and followed a U-shaped curve ($R^2 > 0.77$ and 0.83, respectively). Estimated PECAD-OPT (63 ± 13 rpm for 40% MAP and 62 ± 8 rpm for 60% MAP) and EMGCAD-OPT (61 ± 8 rpm for 40% MAP and 65 ± 9 rpm for 60% MAP) did not significantly change with power output ($P > 0,69$). For both power outputs, PECAD-OPT and EMGCAD-OPT were not significantly different ($P > 0.35$).
CONCLUSION: To our knowledge, this study is the first to describe the effects of cadence on both EMG and PE, for ECC cycling at different power outputs. Both PE and EMG were affected by cadence and showed maximal values for extreme cadences, while the lowest values appeared at intermediate cadences. As lower ECC cadences require greater force production on the pedals, these likely involve the recruitment of additional motor units (3), as evidenced by an increased EMG. In addition, a greater motor command would be related to higher PE (4). Conversely, high ECC cadences may require a suboptimal muscle coordination pattern that would increase EMG (and thus PE) compared with intermediate cadences (5). Additional research is required to examine the short- and long-term effects of using low versus high ECC cadences following fatiguing exercises and training programs.

**INTER- AND INTRA-INDIVIDUAL RELIABILITY OF A 30-MINUTE RPE CLAMP CYCLING EXERCISE**

OMALLEY, C.A., FULLERTON, C.L., MAUGER, A.R.

*UNIVERSITY OF KENT*

INTRODUCTION: Exercise protocols at a fixed rating of perceived effort (RPE) are useful for exploring the psychophysiological influences on exercise performance. However, studies that have employed these "RPE clamps" have arbitrarily selected RPE values without considering physiological state and intensity domains at a given RPE. Therefore, incorporating a validated and justified approach which aligns RPE intensities with established physiological boundaries seems beneficial. Yet, no research has assessed if such a protocol is reliable at both the inter- and intra-individual level.
METHODS: Eight recreationally trained, active cyclists completed eight laboratory visits. Within the first two visits, participants underwent identical cycling ramped incremental tests to identify gas exchange threshold (GET). A linear regression model plotted RPE responses during this ramped test alongside gas parameters to establish individual RPE responses corresponding to GET (RPEGET) and 15% above GET (RPE+15%GET). The next six experimental visits involved participants completing three randomised trials at each intensity. Performance (power output), physiological (gas parameters, heart rate, blood lactate), and psychological (affect, self-efficacy) measures were obtained throughout and averaged across five- and thirty-minute intervals. Data from these RPE-clamped trials were assessed for reliability using intraclass correlation coefficients (ICC), coefficients of variation (CoV) and 95% confidence intervals (95% CI). Repeated measures ANOVAs and paired samples t tests assessed differences over time and between conditions.
RESULTS: Power output and all gas parameters showed excellent levels of test-retest reliability (ICC = >.900) across both intensities. Power output, gas parameters and heart rate demonstrated good intra-individual reliability (mean CoV = <5 %) in both conditions. Narrower 95% CI were observed in the RPE+15%GET condition (range = 1.1 – 5.2 %) compared to the RPEGET condition (range = 2.0 – 8.4 %). Plots of time-lapsed physiological data during the 30-minute RPE clamp exercise showed that blood lactate, V̇O2 and V̇O2.kg-1 were closely aligned with power output changes in both conditions. Psychometric data showed significant differences (P = <.05) at all time intervals between conditions.
CONCLUSION: Recreationally trained, active cyclists can reliably replicate RPE clamp exercise when RPE is aligned to physiological thresholds. Evidence suggests that exercise at higher RPE values (RPE+15%GET) may be more reliable than lower RPE values (RPEGET). Moreover, it appears that sensations emanating from the muscle (e.g., blood lactate) and oxygen demand (V̇O2) are the main regulators of exercise performance at a fixed RPE. However, to further substantiate this finding, future research could probe the underlying decision-making processes that determine exercise intensity during fixed RPE exercise to corroborate psychophysiological data.

**PERFORMANCE CHARACTERISTICS OF TOP5 VERSUS NOT-TOP5 RACES IN FEMALE PROFESSIONAL CYCLING**

LAMBERTS, R.P., VAN ERP, T.

*STELLENBOSCH UNIVERSITY*

INTRODUCTION: Maximal mean power output (MMP) is commonly used to describe the demands and performances of races within professional male cycling. Within the female professional cyclist domain, however, there is limited knowledge regarding MMPs in races.1-4 Therefore, this study aims to describe MMPs within female professional cycling races whilst investigating differences between TOP5 and NOT-TOP5 races.
METHODS: Race data (n=1324) were collected from 14 professional female cyclists between 2013-2019. Races were categorized as TOP5 or NOT-TOP5. MMPs were consequently determined over a range of different timeframes (5sec to 60min). To provide these MMPs with additional context, two factors were determined: when these MMPs were attained in a race (based on duration and kJ spent [kJspent·kg-1]) and these MMPs relative to the cyclist's season's best MMP (MMP%best). All performance indicators from TOP5 races are compared to NOT-TOP5 through a multilevel random intercept model using Tukey's method for pairwise comparisons in R (Statistical computing, Vienna, Austria). Random effect variability was modelled using a random intercept for each individual participant. The level of significance was set at P <0.05.
RESULTS: Short-duration power outputs (≤1min) were higher in TOP5 races compared to NOT-TOP5 races. In addition, the timing (both duration and kJspent·kg-1) of all MMPs was later and after more workload in the race in TOP5 compared to NOT-TOP5 races. In contrast, no difference in MMP%best was noted between TOP5 and NOT-TOP5 races.
CONCLUSION: TOP5 races in female cycling are presented with higher short duration MMPs (≤1min) when compared to NOT-TOP5 races and cyclists were able to reach a higher % of their seasonal best MMP when they were able to finish TOP5. In addition, these MMPs are performed later and after more kJspent·kg-1 in TOP5 vs NOT-TOP5 races, which confirms the importance of "fatigue resistance" in professional (female) cycling.

### OP-AP11 Sprinting Performance

**EFFECTS OF VELOCITY BASED RESISTED SPRINT TRAINING ON PERFORMANCE IN SOCCER PLAYERS.– A PILOT STUDY.**

LIZANA, J.A.1,2, GARRIDO, A.1, ARTACHO, G.1, GARCÍA, F.1, PAREJA-BLANCO, F.

*PABLO DE OLAVIDE*

INTRODUCTION: The effects of resisted sprint training (RST) on performance are currently a question of discussion in scientific literature. Traditionally, not reducing the athlete's velocity by more than 10% from unresisted sprinting have been recommended. [9] However, some authors have recommended the use of sled loads heavier than 20% BM for enhancing the initial acceleration phase, where velocity is low

and resistive forces are high, and lighter loads (ie, <10% BM) for improving the maximal velocity phase, where velocity is higher and resistive forces are lower. [10] The aim of this study was to compare the training effects of resisted sprint with 3 different external loads that reduced sprint mean velocity by 10, 25 and 40% on 20-m sprint, change of direction and jump performance in Soccer players.
METHODS: Eighteen amateur soccer players performed 2 unresisted and resisted 20-m sprint with 10, 30, 50 and 70% body mass recording sprint time (Photocell timing gates Witty; Microgate). Percentage mean velocity loss (%VL) compared to unloaded condition were used to allocate players into 3 groups: Low load resisted sprint training group (G10%VL, n = 6), medium load resisted sprint training group (G25%VL, n= 5) and high load resisted sprint training group (G40%VL, n = 3). Pretraining and posttraining assessments included 20-m sprint time, countermovement jump and change of direction time. All groups were trained twice a week for 6 wk and completed the same training program, but with different loads (10% vs 25 vs 40% VL). Data were analyzed using a 3 (group) × 2 (time) factorial analysis of variance with Bonferroni post hoc comparisons. Statistical significance was established at the P < .05 level.
RESULTS: No significant "time × group" interactions were observed. For sprint performance, only G10%VL showed significant (P = .017) decreases. Regarding CMJ, only G10%VL and G25%VL showed significant (P = .011 and .018 respectively) improvements. Any group showed significant improvements in COD time.
CONCLUSION: In soccer players, no significant differences in sprint, countermovement jump and change of direction performances were detected after 6 weeks of different resisted sprint training programs. Future studies should, therefore, be devoted to how sprint training should be individualized to maximize performance.

**RELIABILITY OF AN ISOTONIC SPRINT DEVICE IN RECREATIONALLY TRAINED PARTICIPANTS**

OSTERWALD, K., KELLY, D., Ó CATHAIN, C.
*TECHNICAL UNIVERSITY OF THE SHANNON*

INTRODUCTION: An increasing number of coaches have employed isotonic sprint devices to provide an external resistance while sprinting. The device has been demonstrated to help improve sprint performance [1], however from a scientific perspective it is currently unclear if such a device provides external load in a reliable manner. This is important as the magnitude of load dictates adaptation, therefore it is crucial to understand if this load prescription is reliable within and between sessions, in order to be used with confidence [2]. The main purpose of this study was to determine the reliability of an isotonic sprint device in recreationally trained individuals. More specifically, the question was: does it result in changes of split times at the same load over multiple runs, and between sessions?
METHODS: Thirteen recreationally active participants (age, 21 ± 1.61 years; height (cm), 180.08 ± 2.88cm; weight (kg), 84.27 ± 10.87 kg) were recruited and required to complete 2 testing days, 5-7 days apart. Three maximal 20m sprints, with an isotonic resistance device (Exer-Genie, Thousand Oaks, CA, USA), at three resistance levels (2oz, 5oz & 8oz) on a sprint track were undertaken, in a randomized order on two separate testing days (18 sprints in total). The device was attached to the participant by a waist harness which connected on to the rope (36m) via a safety clip. The device itself was attached to the railing of the sprint track via an anchor strap (91.44cm) and safety clip. Sprint time was assessed using photocells, which were set up at 5-meter intervals. Intrasession (comparison of the 3 sprints of the second session) and intersession (comparison of the average of the 3 sprints across days) reliability of sprint time for 5m, 10m, 15m & 20m at all resistance levels, were assessed by intrasession correlation coefficient (ICC) and coefficients of variation (%CV) and associated 90% confidence intervals (CI). The scale of magnitude for effect statistics used were rated as trivial (<0.1), small (0.1-0.29), moderate (0.3-0.49), large (0.5-0.69), very large (0.7-0.89) or nearly perfect (0.9-0.99) [3].
RESULTS: The device showed moderate intersession reliability for 2oz & 5oz and large reliability for 8oz across all distances (ICC 0.18 – 0.77), (%CV 5.6 – 12.9). Intrasession reliability was moderate to nearly perfect across the distances for the resistance level of 2oz (ICC 0.35 - 0.91), (%CV 3.1 - 14.6%). At 5oz reliability ranged from large to nearly perfect across the distances, (ICC 0.58 - 0.95), (%CV 2.9 - 10.7%). At 8oz reliability ranged from very large to nearly perfect across the distances, (ICC 0.80 - 0.97), (%CV 3.9 - 8.4%).
CONCLUSION: To conclude, isotonic resistance appears to be a reliable method to provide a desired training stimulus to athletes engaging in sprinting activities and therefore could be considered as part of a training programme for those wishing to enhance their performance.

**RAMP ORDER FROM SKIP TO SPRINT**

FAHEY, J., RIPLEY, N.
*UNIVERSITY OF SALFORD*

INTRODUCTION: Isolation drills are often utilised to decompose and aid the learning and refine key aspects of sprinting technique1. Popular drills include A-skips; calf dribble (CD), straight leg skip (SLS); bounding (BD) and submaximal percentage effort sprints2. However, there is limited knowledge on how these drills in isolation transfer to overall sprinting performance and how the intensity of each drill varies. The aim of this study was to determine if any relationships exist between submaximal running drills and maximal sprinting (MS) and to develop a continuum of submaximal running drills based on average velocity.
METHODS: Twenty-five physically active individuals (17 male, 8 female, 22.6±5.4 years, 175.2±7.7 cm, 75.2±11.6 kg) performed three repetitions of 20m, with a split at 15-20m MS and submaximal running drills: A-skips, CD, SLS, BD; 80% sprint; and 90% sprint over three consecutive weeks using electronic timing gates (Draper, Utah, USA), with the first week used for familiarisation purposes. Average velocity of the 15-20m split is presented as mean±SD. Pearson's r and R2 were used to observe if any relationships existed between MS and running drills, a series of RMANOVA with Bonferroni post-hoc analysis were performed to compare between drills. Significance was set at $p<0.05$.
RESULTS: A-skip (3.21±0.86 s) and CD (4.24±0.94 s) were moderately correlated with MS ($r=0.303$ $p=0.048$ & $r=0.465$ $p=0.002$). A large correlation was observed between SLS (4.43±0.93 s) and MS ($r=0.553$ $p<0.001$). A very large correlations was observed between MS (7.20±0.91 s) and BD (5.41±0.88 s, $r=0.722$ $p<0.001$). Large and moderate correlations were observed between MS and 80% sprint (5.75±0.88 s, $r=0.594$ $p<0.001$), and 90% sprint (5.73±1.01 s $r=0.487$, $p<0.001$). Non-significant ($p>0.05$) differences were observed between 80- and 90% sprint, between 90% sprint and BD and between SLS and CD. All other pairwise comparisons were significant ($p<0.021$).
CONCLUSION: Despite popularity2, A-skips accounted for 9.2% of the variance in sprinting performance, whereas bounding was able to explain 52.1% of sprinting performance. The remaining drills were able to explain between 21.6-35.3% of sprinting performance. A-skips had the slowest average velocity, closely followed by the SLS, CD and BD. Sprinting at 80- and 90% effort had almost identical velocities, with 80% being greater than 90%, highlighting a lack of speed regulation4. Although the skips and drills closely mimic aspects of sprinting technique, they lack similar muscle activation levels and magnitude and orientation of ground reaction forces in MS3. The results of the present study could be utilised in prescribing training or warm up activities, with a RAMP based or control-chaos progression based on intensity.

**EFFECTS OF RESISTED AND MAXIMUM VELOCITY SPRINT TRAINING ON THE ACCELERATION PERFORMANCE OF TEAM SPORT ATHLETES**

WARD, C., NÍ CHÉILLEACHAIR, N., Ó CATHÁIN, C., KELLY, D.T.

*TECHNOLOGICAL UNIVERSITY OF THE SHANNON, ATHLONE, IRELAND.*

INTRODUCTION: Sprint speed is considered an essential performance attribute for field-based invasion team sport (FITS) athletes, and is associated with the successful completion of key attacking and defensive performance indicators [1]. A large volume of short distance sprints (10-20m) within FITS's [2] highlights the importance of developing acceleration performance. While a number of methods are used to improve this phase, resisted sprint training (RST) applies an external resistance to the sprinting movement and is frequently utilised to develop acceleration specific speed due to its ability to influence key acceleration determinants such as horizontal force production [3]. Alternatively, research indicates a moderate to strong relationship between an athlete's maximum velocity (MV) and their ability to accelerate [4], thus suggesting that players with a higher MV may hold an advantage over players with a lower MV when performing shorter sprints. Therefore, the aim of this study was to investigate and compare the impact of RST and maximum velocity sprint training (MVST) on the acceleration performance of FITS athletes.
METHODS: Elite level, male Gaelic football players were randomly assigned to RST (n=8) or MVST (n=7). Both groups underwent force-velocity profiling, with the RST group utilising sled sprints at 50% velocity decrement and the MVST group performing flying sprints (12-20m) with a preceding 25m submaximal build-up phase. Participants completed 7 training sessions across 4 weeks. Sprint, vertical and horizontal jump performance were measured at baseline and after 4 weeks.
RESULTS: Significant increases in 0-5m, 0-10m, 0-15m and 0-20m were found following RST only. However, results showed significant differences in baseline speed parameters between the RST and MVST groups. When controlling for baseline sprint performance, there were no significant differences between RST and MVST groups post intervention over 0-5m, 0-10m, 0-15m and 0-20m distances or at maximum velocity (Vmax). Finally, vertical and horizontal jump performance did not significantly change after 4 weeks.
CONCLUSION: Marked increases in acceleration performance can be attained by FITS athletes with just 7 RST sessions over a 4-week period. Failure to detect significant change following MVST may be due to the length of the intervention, number of sessions or baseline values of the training group, as those with the lowest initial values of a physiological system have the greatest capacity for improvement in response to training. Further work is required to determine the effectiveness of RST and MVST in FITS athletes under controlled conditions.

### OP-MH07 Injury and Team Sports

**MULTI-SEASON INJURY SURVEILLANCE IN RUGBY UNION: ADDRESSING THE CHALLENGES OF DATA COLLECTION.**

RUBIO DEL CASTILLO, E., FORTINGTON, L., NIMPHIUS, S., TOOHEY, L., MCDONALD, W.

*EDITH COWAN UNIVERSITY, RUGBY AUSTRALIA, AUSTRALIAN INSTITUTE OF SPORT.*

INTRODUCTION: Rugby Union has a relatively high injury rate in line with field-based full-contact sports. The injury rates are well studied in single seasons. The next progression of understanding would come from multi-season studies of injury rates. Multi-season studies must consider the effect of varying data collection practices over time. Changes across seasons can influence the comparability of data. We aimed to examine how modifications to data collection procedures influenced data quality and overall injury outcomes (injury incidence rates and injury severity) from surveillance over a 6-year period in Australian professional rugby.
METHODS: Game sustained time-loss injuries were included in this study. The data were reported by all five Australian franchises in Super Rugby (2016-2021) using a common collection tool. Match exposure hours and injury incidence rate per 1000 player-game-hours are presented, alongside descriptions of key changes to data collection procedures. Main changes in the data collection procedures included the facilitation of support resources to the teams, discussions with the field practitioners on the objectives of the system and refining of the variables to collect. Injury severity was calculated as the number of days the player was unable to participate in the competition or/and training.
RESULTS: There were 368 game sustained injuries in 195 players from 8229 player-game-hours. The match sustained injury incidence was 44.7 injuries per 1000 game hours, with a median severity of 31 (IQR±58) days missed per injury. The differences in injury incidence rates by season were notable with 12.8 injuries per 1000h in 2016, and 52.1 injuries per 1000h in 2018. This is credited to the increased engagement of the teams with the system as a result of the support resources and involvement of the field practitioners with the system, and the refinement of the variables collected.
There was also a notable change in the median severity of injury in 2016 [median 66 (IQR±174) days] and 2018 [median 31 (IQR±48) days]. This is attributed to improved processing of injuries that are deemed to be recovered.
CONCLUSION: Questions should be asked if the differences in severity and incidence across seasons are reasonable or if they are attributable to changes in the data collection processes. Modifications in the data collection procedures influence the outcomes of the system. The growth of engagement and improved processing of the collection system increased the incidence of the game injuries but decreased the

severity. The data in later years show a decrease in variability in incidence and severity. But only major changes across seasons influenced the comparability of the data.
Good output data is needed to correctly inform organisational decisions, and this is dependent on the quality of the input data.

**INFLUENCE OF EXECUTIVE COGNITIVE PERFORMANCE ON INJURY RISK IN PROFESSIONAL FOOTBALL PLAYERS**

ŠLOSAR, L.1, GIESCHE, F.2, PESKAR, M.1,3, PIŠOT, R.1, MARUSIC, U.1,4

*1 SCIENCE AND RESEARCH CENTRE KOPER, SLOVENIA; 2 UNIVERSITY OF FRANKFURT, GERMANY; 3 TECHNISCHE UNIVERSITÄT BERLIN, BERLIN, GERMANY; 4 ALMA MATER EUROPAEA – ECM, MARIBOR, SLOVENIA*

INTRODUCTION: Systematic evidence suggests that team sport athletes with lower baseline cognitive performance are at higher risk of sustaining non-contact injuries (Avedesian et al. 2022). While previous studies have focused primarily on rather lower cognitive functions (e.g., reaction time and visual perception) (Avedesian et al., 2022), the aim of this study was to investigate the potential influence of executive performance measures (e.g., cognitive flexibility, working memory) on the risk of sustaining a non-contact injury in elite football players.
METHODS: Seventy-nine professional male football players (4 teams of first Slovenian league, age: 24.4±4.5 years; BMI: 21.3 Kg/m2) participated in our prospective case-control study. Computerized (PsyToolkit) and pen-and-paper tests (Trail-Making-Test) were used to compare baseline cognitive performance (visual screening, simple and choice reaction time, working memory, cognitive flexibility,) between players who experienced at least one non-contact injury (n=29) and those who remained uninjured (n=35, con-trols) during the one-year follow-up period. Variance analyses were applied to investigate potential differences between groups.
RESULTS: The majority of non-contact injuries affected the lower extremity (79.3%), with thigh (56.7%) and knee (28.2%) being the most common injury sites. Both groups differed significantly in terms of age (25.7 vs. 23.3; $p = 0.04$) but not for BMI ($p = 0.458$). Analysis of covariance (age as covariate) showed a signifi-cantly faster visual screening performance for the non-contact injury group compared to the controls (14.6 vs 17.8 sec, $p=0.019$). No significant between-group differences were found for the other cogni-tive measures assessed ($p > 0.05$).
CONCLUSION: Our findings seem to contradict previous evidence. Better visual screening skills may predispose higher in-game performance increasing the odds of being a regular player. The longer playing exposure times might have made them more vulnerable to injuries than players with less playing time. However, this interpretation is speculative based on our data. To further elucidate how the occurrence of non-contact injuries relates to executive cognitive performance in professional football, the assessment of playing status (e.g., regular or substitute player), position and exposure time is crucial.

**A SYSTEMATIC REVIEW OF INJURY INCITING ACTIVITIES IN MALE AND FEMALE FOOTBALL PLAYERS**

AIELLO, F.1,2, IMPELLIZZERI, F.M.3, BROWN, S.J.2, SERNER, A.4, MCCALL, A.1,2

*1 ARSENAL FOOTBALL CLUB; 2 EDINBURGH NAPIER UNIVERSITY; 3 UNIVERSITY OF TECHNOLOGY SYDNEY; 4 FÉDÉRATION INTERNATIONALE DE FOOTBALL ASSOCIATION*

INTRODUCTION: A comprehensive examination of the sport-specific activities performed at the time of injury is important to hypothesise injury mechanisms, develop prevention strategies, improve management, and inform future investigations. The aim of this systematic review is to summarise the current literature describing the activities performed at the time of injury in football (soccer).
METHODS: A systematic search was carried out in PubMed, Web of Science, SPORTDiscus, and OpenGrey. Studies were included if participants were football players aged > 13 years old and the activities performed at the time of specific injuries (e.g., ACL, hamstring injuries) were reported together with the total number of injuries. Risk of Bias was assessed using an adapted version of checklists developed for prevalence studies. The activities reported by the studies were grouped to account for inconsistent reporting, and the proportion of each activity performed at the time of injury was calculated. Data were not meta-analysed due to high heterogeneity of methods and classification criteria. The review was performed following the PRISMA 2020 guidelines and the protocol was registered at the Open Science Framework (https://doi.org/10.17605/OSF.IO/U96KV).
RESULTS: In total, 29 studies were included in this systematic review. ACL injures were analysed by 12 studies, ankle/foot and knee injuries were analysed by 5 studies, thigh injuries were analysed by 4 studies, hip/groin injuries were analysed by 3 studies and hamstring injuries were analysed by 2 studies. Two studies analysed more than one type of injury. Running and kicking were the predominant activities leading to thigh and hamstring injuries. Changing direction and kicking were the predominant activities leading to hip and groin injuries and duels were the predominant activities leading to ankle injuries. Results for ACL and knee injuries were inconsistent among the included studies. High or medium risk of bias was observed in 80% of studies for injury definition and in 95% of studies for the measurement of inciting activities.
CONCLUSION: High intensity running and kicking activities seem to be the main activities leading to thigh and groin injuries, which is in accordance with what has previously been hypothesised [1, 2]. Duels seem to be the most frequent activity leading to ankle injuries which is in contrast with the literature available for other sports [3]. Results for other injuries were inconsistent between the studies. Most of the studies included in the review did not implement an appropriate definition of injury and/or a validated or standardised classification system for the inciting activities, therefore these results need to be interpreted carefully. It is paramount that future studies implement standardised injury definitions and standardised systems to classify the inciting activities in order to have consistent data that can be compared among studies.

**SURVEY OF THE CURRENT PRACTICES OF GERMAN FOOTBALL ACADEMIES TOWARDS BIOLOGICAL MATURITY AND TRAINING LOAD AND CLUB BELIEVE ON EVIDENCE-BASED PRACTICE**

ARENAS, L., FRENGER, M., SKORSKI, S., MEYER, T.

*SAARLAND UNIVERSITY*

INTRODUCTION: Despite the structural development of youth academies and the ongoing professionalism there appears to be the necessity of further investigations into their operational behavior. Injury surveillance studies of maturing football players emphasize the im-

portance to implement load monitoring into a youth football academy and to modify and adapt the imposed demands during sensitive growth phases [1]. Therefore, it has become increasingly common for practitioners in the Premier League to utilize non-invasive equations to estimate maturity status and timing for talent development [2]. Therefore, this study aims at (1) providing an overview of the practices towards load and maturity monitoring in German football academies and (2) examining the club belief towards the benefit of evidence-based practice (EBP).
METHODS: An online survey was conducted, consisting of multiple choice and Likert scale questions, which was distributed towards all 56 licensed German youth academies with full survey completion of 71% (n = 40). The survey was built on maturity and training load themes previously surveyed [2] and considering current research results towards maturity and training load assessment and application. The average response to five Likert Scale questions was used to describe the club belief on the importance of EBP.
RESULTS: The result indicates that the sport science staff were mostly responsible for data collection and analysis (84%) regarding monitoring load and maturity. 87% of respondents agreed that considering biological maturation and load monitoring is important for the overall development and injury prevention of youth football players whereas a formal assessment of maturity was implemented by 48% (n = 19) and load monitoring practices by 58% (n = 23) of the respondents. Of the 19 practitioners of maturity assessment, six (31%) perform regular adjustments in their football training and ten (52%) adjust their strength and conditioning training considering the maturity status. Regular application for maturity matched official competitions as bio-banded tournaments does not take place (n = 0). Further results indicate lower attribution of importance to the benefit of evidence-based practices in lower leagues (Bundesliga n = 12, 3,05 ± 1,87; 2. Bundesliga n = 15, 3,2 ± 2,87; 3. Liga n = 7, 1,75 ± 0,78, Regionalliga n = 6, 1,28 ± 0,81).
CONCLUSION: Practitioners in German football youth academies assign high significance to the assessment of biological maturation and load monitoring for a sustainable youth player development. Nevertheless, there is only a limited application and consideration for various training content. Despite the rise of bio-banded soccer tournaments by the Premier League, such a regularly implementation has not been found in Germany so far.

### TACKLER AND BALL-CARRIER INJURY MECHANISMS DURING MODERATE AND SEVERE INJURIES (≥8 DAYS LOST) IN ELITE RUGBY UNION

HENDRICKS, S., FORSHAW, P., MEINTJES, V., STARLING, L., DEN HOLLANDER, S., LAMBERT, M.I., READHEAD, C., VILJOEN, W.
*UNIVERSITY OF CAPE TOWN*

INTRODUCTION: Tackle injuries have the highest injury incidence, may cause the greatest number of days lost (severity) and carry a high injury burden. Moderate and severe injuries may have financial, psychological and team performance implications. Video analysis is a useful tool to understand injury mechanism during competition. This information can be used to develop effective injury prevention strategies. Therefore, the purpose of this study was to analyse tackler and ball-carrier injury mechanisms during moderate and severe contact injuries in professional rugby union from 2014 to 2018.
METHODS: Injury surveillance was conducted during The Currie Cup (South Africa's annual premier domestic competition) between 2014 and 2018 as part of the SA Rugby Injury and Illness Surveillance and Prevention Project (SARIISPP). Using the SARIISPP injury surveillance data, video footage of injuries with a 'moderate' and 'severe' severity (≥8days' time loss) were identified. Player-matched and team-matched non-injury events were also identified as controls. A total of 579 total injuries occurred over the four-year period, with 237 injuries recorded as 'moderate' and 'severe' (≥8 days' time lost). One-hundred and eight (n=108) of these injuries were clearly identifiable on the video footage. Of the 108 injuries, 87 injuries were tackle-related. A total of 965 non-injury tackles were analysed as controls. Injured and non-injured tacklers and ball-carriers were coded for pre-contact, contact, post-contact, and contextual variables. Multinomial logistic regression was used to determine the relative risk ratio (RR) for an injury or non-injury outcome based on the observed characteristics.
RESULTS: Ball-carriers were less likely to be injured when they made contact at 'high' intensity compared to 'medium' intensity (own control RR = 0.14, 95% CI, 0.05 – 0.38, $p < 0.05$; team control RR = 0.14, 95% CI, 0.05 – 0.39, $p < 0.05$). Tacklers had a higher risk of injury when their body position before contact was 'medium' (own control RR = 3.02 [95% CI, 1.18 – 7.74], $p < 0.05$; team control RR = 2.52 [95% CI, 1.04 – 6.13]; $p = 0.041$) or 'upright' (own control RR = 4.56, 95% CI, 1.31 – 15.90, $p < 0.05$; team control RR = 3.40, 95% CI, 1.01 –11.43; $p < 0.05$) compared to a 'low' body position. Tacklers were less likely to be injured when they approached the ball-carrier at a 'fast' speed (own control RR = 0.21 [95% CI, 0.06 – 0.75], $p < 0.05$; team control RR = 0.27 [95% CI, 0.08 – 0.93]; $p < 0.05$), and contacted the ball-carrier at the arm (own control RR = 0.15 [95% CI, 0.04 – 0.52], $p < 0.05$; team control RR = 0.22 [95% CI, 0.06 – 0.75]; $p < 0.05$) or hip (own control RR = 0.11 [95% CI, 0.02 – 0.53], $p < 0.05$; team control RR = 0.18 [95% CI, 0.04 – 0.81]; $p < 0.05$).
CONCLUSION: Our results suggest that attempts to reduce speed into contact and contact intensity may not be worthwhile injury prevention strategies. Rather, rugby stakeholders should focus injury prevention efforts on player tackle technique and conditioning.

### OP-BM19 Youth II

### PROFILING OF AGE-RELATED DEVELOPMENT OF METABOLIC PERFORMANCE DETERMINANTS IN ELITE YOUTH SOCCER PLAYERS: CONVENTIONAL STATISTICS AND CONTRIBUTIONS OF MACHINE LEARNING

JI, S.1,2, BROICH, H.3,4, MESTER, J.2, WIGGER, U.5, WAHL, P.1,2
*1. GERMAN SPORT UNIVERSITY COLOGNE; 2. GERMAN RESEARCH CENTRE OF ELITE SPORT ; 3. FC BAYERN MÜNCHEN AG; 4. MEDICAL SCHOOL HAMBURG; 5. SPORT-IT-CONSULTING, GERMANY*

INTRODUCTION: Performance diagnostic is an indispensable process for optimizing individual training programs and monitoring an athlete's development in all sports disciplines. Due to the high impact of biological maturation on performance development of young athletes, systematic and continuous physiological monitoring is even more important in this population than in senior athletes (Barker & Armstrong, 2010). However, data on physiological performance determinants and their time-course changes in young elite athletes is

limited and rather complemented with data from untrained children and adolescents. Thus, this cross-sectional study aimed to explore physiological characteristics regarding endurance performance and the longitudinal development of elite youth soccer players based on chronological age and age groups.
METHODS: 221 male elite youth soccer players (17.0±2.9 yrs) performed an incremental step test till exhaustion (start at 2.8 m/s +0.4 m/s every 5 min), to determine physiological determinants of endurance performance such as running velocity at lactate thresholds (vLT1 & vLT2), maximal oxygen uptake (VO2max), oxygen cost of running (CR), and total distance covered (DTot). For each athlete, 1-10 tests were carried out in a period of 4 years (number of tests: U15 = 72, U16 = 136, U17 = 204, U19 = 201, U23 = 188). The data were organized in a "data warehouse" and used for conventional statistics and machine learning, such as clustering and decision trees.
RESULTS: There was no significant difference between age groups (mean±SD) regarding VO2max (ml/kg/min; U15 = 55.5±3.8, U16 = 55.1±4.4, U17 = 54.6±4.0, U19 = 55.3±4.5, U23 = 53.7±4.1). In contrast, the key indicator of overall treadmill performance (i.e. DTot; m) increased with age: U15 = 4598±855, U16 = 5089±868, U17 = 5241±911, U19 = 5667±890, U23 = 5836±888. At the same time, improved CR (ml/kg/m) with increasing age was found: U15 = 0.241±0.019, U16 = 0.232±0.022, U17 = 0.224±0.017, U19 = 0.216±0.015, U23 = 0.208±0.014. A similar development pattern in these variables was also observed in the intra-individual analyses.
Due to the large number of experimentally available variables an important consideration is the strategy of "dimension reduction" to gain a better understanding of complex key indicators. For this purpose, factor-analyses with varimax-rotation have been used. Two major factors with an explained variance of 68% were extracted, which can be associated with dominant aerobic (52%) and anaerobic energy supply (16%).
CONCLUSION: Our results indicated an age-related improvement in CR without a change in VO2max resulting in improved endurance performance. Although the positive impact of growth and maturation cannot be ruled out (Ariens et al., 1997), the decreased metabolic demand of running (CR) per se can be associated with performance development in elite youth soccer players. Metabolic profiling and player grouping using machine-learning can help to better understand and improve an athlete's performance development.

**HIGH MUSCULAR FITNESS LEVEL MAY POSITIVELY AFFECT BONE STRENGTH AND BODY COMPOSITION IN CHILDREN WITH OVERWEIGHT AND OBESITY**

COMERAS-CHUECA, C., VILLALBA-HEREDIA, L., LOZANO-BERGES, G., MARÍN-PUYALTO, J., MATUTE-LLORENTE, A., GERMÁN-VICENTE, G., GONZALEZ-AGÜERO, A., CASAJÚS, J.A.

*UNIVERSITY OF ZARAGOZA*

INTRODUCTION: Obesity has become a major global health challenge because of its increased prevalence. Bone mineral content (BMC) is higher in obese children than in normal weight peers because body adiposity represents a mechanical load, but the fractures of the lower limb are much more frequent in obese children due to the excessive mechanical loading due to excessive adipose tissue and hormonal negative effects (Rinonapoli et al. 2021). Higher muscular fitness (MF) may attenuate the adverse hormonal effect of childhood obesity on bone mass (Gil-Cosano et al. 2020). The aim of this study was to compare bone health and the body composition between overweight and obese children with different (MF) level.
METHODS: A total of 59 children with overweight and obesity were included in this study. (MF) was measured by a countermovement jump (CMJ), handgrip and maximal isometric strength of knee extension. Participants were divided into four groups depending on their (MF) level as follow: 16 children with high MF (HMF) in both isometric (knee and handgrip) and CMJ (10.7±0.6 y, 8 males), 18 with high performance in isometric strength (HIS) (10.2±0.9 y, 10 males), 15 with high performance in CMJ (HCMJ) (9.7±0.9 y, 10 males) and 10 with low (MF) (LMF) (9.5±0.6 y, 4 males). A k-means cluster analysis was conducted to create these (MF) levels from handgrip and CMJ test. Body composition values were measured by DXA to obtain BMC, bone mineral density (BMD), fat mass (FM), lean mass (LM) and their indexes. Bone strength values were measured at the 8%, 38% and 66% sites of the length of the non-dominant tibia by peripheral quantitative computed tomography (Stratec XCT-2000 L pQCT scanner). Multivariate analysis of covariance test was applied to analyze bone strength differences between overweight and obese children who had different (MF), using maturity offset, height and weight as covariates.
RESULTS: Results show that HMF had better body composition.Despite having more FM than LMF, it had lower fat mass index (FMI) and lower fat mass index z-score. In addition, HMF had significantly lower FM and FMI than HIS and higher LM and lean mass index (LMI). HIS showed higher LMI than the worst performing group, and HCMJ showed higher LM and LMI than LMF.
On the other hand, the bone health variables are in the same direction. HMF showed higher bone mineral content and bone mineral density than LMF. In addition, LMF showed a significantly lower fracture load in X-axis and polar strength strain index compared to HMF and HIS. HCMJ showed a lower fracture load in X-axis also compared to HMF. Finally, LMF showed a smaller cortical area compared to HMF and HIS, and a smaller trabecular area compared to HMF and HCMJ.
CONCLUSION: MF plays a major role in bone health and body composition in overweight and obese children. It is key that the development of this muscle fitness is both absolute isometric strength and dynamic strength in which ones own body weight has to be moved.

**WALKING ONTOGENESIS IN TYPICAL DEVELOPING PRESCHOOL CHILDREN: WAVEFORM KINEMATIC ANALYSIS**

RYGELOVÁ, M., UCHYTIL, J., MALUS, J., ESTEVAN, I., JANURA, M.

*UNIVERSITY OF OSTRAVA*

INTRODUCTION: The development of walking in preschool children is a variable process that mainly affects the maturation of the central nervous system, but also gender, age, and anthropometric characteristics (1). Results of studies often differ on the age of children and their walking maturity, which resembles the adult walking pattern (2). There are several stages that may be considered important milestones in walking development. Various authors commonly agree on the age range of 4 to 8 years (3,4). Thereafter, the walking patterns of children begin to resemble an adult walking pattern most closely. During child development, kinematic parameters are constantly changing and are often cross-sectionally described by discrete variables (5). However, there are several longitudinal studies that may have been conducted on older children (6). To date, it has not been accurately described at which phases of the step cycle the greatest changes occur and how these changes manifest themselves in ontogeny during longitudinal tracking. This study aimed at investigating ontogenetic differences in kinematics walking during the stance phase of gait in typically developing preschool children.
METHODS: Six (3 boys and 3 girls) preschool typically developing children participated in the longitudinal study (age: 4.47 ± 0.89 years, height: 105.82 ± 6.94 cm, and mass: 17.3 ± 2.36 kg). The children participated in three measurements (1 per 12 months). Children walked on a 10m walkway marked with cones. Kinematic data were collected for 8 barefoot trials at a self-selected speed. Statistical parameter

mapping (SPM) was used for foot, ankle, and knee curves. SPM independent sample t-test determined significant differences between age group categories. The significance level was set at p<0.05.
RESULTS: SPM analysis of foot angle curve showed significant differences between 3-4 years children (p<0.001) from 0-96,5% step phase (SP), at comparison 3-5 years old (p=0.037) from 9% to 17,5% SP, (p=0.033) from 24,5% to 34% SP and between 4-5 years old (p<0.001) from 13% to 90% SP. Ankle angle differences were found between 3-4 years (p<0.001) during 100% SP, between 3-5 years (p=0.045) from 0% to 6,5% SP, (p<0.001) from 23,5% to 66% SP, (p=0.037) from 89,5% to 100% SP and between 4-5 years was no significant found. There were no significant differences between 3-4 at knee angle. For other two group age 3-5 and 4-5 were differences (p<0.001) during 100% SP and 4-5 years (p<0.001) from 44% to 84% SP respectively.
CONCLUSION: The greatest changes occur between 3-4 years of age in the type of stride and the ankle angle joint during the stance phase. From 4 years of age, significant differences also occur in the knee joint angle. The results suggest that gait maturation occurs gradually from distal to proximal segments.

**THE RELIABILITY OF A HIP EXTENSION SPEED-TEST IN TEAMGYM GYMNASTS AND ITS CORRELATION WITH SELF-REPORTED SKILL LEVEL**

NEISS PALLISDAL, A.
*UNIVERSITY COLLEGE ABSALON*

INTRODUCTION: Teamgym gymnasts commonly consider fast hip extension as an essential movement in trampet and vault disciplines. However, how hip extension speed influences the skill level has yet to be investigated. Therefore, we investigated how hip extension speed correlates with self-reported skill level on the trampet and vault disciplines. Likewise, we investigated the reliability of the proposed hip extension speed-test setup.
METHODS: This cross-sectional reliability study included 120 gymnasts aged 13-29 years old (male n=47; female n=73). Anthropometric measurements, self-reported skill level in the disciplines trampette and vault and hip extension speed test was conducted for all participants to investigate correlations between hip extension speed and self-reported skill level. Sixty-seven participants were tested a second time a week later to establish the reliability of the hip extension speed-test.
RESULTS: The Intertester reliability for the hip extension test was considered good ICC=0,8 (CI95% 0,676 - 0,876).
Further, we found a strong correlation between the hip extension speed test and trampet skill level (Spearman's rho=-0,633, CI95% -0,732 - -0,508)(p<0,01) as well as the hip extension speed and vault (Spearman's rho=-0,633, CI95% -0,732 - -0,508)(p<0,01). When adjusting for anthropometrics of the height:leg length-ratio no significant influence was observed on the relationship.
CONCLUSION: The hip extension speed test shows good reliability and can easily be conducted in teamgym gymnasts. We observed strong correlations between the hip extension speed test and self-reported skill level, indicating that hip extension speed is a significant variable when performing trampet and vault disciplines. Targeting greater hip extension speed might be essential to increase skill level in these disciplines.

## Oral presentations

### OP-SH05 Equality and diversity

**EQUALITY IN THE PHYSICAL EDUCATION IN SWEDEN DURING TWO DECADES**

JANSSON, A., MATTSSON, T.
*MALMÖ UNIVERSITY*

INTRODUCTION: Education equality is a central goal in well-fair states around the world. In Sweden, the school and the subject physical education (PE) should be equal and compensate for students' different backgrounds, e.g. socioeconomic, - and migration background. Although equality is a central goal, little is known about how equality in PE has changed during the last decades (Jansson et al., 2021). One approach to study equality is to analyze how grades for biological siblings correlate – this captures all aspects that siblings share, among others, socioeconomic, - and migration background. Although this approach is well established in educational research, there are no studies in PE-research (Jansson et al., 2021). As a result, there is limited knowledge about the extent to which students' backgrounds have affected their grades in PE. Therefore, the aim of this study is to analyze how equality in PE in Sweden has changed over the last two decades.
Method: The method is based on quantitative analyzes of students' (N = 5,848,642) grades in PE, between the years 1999-2019. The method is based on analyzing correlations between siblings' grades, using variance decomposition. More precisely, analyzing the correlation between full siblings, born within a three-year window, and their annually standardized grades in PE. In addition to socioeconomic, - and migration background, the measure takes into account all the aspects that full siblings share, such as: upbringing, genetic factors, living conditions, parenting and regional factors.
Results: In relation to the total variation in students' grades in PE, the proportion explained by variation between siblings has increased between the years 1999-2019. That is, the results indicate that the importance of students' family background, over the past two decades, has become more important for students' grades in PE. Furthermore, the largest increase in sibling correlation is found within the group of students born abroad.
Discussion: The results indicate that equality in PE in Sweden has deteriorated. This can be explained by that, between 1999 and 2019, (i) the student group has become more heterogeneous, i.e., it has become more difficult to compensate for students' different backgrounds; (ii) PE has become worse at compensating for students with different backgrounds, e.g. lower socioeconomic background.

Topic: Physical Education and Pedagogics.

## GENDER AND ECONOMICAL STATUS MAKE A DIFFERENCE AT PERCEIVED SOCIAL SKILLS DURING PHYSICAL EDUCATION LESSONS IN CHINA RURAL AREA

PRIMO, L.1, GONZÁLEZ, J.2, YANG, Y.3, LOPEZ DE SUBIJANA, C.1

*1 UNIVERSIDAD POLITÉCNICA DE MADRID, SPAIN 2 UNIVERSIDAD DE GRANADA, SPAIN 3 BEIJING SPORT UNIVERSITY, CHINA*

Introduction

All human societies value prosocial actions, and the expression of prosocial behavior is an integral aspect of all social animals. Such behaviors are essential to developing and maintaining harmonius relationships. A more prosocial behavior-specific approach has important real-world implications for intervention development and policymaking (Padilla-Walker & Carlo, 2015). Physical Education (PE) classes are a great opportunity to develop not only physiologically, but also psychosocially (Mischenko et al., 2020), and life skills in sport is in its infancy suggests that life skills transfer to to other life contexts may occur either explicitly or implicitly (Turnnidge, Côté, & Hancock, 2014). This study analyzed the relationships between social skills, Physical Education and motivational perceptions in a sample of disadvantaged Chinese students under the postulates of the Self-Determination Theory (SDT). so this study aims to investigate the relationship between students social skills and the three variables: motivation towards PE, perceived support (PS; parents, teachers and peers) and basic needs satisfaction (BNS).

Methods

Two hundred seven students enrolled in a camp organized by an NGO in Chengdu province (15.9 ± 1.7 years; 72.6% female and 25.5% male) completed the Chinese versions of the SDT-related and social skills questionnaires: LCQ, AFS, PLOC and MESSY (Chou, 1996; Goudas et al., 1994; Matson et al., 1983; Reeve & Sickenius, 1994; Williams & Deci, 1997; Yang et al., 2019; Zhou et al., 2017; Zhou et al., 2019).

ResultsThe results revealed a significant direct correlation between all the variables studied ($p<.01$). Perceived autonomy support from PE teacher was higher among female and those students that were practicing teams sport their PE lessons ($p<.05$). Basic needs satisfaction (autonomy, competence and attribution) were higher among those students that practice any sport out of school self-organized ($p<.05$). Intrinsic motivation was higher at male, those students practicing team sports at PE lessons and those practicing any sport out of school self-organized ($p<.05$).Social skills were perceived higher among male students and among those students which parents earned more than 50.000 RMB as family income ($p<.05$). The regression model to predict social skills based on PS, BNS and motivation towards PE was significant ($F(3,204) = 25.6$; $p<.001$; $R2=.27$; Cohen's $f2 = 0.37$). PS ($\beta$ =.024-.128; $p=.004$) and PE motivation ($\beta$ =.045-.120; $p<.001$) were positively associated with social skills.

Discussion

In line with previous studies (do Nascimento-Junior et al., 2021), the present study established a relationship between motivation towards PE, PS and social skills. However, according to these results, BNS does not seem to be associated with social skills.

Politécnica de Madrid (VSEMILLA22GLS).

## THE DEVELOPMENT OF SPORTSMANSHIP IN THE SOCCER SOCIO-SPORTS SCHOOLS OF THE REAL MADRID FOUNDATION

GIMENEZ, F.

*UNIVERSITY OF HUELVA*

The development of sportsmanship in the Soccer Socio-Sports Schools of the Real Madrid Foundation
Real Madrid Foundation, Spain
Giménez, F. J. , Ortega, G. , Robles, J. , Alarcón, F. , Ortega, E. , Silla, A. , & Abad, M. T.

Introduction

The practice of sports during the school stage must have a clear educational orientation that contributes to the comprehensive education of young people. In this sense, the Real Madrid Foundation (FRM) has been designing a sports model for years in which the promotion of values is its most important backbone. Therefore, the objective of this study was to know how the sport model of the FRM influences the personal and social factors of sportsmanship, and to know if there are differences according to the sex or the categories of the athletes.

Methodology

The study involved 1139 players belonging to the Sociodeportivas de Soccer Schools of the FRM of the Community of Madrid, aged between 8 and 15 years (M= 10. 57; SD= 2. 00). The sample consisted of 1110 boys (97. 5%) and 29 girls (2. 5%). Regarding the different categories and modes of soccer, 753 (66. 1%) belonged to the categories youngest (n=409) and alevin (n=344), football mode 7, while 386 (33. 9%) belonged to the categories children (n=269) and cadet (n=117), football mode 11.

The Multidimensional Scale of Orientation towards Sports was used (Lamoneda, Huertas, Córdoba and García, 2014). This questionnaire consists of 21 items and is subdivided into two dimensions: personal and social factors. Each item is answered on the basis of a Likert scale of 5 answer alternatives that express the degree of agreement or disagreement with each of the different questions where. Internal consistency analyses (Cronbach's alpha) yielded values of . 844 for the entire scale. Regarding alpha by dimension, the following data were observed: personal factors . 749 and social factors . 779.

Results

Regarding the differences of sex, it was observed that the girls presented higher values in the variables related to the one of sportsmanship, however, no significant differences were detected. The data also showed that the smaller athletes had higher values in both dimensions (personal and social), although only significant differences were found in the social factors, with a small effect size. Finally, considering the time spent in sports at the Social Sports Schools of the Real Madrid Foundation, no significant differences were observed in the variables related to sportsmanship.

Conclusions

Football training through sports models such as the FRM has a positive influence on the development of sportsmanship (both the personal and the social factor) among young players.

## OP-SH15 Talent development

### A QUALITATIVE INVESTIGATION OF EXPERTS' PRACTICE AND COACHING STRATEGIES TO PROMOTE SOCCER-SPECIFIC COMPETENCIES IN PLAYERS ON A TALENT PATHWAY

BERGMANN, F.1, WACHSMUTH, S.1, O'CONNOR, D.1,2, LARKIN, P.3,4, DUGANDZIC, D.5, HÖNER, H.1

*1 EBERHARD KARLS UNIVERSITY TÜBINGEN, GERMANY; 2 UNIVERSITY OF SYDNEY, AUSTRALIA; 3 UNIVERSITY OF MELBOURNE, AUSTRALIA; 4 MARIBYRNONG SPORTS ACADEMY MELBOURNE, AUSTRALIA; 5 GERMAN FOOTBALL ASSOCIATION*

Introduction
The development of soccer-specific competencies in aspiring players is a major challenge for coaches working in a talent development context. In support of coaches' efforts, research examining the effectiveness of practice and coaching approaches is valuable to enrich practical knowledge. However, methodological weaknesses and a sparse focus on talent development in past research restrict practical implications thereof [1]. To further improve the empirical knowledge base, the present study aims to investigate the practice and coaching strategies of experts to facilitate soccer-specific competencies in early-adolescent players.
Method
Twelve semi-structured interviews with international A- and PRO-licensed coaches and coach educators/developers were conducted. The interviews focused on supportive characteristics of the learning environment and practice tasks as well as strategies to optimally address specified soccer-specific competencies. In this respect, the experts were also asked to provide a rationale for their methodological decisions. A reflexive thematic analysis was conducted to identify thematic patterns across the data [2].
Results
Preliminary results reveal the experts consider a safe learning environment that encourages players to collect multifaceted experiences in the game as crucial for learning (theme I). According to the interviewees, coaches should try to develop practice tasks that pursue specific practice goals and stimulate players' problem-solving (theme II). Specifically, simplified game situations that guide players to certain actions were considered conducive for learning. The experts further suggested the learning process may be supported through implicit coaching strategies (e.g., modifications of the rules) as well as periods of explicit reflection to improve players understanding of the game (theme III). Though to a lower extent, individualized technically focused drill practices were considered supportive to address movement-related characteristics of techniques and to improve the players self-efficacy to apply the skills in the game (theme IV).
Conclusion
Overall, the experts recommended strategies that encourage players' exploration of functional solutions to presented problems. Hereby, the need for various practice and coaching "tools" is considered crucial to allow individualized support. Thus, strategies that were associated with different theoretical frameworks to skill acquisition are considered complementary to promote soccer-specific competencies, depending on the practice goals and the talents' needs.

### THE RELATIONSHIP BETWEEN TECHNICAL SKILLS, PERCEIVED TACTICAL SKILLS AND SELF-REGULATORY SKILLS IN YOUTH ELITE TENNIS PLAYERS

KOLMAN, N.

*UNIVERSITY OF GRONINGEN*

INTRODUCTION: Technical skills have been demonstrated crucial for tennis performance. Ball speed and accuracy are usually considered the two most important components of technique in tennis (Landlinger et al., 2012). These components are not only crucial for current tennis performance, but also vital for future tennis success in youth tennis players. Tactical skills and the perceptions thereof have been suggested to influence these skills, and self-regulatory skills may be beneficial for technical skills in various tactical situations (Kolman et al.,2019; Kolman et al., submitted). However, the relationship between technical skills in a tennis-specific situation and perceived tactical skills has not been investigated yet, and also the association with self-regulatory skills is unknown. Therefore, the purpose of this study is to explore the relationship between technical skills in various tactical situations, perceived tactical skills and self-regulatory skills among 21 youth elite tennis players (13 males, 8 females; age range 12-18 years).
METHODS: Using the Dutch Technical-Tactical Tennis Test (D4T), the Perceived Tactical Skills Scale in Tennis (PTSST) and the Self-Regulated Learning for Sport Practice (SRL-SP), this study aims to determine (i) whether there is a correlation between technical skills (i.e. ball speed, accuracy, percentage errors and spin rate) and perceived tactical skills, (ii) whether there is a correlation between technical skills in various tactical situations (offensive, defensive and neutral) and game situations (fixed and variable) and any of the four subscales of the PTSST (Anticipation and positioning, Game intelligence and adaptability, Decision-making and Recognizing game situations) (iii) which of the five domains of self-regulatory skills (Planning, Checking, Evaluating/Reflecting, Self-Efficacy for Challenges and Effort) is correlated with technical skills or perceived tactical skills and (iiii) whether technical skills, perceived tactical skills and self-regulatory skills differ according to gender or age category.
RESULTS: Preliminary results show a negative relationship between percentage errors and perceived tactical skills, decision-making and recognizing game situations. There is a positive relationship between perceived skills in recognizing game situations and accuracy in variable game situations. Preliminary results also show a positive relationship between perceived tactical skills and self-regulatory skills and the underlying subscale planning
CONCLUSION: These preliminary findings provide players, coaches and other professionals with insight into the relationship between technical skills, perceived tactical skills and self-regulatory skills. This can have important implications for talent development and optimizing performance in youth tennis players.

**PACING BEHAVIOUR DEVELOPMENT OF SWIMMERS: A LONGITUDINAL ANALYSIS OF THE 200M FREESTYLE.**

MENTING, S.G.P., POST, A.K., NIJENHUIS, B.S., KONING, R., VISSCHER, C., HETTINGA, F.J., ELFERINK-GEMSER, M.T.

*UNIVERSITY MEDICAL CENTER GRONINGEN*

INTRODUCTION: Due to the low efficacy of the swimming movement and relatively high resistance of water, pacing is crucial for swimming performance [1]. Cross-sectional studies show that in the 200m freestyle event, adolescent swimmers tend to start too fast, as an even pacing behaviour has been proposed to yield the best performance and is preferred by elite adult swimmers [1,2]. Studies in speed skating have indicated that during adolescence, pacing behaviour develops to better fit the task demands and that an early development of pacing behaviour relates to a higher performance level in adulthood [3]. It is therefore hypothesised that the pacing behaviour of 200m freestyle swimmers will develop towards a more even pacing behaviour during adolescence, and adolescent swimmers of a higher performance level already exhibit a more even pacing behaviour.
METHODS: Total race time and 50m split times were gathered of male (m) and female (f) swimmers' season best 200m freestyle performances between 2000 and 2021 (n=16645, 6848 female; 4.1±1.3 observations per swimmer). Included swimmers had a minimum of three season best times (SBT) between 12-18 years old and were categorized by comparing their best SBT to the prevailing world record: competitive (<116%) or recreational (116-125%). Using the lmer4 package in R, longitudinal multilevel models, in which repeated measures (level 1) were nested within individual swimmers (level 2), were used to analyse the effect of age and performance level on the normalized velocity in each 50m section ($p<0.05$).
RESULTS: Comparing 12 and 18 years old swimmers, the models predicted older swimmers to go relatively slower in the initial 50m (m: -1.22%, f: -1.12%), faster in the 50-100m (m: 1.20%, f: 0.77%) and 100-150m sections (m: 1.31%, f: 1.12%), and slower in the final section (m: -1.56%, f: -1.02%). Compared to the recreational swimmers, the competitive swimmers were relatively slower in the initial section (m: -1.20%, f: -1.01%) and faster in the 100-150m (m: 0.64%, f: 0.56%) and 150-200m sections (m: 0.38%, f: 0.11%). In the 50-100m section, competitive males were slower (-0.04%) and competitive females were faster (0.16%) than their recreational peers.
CONCLUSION: With age, adolescent swimmers hold back at the start of the race to achieve a higher velocity in the middle sections, overall achieving a more even pacing behaviour. Higher performing adolescent swimmers already exhibit a more even pacing behaviour compared to lower-performing swimmers. The current study used a rigid longitudinal design and large sample size to provide robust evidence that pacing behaviour of swimmers develops during adolescence and that pacing behaviour is linked to performance during adolescence. Coaches could use the data provided in the current study as benchmarks to monitor their swimmers' pacing behaviour development, guiding junior swimmers on the road towards elite performance.

**AN EXPLORATION OF THE NORWEGIAN ACADEMY CLASSIFICATION MODEL FOR TALENT DEVELOPMENT IN FOOTBALL**

NILSEN, A., KJÆRLAND, G., MOE, V.F.

*WESTERN NORWAY UNIVERSITY OF APPLIED SCIENCES*

Introduction
Top football is provided with constantly changing requirements, which has led to an increased professionalization of younger players. National plans for payer development have been revised or created to meet these conditions. A major change in Norwegian football came in 2017 with the Academy Classification Model (ACM), a new national plan introduced and developed by the Norwegian Top Football, the interest organization of the clubs in the two top divisions in Norway. The model aims to improve football by developing more quality players within the top clubs. Research on player development is vast; however, few studies include an analysis of national plans.
This study aims to explore the ACM documents through a pedagogical lens, and in specific using sports pedagogical models as a framework. Such models consist of special characteristics to ensure learning outcomes. For example, the model must prescribe some specific `non-negotiable` features that make it distinctive. It must leave enough space for local adaption, which is vital to successful sustainable practice, and the content should be based on an explicit knowledge base and values. Research has also pointed at the need for more studies regarding ethics and values within the domain of talent development, which include looking at national documents at the macro-level.
The research question illuminated; What are the value and knowledge base of the ACM, the basic characteristics, and the strategies needed to develop talented football players?
Method
A document analysis was conducted by closely reading seven texts connected to the ACM, containing the models background and the requirements for different classification levels. A hermeneutic approach was used to analyze the texts, and to ensure trustworthiness, all authors participated in the analysis work.
Results and discussion
The ACM represents tools and transparent standards for working with player development. In specific, the model consists of eleven areas, each area containing objective goals and criteria to be benchmarked. Of the eleven areas, three are threshold areas on which every club is assessed. There is no room for compromise in these areas, which can be linked to the non-negotiable features of the sports model framework. The remaining areas also release points, and how many the clubs get in total determines the classification level and the incentives provided. Despite the models detailed characteristics, there is room for local adaptation for player development, which is vital to succeeding within a sports model framework. The knowledge base and values are not explicit in the ACM apart from a few exceptions.
This study can contribute to policymaking, especially regarding designing documents aimed at young players. Using a sports pedagogical framework is also a new approach to analyzing these documents, which seems beneficial when also including value questions.

### IS-PN05 Determination and regulation of blood volume with an emphasis on exercise, doping and gender.

#### DETERMINATION AND REGULATION OF BLOOD VOLUME

LUNDBY, C.

*UNIVERSITY OF LILLEHAMMER*

New data suggest that well established differences in blood volume between female and male largely disappear if blood volume is expressed per lean body mass. In a similar manner the aging population does not differ from the younger population if blood volume is expressed per lean body mass. In support that lean body mass is a strong predictor for blood volume, elite endurance athletes also have only slightly higher blood volumes/ lean body mass when compared to untrained but healthy individuals. Although blood volume is rather constant in humans, both acute and chronic changes occur with environment, behaviour, and disease. New findings will be presented showing rather remarkable adjustment strategies.

#### BLOOD VOLUME ADAPTATIONS AND LIMITATIONS TO EXERCISE: GENDER FOCUS

MONTERO, D.

*INSTITUTE OF CARDIOVASCULAR SCIENCE AND MEDICINE*

Endurance training provides the most effective stimuli to enhance cardiac reserve and aerobic capacity in humans. Yet, as far as we know, women do not adapt to the same extent and quality to a given dose of training compared with men. Notably, the eccentric enlargement of the heart is generally blunted in women, which seems to primary limit their maximal cardiac filling and output in the systemic circulation. Based on recent findings, in this presentation we will propose a novel hypothesis linking blood volume, central/peripheral cardiovascular variables and body composition. Potential integrative mechanisms and direct implications for the design of effective training programs in women will be discussed.

#### INFLUENCE OF GENDER IN ANTI-DOPING WORK RELATED TO BLOOD MANIPULATION

FAISS, R.

*UNIVERSITY OF LAUSANNE*

Current anti-doping work includes the athlete biological passport in which individual changes in blood parameters are monitored longitudinally. These may be altered by alterations in plasma volume (PV) unrelated to doping practice. PV variations and haematological variations in conjunction with hormonal changes in active women taking oral contraceptive pill (OCP) are largely unknown. Data will be discussed from recent studies where measured PV variations using a validated carbon monoxide rebreathing method and are correlated to changes in haematological biomarkers (e.g., hemoglobin concentration ([Hb]), reticulocytes concentration, Transferrin (sTFN), ferritin (FERR), albumin (ALB), calcium (Ca), creatinine (CRE), total protein (TP), and low-density lipoprotein (LDL) in women taking OCP over a duration of 8 weeks. Data will be presented in context of other non-doping activities that may affect plasma and red blood cell volume and thereby potentially influence the ABP.

## Invited symposia

### IS-MH05 Skeletal Muscle Power: A Critical Determinant of Physical Function In Older Adults

#### EFFECTS OF SEX HORMONES ON SKELETAL MUSCLE POWER AND PHYSICAL FUNCTION

SIPILA, S.

*UNIVERSITY OF JYVÄSKYLÄ*

Human ageing is accompanied with deterioration in endocrine functions the most notable and well characterized of which being the decrease in the production of sex hormones. Current research literature suggests that low sex hormone concentration may be among the key mechanism for age-associated muscle loss, loss in fast muscle function (power), and accumulation of fat in skeletal muscle. In the present talk, the role of sex hormones, estrogens and testosterone, in causing the aging-related loss of muscle mass and function will be discussed.

#### MUSCLE POWER: AGE TRAJECTORIES AND APPLICATION OF COUNTERMEASURES IN THE CLINICAL SETTING

ALCAZAR, J.

*UNIVERSITY OF CASTILLA-LA MANCHA*

Muscle power increases progressively during the childhood and remain at peak levels during the early adulthood. However, age-related decreases in muscle power are already evident in middle-aged adults and are progressively accentuated in older adults. Due to muscle power is the product of force and velocity, physiological traits related with both capabilities are involved in the age-related loss of muscle power (i.e. slowing of action potentials transmission, specific atrophy of type II fibers, infiltration of connective and fat tissue within skeletal muscles, loss of muscle mass, changes in tendon stiffness, etc.). However, age-related declines in muscle power are more evident during fast vs. slow muscle actions, which may be caused by the greater severity of changes observed with age in some of these physiological

determinants. Notably, muscle power is one of the first capabilities declining with age, making the loss of muscle power an important hallmark of aging. The loss of muscle power with age is also one of the main determinants of impaired functional ability in older people. Specifically, relative muscle power (i.e., normalized to body mass) has been found to be more strongly associated to physical performance in older people in comparison with absolute muscle power, handgrip strength and sarcopenia. This would be due to most of the activities of daily living being weight bearing tasks (e.g., walking, chair rising or stair climbing). Nevertheless, the lack of feasible tests and normative data for older people has prevented the widespread testing of muscle power in older people in the past. Recently, a feasible test to evaluate relative lower-limb muscle power in older people has been validated: the sit-to-stand muscle power test. In addition, normative data, cut-off points and an operational algorithm to diagnose low relative muscle power in older people has been provided. Importantly, older people having low relative muscle power presented a higher risk of mobility limitations, frailty, disability, hospitalization, and all-cause mortality. Fortunately, power-oriented resistance training performed throughout a relative wide range of loads has been provided as an effective treatment to revert low muscle power in older people. With the advent of increasingly aging societies, and with main healthy aging goal of maintaining functional ability, the monitoring and treatment of low relative muscle power with aging should be a public health priority. Finally, and with this purpose, a free-cost smartphone app (PowerFrail App®) that integrates the sit-to-stand muscle power test is available.

**LOSS OF MUSCLE POWER AND PHYSICAL FUNCTION AT OLDER AGE: DISUSE OR AGING?**

SUETTA, C.

*RIGSHOSPITALET, UNIVERSITY OF COPENHAGEN*

The age-related loss of muscle power and physical function is associated with lower quality of life, frailty, and sarcopenia, and can increase risk of falling, fractures and hospitalization; however, it is not yet clear to which extent the deterioration can be attributed to an inherent biological ageing process and/or sedentary lifestyle. Notably, even brief periods of hospitalization, immobilization and bed rest result in rapid loss of muscle power and muscle mass at all ages, although there seems to be age-related differences. Thus, the effects of many years of a sedentary lifestyle may confound our understanding and expectations of the properties of a muscle for a given chronological age.

## Oral presentations

### OP-BM04 Hamstring and testing

**A COMPARISON BETWEEN DISCRETE AND ANGLE-SPECIFIC HAMSTRING QUADRICEP RATIOS IN ELITE FOOTBALL PLAYERS**

LUNN, D., NICHOLSON, G., WALKER, J.

*LEEDS BECKETT UNIVERSITY, CARNEGIE SCHOOL OF SPORT*

INTRODUCTION: Conventional and functional knee strength ratios, defined using peak joint moment of the flexors and extensors, are used in practice to estimate injury risk (Baroni et al., 2020). Despite literature commonly reporting these values there remains uncertainty regarding their functional value (Kellis et al., 2022). It has been suggested that using a time-series metric from angle-specific joint moments might be more successful at identifying injury risk (Read et al., 2022). Therefore, the aim of this study was to compare discrete strength ratios commonly used in practice with angle-specific ratios to determine the differences between the two measures.
METHODS: Twenty-eight footballers were recruited from the same English Premier League club (age: 22±4 y; stature: 1.81±0.07 m; body mass: 75.2±6.8 kg). Isokinetic testing was conducted for the knee flexors and extensors in a concentric motion at two angular velocities (60°/s and 240°/s) and in an eccentric motion (for the knee flexors only) at one angular velocity (30°/s) using an isokinetic dynamometer (Biodex Medical Systems). Conventional, discrete H:Q ratio's (c HQR-D) were calculated as the ratio between peak joint moment in the flexors and extensors at 60°/s. Functional, discrete H:Q ratio's (f HQR-D) were calculated as the peak joint moment in the flexors during the eccentric condition (30°/s) and the extensors at 240°/s. Angle-specific ratios (cHQR-AS and fHQR-AS) were computed as the ratio between flexor and extensor joint moments for all angles where both muscle groups were in the isokinetic range. Mean absolute residuals were then computed to compare between discrete and angle specific ratios.
RESULTS: Peak joint moment for flexors and extensors at 60°/s was 129.4±21.6 and 240.9±35.6 Nm, respectively (cHQR-D = 0.54±0.07). Eccentric peak joint moment for the flexors was 165.9±34.6 Nm, and concentric peak moment for the extensors at 240°/s was 145.3±18.4 Nm (fHQR-D = 1.15±0.21). Throughout the isokinetic range, average cHQR-AS ranged from 0.41-0.98 with a mean absolute residual of 0.11±0.11 versus cHQR-D. In comparison, the average fHQR-AS ranged from 0.98-1.33 with a larger mean absolute residual of 0.26±0.14 versus fHQR-D.
CONCLUSION: Neither conventional nor functional discrete ratios were fully representative of angle-specific ratios throughout the isokinetic range. However, the average residual for the conventional ratio was lower than the functional ratio, despite a greater range of values for cHQR-AS. Suggesting that discrete conventional ratios are more representative of angle-specific ratios over a greater range of joint angles, compared to discrete functional ratios. Furthermore, discrete functional ratios are not representative of angle specific functional ratios, which could mask athletes who may have fHQR deficits and may be at risk of injury.

### MUSCLE ELASTICITY, STRENGTH AND FLEXIBILITY IN HIGH ELITE ATHLETE WITH HAMSTRING STRAIN INJURY HISTORY

GIROUX, C., HOLLVILLE, E., HEGYI, A., CAUMEIL, B., MORALES, A., NORDEZ, A., RUFFAULT, A., EDOUARD, P., COUTURIER, A., RABITA, G., GUILHEM, G.

*NATIONAL INSTITUTE OF SPORT*

INTRODUCTION: Hamstring strain injury (HSI) is recognized to impair isometric strength and range of motion (ROM) during a passive straight leg raise (SLR)(1). While such deficits have been reported in various sports, little is known regarding injury-induced impairments in elite athletes. Moreover, SLR amplitude is a global measurement and does not provide information about the localized adaptations close to the injury locations. Therefore, the aim of this study is to determine the effect of HSI history on strength, flexibility and local muscle elasticity in high elite athletes.
METHODS: Among the fifty-one elite athletes (participating in the Olympic, World and European competitions in athletics, rugby seven and bobsleigh) that completed a survey on their injury history, fourteen participants (age: 25.0±5.3 years, height: 178.5±10.7 cm, weight: 79.7±17.8kg) reported HSI on one side, more than 30 days prior to the testing. Maximal ROM during a SLR test, maximal knee flexor force during Nordic hamstring exercise (NHE), peak torque during 60°.s-1 isokinetic eccentric knee flexion (ECC), peak torque during isometric contraction (MVC) were evaluated for knee flexors and hip extensors. Muscle elasticity was assessed using shear-wave elastography on the biceps femoris (BF), semitendinosus (ST) and semimembranosus (SM).
RESULTS: No significant differences were observed between previous HSI side and non-injured (NI) side in any of the variables. The mean and standard deviation for HSI side and NI side were respectively 7.8±1.9 vs 8.0±1.1 N.kg-1 (674±235 vs 637±188N) for NHE (p=0.83), 2.3±0.5 vs 2.3±0.7 N.m.kg-1 (123±87 vs 144±92 N.m) for the ECC torque of knee flexors (p=0.35), 1.7±0.5 vs 1.9±0.7 N.m.kg-1 (172±69 vs 184±72 N.m) for the MVC of hip extensors (p=0.37), 2.2±0.6 vs. 2.4±0.5 N.m.kg-1 (132±59 vs 148±78 N.m) for the MVC of knee flexors (p=0.94). ROM on SLR was 93±11 vs 91±10° for HSI side and NI side respectively. For muscle elasticity, for HSI side and NI side results were respectively, 17.4±6.0 vs 18.2±6.9 for BF (p=0.66), 19.6±5.2 vs 18.9±5.1 for SM (p=0.61) and 17.7±6.2 vs 15.3±4.6 KPa for ST (p=0.07).
CONCLUSION: Descriptive data of this study provides reference values for elite athletes from sprint-based sports. HSI history does not seem to be associated with deficit in strength or flexibility in elite athletes. These findings differ from some previous studies and may reflect the positive adaptations to thorough rehabilitation implemented for athletes involved in Olympic quest. The lack of difference in bilateral muscle elasticity infirm the hypothesis that post-injury collagen inclusion in injured muscle would increase muscle stiffness.

### 3D FASCICLE ARRANGEMENT OF THE BICEPS FEMORIS INDICATE THE NEED TO TAKE CURVATURE AND BENDING OF FASCICLES INTO CONSIDERATION WHEN ASSESSING THE ARCHITECTURAL PARAMETERS

MANTECON TAGARRO, C.1,2, KAWAKAMI, Y.1, MAAS, H.2, WEIDE, G.2

*1. WASEDA UNIVERSITY, FACULTY OF SPORT SCIENCES, JAPAN, 2. VRIJE UNIVERSITEIT AMSTERDAM, FACULTY OF HUMAN MOVEMENT SCIENCES, THE NETHERLANDS*

INTRODUCTION: The muscle architecture-function relationship is an important determinant in health and disease. Parameters of muscle architecture such as fascicle length (FL) have been conventionally measured with 2-dimensional ultrasound (2DUS). However, in muscles with longer fascicles, as the biceps femoris long head (BFlh), 2DUS can give rise to substantial errors. Three-dimensional ultrasound (3DUS) may solve these issues, but needs to be validated. This study aims to assess the BFlh architecture by a 3DUS approach and (2) to investigate if muscle FL can be assessed using a 2D analysis.
METHODS: 11 healthy adults between 18 to 30 years old participated. Due to poor visualization of the fascicles or the aponeurosis, we present data from only three subjects (1 female, 2 males). Before the measurements, the subject performed a contraction at 50% of MVC to ensure maximal shortening of the fascicles. Then, cross-sectional ultrasonograms of BFlh were taken through a single sweeping from 30% to 70% of the thigh length while capturing the probe orientation in 3D space. The measurement was performed at three knee flexion angles, i.e. 0º, 30º and 60º. An open source software (MITK) was used to analyze the US scan. We calculated FL in two ways: 1) customary FL (CFL), i.e. using one 2DUS plane and representing the target fascicle in the mid-belly of BFlh by a straight line, and 2) true fascicle length (TFL), i.e. combining two planes visualizing the proximal and distal part of the target fascicle respectively. A non-parametric Friedman's test with post-hoc Tukey HSD tests were used to compare the FL differences between CFL and the TFL at each knee angle.
RESULTS: As expected, FL decreased when KF angle increase. For each subject and at each knee angle, CFL was significantly higher than TFL (CFL: 93.11±0.44, TFL: 83.79±0.39 at 0º KF; P<.05). There was an increase of the percentage of change of FL between methods along the different KF angles, with a higher FL difference at higher knee angles (0º KF:9.94%, 30º KF:11.04%, 60º KF:12.82%).
CONCLUSION: Our study presents a 3DUS approach for the assessment of FL in the BFlh. Results show that in BFlh fascicles located in the mid-belly are curved and do not run within a 2D plane. Additionally, the differences between methods are dependent on knee angle. Therefore, we conclude that a 3DUS approach taking fascicle bending into account is needed for an accurate assessment of fascicle length in BFlh.

### CHANGES IN HAMSTRINGS MUSCLE SIZE AND STRENGTH AFTER ISOMETRIC KNEE FLEXION TRAINING PERFORMED AT THE KNEE EXTENDED (MUSCLE LENGTHENED) VERSUS AT THE OPTIMAL JOINT ANGLE

MAEO, S.1, SAKURAI, H.1, EIHARA, Y.1, SUGIYAMA, T.1, FOLLAND, J.P.2, KANEHISA, H.1, ISAKA, T.1

*1: RITSUMIEKAN UNIVERSITY, JAPAN, 2: LOUGHBOROUGH UNIVERSITY, UK, *: CO-FIRST AUTHORS*

INTRODUCTION: Growing evidence suggests that training at long muscle lengths produces greater hypertrophy than training at short muscle lengths (Oranchuk et al., 2019; Maeo et al., 2021). However, it is unknown whether this superiority holds true when compared to training at the optimal joint angle for maximum torque production. We therefore compared the effects of isometric knee flexion training performed at the knee extended (muscle lengthened) versus at the optimal joint angle on hamstrings muscle size and strength.
METHODS: Twenty healthy males performed isometric knee flexion training in a seated position unilaterally with each leg: one leg at the knee fully extended angle (EXT: 0° of knee flexion) where the knee flexors are at long muscle lengths, and the other leg at the individually assessed optimal knee joint angle for knee flexion torque (OPT: 39 ± 18°). Both legs completed 5 sets of 10 repetitions (5-s contraction and 5-s relaxation per rep) at 70% of maximum voluntary torque of the corresponding joint angle during each training session, and 2 ses-

sions/week for 12 weeks. Another 11 healthy males served as controls (CON). Isometric maximum knee flexion torque (at 0, 20, 30, 40, 50, 65, 85° of knee flexion) and muscle volume of the individual and whole hamstrings were assessed before and after the intervention for each leg in all participants.
RESULTS: Throughout the intervention period, absolute torque output was always greater (+10% on average, $P < 0.05$) for the OPT than EXT as expected. After the intervention, no significant changes were found in all variables in the CON. In the trained legs, changes in muscle volume of the whole hamstrings were greater in the EXT than OPT (15% vs 8%, $P < 0.001$). In each hamstring muscle, changes in muscle volume were largely greater for the EXT vs OPT ($P < 0.001$) in the biceps femoris long head (15% vs 5%) and particularly in the semimembranosus (12% vs 0%), but not significantly different between the EXT vs OPT in the biceps femoris short head (12% vs 13%) and semitendinosus (20% vs 19%). Changes in muscle strength demonstrated joint-angle specificity in both training conditions (i.e., pronounced increases around the training angle), but changes in muscle strength over the entire knee joint angles (assessed as area under the curve) were not significantly different between the EXT vs OPT (+31% vs +43%, $P = 0.405$).
CONCLUSION: Training at a long muscle length produced greater hypertrophy than training at the optimal joint angle, suggesting that muscle length (joint angle) rather than absolute torque output is a more influential factor for stimulating muscle hypertrophy during resistance exercise. It is of clinical relevance that the biceps femoris long head and semimembranosus, that are susceptible to strain-injury, are very (or even only) responsive to the training at long muscle length.

**HAMSTRING INJURIES IN PROFESSIONAL SOCCER PLAYERS GET COLDER. INFRARED THERMOGRAPHY AS AN ADDITIONAL TECHNOLOGY FOR RETURN TO PLAY DECISIONS**

FERNANDEZ-CUEVAS, I., ESCAMILLA-GALINDO, V., ESTAL-MARTINEZ, A.
*TECHNICAL UNIVERSITY OF MADRID*

INTRODUCTION: Hamstring injuries are one of the most common injuries in professional soccer players (Diemer et al., 2021). Infrared Thermography (IRT) is a technique that allows measuring Skin temperature (Tsk) and has recently been shown as a technique to prevent and monitor injuries in football (Côrte et al., 2019). The aim of this study was to describe the thermal evolution of Tsk asymmetries before and after hamstring injuries in professional soccer players.
METHODS: 25 professional soccer players (age: 24.88±3.81 years; height: 1.78±0.05 m; weight: 72.32±5.57 Kg) from different top elite European professional teams were assessed before (15 cases) and after (25 cases) being diagnosed with a hamstring injury (biceps femoris, semitendinosus or semimembranosus) by physical examination and ultrasound and/or MRI. Thermal pictures from the hamstring region were taken using an infrared camera (FLIR T530) under controlled conditions and before training or treatment. ThermoHuman® software was used to extract Tsk asymmetries between injured region of interest (ROI) and healthy ROI. ANOVA multivariate analyses of repeated measures were performed to test for differences in Tsk asymmetries over time.
RESULTS: ANOVA multivariate analyses revealed significant changes on the thermal asymmetry evolution between the data before and after injury occurred ($p<0.01$). The average Tsk asymmetry before injury was 0.12±0.36. We found a significant reduction in the assessments performed during the 48 hours after the injury (-0.61±0.28), and during the first 15 days after the injury (-0.57±0.33) when compared to the values before injury ($p<0.01$). The values later than 15 days after injury showed a progressive reduction in Tsk asymmetries: between 15 to 30 days after injury (-0.29±0.28), 30 to 90 days after injury (-0.07±0.24) and more than 90 days after injury (-0.04±0.29).
CONCLUSION: Those results show a significant hypothermic pattern on the Tsk of the muscle region after the injury. During the recovery period, these values stayed significantly colder, coming back progressively to the values described before the injury. These outcomes show the value of Tsk as an objective indicator to describe the physiological evolution of the hamstring injury. In addition to that, the results show the potential of IRT as technique to add value and support return to play decisions.

**EFFECTS ON CARDIORESPIRATORY PARAMETERS, BODY COMPOSITION AND CIRCULATING MESENCHYMAL STEM CELLS DIFFERENTIATION OF A 4400KM ULTRA-ENDURANCE UNSUPPORTED NON-COMPETITIVE RACE IN MALE AMATEUR CYCLISTS**

BRAGGIO, M., MINOIA, A., DORELLI, G., BERTACCO, J., COMINACINI, M., VALENTI, M.T., DALLE CARBONARE, L.
*UNIVERSITÀ DEGLI STUDI DI VERONA*

INTRODUCTION: NorthCape4000 (NC4000) is the most participated ultra-endurance cycling race: it covers 4,400 km with an elevation gain of 40,000 m. Most of the studies on cycling report acute effects on body composition and cardio-respiratory parameters in shorter races and data for longer distances are lacking. In addition, little is known regarding ultra-endurance modifications of circulating mesenchymal stem cells (MSCs) commitment. Therefore, we analyzed the effects of NC4000 in body composition, cardio-respiratory parameters and MSCs.
METHODS: Eight male healthy amateur Caucasian cyclists (47.5±13.5 yrs) were evaluated before the preparation period (PP), the week before NC4000 (BN) and 5.8±2.2 days after NC4000 (AN). Each evaluation included clinical assessment, bioelectrical impedance analysis (BIA), cardiopulmonary exercise testing (CPET) and blood samples. During PP and BN the self-managed training program was collected. Whole body dual-energy X-ray absorptiometry (DXA) was taken BN and AN to measure total and appendicular fat (FM) and lean mass (LM), while BIA was used to measure weight and to estimate FM. CPET assessed maximal oxygen uptake ($VO_2max$), the ventilatory thresholds and the ventilatory efficiency, estimated through $VE/VCO_2$ slope. MSCs were obtained from peripheral blood mononuclear cells (PBMCs). Expression of transcription factors RUNX2 and PPARG2 was analyzed. Skeletal muscle cells (SKMC) were obtained from PromoCells and examined in presence of subjects pooled sera to evaluate levels of sestrins (SESN1, SESN2) and sirtuin.

RESULTS: NC4000 finishing time was 21.2 ± 8.4 days, with a speed of 229.9 ± 68.8 km per day. Total body weight decreased during the preparation period (79.3±9.0 Kg vs 77.7±8.2 kg; p=0.042), but there were no substantial differences before and after the race (77.7±8.2 kg; 76.2±6.7 kg; p=0.105). FM decreased significantly between PP and BN (13.8±6.4 kg vs 11.2±5.1 kg; p=0.014) and after the race (11.2 ± 5.1 vs 9.2 ± 3.8 Kg; p=0,042). VO2max did not change significantly between PP and BN (49.6±10.5 ml/min*kg-1 vs 49.4±7.6 ml/min*kg-1; p=0.884), as well as BN and AN (49.4±7.6 ml/min*kg-1 vs 48.7±5,6 ml/min*kg-1; p=0.587). VE/VCO2 slope increased significantly only after the race (27.5±2.2 vs 30.4±3,2; p=0.014). Training significantly increased SESN1,2 and sirtuine-1 levels in SKMCs. In circulating MSCs, SESN1, UCP1, RUNX2 and PPARG2 expression were positively affected by training and NC4000.
CONCLUSION: In our sample, data show that ultra-cycling race leads to an increase in LM percentage and a decrease in FM without altering body weight. Despite no substantial modification in VO2max, a decrease in ventilatory efficiency is seen. Training for NC4000 leads to higher levels of sestrins and sirtuin-1 in SKMCs, counteracting adipogenesis and ageing. Conversely, ultra-cycling can lead to a reduction of SESN1 and SESN2 in SKMCs, while can increase UCP1 and sirtuin-1 levels in MSCs. These results suggest that ultra-cycling modifies cellular metabolism.

### TRIATHLETES EXPERIENCE DIVERSE AND EXTREME ENVIRONMENTAL CONDITIONS DURING THE IRONMAN WORLD CHAMPIONSHIP

PAHNKE, M.D., REIMEL, A.J., BONSIGNORE, J.L., DE CHAVEZ, P.J., CARTER, J.M.

*PEPSICO, INC.*

INTRODUCTION: Extreme environmental conditions are associated with adverse changes in health and performance. Changing environments during exercise can also impact nutritional needs. The IRONMAN World Championship (IMWC), held on the island of Hawai'i, sees athletes race 226.2 km through 4 climate zones across ~8 to 17 hours. The purpose of this investigation was to describe the environment that triathletes encountered during the 2019 IMWC and compare those conditions vs. the host-city temperature.
METHODS: We recorded a 10-min mean, environmental measurement (wet bulb globe temperature (WBGT), dry bulb (DB)) experienced by the leader (LEAD) and athletes finishing in ~9 (FRONT) and 11.5 h (MID). Measurements were taken at transition 1 (T1), three bike locations (~56, 100, 145 km; B56, B100, B145, respectively), transition 2 (T2), two run locations (5, 27 km; R5, R27, respectively) and the finish. Online reported DB temperature was also recorded for Kailua-Kona. Solar irradiance (W/m2) was measured for LEAD. Measurements were taken at 12 time points for each group, from ~06:30 to 18:50. Duration in WBGT heat stress flag levels was calculated for bike and run segments. Box Cox transformation was applied prior to ANOVA, followed by Tukey's HSD if significant ($p<0.05$).
RESULTS: There were significant differences in WBGT ($p=0.026$) and DB ($p<0.001$) on course, but not between groups. WBGT (°C) ranges were 24-30 (T1), 27-31 (B56), 25-28 (B100), 29-32 (T2), 28-30 (R8), 25-30 (R27), 29-30 (FINISH). The online reported DB for Kailua-Kona was significantly lower than what athletes experienced on course (29.1±0.22 vs. 30.5±0.53 °C, respectively, $P<0.001$). DB (°C) for LEAD, FRONT, MID, respectively, was 26.0, 28.1, 28.6 (T1), 29.6, 31.3, 31.2 (B56), 26.6, 27.8, 27.9 (B100), 31.3, MD, MD (B145), 35.5, 33.3, 33.5 (T2), 29.1, 30.4, 29.9 (R5), 31.7, 31.3, 29.2 (R27), 32.6, 32.1, MD (FINISH). Online DB (°C) for LEAD, FRONT, MID, respectively, was 26.4, 27.2, 27.2 (T1), 27.8, 28.6, 29.2 (B56), 28.9, 29.4, 30.0 (B100), 29.4, 30.0, 30.0 (B145), 30.0, 30.0, 29.4 (T2), 30.0, 30.0, 29.4 (R5), 30.0, 29.4, 28.6 (R27), 29.7, 29.2, 27.8 (FINISH). Solar irradiance for LEAD ranged from 17-1005 W/m2. Duration (h) in high stress was 4.2 (LEAD) and extremely high 2.8 (LEAD), 7.8 (FRONT).
CONCLUSION: While mean environmental conditions were similar between groups, athletes experienced changing conditions during the race. Importantly, leaders spent less time in high/extremely high heat stress conditions compared to slower racers, which may have implications for pacing strategy of the latter. Easing race intensity during the bike may, therefore, enable higher intensities during a run performed in less extreme environmental conditions. As environment impacts exercise performance and nutritional needs, when developing a racing and nutrition strategy for events in extreme environments, athletes should consider both the environment for the host city and how the environment may change based on the course and expected finishing times.

### A HIGH DOSE OF ISOMALTULOSE ALTERS IMMUNE CELLS COUNT AFTER PROLONGED CYCLING EXERCISE

TRISKA, C.1,2, MOITZI, A.1, TSCHAN, H.1, REIF, A.1,2, WESSNER, B.1

*1UNIVERSITY OF VIENNA, VIENNA, AUSTRIA. 2LEISTUNGSSPORT AUSTRIA, BRUNN AM GEBIRGE, AUSTRIA.*

INTRODUCTION: It is well established that prolonged and intense exercise alters immune system cell count [1]. Increased hemodynamics and the release of catecholamines and glucocorticoids are responsible for white blood cells (WBC) to demarginate to the blood compartment [2]. This is caused by a greater mechanical force on the endothelium. Previous works have demonstrated that the ingestion of carbohydrates (CHO) alters the response of the immune system during exercise. There is strong evidence that CHO supplementation with a high glycemic index attenuates stress hormone response and consequently lowers WBC count [3]. The aim of this study was to investigate whether there is a dose-dependent effect of a low-glycemic CHO on immune cells count during and after cycling.
METHODS: After a preliminary incremental exercise test, 12 triathletes (age: 29.7±5.3yrs; peak oxygen uptake: 59.1±6.8mL/min/kg) performed four experimental 120 min constant load cycling ergometer trials at a Delta25% intensity and a subsequent 15-min self-paced time trial. During the trials participants were instructed to ingest in total 1.6 L lemon-flavored water with isomaltulose concentrations of either 0, 20, 40, or 60g/h. WBC and its subtypes (i.e., granulocytes, lymphocytes, and monocytes) were assessed using blood samples obtained from an antecubital vein prior, every 30min during and immediately after cessation of the time-trial. A two-way repeated measures ANOVA with Bonferroni-corrected post-hoc tests was used to determine main and interaction effects (time*concentration). Significance was accepted at $P<.050$.
RESULTS: A significant effect of time*concentration interaction was found for WBC ($P=.019$) and granulocytes ($P=.003$), but not for lymphocytes ($P=.557$) and monocytes ($P=.406$). Post-hoc procedures revealed that after the time-trial, WBC count was significantly lower using the highest concentration of isomaltulose (i.e., 60g/h) compared to the placebo (81.1x10^9 vs 65.5x10^9; $P=.019$). The rise in granulocytes was significantly alleviated from 120 min on also when using the highest concentration of isomaltulose compared to the placebo (45.8x10^9 vs. 33.4x10^9; $P=.040$ for 120 min and 53.4x10^9 vs. 38.1x10^9; $P=.009$ for 137 min). For lymphocytes and monocytes, a significant rise in cell count over time was detected (both at $P<.001$), however, no effects of interaction ($P>.050$) or concentration ($P>.050$) were observed.
CONCLUSION: The novelty of this work is that a dose of <60 g/h of isomaltulose is not sufficient to significantly reduce the number of WBC. Therefore, a dose as high as 60 g/h or even higher has to be ingested. It is noteworthy, that when ingesting a dose >60 g/h multiple transportable CHO have to be used. However, it is currently unclear if a reduced number of WBC has a significant effect on immune function and furthermore if this effect has a physiologically meaningful impact on performance.

### VALIDATION OF A NOVEL EQUATION MODEL TO PREDICT HEART RATE OVER TIME IN YOUNG ADULTS

TESO, M., RIZZO, M., LOI, M., COLOSIO, L.A., BOONE, J., POGLIAGHI, S.
*UNIVERSITY OF VERONA*

INTRODUCTION: An increase in Heart rate (HR) over time (heart rate drift of slow component HRsc), totally or partially dissociated from the oxygen uptake (V̇O2), has been observed during constant-load exercise in young and older adults. Unless this HRsc is accounted for, prescription of exercise using HR targets can lead to an undesired reduction in metabolic intensity over time. A mathematical model that estimates the HRsc based on relative exercise intensity has been developed in postmenopausal women; if confirmed accurate outside the original population, this tool could allow the adjustment of HR targets over time to grant stability of training intensity. The study tested the validity of the model for the prediction of HRsc in young individuals of both sexes.
METHODS: 14 adults (7 female, 25 ± 3 yrs) performed on a cycle ergometer: a ramp incremental test for gas exchange threshold (GET), respiratory compensation point (RCP), and V̇O2MAX detection and a total of six, 9-min constant-load trials, two GET/RCP/ RESULTS: Increments in HR between the 5th and the 9th min of exercise were confirmed at all relative exercise intensities, their amplitude being significantly larger with increasing intensity ($p<0.001$). Overall average HRpredicted and HRdirect were highly correlated ($r2=0.99$; $p<0.001$) yet significantly different (142±31 and 144±31 b•min-1 respectively, $p<0.001$), with a significant bias (-3.4 b•min-1) and a fair precision (3.1 b•min-1). The gap between HRpredicted and HRdirect increased significantly as function of intensity relative to RCP ($p<0.001$, $r2=0.37$).
CONCLUSION: Our data confirm the necessity to adjust HR targets over time to account for the existence of an intensity-dependant HRsc or drift. The prediction model developed in postmenopausal women significantly underestimates the dynamic of HR that is observed in young adults, providing an insufficient correction of the HR targets over time, the more so with increasing intensity. A higher potential for HR excursion inherent with younger age could explain this finding. More research is needed to explore the combined effects of age, sex, and exercise intensity towards the development of prediction models with a generalized validity.

### OP-BM11 Tendon mechanics

### QUANTIFICATION AND PREDICTION OF PATELLAR TENDON STRAIN DURING LOADED BACK SQUATS

WEIDLICH, K., DOMROES, T., SCHROLL, A., ARAMPATZIS, A., MERSMANN, F.
*HUMBOLDT-UNIVERSITÄT ZU BERLIN*

INTRODUCTION: The loaded back squat is an important exercise to load the patellar tendon in athletic and rehabilitation praxis. Recommendations for the individual loading for tendon anabolic responses are commonly based on the percentage of one repetition maximum (1RM) (1). However, the patellar tendon strain - a key determinant for tendon adaptation - achieved during squats has not been previously examined. The primary objective of this study was to quantify patellar tendon strain during back squats in different percentages of 1RM as a proxy for tendon mechanical loading. A secondary objective was to predict the individual patellar tendon strain in back squats by using simple predictor variables.
METHODS: In 10 experienced lifting athletes (30.5±3.49 yr., 172.62±11.7 cm, 73.58±15.47 kg) we measured the elongation of the patellar tendon using ultrasonography, calculated the knee joint moments by inverse dynamics and measured the electromyographic activity (EMG) of the vastus lateralis, vastus medialis, rectus femoris and biceps femoris during back squats with 40% (s40), 60% (s60) and 80% (s80) of 1RM. In an additional trial, the maximum patellar tendon strain during maximum voluntary isometric contractions (iMVC) for each participant has been measured. Linear mixed-effects models (LMMs) were used to investigate the main effect of load. A fitting procedure with maximum strain during the iMVC and percentage of the 1RM as variables was used to predict the individual tendon strain in the back squats.
RESULTS: Patellar tendon strains during the squats were 4.67±0.95% in s40, 6.35±1.19% in s60 and 8.22±1.46% in s80. The resultant knee joint moments were 126.0±68.5 Nm in s40, 184.5±102.6 Nm in s60 and 226.5±106.1 Nm in s80. LMMs showed a significant influence of loading ($p < 0.001$) on both tendon strain and knee joint moment. The maximum tendon strain during the iMVC was 10.31±1.95% and related curvilinear to the s40, s60 and s80 strain values. Further, the maximum iMVC-strain showed a negative relationship to the EMG activity of the knee extensors during the squats. The accuracy of the individual tendon strain prediction was greater than 80%.
CONCLUSION: Our findings evidenced for the first time that patellar tendon strain is in the range that is considered optimal for tendon adaptation (4.5 to 6.5% strain) already in the lightweight (s40) to middleweight squats (s60). However, and despite the existence of a quasi-linear relationship between tendon strain and percentage of 1RM, the individual variability was too high to generalize these findings to all participants. The proposed prediction of individual patellar tendon strain may introduce new insights and possibilities in the individualized training control (2) in clinical and athletic praxis.

### ACTIVE HEAT ACCLIMATION DOES NOT ALTER MUSCLE-TENDON UNIT PROPERTIES

MORNAS, A., BROCHERIE, F., GUILHEM, G., GUILLOTEL, A., LE GARREC, S., GOUWY, R., BEUVE, S., GENNISSON, J.L., RACINAIS, S.
*FRENCH INSTITUTE OF SPORT*

INTRODUCTION: Heat acclimation is strongly recommended before competing in hot and humid conditions (1). Repeated heat exposures have also been suggested to increase muscle strength (2), potentially related to positive changes in skeletal muscle contractile properties (3). However, such effects on muscle and tendon mechanical properties are not yet fully understood in humans. This study aimed to de-

termine the mechanical adaptations of gastrocnemius medialis (GM) muscle-tendon unit elicited by repeated acclimation cycling sessions in the heat (38°C). We expected positives changes in skeletal muscle structure (i.e., increased in muscle thickness), while the effect on muscle-tendon unit properties were exploratory.
METHODS: Thirty recreationally active male (n=16) and female (n=14) participants (26.6±3.4 yrs) were tested before and after 13 low-intensity cycling sessions (~1.3-2.5 W/kg), distributed over a 17-days period. Participants performed cycling sessions in control (CON: ~23°C, ~35% relative humidity [RH]; n=15) or in hot ambient environment (HOT: ~38°C, ~58% RH; n=15). During testing, maximal voluntary contraction (MVC) torque, GM muscle architecture, ankle joint and fascicle force-velocity relationship, passive muscle stiffness (i.e., shear modulus) and active tendon stiffness were assessed.
RESULTS: Muscle (38.4±0.5°C vs. 37.3±1.1°C) and core (39.4±0.4°C vs. 38.3±0.3°C) temperatures were higher after cycling 1 hour in HOT vs. CON (P<0.01). Core temperature and heart rate decreased from the first to the last session in HOT (-0.39±0.3°C and -13±10 beats.min-1; both P<0.01), suggesting heat acclimation. MVC torque was not affected in HOT and in CON (129±20 vs. 136±23 N.m-1 in HOT and 127±32 vs. 131±31 N.m-1 in CON; all P≥0.508). Fascicle length, pennation angle and muscle thickness were unchanged (respectively, 5.2±0.5 vs. 5.2±0.5 cm, 16.4±1.6 vs. 16.3±2.3° and 1.5±0.2 vs. 1.5±0.2 cm in HOT; 5.4±0.5 vs. 5.5±0.5 cm, 16.6±1.9 vs. 16.6±2.1° and 1.6±0.2 vs. 1.6±0.2 cm in CON; all P≥0.267). Muscle joint and fascicle force-velocity relationship did not change in HOT and in CON (all P≥0.22). Passive muscle stiffness and active tendon stiffness were not affected (respectively, 13.2±1.6 vs. 13.1±1.5 kPa and 26.0±8.1 vs. 25.6±7.4 N.mm-1 in HOT and 15.2±2.3 vs. 14.3±1.9 kPa and 23.4±6.1 vs. 23.6±6.7 N.mm-1 in CON; all P≥0.30).
CONCLUSION: The present findings show that 13 sessions of effective heat acclimation did not modify muscle-tendon unit properties. Previously reported improvement in muscle strength was not observed and may not be associated to such adaptations in muscle-tendon mechanical properties (2, 3). These data suggest that an active heat stress acclimation is beneficial from a physiological point of view without altering muscle architecture and muscle-tendon mechanical properties.

### ACHILLES TENDON MECHANICAL BEHAVIOR AND ANKLE JOINT FUNCTION AT THE WALK-TO-RUN TRANSITION

MONTE, A., TECCHIO, P., NARDELLO, F., ZAMPARO, P.
*UNIVERSITY OF VERONA*

INTRODUCTION: Humans switch from walking to running at a spontaneous speed of about 7-7.5 km/h (1) but the underpinning mechanisms of the walk-to-run transition are still not completely understood. The largest part of the total mechanical power generated during locomotion is provided by the ankle joint (2), and the majority of the ankle power is attributable to the Achilles tendon mechanical behavior. Investigating the mechanical behavior of the Achilles tendon and the ankle joint function at the walk-to-run transition could thus provide further insight into this topic.
METHODS: Ten healthy subjects (28.5 ± 5.3 years; 1.70 ± 0.05 m; 65.2 ± 7.2 kg) were recruited for the study. Kinetic data and the kinematics of the body segments were recorded during overground walking and running at speeds from 5.5 to 8.5 km·h-1; in addition, we recorded ultrasound data of the gastrocnemius medialis muscle-tendon junction. Based on these data the Achilles tendon force (ATf) and power (ATp) were calculated (during the propulsive phase) according to (3). and the ankle functional indexes (i.e. damper, strut, spring and motor like-function) according to (4).
RESULTS: ATf decreased as a function of speed in walking and increased as a function of speed in running. Significant differences in ATf between walking and running were observed at speeds > 7.5 km/h. ATp was higher in running (from 174±10 to 224±10 W at 6.5 and 8.5 km/h, respectively) than in walking (from 65±10 to 120±23 W at 5.5 and 7.5 km/h, respectively). Joint functional indexes were affected by speed in walking: strut index increased (from 24 to 30% at 5.5 and 8.5 km/h) and spring index decreased as a function of speed (from 60 to 52% at 5.5 and 8.5 km/h). No significant differences in joint functional indexes were observed in running and no significant differences were observed in terms of damper, motor and strut indexes at all the investigated speeds between walking and running. However, the spring index was higher in running than in walking at speeds > 7.5 km/h.
CONCLUSION: Our data suggest that the force acting along the Achilles tendon is impaired at walking speeds higher than 7.5 km/h. At this speed, the spring index of the ankle joint is lower in walking than in running and this suggest that the spontaneous walk-to-run transition that normally occurs around 7-7.5 km/h could be explain, among the others, by the need to preserve the spring-like function of the Achilles tendon.

### SEX DIFFERENCES IN ACHILLES TENDON T2* RELAXATION TIME IN RUNNERS

JANDACKA, D.1, JURAS, V.2, JANDACKOVA, V.K.1, SKYPALA, J.1, PLESEK, J.1, BLASCHOVA, D.1, URBACZKA, J.1, UCHYTIL, J.1, MINARIK, R.1, HAMILL, J.1,3
*UNIVERSITY OF OSTRAVA*

INTRODUCTION: There is a higher incidence of Achilles tendon (AT) injury in males than in females [1]. In addition, chronic AT injury was reported to have the highest incidence of all running-related injuries [2]. Early stages of Achilles tendinopathy usually alter biochemical but not morphological tendon properties [3]. Biochemical structural properties may be expressed by the AT T2* relaxation time which has been shown to be associated with Achilles tendinopathy [4]. Therefore, the purpose of this study was to compare AT structure between male and female runners across running distance groups. The population with AT pathology shows longer relaxation times [4], therefore we hypothesized that males would have longer AT T2* relaxation time than females.
METHODS: Middle aged runners between 30-50 years (n = 293 total/ 196 males/97 females) were selected from the 4HAIE study [5]. Runners were divided into three groups according to running distance (6-20, 21-40 and more than 40 km/week). The main dependent variable was the AT T2* relaxation time of the AT insertion measured by Magnetic Resonance Imaging using 1.5 Tesla system. We controlled for covariates and there were no significant differences in age, VISA-A Total Score', running footfall pattern measured by Strike

index (%), step mean count per day and running distance per week between overall the male and female groups. We used Mann-Whitney U Test to test the hypothesis that the distribution of the AT T2* relaxation time would be the same between sexes. In addition, we used two-way ANOVA (sex, running distance).
RESULTS: On average, males (2.7 ms; CI 2.5-2.9 ms) were shown to have longer AT T2* relaxation time than females (2.3 ms; CI 2.1-2.6 ms) (p=0.014). The mean score for AT T2* relaxation time was longer for males in all three running distance groups (main effect p = 0.016).
CONCLUSION: Longer AT T2* relaxation times in male runners may be related to a higher incidence of AT injury in males compared to females [1]. This finding suggests that male runners may have altered water content and collagen orientation and thus greater risk of injury with compare to female runners.

### OP-BM25 Neuromuscular Physiology: Fatigue I

#### KINETICS OF NEUROMUSCULAR FATIGABILITY DURING CYCLING AT A FIXED RATE OF PERCEIVED EFFORT IN DIFFERENT ALTITUDE-LIKE SIMULATION METHODS.

BEAUME, J.B.1, DI DOMENICO, H.1, BOWEN, M.1, HINTZY, F.1, MILLET, G.Y.2, PAGEAUX, B.3, DEBEVEC, T.4, RUPP, T.1

INTRODUCTION: This study aimed to investigate the effects of different training interventions known or believed to induce hypoxia on knee extensors neuromuscular fatigability (NMF). Specifically, the goal was to compare NMF during sub-maximal cycling at a given rate of perceived effort (RPE) in (i) systemic hypoxia vs (ii) localised blood flow restriction (BFR) vs an airflow restriction mask (ARM).
METHODS: Seventeen healthy, young male participants, cycled twenty minutes at a self-selected power output (PO) corresponding to a hard effort (15 on the 6-20 Borg scale). Exercise was performed on an innovative cycle ergometer allowing evaluation of the lower-limbs neuromuscular function without delay. Participants underwent the following 4 conditions in a randomized order: normoxia (NOR), normobaric hypoxia (SyH, inspired fraction of O2 = 0.13), BFR on lower limbs (50% of arterial occlusion pressure), and ARM supposed to simulate altitude (~3500m). Isometric maximum voluntary contraction of knee extensors (IMVC), along with central (voluntary activation, VA), and peripheral (peak twitch, Pt; low- to high-frequency doublets ratio, LF/HF) indices were measured before and regularly during cycling (at min 5, 10, 15 and 20). In addition, PO and SpO2 were continuously measured. Perception of quadriceps pain was assessed with the CR-100 scale throughout exercise.
RESULTS: No time effect was observed for PO throughout exercise. However, a condition effect was found ($p<0.05$), revealing that PO was lower in BFR and SyH compared to NOR and ARM (134±30, 159±21, 195±30, 194±28, respectively) with lower values in BFR than in SyH ($p<0.05$). SpO2 was significantly reduced in SyH only (mean of 77±4% throughout exercise). Compared to baseline, IMVC decreased in all conditions at min 5 then exhibited a plateau (~ -10 to -20% for NOR, SyH and ARM) except in BFR, where IMVC decrease was greater and continued to decline from -27±12% at min 5 to -40±14% at min 20. A main time effect also existed for VA which significantly decreased from min 15 ($p<0.05$). VA decreased more in BFR than in the other 3 conditions ($p<0.001$), reaching -24%±15% at min 20 and mirroring IMVC exacerbated alterations. A time effect was reported in peripheral neuromuscular indices, with no differences between conditions, e.g. mean decrease for all conditions around -14±6% for Pt and -11±3% for LF/HF at min 5, and then plateaued. Pain perception throughout exercise was higher in BFR compared to NORM (58±18 vs 36±16, respectively, $p<0.05$).
CONCLUSION: For a given RPE, a 20-min submaximal cycling exercise induced more neuromuscular fatigue in BFR than in the other 3 conditions. Similar levels of peripheral alterations were found but significantly greater reduction in VA was found, suggesting higher levels of central fatigue. This result may be due at least in part to enhanced pain in the lower limbs and illustrates the psychophysiological impact of pain on both maximal and submaximal motor production.

#### NEUROMUSCULAR FATIGUE IS DETERMINED BY THE AMOUNT OF WORK PERFORMED ABOVE THE CRITICAL POWER WHEN CYCLING IN THE EXTREME INTENSITY DOMAIN

LAVIGNE, C., LOVERA, M., MONS, V., BLAIN, G.M.

*UNIVERSITÉ CÔTE D'AZUR*

INTRODUCTION: Recently our laboratory has found that exercise of different durations-intensities performed to exhaustion (EXH) within the severe-intensity (SI) domain (i.e., above critical power; CP) is not dependent on the curvature constant (W) of the power-duration relationship but on the level of muscle activation, owning to a greater magnitude of neuromuscular fatigue (NMF) with increased power output (PO) and decreased duration (1). However, for work rates above SI, i.e., the extreme-intensity (EI) domain (EXH < 2-3 min), where the level of muscle activation is nearly maximal, the development of NMF regarding the influence of PO and depletion of the W remains unknown. We examined the etiology of NMF after work-matched EI exercises leading to the controlled partial and full depletion of W, with or without a fast start.
METHODS: Seven recreationally active participants (mean ± SD; age, 25.4 ± 4.7 yrs; 3 female) completed two 3-min all-out cycle tests against a fixed resistance for the estimation of CP and W. On separate days, participants performed six randomized cycling trials with (n = 3) or without (n = 3) a fast start (to modulate PO) in the EI domain set to deplete W into phases of 25%, 50%, and 100%. PO during the EI trials without a fast start (EICWL) were maintained at a constant workload of 487 ± 175 W. In the first half of the fast start EI trial (EIFS), PO was set to 487 ± 175 W, followed by the second half at a reduced PO above CP (270 ± 67 W). Global, central and peripheral fatigue was quantified via pre- to post-exercise (10-s through 15-min recovery) changes in maximal voluntary isometric contraction (MVC), voluntary

activation (VA) and potentiated twitch force, respectively. VA was measured using the interpolated twitch technique, and potentiated twitch force was evoked by single (QTsingle) and paired [10-Hz (QT10) and 100-Hz (QT100)] electrical stimulations of the femoral nerve.
RESULTS: The CP estimate in the 3-min all-out test was 195 ± 62 W and the W was 13.2 ± 7.4 kJ. ΔMVC force decreased to a greater extent when 100% W was depleted compared with 25% (–13 ± 4% vs. –22 ± 12%, p = 0.037). ΔQT100 (p = 0.008), ΔQT10 (p = 0.003), and ΔQTsingle (p = 0.004) were less in the 25% phases (–15 ± 6%; –26 ± 11%; –29 ± 12%) compared with 100% (–30 ± 17%; 49 ± 20%; –51 ± 19%), respectively. Reductions in QTsingle indices during the different phases were correlated to the % depletion of W (r = 0.51, p < 0.001). No exercise-induced reduction in VA was found in both conditions (p = 0.278). There were no main effects of condition (all p ≥ 0.449), nor condition × time interactions (all p ≥ 0.660) for any variable.
CONCLUSION: These results suggest that regardless of the level of PO (modulated with the use of a fast start), the magnitude of NMF remains the same when depletion of the W is controlled. Therefore, NMF during exercise within the extreme intensity domain is dependent upon the depleted amount of W.

### NO REPEATED BOUT EFFECT ON KNEE FLEXOR NEUROMUSCULAR FUNCTION AND KNEE POSITION SENSE AFTER SUBMAXIMAL FATIGUING ECCENTRIC CONTRACTIONS

DA SILVA, F., MONJO, F., CORCELLE, B., PIPONNIER, E., GIACOMO, J., GIODA, J., COLSON, S.S.
*UNIVERSITÉ CÔTE D'AZUR - LAMHESS (UPR 6312)*

INTRODUCTION: Significant position sense alterations have been observed following submaximal and maximal eccentric (ECC) contractions of knee extensors in human studies [1]. However, only one study focused on the effects of maximal ECC contractions of knee flexors (KF) on position sense [2]. Therefore, in view of the lack of information following submaximal ECC contractions, we investigated immediate and delayed effects of submaximal KF ECC contractions on knee position sense. We also investigated whether the protective effect (RBE) commonly observed after a first bout of ECC contractions [3] could extent to knee position sense.
METHODS: Sixteen healthy males performed two bouts of unilateral KF ECC contractions one week apart until reaching a 20% decrease in maximal voluntary isometric contraction force. During each bout, KF neuromuscular function and knee position sense were evaluated at three time points: before (PRE), immediately after (POST) and 24 hours after (POST24) the ECC exercise. Bilateral joint position matching tasks were used to evaluate knee position sense at 40° and 70° of knee flexion in seated (JPMS40 and JPMS70) and prone (JPMP40 and JPMP70) positions. The components of KF neuromuscular fatigue (i.e., central and peripheral fatigue) were assessed using voluntary and electrically evoked contractions. Muscle soreness was evaluated using a 0-10 numerical rating scale. These parameters were analyzed using two-way repeated measures ANOVAs (bout × time point).
RESULTS: No bout × time point interaction effect was found for any neuromuscular function and position sense parameters (p > .11), suggesting that no RBE occurred. The ECC exercise generated neuromuscular fatigue involving central and peripheral components at POST, as indicated by significant decreases in voluntary activation levels (p < .01) and electrically evoked torques (p < .05). At this time point, position errors towards knee flexion were only observed during JPMS40 tasks (p < .01). Although KF neuromuscular function had recovered at POST24, position errors towards knee flexion were still detected during JPMP40 task in presence of muscle soreness (p < .01).
CONCLUSION: Whatever the joint position matching task and time point, participants adopted a more flexed position at the knee of the fatigued limb at long muscle lengths (i.e., 40° of knee flexion). We postulate that such alterations represent an injury protective mechanism. In addition, while a previous study showed a correlation between the level of central fatigue and position sense alterations [4], the position errors observed at POST24 in the present study conflict with a central-based explanation. Future studies should thus focus on the relationship between muscle damage and position sense alterations.

### BALANCE TRAINING UNDER FATIGUE: A RANDOMIZED CONTROLLED TRIAL ON THE EFFECTS OF BALANCE TRAINING IN AN UNFATIGUED OR FATIGUED STATE ON NEUROMUSCULAR PERFORMANCE

KELLER, M., ROTH, R., LICHTENSTEIN, E., FAUDE, R.
*UNIVERSITY OF BASEL*

INTRODUCTION: Balance training has been shown to improve postural control and power as well as to reduce injuries, particularly ankle injuries, in a variety of sports, populations and settings. One can, however, question the existing practice of putting the balance programs at the start of a training session, i.e. to train in an unfatigued state, because injuries occur more often at the end of the first half or at the end of the match and this has often been associated with fatigue. Furthermore, there is evidence that adaptations to balance training are task specific and balance requirements are also essential in fatigued conditions. The aim of the present study was therefore to assess the influence of balance training in a fatigued and unfatigued state on neuromuscular performance when tested in fatigued and unfatigued states.
METHODS: Overall, 52 volunteers (mean age 27.9 y; 19 women) were recruited for this study. The participants were randomly allocated to one of three different groups. All groups took part in the identical measurements before and after a 6 weeks intervention period and all groups trained the identical balance tasks. The time spent before and/or after the balance training, however, differed between groups. The reference group (BT) participated solely in the balance training (25 minutes per session). The other two groups trained the balance tasks either before (group BT-HIIT) of after (group HIIT-BT) a high-intensity interval training session. Thus, these groups trained the balance tasks either in a fatigued or unfatigued state. In PRE and POST measurements, balance (conditions single-leg stance on solid ground, soft mat, wobble board) and jump performance was obtained in a fatigued and, additionally, in an unfatigued state. Furthermore, we assessed shuttle-run performance to detect adaptations in endurance capacity. General linear models were calculated to evaluate potential training adaptations within and between groups.
RESULTS: The preliminary data analysis revealed enhanced shuttle-run performance after the intervention period in BT-HIIT (+12%) and HIIT-BT (+12%) but not in BT (+3%). Jump height did not differ from PRE to POST. The balance training that was performed by all groups resulted in reduced sway paths in all groups. However, the general linear models revealed larger adaptations in BT-HIIT and BT when compared to HIIT-BT. This effect was consistent for the testing conditions “unfatigued” and “fatigued”.

CONCLUSION: This is the first study that investigated the influence of balance training under fatigue on neuromuscular performance in a fatigued and unfatigued state. The data revealed that balance training under fatigue results in diminished adaptations, even when tested in a fatigued state. Thus, balance training should be implemented at the start of a training session or in an unfatigued state.

### TOWARDS AN IMPROVED UNDERSTANDING OF PROXIMITY-TO-FAILURE IN RESISTANCE TRAINING AND ITS INFLUENCE ON SKELETAL MUSCLE HYPERTROPHY, NEUROMUSCULAR FATIGUE, MUSCLE DAMAGE, AND PERCEIVED DISCOMFORT

REFALO, M.1, HELMS, E.2, HAMILTON, D.1, FYFE, J.1

*1. CENTRE FOR SPORT RESEARCH, SCHOOL OF EXERCISE AND NUTRITION SCIENCES, DEAKIN UNIVERSITY, AUSTRALIA; 2. SPORT PERFORMANCE RESEARCH INSTITUTE NEW ZEALAND, AUCKLAND UNIVERSITY, NEW ZEALAND*

INTRODUCTION: The repetitions performed in a resistance training (RT) set lie on a continuum whereby the maximum termination point is "momentary muscular failure", defined as when an individual is unable to complete the concentric portion of a given repetition with a full range-of-motion and without deviation from the prescribed form of the exercise. Set termination may also occur a given number of repetitions from momentary muscular failure. This "proximity-to-failure" is considered an important RT prescription variable, but its influence on short-term and long-term responses to RT is uncertain.
METHODS: Given the ambiguity in the literature, a scoping review was undertaken to summarise evidence for the influence of proximity-to-failure on physiological adaptations (e.g., muscle hypertrophy) and short-term responses (e.g., neuromuscular fatigue, muscle damage and perceived discomfort) to RT. The literature search followed the PRISMA-ScR guidelines.
RESULTS: The initial search yielded 1214 results and after duplicates were removed, 715 articles were entered for title and abstract review. Subsequently, 38 out of the 72 articles that went through full text review were eligible to be included in the scoping review. The literature search identified three broad themes of studies comparing either: i) RT performed to momentary muscular failure versus non-failure, ii) RT performed to set failure (defined as anything other than the definition of momentary muscular failure) versus non-failure, and iii) RT performed to different velocity loss thresholds.
CONCLUSION: A major limitation of the current literature is not only that there is not a consensus definition of set failure, but many studies fail to explicitly state the definition of set failure applied. As a result, each study including in this scoping review was grouped into one of the three themes to improve the validity of study comparisons and interpretations within each theme. Further, in many of the studies reviewed, the proximity-to-failure achieved by participants in non-failure conditions was unclear and likely subject to within- and between-study variability, influencing the absolute difference in proximities-to-failure being compared and thus affecting study findings. Nonetheless, current research suggests that performing RT to set failure is likely not superior to non-failure RT to maximise muscle hypertrophy, but the optimal proximity to failure for muscle hypertrophy remains unclear, and may be moderated by other RT variables. Performing RT to set failure also induces greater neuromuscular fatigue and muscle damage (lasting up to 48-hours post-RT), and greater post-set perceived discomfort than non-failure RT. Increasing the time-course for recovery of neuromuscular function post-RT could limit the volume and/or frequency of subsequent RT, and higher ratings of perceived discomfort may negatively influence long-term adherence to RT, both of which may negatively impact long-term muscle hypertrophy responses.

### CAN THE MINIMUM TOE CLEARANCE DURING WALKING BE USED AS AN INDICATOR OF MOTOR PERFORMANCE FATIGUE IN MULTIPLE SCLEROSIS?

BROSCHEID, K.C., BEHRENS, M., BILGIN-EGNER, P., PETERS, A., DETTMERS, C., JÖBGES, M., SCHEGA, L.

*OTTO VON GUERICKE UNIVERSITY MAGDEBURG*

INTRODUCTION: Fatigue is one of the most limiting symptoms in people with Multiple Sclerosis (pwMS). So far, no gold standard for the assessment of motor performance fatigue (the temporary decline in motor performance) in pwMS exists. The majority of studies assessing motor performance fatigue in pwMS used single muscle or muscle group performance tests, while only a few studies employed whole-body exercises such as walking. The latter is important because of its relevance for activities of daily life. Most walking test procedures were based on the 6-min walk test (6MWT) and referred to changes in walking speed as primary outcome. However, there are conflicting results regarding the suitability of the 6MWT and walking speed as the primary outcome to assess motor performance fatigue in pwMS. Therefore, we investigated not only 'classical' spatio-temporal gait parameters during the 6MWT, but also the minimum toe clearance (MTC), whose decreasing variability has been interpreted as a sign of motor performance fatigue.
METHODS: Twenty mildly to moderately affected pwMS (12 females/7 males; 47.8 ± 9.0 years; expanded disability status scale: 2.7 ± 1.0) and 24 healthy controls (15 females/9 males; 48.8 ± 7.6 years) completed the 6MWT equipped with inertial measurement units. The 6MWT was performed on a circular quite corridor at the clinic with a length of 34 m. The subjects should walk as fast as possible but safely and were accompanied by a physiotherapist. Data was analyzed using the attractor method to compare stability of gait parameters and spatio-temporal gait parameters including the MTC were calculated.
RESULTS: Motor performance fatigue could not be detected based on spatio-temporal gait parameters including the MTC during the 6MWT in both groups. Descriptive analysis indicated a decrease in MTC variability towards the end of the 6MWT in some pwMS, which is assumed to be indicative for motor performance fatigue.
CONCLUSION: Surprisingly, we found little evidence for statistically significant and uniform motor performance fatigue in all pwMS. Therefore, future studies should investigate motor performance fatigue during more intense and/or longer walking protocols adjusted to the level of disability in pwMS.

## OP-AP06 Strength testing

### THE EFFECT OF FLYWHEEL INERTIA ON PEAK POWER AND ITS INTER-SESSION RELIABILITY DURING TWO UNILATERAL HAMSTRING EXERCISES: LEG CURL AND HIP EXTENSION

DE KEIJZER, K.L., MCERLAIN-NAYLOR, S.A., BEATO, M.

*UNIVERSITY OF SUFFOLK*

INTRODUCTION: It is of interest to better understand how different unilateral flywheel hamstring exercises respond to changes in moments of inertia for developing training management and prescription. The aim of the study was to determine the impact of different flywheel moments of inertia (0.029, 0.061, and 0.089 kg·m2) during unilateral flywheel leg curl and hip extension on concentric and eccentric peak power and eccentric:concentric peak power ratio.
METHODS: A cross-sectional design was employed, whereby twenty amateur male soccer athletes attended five visits – performing three sets of eight repetitions of either unilateral flywheel leg curl or hip extension exercise (all three inertias) per visit. Repeated measures analysis of variance (ANOVA) were employed to measure potential within condition (flywheel moment of inertia) differences for the unilateral leg curl and hip extension. Paired-samples t-tests were applied to analyse differences between concentric and eccentric peak power outcomes.
RESULTS: No differences existed between inertias ($p = 0.479$) but higher eccentric than concentric power was present for all inertias during leg curl ($p < 0.001$). Differences between inertias were reported for all measures during hip extension ($p \leq 0.002$). Specifically, 0.029 kg·m2 elicited the greatest concentric power ($p = 0.022$), no differences for 0.061 kg·m2 ($p = 0.391$), and 0.089 kg·m2 elicited the highest eccentric peak power ($p = 0.036$). Peak power measures obtained acceptable to excellent reliability while eccentric:concentric ratio reported unacceptable to good reliability.
CONCLUSION: Although the eccentric:concentric ratio should not be utilized for monitoring training outcomes, peak power measures should be utilised. Specifically, leg curl reliability varied from acceptable to good while hip extension reliability excellent. Moments of inertia impact two unilateral flywheel hamstring exercise outcomes differently with the same population. Even though similar peak power measures were seen between moments of inertia during the leg curl exercise, higher moments of inertia obtained higher peak power outputs. The moment of inertia-power relationship between the two exercises may differ due to biomechanical differences between the exercises. Such differences must be accounted for during training preparation and periodisation. Individualization of moment of inertia may be warranted to optimize peak power.

### A ROBOT FOR CLIMBING SPECIFIC FINGER STRENGTH TRAINING AND ASSESSMENT WITH REDUCTION OF SHOULDER LOAD

WOLF, P., DI PIETRO, T., BÉGUELIN, A., MEIER, S., WILHELM, E., WITTMANN, F.

*ETH ZURICH*

INTRODUCTION: Climbing performance is strongly correlated with finger flexor strength (1). To train and assess finger strength, climbers commonly hang on a board which creates high loads on the shoulder. Accordingly, climbers who suffer from shoulder injuries, which are quite common among them, need to reduce or cease finger training. We developed a robot that creates forces on the fingers via a linear actuator (2). The counter force is in part created by a palm rest. The aim of this study was to estimate shoulder load reduction and correlate assessments with those performed during hanging to prove the robot's validity.
METHODS: A common wooden rung (depth of 23mm) was mounted on an actuated plate (up to 1000N pull force). Load cells measured forces applied on the rung and palm rest at 1kHz, sent to a PC for logging and visualization.
In Hangboard condition, the plate was fixed, palm rest was removed, the robot was mounted vertically, with the rung at above-head-height. Participants were standing and shifted their weight from their feet to the hold by bending knees. Ten experienced climbers performed maximum voluntary contractions (MVC) and intermittent contractions (INT) with visual feedback.
For the MVC assessment in Robot condition, climbers had to maintain their initial finger position (three fingers, open hand), while the robot attempted to move away from the initial position at 280mm/s. Once a deviation of 3mm to the initial position was reached, the robot stopped. In Hangboard condition, climbers had to smoothly increase the load on the hold until the largest force they could exert. INT was performed at 40% of MVC, with ten 7s contractions followed by 13s rest each. Each session started with a warm-up, followed by MVC assessment, with three consecutive repetitions for both conditions, with 3min rest. After another 10min rest, INT was performed once in each condition, with 10min rests in between.
In the Robot condition, the shoulder force was estimated as difference between measured finger force and palm rest force.
RESULTS: MVC in Robot and Hangboard condition were strongly correlated ($R2 = 0.63$, $p < 0.05$). For INT, median RMSE between desired and applied force was higher in Robot condition (median 14%, range 7% to 20%) than in Hangboard condition (median 10%, range 7% to 12%), but difference was not significant ($p = 0.21$). In Robot condition, the shoulder load was reduced by 31% to 99% (median 78%) for MVC and 41% and 97% (median 61%) for INT.
CONCLUSION: Assessment and training, as traditionally performed with a hangboard, can be performed with our robot, leading to comparable results for MVC and similar deviation from the desired force during INT. Shoulder load reduction varied drastically suggesting that proper utilization of the palm rest is important and can allow for a near complete reduction of shoulder load.

## DATA ACQUISITION FOR STRENGTH-ENDURANCE PROFILES: COMPARING SINGLE-VISIT TO MULTIPLE-VISIT PROTOCOLS

MITTER, B., RAIDL, P., CSAPO, R., BAUER, P., TSCHAN, H.

*UNIVERSITY OF VIENNA, ISW SCHMELZ*

INTRODUCTION: The modeling of “strength-endurance profiles”, which express the individual relationship between load and repetitions to momentary failure (RTF) in a resistance training exercise, recently started to draw interest in sport science. Respective models provide substantial value for practitioners as a descriptive tool to analyze exercise-specific strength endurance, or as a prescriptive tool to guide the programming of resistance training with respect to the intended level of effort. Recently, individual strength-endurance profiles were shown to yield higher predictive accuracy compared to models that generalize the relationship across individuals. However, their computation depends on the availability of unbiased data from sets performed to momentary failure at different loads. The present study applied a randomized crossover design to compare two different approaches of data acquisition: an economic single-visit (SV) protocol and a multiple-visit (MV) protocol.
METHODS: Ten resistance-trained men (age: 24.2 ± 1.5 y, body mass: 85.2 ± 9.3 kg, bench press 1-RM relative to body mass: 1.49 ± 0.23 kg·kg-1) visited the laboratory on five occasions. On day 1, participants completed a one-repetition maximum (1-RM) test in the barbell bench press. On day 2 through 5, they were tested for the RTF they could complete at 70%, 80% and 90% of their 1-RM, once in the form of a SV protocol (i.e., all loads being tested in the same session with extended rest intervals in between) and once following a MV approach (i.e., loads being distributed across three sessions). Stratified randomization was applied to account for different sequences of tests. A Bayesian mixed effects model with weakly informative priors was calculated, using RTF as dependent variable and adjusting for load and test sequence as moderator variables. Posterior distributions were interpreted according to their means and 90% Highest Density Intervals (HDI).
RESULTS: Analysis revealed a substantial main effect and moderator effect for load, but not for test sequence. There was a high probability for the MV protocol to result in a larger number of RTF compared to the SV protocol at 70% 1-RM (mean [90% HDI] = 1.9 repetitions [0.9, 2.9]) and 80% 1-RM (0.8 repetitions [0.1, 1.5]), but not at 90% 1-RM (-0.3 repetitions [-1.3, 0.7]). The applied model yielded an adjusted $R^2$ of 0.78 [0.74, 0.82].
CONCLUSION: It could be assumed that the SV protocol resulted in the accumulation of fatigue across the tested loads, therefore reducing the maximum number of attainable repetitions at lighter loads. To avoid systematic bias during the assessment of individual strength-endurance profiles, practitioners should consider splitting the required sets to momentary failure across multiple training days close to each other, allowing athletes to perform under rested conditions.

## “ASSOCIATIONS BETWEEN ISOLATED LUMBAR EXTENSION STRENGTH MEASURED WITH A NOVEL EXERCISE DEVICE AND TRUNK EXTENSION ENDURANCE IN HEALTHY SUBJECTS”

DOMOKOS, B., ETTINGER, J., RASCHKA, C., SPANG, C.

*PRAXIS DR. ALFEN*

INTRODUCTION: Increasing evidence shows that optimal function of the deep M. multifidus is required for spinal health [1]. Thus, accurate functional assessment of this lumbar extensor muscle becomes more important in clinical practice. Measures such as the trunk extension endurance (TEX) test and the isometric, isolated lumbar extension strength (ILEX) measurement are ways to assess lumbo-pelvic functional capacity [2]. However, there is now an updated, digitally supported ILEX device allowing for a more accurate, segmental assessment. Therefore, the aim of this study is to reevaluate the use of ILEX in relationship to TEX with this novel exercise device and to give suggestions for appropriate assessment in clinical settings.
METHODS: 15 male and 15 female healthy subjects (BMI: 23,02 ±2,34) participated in this cross-sectional study. A modified version of the Biering-Sorensen test was used to measure TEX endurance. A maximal isometric ILEX strength test was performed using a novel device (Powerspine Back) allowing for standardized adjustments to the L4 lumbar spine segment pivot point by the use of a laser and a finely adaptable sitting height. A strength test was performed in six angles from 0° (extension) to 60° (flexion).
RESULTS: A Pearson’s correlation revealed only one significant moderate correlation in 12° (r = -0,378, p = 0,040) between TEX endurance and ILEX strength with no significant results in other angles (0°: r = -0,286, p = 0,125; 24°: r = -0,336, p = 0,070; 36°: r = -0,336, p = 0,069; 48°: r = -0,316, p = 0,097, 60°: r = -0,309, p = 0,089). TEX endurance correlates negatively with BMI (r= -0,456, p=0,011), while ILEX isometric strength (measured in angle 48°) showed a strong positive correlation with BMI (r = 0,556, p = 0,001).
CONCLUSION: The results of this study show that ILEX and TEX are not necessarily associated even though there is a trend. In contrast, BMI is a major influencing factor for both measures. This finding underlines that both ILEX and TEX provide important information for clinical practice and are relevant depending on whether a more focused segmental assessment or a more global assessment of the trunk and the hip extensors is of interest [2]. The features of the novel device offer many opportunities for further investigations at different segmental levels and/or with low back pain patients.

## OP-AP04 Swimming II

### OPTICAL HEART RATE MONITORING IN COMPETITIVE SWIMMING – AN AGREEMENT STUDY

GOEBE, L.M.1, SCHNEIDER, C.1, TOERPEL, A.2, FERRAUTI, A.1

*1 RUHR UNIVERSITY BOCHUM , 2 GERMAN SWIMMING FEDERATION*

INTRODUCTION: In many sports, heart rate (HR) monitoring is used to quantify internal training load and to control and steer exercise intensity [1]. In swimming, the standard method of ECG-based HR recording is error-prone, as chest straps may slip during swimming and wall push-offs, especially when no swim suit is worn. The optical HR sensor Verity Sense (VS) by Polar may overcome the practical limitations of chest straps due to fixation on the swimming goggles. In this study [2], we evaluate the agreement between the VS and Polar H10 chest strap sensors during swimming.
METHODS: 36 competitive swimmers (12-31 yrs) were equipped with VS and H10 HR sensors during regular swimming practice (various intensities, rest periods, swimming styles and drills). The VS and H10 were worn as recommended by Polar, at the right temple and at the chest covered by a swim suit. Agreement between HR data series (stored with 1 HR value per second and manually synchronised for optimal overlap) was analysed at the individual level using Bland-Altman analysis [3]. Group summaries are presented as medians (interquartile ranges). In addition, qualitative analyses were performed by visual inspection of individual Bland-Altman plots and HR time series to identify potential sources of training content-related measurement error.
RESULTS: First analyses included datasets with 3199-9139 data pairs per athlete. The median standard deviation of differences (SDdiff) between sensors was 5.4bpm (interquartile range 4.2, 7.3) with median 95% limits of agreement from -10bpm (-15.4, -7.8) to 10bpm (8, 13.7). The median bias of the VS was -0.2bpm (-0.8, 0.1) compared to the H10. Intra-individual results varied substantially between swimmers with agreement ranging from excellent to unacceptable (95% limits of agreement minimum -4 to 4bpm, maximum -28 to 18bpm). Visual analysis indicated that larger errors tend to be present at low to moderate HR values, e.g. typically during rest periods or at the start and end of exercise sets.
CONCLUSION: Our preliminary analyses revealed an acceptable median agreement of the VS during regular swimming practice (SDdiff interquartile range ≤7bpm), with a substantial variability in results between swimmers. Qualitative analyses further indicated that a notable proportion of the observed errors occurred during specific exercise or rest periods. In summary, optical HR monitoring using the VS represents a practical alternative to the error-prone use of chest strap sensors (when used without a swim suit) for monitoring internal load and controlling exercise intensity in swimming. Nevertheless, users must be aware that measurement error can be unacceptably high in some athletes or during specific training periods, calling for familiarisation and an evaluation of whether the measured values are physiologically plausible.

### HOW MUCH STRENGTH THE YOUNG COMPETITIVE SWIMMERS ARE ABLE TO TRANSFER FROM DRY LAND TO WATER? A PILOT STUDY

SANTOS, C.C.1, MARINHO, D.A.1, COSTA, M.J.2

*1 UNIVERSITY OF BEIRA INTERIOR, CIDESD, COVILHÃ, PORTUGAL; 2 UNIVERSITY OF PORTO, CIFI2D, PORTO, PORTUGAL*

INTRODUCTION: Propulsive force plays a major role in the swimming performance being produced mainly by the upper limbs through the shoulder internal rotation (IR). While the shoulder rotators´ strength has been widely investigated in young competitive swimmers, the propulsive force mechanism retained little attention (1). Moreover, to our best knowledge, there is not any study aimed to quantify the relative force transfer (RFT) from land to in-water actions. Thus, the aim of this study was to analyze the RFT from land to water in young swimmers at the front-crawl stroke.
METHODS: Eleven young swimmers, eight boys and three girls (12.00±0.60 years, 49.95±7.19 kg, 156.41±8.26 cm of height and 263±56.78 FINA POINTS in 50-m freestyle short course), were recruited at the beginning of the competitive season. Dry land strength variables were measured with a digital handheld dynamometer (microFET®2, Hoggan Scientific, USA) allowing to retrieve the isometric peak strength of shoulder internal rotator (in Newton, N) for the dominant (IRD) and non-dominant (IRND) upper limbs. All swimmers underwent a 10-min warm-up, followed-up by a familiarization set (one set of two submaximal and one maximal repetition by each limb). Subsequently, the data were collected from two maximal IR repetitions, as described elsewhere (2). The highest value was considered for further analysis. The in-water propulsive force (N) at a 25-m front crawl (maximal bout) was measured with a differential pressure system (Aquanex 4.1, STR, USA) and values for the dominant (PFD) and non-dominant (PFND) upper limbs were retrieved as previously reported (3). The RFT (in %) was calculated for both limbs as: RFTD = [(100*PFD)/(IRD)]; RFTND = [(100*PFND)/(IRND)]. The paired sample t-test was used to compare the upper limbs in all variables.
RESULTS: Dry land strength was significantly higher when compared to in-water propulsive force in dominant (IRD: 92.55±20.88 N, PFD: 38.65±7.33 N; $p<0.01$) and non-dominant (IRND: 87.60±23.02 N, PFND, 37.16±6.16 N; $p<0.01$) upper limbs. No differences were found when comparing upper limbs at the same environment. The RFT on water based on dry-land assessment was 43.58±12.19 % and 44.30±11.15 % for the dominant and non-dominant upper limbs, respectively
CONCLUSION: Young competitive swimmers seem able to transfer approximately 44% of their maximum strength from land to the water during front crawl actions. The current results provide a first clue about the strength level that young swimmers could apply in water by considering the dry land assessment. Despite both upper limbs eliciting similar strength, the swimming coaches should be aware of the hypothetical muscle imbalances that could impair the force transfer and, therefore, swimming performance.

**THE EFFECTS OF WARMING-UP USING AN UNDERWATER PARACHUTE ON 50-M FREESTYLE SWIMMING PERFORMANCE**

LIMA, L.C.R., BUFALO, S.S., BENAZZI, G.R., BASSAN, N.M., BARRETO, R.V., DENADAI, B.S., GRECO, C.C.

*SALESIAN UNIVERSITY CENTER OF SÃO PAULO*

INTRODUCTION: Post-activation performance enhancement (PAPE) is a phenomenon that occurs when explosive efforts are potentiated in response to warm-up routines consisting of near-maximal efforts such as resistance exercises and/or powerful actions. Several studies have investigated different warm-up interventions aiming to potentiate swimming performance, with most of them requiring methods and materials that are not easily adaptable to training/competition settings. The aim of our study was to investigate the effectiveness of an ecologically valid warm-up routine consisting of parachute-resisted sprints in improving 50-m freestyle performance in trained swimmers.
METHODS: Twelve trained swimmers (23.9±2.2 years, 179±7 cm, 77.1±10.6 kg) volunteered to participate in this study. They performed two bouts of swimming at the same day separated by 40 minutes of recovery, in a randomized order. The warm-up routines performed prior to 50-m freestyle swims consisted of 500 m of swimming at a self-selected velocity followed by two minutes of resting interval and four maximal 10-second sprints separated by 1-minute rest intervals. During the experimental (EXP) warm-up, the participants performed the sprints using hand paddles and a swimming parachute attached to their waists while during the control (CON) warm-up, sprints were performed freely. Six minutes following each warm-up routine, participants swam a simulated 50-m freestyle race in a 25-m swimming pool. Mean stroke frequency and length, and propulsive time were determined during each 25-m lap of the swim by under- and overwater filming, and 25- and 50-m time partials were calculated. Student's t tests for paired samples were used to screen for significant ($p<0.05$) differences between conditions.
RESULTS: No significant differences in 25- and 50-m times (CON: 12.6±0.8 s vs EXP: 12.5±0.8 s; and CON: 26.8±1.6 s vs EXP: 26.7±1.7 s, respectively) were observed between conditions. Mean stroke length (CON: 1.84±0.26 m·cycle-1 vs EXP: 1.81±0.25 m·cycle-1), stroke frequency (CON: 0.92±0.09 cycles·s-1 vs EXP: 0.94±0.09 cycles·s-1), and propulsive time (CON: 0.62±0.07 s vs EXP: 0.61±0.06 s) were also not different between the investigated conditions.
CONCLUSION: The addition of external load conferred by wearing a swimming parachute and hand paddles during the experimental warm-up routine did not result in enhanced 50-m freestyle swimming performance in the present study. It is possible that the stress imposed by the four unresisted sprints performed at the CON warm-up is enough to induce the priming effects that result in PAPE. It is also possible that the additional resistance imposed during EXP sprints might have primed the athletes further while also inducing greater amounts of fatigue, which culminated in negligible effects on swimming performance. We conclude that performing parachute-resisted sprints during warm-up does not enhance 50-m freestyle swimming performance in experienced swimmers.

**REDUCED VENTILATION DURING UNDERWATER FIN-SWIMMING IN HYPEROXIA**

JACOBI, E.1, MÖLLER, F.1,2, HOFFMANN, U.1, VOGT, T.2

*GERMAN SPORTS UNIVERSITY COLOGNE, COLOGNE, GERMANY*

INTRODUCTION: Normobaric hyperoxia reduces ventilation (V'E), heart rate (HR), and whole blood lactate [Lac-] during exercise depending on intensity and modality (1). The effect might be allocated to an elevated arterial oxygen partial pressure ($PaO_2$), enhancing muscular diffusion and reducing local $O_2$ deficits (2,3). In turn, anaerobic metabolism and respiratory acidosis might be delayed (4). These laboratory results become practically relevant in SCUBA-diving, where an increased ambient pressure creates hyperoxic conditions with normal air. 40% $O_2$, equal to 56 kPa inspiratory oxygen pressure ($PIO_2$) at 4m depth, reduces V'E during high-intensity fin-swimming compared to air (29 kPa, 4m) (5). However, higher $PIO_2$ is common in SCUBA diving and we hypothesize deviating effects for transient exercise intervals (TI) and steady-state intervals (SSI) which have to be distinguished for applied scenarios. All effects on V'E are highly relevant for dives with limited gas supply.
METHODS: 15 healthy (5 female; 28±6.2 age), physically fit participants performed an underwater incremental step test at 4m depth, determining resting and maximum values for HR and [Lac-] (6). Subsequently, 8 min each of low (LOW), moderate (MOD), and vigorous (VIG) exercise intensity were conducted on 3 separate days differing solely by the breathing gas (21%, 40%, 100% $O_2$). V'E, HR, and velocity (v) were recorded continuously and [Lac-] sampled post-exercise. ANOVAs with repeated measures were performed on the factors gas and intensity for v, V'E for TI (min 2-3) and SSI (min 6-7), and max [Lac-].
RESULTS: Significant main effects were found for V'E at TI and SSI for gas, intensity, and a gas*intensity interaction (TI: all $P\leq0.003$; $\eta2p\geq0.258$; SSI: all $P\leq0.014$; $\eta2p\geq0.274$). V'E was significantly lower for 100% and 40% compared to air (TI: all $P\leq0.021$; SSI: all $P\leq0.029$). [Lac-] and v significantly differed between intensities but were unaffected by gas.
CONCLUSION: A sufficient $PaO_2$ supply to the working muscle with air is assumed during LOW, explaining no beneficial effect of increased $PIO_2$. Significant reductions in V'E with $PIO_2$ of 56 kPa and 140 kPa (100% $O_2$, 4m) during TI and SSI for MOD and VIG compared to air might reduce V'E. However, missing reductions from 56 kPa to 140 kPa indicate that $PIO_2$ >56 kPa might not benefit oxidative processes any further. Since [Lac-] and v were not influenced by gas, increased $O_2$ capacity at muscle level might be compensated by an increased sport-specific movement in the attempt to swim faster, whereby water resistance can no longer be overcome after a certain point. Otherwise, it is to speculate whether this increased exercise attempt takes advantage of the increased $O_2$ capacity resulting in similar V'E and [Lac-] values to 56 kPa $PIO_2$ rather than increasing them. Any possible [Lac-] delay effect at TI was reversed with duration.

### ANALYSIS OF AERODYNAMIC FORCES ACTING ON A SKI JUMPER FROM TAKEOFF TO LANDING USING COMPUTATIONAL FLUID DYNAMICS

YAMAMOTO, K.

*HOKUSHO UNIVERSITY*

INTRODUCTION: In biomechanical studies of ski jumping, the sequence of jumping movements is often divided into six phases: inrun, takeoff, initial flight, stable flight, preparation for landing, and landing. Each phase has a unique function to maximize the flight distance. It is also believed that the performance in one phase depends on the previous phase (Schwameder, 2008). The purpose of this study was to construct an aerodynamic analysis system that can consider the body shape and movements of individual athletes, and to build a framework that can analyze the aerodynamic characteristics in a series of ski jumping movements.
METHODS: For motion measurements, we used an IMU sensor-based motion capture suit. At the same time, we measured the flight trajectory of the ski jumper by collecting position information using a GNSS sensor. Next, we measured the three-dimensional morphology of the ski jumper and the ski using a laser scanner. A 3DCG animation was created by superimposing the joint angles obtained from the motion measurements on to the 3D geometry of the athlete. Then, the unsteady aerodynamic force acting on the ski jumper with skis was calculated from takeoff to landing phase using Computational Fluid Dynamics (CFD). In this study, a hierarchical Cartesian meshing technique known as Building Cube Method (BCM, Nakahashi, 2001) was adopted for generating the computational grid. In this method, the computational domain is divided into cubic regions called Cubes, and each Cube is further divided into equally spaced regions called Cells. Due to the adoption of BCM for mesh generation and an immersed boundary method for geometry treatment the preprocessing time is very short. This method has high computational efficiency in parallel computation and can reduce the time to solution. In this study, CUBE, which was jointly developed by Kobe University and RIKEN, was used as the fluid analysis software (Jansson et al., 2019). The finite volume method was used to discretize the basic equations (the continuity equation and the Navier-Stokes equations). The QUICK scheme was used to discretize the convective term, and the second-order accurate central difference was used to discretize the viscous term. For the direction and velocity of the airflow, the translational speed of the ski jumper was obtained from the change in positional coordinates obtained from the GNSS sensor, and a uniform flow that changed with time was specified as the inflow boundary condition in the computational domain.
RESULTS: Thereafter, the drag force was found to decrease and then to increase gradually during the flight phase. The lift force, on the other hand, did not decrease as much as the drag force after early flight. And the lift force was found to increase gradually in the flight phase.
CONCLUSION: We have succeeded in analyzing the airflow conditions around the jumper and the changes in aerodynamic characteristics during a series of ski jumping movements.

### EFFECT OF SPEED ON LOWER EXTREMITY COORDINATION IN CROSS-COUNTRY SKIING: A VECTOR CODING APPROACH WITH DOUBLE POLING TECHNIQUE

ZHAO, S., LINNAMO, V.

*NEUROMUSCULAR RESEARCH CENTER*

INTRODUCTION: The vector coding method (VCM) is commonly used in biomechanics to quantify the inter-segmental coordination and joint coupling coordination1. The coordination of several activities in sports have been investigated by the VCM, and the coordination variability can be related e.g. to the skill level and injury status. The aims of this study were to quantify the lower extremity coordination in double poling (DP) technique in cross-country skiing by using VCM and to investigate the effect of skiing speed on lower extremity coordination.
METHODS: 9 experienced male skiers (Age:28.2±7.4 years, Height: 181.3±6.1 cm, Weight: 77.5±9.3 kg) participated in this study. DP technique was performed on treadmill with 13, 15, 17, 19 and 21km/h. Vicon system (Vicon, Oxford, UK) was used to record the three-dimensional trajectories of reflective markers and joint coordination was calculated for hip and knee, knee and ankle (all flexion/extension). The coordination was classified into four patterns: In-phase (joints couples rotate in the same direction), antiphase (joint couples rotate in opposite directions), distal phase (distal joint rotates exclusively), and proximal phase (the proximal rotates exclusively). For each portion of skiing cycle (poling and recovering phase), the pattern frequency of each coordination pattern was determined.
RESULTS: During poling phase a higher anti-phase and knee coordination pattern than other patterns were found in hip-knee couple and in knee-ankle couple. The anti-phase coordination pattern frequency at 17 km/h was significantly lower than that at 13km/h in hip-knee couple ($p<0.05$) and the ankle coordination pattern frequency at 21km/h was lower than that at 13km/h ($p=0.022$) in knee-ankle couple. During the recovery phase a higher anti-phase and a higher knee coordination pattern than other patterns were found in hip-knee couple and knee-ankle couple. The anti-phase coordination pattern frequency at 19km/h was higher than that at 15km/h in hip-knee couple ($p<0.05$) and the in-phase coordination patter frequency at 21km/h was lower than that at 13km/h ($p=0.022$) in knee-ankle couple.
CONCLUSION: Although some differences were observed the coordination was generally stable in the range of speeds used in this study. The pattern of coordination was continuously changing and could not be categorized into one single coordination pattern. Whether the coordinate pattern can be related to skiing performance, skiing economy and skiing injury need further investigation.

## ON-FIELD BIOMECHANICAL ASSESSMENT OF HIGH AND LOW DIVING IN COMPETITIVE GOALKEEPERS' THROUGH WEARABLE SENSORS AND PRINCIPAL COMPONENT ANALYSIS

DI PAOLO, S., SANTILLOZZI, F., ZINNO, R., BARONE, G., BRAGONZONI, L.

*UNIVERSITY OF BOLOGNA: UNIVERSITA DI BOLOGNA*

INTRODUCTION: Diving saves are the most important tasks of football goalkeepers. Effective trainings of diving skills are fundamental in football academies to improve goalkeepers' saving performance. In particular, the assessment of preferred (PS) and non-preferred (nPS) side differences is critical to improve trainings. Few biomechanical investigations have been proposed in this field, and none was conducted in a sport-specific environment.
The purpose of the present study was to investigate the underlying relevant motion characteristics of goalkeepers' dive in relation to their PS and nPS. It was hypothesized that lower limb and trunk kinematical differences would exist in frontal and transverse plane between PS and nPS.
METHODS: Nineteen young competitive goalkeepers (16.5 ± 3.0 years, Tegner Level 9) were enrolled. Every participant performed a series of high and low dives on their preferred and non-preferred side. The dives were performed in a regular football goal on a natural grass football pitch. Full-body kinematics (ankle, knee, hip, pelvis, trunk, shoulder, elbow, wrist joints) was collected through a set of 17 wearable inertial sensors (Awinda, Xsens). Data were normalized from the initial contact of the contralateral foot to the end of the dive [1]. Diving time was compared among the dive height and side (two-way ANOVA). Two separate principal component analyses (PCA) on high and low dives were conducted to reduce kinematic data dimensionality (input matrix 19 participants x 101 data points x 6 trials x 8 angles x 3 axes). The PCA scores were extracted for each kinematic variable and compared between PS and nPS side (Student's t-test with Cohen's d effect size) if the relative explained variability was >5% [1].
RESULTS: Dive timing differed between high and low dives ($p<0.003$, $\eta p^2> 0.041$) but did not differ between PS and nPS ($p>0.05$, $\eta p^2<0.007$). In high dive, participants exhibited greater hip internal rotation ($p=0.008$, ES=0.52) and less trunk lateral tilt ($p=0.047$, ES=0.39) in PS compared to nPS. In low dives, participants exhibited less hip adduction and knee rotation, and greater pelvis and trunk rotation in the initial diving phase in PS ($p<0.037$, ES 0.40-0.57) compared to nPS
CONCLUSION: When diving on their nPS, goalkeepers adopted sub-optimal motion pattern with delayed pelvis and trunk rotation and limited explosiveness towards the diving direction (hip external rotation and adduction). This is in line with current literature highlighting the need to improve horizontal and lateral skills in diving [2-3]. The differences were more evident in the low dives. The present study was the first to investigate academies goalkeepers' biomechanics in a sport-specific environment adopting an innovative approach with wearable sensors plus PCA dimensionality reduction. Such an analysis might be useful to goalkeepers' coaches to define the dominant differences in diving motion between PS and nPS and improve training effectiveness

## VIDEO ANALYSIS METHOD FOR EXTRACTING THE DEPENDENCE OF MOVEMENT BETWEEN BODY PARTS IN BASEBALL HITTING FORM USING TRANSFER ENTROPY

TANAKA, T.1, FUJIWARA, M.2, GOUDA, N.2

*1 2 HITACHI, LTD.*

INTRODUCTION: Sports analytics using IT is introduced actively into competitive sports. In baseball, training efficiency is expected to be improved through data analysis for amateur baseball players. However, it has not been widely used in the past due to the need for special equipment and device for measurement and the difficulty of data interpretation. Therefore, to create an environment where amateur athletes can easily measure their own condition and practice trial and error based on the data, we propose a method to visualize the characteristics of their form from videos taken with smartphones in an easy-to-understand manner.
METHODS: We developed a video analysis method to extract the dependence of movement between body parts in baseball form. Our developed method recognizes the positional coordinates of the skeleton from only videos of athletes captured by a smartphone, quantifies the dependence of the movements between body parts using transfer entropy[1], and visualizes the relationships as a network of directed graphs. This method applies the technique of analyzing the network of a group of players[2]. Data for evaluation was obtained from one amateur baseball player. Ten each of normal toss batting and tee batting, in which the player worked on improvement, were performed and captured on video for analysis. To improve his hitting form in the tee batting, he worked on stabilizing his lower body and strengthening his upper body rotation. In the evaluation, we hypothesized trends in the data for the points of improvement that the player was aware of and made statistical comparisons for each of them. The significance level for statistical evaluation was set at 0.05.
RESULTS: Stabilization of the lower body in the hitting form significantly reduced the variability of transfer entropy in all body parts and also significantly reduced the transfer entropy starting from the lower body part. In addition, enhanced upper body rotation resulted in a significant increase in transfer entropy from the elbow to the wrist. The results were consistent with the hypothesis in terms of players awareness of improvement. This evaluation confirmed that the players themselves intuitively understood and noticed the effects of their improvement effort.
CONCLUSION: As a result of interviews with players, it was evaluated that it was easy to intuitively understand the changes before and after the improvement. Toward the development of data analysis technology for widespread use in amateur baseball, we have concluded that the proposed method is easy for players to understand the characteristics of their own form and that it can contribute to improving the efficiency of training for more players than ever before through the accumulation of future data and the verification of many hypotheses.

## OP-BM18 Motor learning and visual processing

### ARE CORTICAL BIOMARKERS OF VISUAL PROCESSING DURING THE MOTOR PREPARATION PHASE RELATED TO PERFORMANCE ON A COMPLEX MOTOR-COGNITIVE ATHLETIC TASK?

PESKAR, M.1,2, GIESCHE, F.3, MILADINOVIĆ, A.1,4, MARUSIC, U.1,5

*SCIENCE AND RESEARCH CENTRE KOPER*

2 Biological Psychology and Neuroergonomics, Technische Universität Berlin, Germany; 3 Institute of Occupational, Social and Environmental Medicine, University of Frankfurt, Germany; 4 Institute for Maternal and Child Health Burlo Garofolo (IRCCS), Trieste, Italy; 5 Department of Health Sciences, Alma Mater Europaea – ECM, Maribor, Slovenia

Studies have demonstrated the relationship between cognitive measures and reaction times (RT) in a jumping and/or cutting task (Wilke et al., 2020). Also, attention is thought to influence both cognitive and motor task performance (Kida et al., 2017). However, it is not known whether cortical electrophysiological markers of event-related potentials (ERP; the P1, N1, and P2 components) recorded at the time of elevated attentiveness to the upcoming motor task show association with the drop-cutting task performance. This pilot study investigated the relationships between cognitive test performance, drop-cut performance, and ERP components.

Ten healthy males aged 29.5 ± 8.61 years performed 64 drops to a force plate from a 60 cm high platform followed by a cut jump to one of 4 predetermined directions (equidistant, covering frontal 120°, positioned at 150% of leg length distance). The motor preparation cue (blue light activation) signaled a self-paced take-off from the platform, which triggered a yellow light stimulus in one of the 4 jumping directions. A successful trial deactivated the yellow light sensors (the foot landed ≤ 30 cm away) and a single-leg stance was maintained for an additional 2 s. Drop-cut RTs (time between deactivations of blue and yellow sensors; [ms]) and contact times (from landing until jumping to a direction; [ms]) were investigated. Mobile electroencephalography (EEG) was recorded and ERPs time-locked to the blue light activation were extracted from the Oz. The amplitude [mV] and latency [ms] of the P1, N1, and P2 components were examined. Cognition was assessed on sensorimotor speed (simple and choice RT; sRT and cRT; [ms]), and executive function (Trail-Making Test; TMT-A and TMT-B; [s]). The relationship between variables was inspected by correlation analyses.

On average, 73% (± 11.7) of drop-cuts were performed successfully; mean RT was 883 (± 91.8) ms. We observed a relationship between cRT and contact time ($r = .654$, $p = .040$), and P2 latency and TMT-A ($r = .648$, $p = .043$).

The co-occurrence of slower sensorimotor speed and longer contact times could indicate a prolonged decision-making process regarding the execution of the correct motor command. In addition, our data seem to indicate that during attentive states, the effectiveness of executive function and the speed of visual search relate to the latency of the cortical potential at the second positive peak – the visual P2 component. The lack of relationship between ERPs and motor performance might indicate that task-relevant cognitive processing occurs at a later stage during task execution.

### HOW CORTICAL BIOMARKERS OF VISUAL PROCESSING PREDICT LOWER-LIMB VISUOMOTOR RESPONSE PERFORMANCE IN HEALTHY MEN

MARUSIC, U.1,2, PESKAR, M.1, GIESCHE, F.3

*1 SCIENCE AND RESEARCH CENTRE KOPER, SLOVENIA; 2 ALMA MATER EUROPAEA – ECM, MARIBOR, SLOVENIA; 3 GOETHE UNIVERSITY FRANKFURT, GERMANY*

INTRODUCTION: In interceptive sports, executing rapid motor responses to visual stimuli is critical for performance and injury prevention (Wilkerson et al. 2012). While visuomotor response tests provide a general assessment of task performance, the underlying neural mechanisms remain unclear. The primary aim of this pilot study was to investigate how cortical biomarkers of visual perception and processing measured with mobile electroencephalography (EEG) predict lower limb reaction time (RT) performance.

METHODS: Ten healthy men (age: 30±9 years) performed a simple (n=100) and a choice RT task (n=100) with their lower limb in a standing position. Four FitLight sensors (FitLight Trainer™) were equidistantly positioned in front of the participants in semicircular order. For simple RT task, the participants were responding only to a single sensor at each position (n=25). For choice RT task, a random sequence (n=25 each) was used. To measure the accuracy of FitLight the RTs were compared with those calculated from photodiod sensors (gold standard) attached to the FithLight sensors and connected to a Triggerbox. A custom-made pipeline was used for EEG pre-processing and extraction of RTs, and visual evoked potential (VEP) components (P1, N1, and P3; Oz electrode). Paired sample t-test was used to compare simple and choice RTs. The intraclass correlation coefficient (ICC) was calculated to test the reliability of FitLight. Multiple stepwise regression analyses were applied to test the predictive value of ERPs for both RTs.

RESULTS: Mean lower-limb simple RT (482 ms) was significantly shorter ($p<0.001$) than choice RT (561 ms; Triggerbox data). Although the ICC comparing both systems indicated high reliability for both RTs (ICC=0.992, $p<0.001$), mean RTs were significantly shorter for FitLight ($p<0.001$). Simple RT was significantly predicted by P3 amplitude ($p=0.001$) and N1 latency ($p=0.010$) that explained 81% of variance. Choice RT was significantly predicted by P3 latency ($p=0.004$) and explained 63% of variance.

CONCLUSION: Our results show that detection of VEPs associated with lower limb RT tasks is feasible and demonstrate the crucial role of visual processing in reactive motor performance, highlighting the potential of visual training. This could help not only younger athletes who want to improve performance and avoid injuries, but also older adults in whom slowing lower limb RT has been associated with falls (Neville et al., 2020). Future trials examining VEPs in more motor-cognitively demanding tasks are warranted.

**INTENSITY EFFECT OF NEUROMUSCULAR ELECTRICAL STIMULATION COMBINED WITH MOTOR IMAGERY ON CORTICOSPINAL EXCITABILITY**

EON, P., GROSPRETRE, S., MARTIN, A.

*UNIVERSITY OF FRANCHE-COMTÉ*

INTRODUCTION: Neuromuscular electrical stimulation (NMES) consists of evoking muscle contraction by an external electrical current without voluntary activation. On the contrary, motor imagery (MI) is the mental simulation of contraction without its corresponding motor output. Some studies analyzed the impact of MI and NMES on corticospinal excitability highlighted by the motor evoked potential (MEP). The authors reported that MI and NMES performed alone increased the MEP compared to rest (2,3) as well as the combination of both compared to one or the other modality alone (1, 2). However, the intensity of NMES may alter the corticospinal excitability (2). For instance, Saito et al. (2013) showed that the corticospinal excitability was increased only with NMES applied above the motor threshold compared to MI alone. Therefore, these results question the impact of the intensity of NMES on corticospinal excitability when combined with MI. The purpose of the present study is to assess corticospinal excitability during either MI, NMES, or a combination of both at different stimulation intensities of NMES.
METHODS: In this pilot experiment, seven healthy subjects (age: 27.7 ± 5.3) participated in one session consisting of 6 conditions targeting flexor carpi radialis muscle (FCR): rest, MI, NMES evoked at 5 % and 20 % maximal voluntary contraction (MVC) and MI and NMES performed simultaneously (MI+NMES) with both NMES intensities. During each condition, corticospinal excitability was assessed by evoking MEP of FCR by using transcranial magnetic stimulation. Maximal M-wave (Mmax) was measured by using nerve stimulation of the median nerve. The evoked force has been measured as the force-time integral (FTI) during each condition.
RESULTS: Preliminary results showed no significant differences on FTI between NMES and MI+NMES for both 5 % and 20 % MVC. A repeated measures ANOVA revealed a main effect among conditions ($P = 0.01$). We found a significant difference on MEP/Mmax at rest compared to NMES and MI+NMES at 20 % MVC ($P < 0.007$). Furthermore, a two-way ANOVA (condition [NMES, MI+NMES] x intensity [5 %, 20 %]) revealed an intensity effect ($P = 0.04$). The post hoc analysis showed a higher MEP/Mmax during NMES and MI+NMES at both 20 % compared to 5 % MVC.
CONCLUSION: The additional effect of MI on MEP/Mmax may occur with NMES at 20 % rather than 5%. This suggests that a sufficient muscle activation is required to improve the cortical command from MI and enhance the activation of both cortical and subcortical structures. Therefore, the combination of MI and NMES could result in improvement of the corticospinal excitability of FCR.

**CORTICOMOTOR PLASTICITY UNDERLYING THE PRIMING EFFECTS OF MOTOR IMAGERY ON STRENGTH PERFORMANCE**

DOS ANJOS, T., DI RIENZO, F., GUILLOT, A.

*INTER-UNIVERSITY LABORATORY OF HUMAN MOVEMENT*

INTRODUCTION: Neural plasticity is capacity of neurons to reorganize their connectivity in response to cognitive and behavioral demands. Neural plasticity allows short-term modulations of strength through improved cortical gain over motor units. There is now convincing evidence that covert motor strategies such as motor imagery (MI) and action observation (AO) contribute to limit strength loss and prevent maladaptive plasticity [1][2][3]. The main objective of this study is to extend current understandings of the neurophysiological processes underlying strength gains as a result of embedded MI or AO within strength training sessions.
METHODS: In a counterbalanced design involving three experimental conditions (AO, MI, Control) we recorded the total force, the integrated electromyograms of agonist and antagonist muscles (biceps brachii, triceps brachii and anterior deltoideus) and the ongoing electrical brain activity in 20 participants who performed 10 maximal isometric contractions of elbow flexor muscles against a force platform (10 s duration). During the one-minute inter-trial rest periods, participants then randomly performed: i) AO of the same strength task performed by an expert athlete, ii) MI of the task using first-person visual and kinesthetic imagery, and iii) AO of a video documentary about basketball shooting (Control).
RESULTS: The linear mixed effect analysis carried on total force data revealed a CONDITION x MUSCLE interaction ($p= 0.0384$). Irrespective of the trial number, total force values were higher during MI compared to the Control condition ($p= 0.005$). Electromyograms showed a reduced relationship between triceps brachii activity and total force during MI. Also, the relationship between agonist electromyograms and the total force was greater during MI. Eventually, corticomotor connectivity, indexed from coherence between electric brain potentials and the electromyograms of the agonists within the alpha frequency range (8-12 Hz), was greater during MI compared to AO and Control. The topographical distribution of corticomotor connectivity values emphasized sensors located within the central and pre-central regions.
CONCLUSION: Present findings provide new insights to the neurophysiological processes underlying strength gains in response to motor stimulation. The data showed improved strength performance only when MI was performed during the inter-trial recovery periods of strength training sessions. Topographical patterns of corticomotor connectivity provide evidence, for the first time, of the effect of MI training on corticomotor plasticity. Short-term corticomotor plasticity might thus represent an important underlying mechanism to the priming effects of mental training on strength performance.

**CAN TALENTED PLAYERS IMITATE MOVEMENT EXECUTIONS OF A SIDESTEP CUTTING TASK SHOWN BY AN EXPERT?**

NIJMEIJER, E.M., KEMPE, M., ELFERINK-GEMSER, M.T., OTTEN, B., BENJAMINSE, A.

*UNIVERSITY MEDICAL CENTER GRONINGEN*

INTRODUCTION: Unfortunately, current prevention programs do not result in a decrease of ACL injuries in the long term[1]. Observational learning is considered as powerful to promote implicit motor learning[2]. Implicit motor learning is effective in learning complex motor skills[3]. While video instruction is a common tool in practice, little is known about to what extent athletes are able to imitate movement executions shown on video. The aim of this study was to examine if subjects were able to imitate optimal and suboptimal sidestep cutting movement execution of an expert.
METHODS: Frontal and sagittal plane videos of an expert performing a 45° sidestep cut (SSC) were obtained prior to the study. This expert was part of a Regional Talent Centre (RTC) and was selected by coaches and deemed to have excellent motor skills. We demonstrated the imposed optimal (OPT) and suboptimal (SUBOPT) executions using previously reported figures[4] and verbal instructions. OPT and SUBOPT videos were selected based on variables previously shown to be related to ACL injury risk (e.g. knee flexion angle, frontal knee moment and vertical ground reaction force (vGRF)). Ten basketball players (age 15.5±1.2 y, height 189.9±3.1 cm, mass 75.4±7.1 kg) from the same RTC performed SSC trials in baseline followed by two counterbalanced experimental conditions (each 10 trials). Subjects watched the expert videos (matched by sex, height and mass) of OPT and SUBOPT movement executions and were asked to imitate this to the best of their

ability. One-sample t-tests with Statistical Parametric Mapping were performed to examine to which extent the subjects were able to copy the movement execution of the expert (OPT and SUBOPT). Nine variables were examined; sagittal angles and moments of hip, knee and ankle, frontal moments of hip and knee, and vGRF over the entire stance phase (SP) (from first contact till toe-off).
RESULTS: Regarding the OPT condition, subjects showed significantly smaller ankle dorsiflexion angles (p<.001, 0-94% SP), smaller knee flexion angles (p<.001, 0-83% SP) and larger vGRF (p<.001, 0-19% SP) compared to the expert. Significant differences in the SUBOPT were only found for small time frames; smaller ankle dorsiflexion angles (p=.013, 0-10% SP) and larger vGRF (p=.013, 0-8% SP; p=.029, 13-17% SP) in the subjects compared to the expert.
CONCLUSION: In general, the subjects were able to partly imitate movement execution of the expert, especially for the hip and knee moments, but not for ankle placement and vGRF. Furthermore, subjects were better able to imitate the SUBOPT compared to the OPT condition (e.g. knee flexion angle). This study indicates that imitation from video works to change movement execution. Further research should focus on additional instructions (e.g verbal) or feedback methods (e.g. timing of feedback or self-modeling) to increase the effects of observational learning.

### OP-MH14 Body composition

#### DOES AN OBESOGENIC FAMILY ENVIRONMENT MODERATE THE ASSOCIATION BETWEEN SPORTS PARTICIPATION AND BODY COMPOSITION IN CHILDREN? THE ENERGY PROJECT

STAVNSBO, M., STENLING, A., HANSEN, B.H., BERNTSEN, S., WESTERGREN, T., TORSTVEIT, M.T., MANIOS, Y., MOLNÁR, D., VICENTE-RODRÍGUEZ, G., VERLOIGNE, M., CHINAPAW, M.J.M., BERE, E.

*UNIVERSITY OF AGDER*

INTRODUCTION: Obesity among children is a global public health concern. Organized sports participation is an important venue for promoting recommended levels of moderate-to-vigorous physical activity (1), thereby contributing for healthy weight maintenance among children. However, the literature on the association between sports participation and body composition is overall mixed (2). Concurrently, the family home is considered one of the most influential environments on childhood obesity (3). Thus, the association between sports participation and body composition in children might depend on the degree of the obesogenic home environment. The aim of this study was therefore to investigate if an obesogenic family environment moderates the association between organized sports participation and body composition in children.
METHODS: A total of N= 3999 children (11.6 y (SD 0.6), 54% girls) and their parent(s) were included from the ENERGY project. Data on an obesogenic family environment, organized sports participation, and demographic characteristics were obtained by child and parent questionnaires. Ten items related to the PA, food, and media environment in the family were dichotomized and summed up into a composite obesogenic family environment risk score with scores between 0 (low risk) and 9 (high risk). Body mass index (BMI) and waist circumference (WC) were obtained by trained researchers. Path analyses were used to investigate moderation by the obesogenic family risk score on the association between sports participation and body composition, taking school clustering and country into consideration.
RESULTS: A higher composite obesogenic family environment risk score was associated with higher WC (1.11, 95% CI 0.97 to 1.25) and BMI (0.36, 95% CI 0.31 to 0.41). The obesogenic family environment risk score significantly moderated the association between sports participation and both WC and BMI. In children from families with moderate and high obesogenic family environment risk, organized sports participation was significantly associated with lower WC (moderate: -0.29, 95% CI -0.45 to -0.14; high: -0.46, 95% CI -0.66 to -0.25) and BMI (moderate: -0.10, 95% CI -0.16 to -0.04; high: -0.14, 95% CI -0.22 to -0.06), but not in children from a low obesogenic family environment.
CONCLUSION: Enrolling children in sport activities from an early age may be important for a healthy weight maintenance, especially among children from obesogenic family environments.

#### RELATIONSHIPS BETWEEN HEALTH-RELATED PHYSICAL FITNESS, BODY MASS INDEX, AND ACADEMIC ACHIEVEMENT OF MIDDLE SCHOOL STUDENTS QATAR

HERMASSI, S., KETELHUT, S., AL-MARRI, S., KONUKMAN, F., EL GHALI, B., NIGG, C.R.

*QATAR UNIVERSITY*

INTRODUCTION: Physical inactivity is a growing public health and educational concern1. Empirical studies have reported that health-related physical fitness (PF) aids not only children's physical and mental health but also their academic achievement2. This study aimed to investigate associations between academic achievement, body mass index (BMI), and physical fitness status, including aerobic and muscular fitness in adolescent middle school students in Qatar State.
METHODS: Fifty-one males (age: 13.0 ± 0.81 years; body mass: 68.3 ± 17.0 kg; height: 1.63 ± 0.10 m; BMI: 25.2 ± 3.98 kg/m2) were recruited from a school in a Doha Community (Qatar). Different anthropometric measurements (height, mass, and BMI) and physical performance tests (Stork test of static balance; 10 and 15 m sprint; Handgrip Strength Test; agility T-half test; medicine ball throw (MBT)) were performed. Aerobic capacity was evaluated using the Yo-Yo Intermittent Recovery Test level 1 (Yo-Yo IR1). Academic achievement was assessed through school records of grades point average (GPA) in Mathematics, Science, and Arabic.

RESULTS: Between academic and physical performance parameters, we detected the most relevant (r>0.5) correlation coefficients for mathematics. The relations ranged between r = 0.502 (sprint 15 m) and r = 0.691 (Yo-Yo IR1 test). Science was correlated with the Agility T-half test (r = 0.543), and Arabic showed a relevant correlation to the Yo-Yo IR1 test (r = 0.558). The BMI was only related to mathematics (r=-0.675). Three physical performance parameters (sprint 10 m, stork balance test, handgrip strength) did not show any relation to academic performance. Between BMI and science (r = -0.419) and Arabic (r = -0.406) the interactions were considerably lower.
CONCLUSION: Our results suggest that students with high PF levels were more likely to have a high GPA compared to those with low PF levels. Based on these findings, we suggest that interventions aiming to improve PF, such as aerobic exercise and muscular exercise, may have implications not only for health but also for academic success. Therefore, students should be encouraged to engage in regular physical activity. Furthermore, an innovative physical activity curriculum including yoga, fitness, walking, and dance should be implemented in schools.

**FAT-TO-MUSCLE RATIO: EXPLORING ASSOCIATIONS WITH MOTOR COMPETENCE AND PHYSICAL FITNESS IN 7-YEAR-OLD CHILDREN FROM A SEX PERSPECTIVE**

FONT-LLADÓ, R.1,2, LÓPEZ-ROS, V.1,2,3, SINCLAIR, G.1, VASILEVA, F.1, CAZORLA, J.1, SERRANO, J.1, PRATS-PUIG, A.1,4
*UNIVERSITY OF GIONA*

INTRODUCTION: The negative effects of an excessive fat mass on physical fitness (PF) and motor competence (MC) parameters are well known considering body mass index (BMI), the skin-folds, and waist circumference (WC) in children (1). However, less attention has been paid to the role of muscle mass in combination with fat mass in these relations (2). Fat-to-muscle ratio (FMR) is the ratio of fat mass, to muscle mass, and is being used to assess metabolic syndrome and cardiovascular diseases (3) in adults. The objectives are: 1) to explore the association between body composition (FMR, WC and BMI) with MC and PF in 7-year-old children from a sex perspective; 2) to ascertain whether FMR modifies the associations between MC and FF depending on sex. 3) to explain, in boys and girls, the role of fat mass and muscle mass in PF.
METHODS: A total of 171 children (7yr; 84♂, 87♀) were included. Anthropometric (BMI, WC, and FMR -fat and muscle mass were calculated with TANITA), MC (CAMSA test), and PF (the sum of z-scores: 1/2 mile run, handgrip strength, 10x5, standing long jump, and sit and reach tests) variables were collected.
RESULTS: There were no significant differences in WC and BMI, while there was a significant difference in FMR between 7-year-old boys and girls (p=0.008). It also showed stronger and negative associations with motor competence (p<0.0001) and physical fitness index (p<0.0001) than WC and BMI. Sex (p<0.0001), MC (p<0.0001) and FMR (p<0.0001) were independent predictors of PF, explaining together 41.8% of its variability. However, in girls, only MC (p<0.0001) explained 24.9 % of PF variability. While the association between MC and PF was strongest and positive in children with low FMR (p<0.0001), this association is not present in boys with low FMR. Furthermore, only in girls with low FMR, was fat mass (p=0.001) an independent predictor of PF, which, taken together with MC (p<0.0001) and muscle mass (p=0.013), explains a variability of 58,2 %.
CONCLUSION: Studying the relation between FMR and MC improves the assessment of PF in children considering sex. Moreover, children with low FMR have higher MC and PF, and have shown a stronger association between MC and PF than children with high FMR. Further studies are needed to consider the interrelation between fat and muscle mass and the role of skeletal muscle performance, rather than fat mass reduction, in improvements in MC, PF, and body composition in 7-year-old children, especially in girls.

**IS BODY COMPOSITION ASSOCIATED WITH PHYSICAL FUNCTION IN OLDER MEN?**

FOSSTVEIT, S.H., LINDBERG, K., BJØRNSEN, T., SIBAYAN, E.E., FJELLER, J.S., LØVOLD, S., KOLNES, T., VÅRVIK, F.T., BERNTSEN, S., LOHNE-SEILER, H.
*UNIVERSITY OF AGDER*

INTRODUCTION: In a study by Orssatto et al.1, total body fat was negatively associated with physical function (Timed-up-and-go, Stair ascent, and Stair descent) in older adults but not for total lean mass. Many studies have focused on associations at baseline; however, fewer studies have examined associations between training-induced changes. Therefore, the objective of the present study was to investigate the associations between body composition and physical function at baseline and with training-induced changes in these variables in older men.
METHODS: Forty-nine older men (67.7±5.3yrs, 83.4±10.5kg, mean±SD) completed a 10-weeks biweekly power training intervention. Body composition was measured by Dual-energy X-ray absorptiometry. Physical function was assessed as a composite Z-score combining measures from Sit-to-stand power (MuscleLab force plate), Timed-up-and-go time, as well as loaded and unloaded Stair climbing time (15 steps). Linear and quadratic regression analyses were performed to determine associations between body composition and physical function.
RESULTS: At baseline, total lean mass was positively associated with Sit-to-stand power (R2=0.32 B=34.7 [19.3; 50.1], p<0.05), but not with physical function (p>0.05). Total fat mass (R2=0.11, F(2, 45) = 3.92, p<0.05) and body composition expressed as percentage fat mass (R2=0.15, F(2, 45) = 5.26, p<0.01) had a significant quadratic relationship with physical function. The apex of the quadratic regression for body composition was at 21.5% fat mass. Total lean mass (1.3±2.1, p<0.020), Timed-up-and-go time (-1.6±4.9, p<0.017), unloaded Stair climbing time (-5.2±6.6, p<0.001), and loaded Stair climbing time (-4.4±6.1, p<0.01) all improved after the training intervention. Furthermore, there was a significant association between changes in body composition (percentage fat mass) and physical function from pre- to post-intervention (R2=0.15, F(2, 45) = 4.94, p<0.05).
CONCLUSION: The present studys findings indicate that total lean mass is positively associated with Sit-to-stand power, while total fat mass and body composition were associated with physical function in older men at baseline. Furthermore, changes in body composition were

associated with changes in physical function. In accordance with previous research, body composition in older subjects follow a non-linear relationship with physical function.2 Neither excessive nor low levels of body fat seem to be beneficial for physical function in older subjects. In the present study, subjects with a body composition of ~20% fat mass displayed the highest level of physical function. Randomised controlled trials with larger sample sizes, more extended intervention periods, and exercising- non-exercising control groups are needed to examine how body composition variables may influence physical function in older adults.

**BODY COMPOSITION AND LEVEL OF PHYSICAL ACTIVITY OF MIDDLE - AGED PRIMARY SCHOOL TEACHERS**

UVACSEK, M., TÖRÖK, L., BODA-UJLAKY, J.

*UNIVERSITY OF PHYSICAL EDUCATION*

INTRODUCTION: In Hungary, about 77, 000 people work as teachers in primary school. Generally, stressful work negatively affects health and can increase the risk of cardiovascular and metabolic diseases. Teachers health status is often assessed using questionnaires (Seibt et al.2011), and as a result, there is a lack of research using objective measures of body composition and information about the level of physical activity. To collect data about body composition and daily physical activity of middle - aged primary school teachers and to compare some results to the EHIS study results reported in 2019.
METHODS: 102 subjects (mean age: 50.5±6.5 years.) were recruited from different primary schools using the snowball research method. Data collected included body mass index (BMI), body composition (BF%), and information of a health behaviour questionnaire assessing level and frequency of physical activity (WHO 2010). The participants involved were over 35 years of age and had more than ten years' experience as primary school teachers. Descriptive statistical analysis and Chi square tests were used with SPSS Statistics program version 22.
RESULTS: The mean BMI was 26.3±5.1 and BF% was 28.8±5.5 in teachers, 36% were overweight and 19%was obese. According to the questionnaire, 8% was physically active every day, 27% reached the recommended 5 MVPA per week. The frequency of 45% was reported to engage the recommended 150 minutes moderate physical activity per week, and 60% reported participating in different activities. The most popular forms of activities were running, gymnastics and cycling. Compared to data from the European Health Interview Survey (EHIS) teachers in this study were less active (45% vs. 61%) and were the same overweight and obese (55%vs. 54%) as Hungarian women in the general population.
CONCLUSION: According to the results, health-related concepts and physical activity promotion programs for teachers would be essential to prevent the deterioration of their health.

### OP-SH10 Social equality and sustainability

**THE POLICY OF THE INTERNATIONAL OLYMPIC COMMITTEE ON GENDER EQUALITY IN OLYMPIC SPORT**

VOROBIOVA, A.1,2, KELLER, M.2, VASYLENKO, M.1

*1 NATIONAL UNIVERSITY OF UKRAINE ON PHYSICAL EDUCATION AND SPORT; 2 UNIVERSITY OF BASEL*

INTRODUCTION: With the revival of the Olympic Games (OG) in 1896, the IOC opposed allowing women to compete. However, over time, women were admitted to competitions due to socio-cultural influences (including strong influence of feminist organizations) [1]. Nowadays the OG have become one of the biggest global platforms for advancing gender equality in sport (after launching the Gender Equality Review Project in 2017) [2], but some current developments need to be critically discussed. The aim of this study was to discuss the impact of IOC policies on the development of womens sports in the world and the problems that arise in this regard.
METHODS: All data from the Gender equality & inclusion report of the IOC [2] were analysed.
RESULTS: By the 2020 OG in Tokyo, some of the planned actions of the Gender Equality Review Project have already been implemented. In fact, women made up 48% of athletes, 13% of coaches, 38% of international technical officials, 20% of chefs de mission, 38% of IOC members, 33% of the IOC Executive Board, 37% of IOC commission chairs, and 48% of IOC commission members. The increasing number of female athletes can be explained mainly by the introduction of womens competitions in traditional male sports. That leads to active development of such sports for women around the world and could lead to significant problems with their health and social adaptation in future.
For the first time, the IOC has faced the problem of admitting transgender athletes to the OG, and the debate over the issue of hyperandrogenism in sport continues.
CONCLUSION: The IOC is committed to ensuring gender equality by 2024, not just among athletes, but also among coaches, support staff, staff and management of the IOC, NOCs, and sports federations. However, IOC should consider firstly the medical-biological, social and aesthetic aspects of sport, values of the ideals of Olympism [3].
The IOC therefore needs to consider three main aspects: i) to develop traditional womens competitions (at the moment only 2 female sports: artistic swimming and rhythmic gymnastics with 2 medals events each) instead of introducing more events for women in traditionally mens competitions (e.g. 5 medal events in female boxing); ii) to pay attention to threats for the health of female athletes and their subsequent adaptation; iii) to develop recommendations for the athletes with hyperandrogenism and transgender athletes to make competitive conditions equal for all women. In general, the IOC is facing the difficult task of ensuring women's rights and the need to eliminate discrimination while respecting the principles and ideals of the Olympic Movement.

**UNDERREPRESENTATION OF WOMEN IN SPORTS COACHING. A SOCIOCULTURAL ANALYSIS.**

ELIASSON, I.

*UMEÅ UNIVERSITY*

Despite numerous interventions for equality between women and men in sports, the number of women sport coaches has not increased. Even though women's participation in sports and qualification for coaching has increased, the representation of women in sports coaching has rather declined (La Voi, 2014). That said, scholars have recently argued that the underrepresentation of women in the coaching role is a cultural problem related to male dominance, rather than related to women's personal qualification deficits (Knoppers, de Haan, Norman & LaVoi, 2021; Kane, 2016). Thus, the overall aim of this study was to explore coaches' perceptions and understandings of the underrepresentation of women as coaches within organized sports in Sweden and what action is required to facilitate future involvement of women coaches. Data were gathered through semi-structured focus group interviews with 16 floorball coaches, 8 women and 8 men. The results show how sociocultural patterns of interactions, behaviour and perceptions related to the gender of coaches do influence the women's opportunities, difficulties or choices to become a floorball coach and how the male norm is maintained. Furthermore, the study highlights how both women and men find it easier for a man to become and act as a coach in a male-dominated leadership culture.

**COMPREHENSIBLE AND MEANINGFUL, BUT COMPLEX TO MANAGE. SWEDISH SPORT FEDERATIONS' WORK WITH ENVIRONMENTAL SUSTAINABILITY**

LARNEBY, M., RADMANN, J., HEDENBORG, S.

*MALMO UNIVERSITY*

Sport impact the environment and climate through consumption of natural resources, non-renewable resources, production of garment, gear and clothes, and greenhouse emissions (McCullough et al., 2017). Awareness of the environmental issue in relation to climate and a sustainable world is not sufficient. A bigger responsibility and demand is put on sport and its organizations and actors. In Sweden, different sport impact the environment in different ways, due to for instance geographical location, being an indoor or outdoor sport, and different regulations to execute the sport. Of relevance for this study is that sport federations' change to a more sustainable sector is dependent on people's engagement, knowledge and motivation. The aim of this study was to increase knowledge about Swedish sport federations' work with environmental sustainability. The theoretical framework consists of SWOT-analysis and Antonovsky's sense of coherence. The Swedish sport confederation (SEF) and 16 of its affiliated sport federations (SF) were included in the study. The 16 SF websites were analyzed and 10 sustainability coordinators were interviewed. The main results show that many SF recognize the importance of environmental sustainability since climate changes impact possibilities to train and compete (for instance, skiing and access to snow). Most SF have policies and check lists related to environment and to act more sustainable. Still, in many SF the issue of environmental sustainability is not definitely established on the agenda, in some cases due to lack of resources such as time and economy, in others due to a lack of holistic commitment. Transportation and emissions is identified as the main problem, due to the fact that sport's goal (train and compete to strive for achievement) disrupts the environmental sustainability goals. The sense of coherence related to work with environmental sustainability is uneven in most SF. All show adequate levels of comprehensibility and they draw their work mainly on knowledge based on natural sciences. However, different types of knowledge, for instance pedagogical, psychological and historical, is needed to increase awareness of attitudes and behavioral change. The aspect of manageability is more complex, as some SF does not seem to work with the issue as a natural part of its organization. Of importance, though, is that all SF show an established meaningfulness. In conclusion, the 16 SF have initiated a work towards a more environmentally sustainable sport organization, but the issue needs to be established at their agendas. Although national guidelines and policies are provided by SEF, its affiliated SF ask for a clearer governance from either the sport confederation or the government.

**TOWARDS MORE SUSTAINABLE SPORTS – AN ANALYSIS OF ADOLESCENTS' TRANSPORTATION HABITS TO SOCCER PRACTICE IN SOUTHERN NORWAY**

BERE, E.1,2, LAXDAL, A.1, JOHANSEN, B.T.1, SOLSTAD, B.E.1,3

*<1> UNIVERSITY OF AGDER, <2> NORWEGIAN INSTITUTE OF PUBLIC HEALTH, <3> NORWEGIAN INSTITUTE OF SPORT SCIENCES*

INTRODUCTION: Mitigating climate change is a great global challenge demanding efforts from all sectors, and sports are no exception. While transportation is one of the key issues regarding sustainable sports, the methods by which children and adolescents get to practice has not received much attention. Therefore, the objectives of this study were (1) to present how adolescents in Southern Norway travel to soccer practice and (2) to assess how mode of transportation is related to sex, socioeconomic status, age, and distance from home to practice.

METHODS: Cross-sectional data were collected from 558 adolescent soccer players (398 boys and 190 girls) from Southern Norway using a self-reported electronic questionnaire. The participants were 13-19 years old (M =15.7 SD =1.4) and came from 30 different clubs from settlements of varying rurality. The data was analyzed using a logistic regression analysis.

Results: The majority of adolescents opted for passive transportation to practice; 39% by car, 11% by moped/motorbike, 3% by bus and 2% by electric scooter, in total 55%. A total of 45% opted for active transport; 29% by bike, 9% by e-bike, and 8% by foot. Most of the participants lived within cycling distance; 27% within 2 km, 67% within 4 km and 91% within 10 km. A logistic regression analysis found the odds of opting for passive transport to practice to increase with traveling distance (OR was 6.5, 25.0 and 224.9 respectively for those living 2-4, 4-10 and more than 10 km away compared to those living less than 2 km away) and age (OR was 1.4, 1.6, 3.1 and 3.9 respectively for 15, 16, 17 and 18-19 year-olds vs 13-14 year-olds). Sex and socioeconomic status were not significantly associated with mode of transportation from home to practice.

Conclusion: A minority of adolescent soccer players in Southern Norway reported active modes of transportation to soccer practice. While traveling distance and age were associated with active transportation habits, sex and socioeconomic status were not. Further research is needed to examine the main barriers to active travel for this already active population, as active transport represents an opportunity for sports to become more sustainable.

### OP-MH19 Children: Cardiorespiratory fitness

#### THE ASSOCIATION BETWEEN CARDIORESPIRATORY FITNESS AND CLUSTERED CARDIOMETABOLIC DISEASE RISK AMONG ADOLESCENTS FROM SAUDI ARABIA: A CROSS-SECTIONAL STUDY

ALKHRAIJI, M.

*UNIVERSITY OF EXETER*

INTRODUCTION: Cardiometabolic disease risk factors (CMRF) start from early childhood which track into adulthood and predict future CVD burden in adulthood. Cardiorespiratory fitness (CRF) has been shown to be inversely associated with CMRF among adolescents from Europe and the United States of America. The first study in Saudi Arabia was in 1993 that examined the associations between CMRF and CRF among 63 boys 7-12 year old, with a mean VO2max = 48.4 ± 6.0 ml. kg-1. min-1. This study found weak associations between CMRF and CRF. However, since 1993 no study has examined the associations between CMRF and CRF among adolescents of both sexes from Saudi Arabia. Therefore, the aim of this cross-sectional study was to examine the association between CRF and clustered CMRF score in adolescents from Saudi Arabia.
METHODS: Data collection took place in 2019 on a sample of 109 adolescents (males= 53, and females= 56) who were randomly selected from eight schools in Riyadh city, stratified for location (mean age 13.6 ± 1.1 year, stature 154.5 ± 7.5 cm, body mass 53.9 ± 14.9 kg). The PACER 20 metre shuttle run test was used to estimate adolescents CRF, and laps were converted to VO2max using the FitnessGram predicted VO2max equation (VO2max = 45.619 + (0.353 * PACER laps) − (1.121 * age). In addition, males and females were classified as having a healthy CRF if their VO2max ≥42 and ≥35 ml. kg-1. min-1 for male and female adolescents, respectively. CMRF score was calculated using sex-specific z-scores summed from waist circumference, mean arterial blood pressure, fasting HDL cholesterol, LDL cholesterol, triglycerides, and glucose (Lipids and glucose were estimated using CardioChek PA analyser). Participants were also categorised at risk if their CMRF score was >1 SD. Statistical analysis was conducted using linear regression with adjustment of covariates (age, stature, region, and dietary score computed from fruit, vegetables, drink milk or eat milk products, and carbonated soft drinks intake).
RESULTS: Males mean VO2max= 37.9 ± 4.2 ml. kg-1. min-1 and females VO2max= 35± 2 ml. kg-1. min-1, with significant difference between sexes (P= <0.001). Moreover, VO2max of few males n= 8 (15.1%) and almost half of females n= 26 (46.4%) were above the healthy CRF cut-points, with significant difference between sexes (P= <0.001). In addition, males n= 18 (34%) and females n= 21 (37.5%) were at risk of CMRF score >1 SD, with significant difference between sexes (P= <0.001). Linear regression indicated that CRF in both sexes were not associated with CMRF score in males (β= -0.115, P= 0.158) or females (β= -0.133, P= 0.619) after adjustment for confounders.
CONCLUSION: Few males and nearly half of females Saudi adolescents CRF is above the healthy VO2max cut-points, although this does not seem to be associated with CMRF score.

#### THE ASSOCIATION OF CARDIORESPIRATORY FITNESS AND GRAY MATTER VOLUME IN COGNITIVELY NORMAL OLDER ADULTS: A CROSS-SECTIONAL STUDY FROM THE AGUEDA TRIAL

TOVAL, A.1, SOLIS-URRA, P.1, MORA-GONZALEZ, J.1, COCA-PULIDO, A.1, BELLÓN, D.1, TRIVIÑO-IBAÑEZ, E.M.2, BUSTAMANTE-ARA, N.3, STILLMAN, C.4, ORTEGA, F.1, ERICKSON, K.I.1,4, ESTEBAN-CORNEJO, I.1

*1. UNIVERSITY OF GRANADA; 2. VIRGEN DE LAS NIEVES UNIVERSITY HOSPITAL; 3. PONTIFICIA UNIVERSIDAD CATÓLICA DE CHILE; 4. UNIVERSITY OF PITTSBURGH*

INTRODUCTION: Aging is associated with changes in brain structure which, in turn, leads to a decline in brain function and cognition. Fortunately, emerging evidence has shown that this deterioration process may be avoidable. In this sense, cardiorespiratory fitness is a well-known marker of health across the lifespan, and in addition, it has recently been associated with improvements in various cognitive functions. However, evidence of the relationship between cardiorespiratory fitness and brain structure in this sensitive population (older people) is still scarce. In the present study, we examined the association between cardiorespiratory fitness and gray matter volume in cognitively normal older adults.
METHODS: A cross-sectional study involving 84 cognitively normal older adults (65 to 80 years old; 59.5% women) from the AGUEDA trial was carried out. We assessed cardiorespiratory fitness using the 6-minute walking test and the 2-kilometer walking test, and total completion distance and time were registered, respectively. For the 2-kilometer test, longer time indicates poorer performance, so the variable was inverted (multiplied by -1) so that higher scores indicate better performance in both cardiorespiratory fitness tests. Gray matter volume was determined by magnetic resonance imaging, using voxel based morphometric analysis. General linear models were performed to determinate the association between cardiorespiratory fitness and gray matter volume, adjusting by sex, age, and years of education. AlphaSim spatial extent threshold and Hayasaka correction were applied.
RESULTS: Results from whole-brain volumetric analysis showed that cardiorespiratory fitness, measured by the 6-minute test, was not positively or negatively associated with gray matter volume in any region of the brain. No brain regions showed a significant positive association with the 2-kilometer test. Conversely, better performance in the 2-kilometer test was negatively associated ($p<0.001$) with gray matter volume in solely one cluster corresponding to thalamus region ($k=113$, $t=-3.6$).
CONCLUSION: Higher cardiorespiratory fitness, measured by the 6-minute walking test and the 2-kilometer walking test, is not associated with higher gray matter volume in cognitively normal older adults. However, a solely and unexpected association was found between better performance in the 2-kilometer walking test and lower gray matter volume in the thalamus. Future exercise-based randomized controlled trials should examine whether exercise-induced changes in cardiorespiratory fitness may influence gray matter volume in this population.

**COMPARISON OF 12-WEEK POLARIZED TRAINING VS. HIGH INTENSITY INTERVAL TRAINING ON CARDIORESPIRATORY FITNESS, BODY COMPOSITION AND FAT METABOLISM IN OBESE ADULTS.**

D´ALLEVA, M.

*UNIVERSITY OF UDINE*

INTRODUCTION: The positive effects of High Intensity Interval Training (HIIT) and Moderate Intensity Continuous Training (MICT) on peak O2 uptake (V'O2peak) and body composition are well documented in obese adults (1). The combination of HIIT and MICT, called Polarized Training (POL), induces greater improvements in body composition, and maximal oxygen uptake (V'O2max) in well-trained athletes compared to HIIT or MICT alone (2,3). However, POL has never been applied in adult males with obesity. Thus, the purposes of this study were to investigate changes in body composition, physical capacities and fat oxidation, induced by a 12-week either POL or HIIT program in obese male adults under their normal living conditions
METHODS: Thirty-four male patients (mean age 39 y; mean body mass index [BMI] 33 kg·m−2) participated in this study (n: 18 POL, n: 16 HIIT), attending ~ 36 sessions of training, supervised online by researchers. At baseline (PRE) and at the end of the training period (POST) body composition, V'O2peak, and fat oxidation rates were measured. The POL group performed ~45min of training per session, while HIIT group performed ~33min of training per session. The two training programs were iso-caloric. A two-way repeated measures ANOVA was performed to detect differences in means on endpoints. Significant main effects were followed-up by Šídák post-hoc procedures. Significance was set at P<0.05.
RESULTS: At POST, body mass (BM) decreased by -3% (P < 0.05) in a similar way for POL (PRE: 106.6±10.8, POST: 104.0±16.0 kg, P= 0.004) and HIIT (PRE: 103.8 ± 9.3, POST: 100.2 ±9.6 kg, P= 0.001) groups, as well fat mass (FM) decreased by -9% (P < 0.05) in both groups POL (PRE: 43.6±10.2, POST: 40.1±10.2 kg, P= 0.001) and HIIT (PRE: 38.1±4.7, POST: 34.2±4.7 kg, P= 0.001). V'O2peak increased in both groups by 16% (P < 0.05), POL (PRE: 2.95±0.43, POST: 3.42±0.40 L min-1, P< 0.001) and HIIT (PRE: 3.12±0.45, POST: 3.58±0.52 L min-1, P< 0.001). Fat oxidation rates increased in POL (P<0.001) and HIIT (P=0.009) without differences between groups at all exercise intensities (P=0.984). Exercise intensity corresponding to maximal fat oxidation (MFO), expressed as a percentage of V'O2peak, increased in a similar manner in both groups (by 6±7%, P= 0.006), without group effect (P=0.430).
CONCLUSION: POL and HIIT were equally effective in improving V'O2peak, body composition and fat oxidation in obese subjects. At the same time, POL training proved to be less intense and more tolerable than HIIT. The results of this study could provide the foundation for a correct combination of HIIT and MICT during a single training session, in a weekly schedule, and represent a good alternative from HIIT to improve anthropometric characteristics, physical capacities and fat oxidation in obese subjects.

**RISK FACTORS OF NON-COMMUNICABLE DISEASES, FUNCTIONAL PERFORMANCE AND CARDIORESPIRATORY FITNESS IN WOMEN FROM A LOW-RESOURCED COMMUNITY: B-HEALTHY-STUDY**

OVIEDO GUILLERMO, R., TAMULEVICIUS, N., PHIDZA, M., MOSS, S.J.

*UNIVERSITY RAMON LLULL / THE UNIVERSITY OF TAMPA / NORTH-WEST UNIVERSITY*

INTRODUCTION: Non-communicable diseases (NCDs) are responsible for 71% of global deaths and 77% of deaths in low-and middle-income countries (1). Risk factors that arise around NCDs often lead to persons avoiding physical activity, which results in a decrease in functionality and deleterious effects on the cardiorespiratory system and general health of people (2). Socially disadvantaged, vulnerable and older people tend to suffer the most from NCDs. In low-resource communities, NCDs deplete family incomes and increases the risk of unemployment.
Aim: This study aimed to analyse and determine the relationship between risk factors of NCDs, functional performance, and cardiorespiratory fitness in women from a low-resourced community.
METHODS: Eighty-one adult women (AW) (48.15 ± 8.30 years) and 99 senior women (SW) (68.58 ± 7.02 years) accepted to be part of this study. Risk factors that arise around NCDs and functional performance were assessed with a view to the following activities: sit to stand, handgrip (HG), timed up and go (TUG), static balance, and cardiorespiratory fitness test for maximum oxygen consumption (VO2max). All variables were summarised using mean ± SD. A partial correlation was performed with adjustment of age. Independent t-tests were used to compare adults vs. seniors.
RESULTS: The results show a significant relationship between BMI and TUG in both groups (AW: p = .019; SW: p = .031). In the AW the waist circumference (WC) correlated with TUG (r =.348; p = .006). High-density lipoprotein cholesterol (HDL-C correlated inversely with the right HG (r = -.301; p = .019). WC correlated positively with the right HG (r = .259; p = .039) and inversely with the left single leg stance (SLS) (r = -.254; p = .042) in the SW. We also found significant relationship between VO2max (p < 0.001) and both right and left HG (p < 0.001). The adult's sit to stand test correlated positively with VO2max (p ≤ .001). A significant inverse relationship was reported between the TUG and VO2max in both groups: (r = -.471; p < 0.001) and (p = .003) respectively. The right- and left single leg stance correlated with VO2max in adult and senior groups: (r = .261; p = .037 and r = .274; p = .028) and (r = .265; p= .032 and r = .354; p = .004).
CONCLUSION: Our findings suggest that an increase in obesity as a risk factor related to NCDs corresponds with a reduction in balance and handgrip strength. Our results support and further substantiate previous studies showing that improved functional performance is associated with high levels of aerobic capacity.
Future interventions targeting risks of suffering NCDs such as obesity should be delivered through primary health care institutions to improve functional performance and aerobic capacity of women from low-resourced communities.

### OP-PN18 Amino acids and proteins III

**NON-ANIMAL AND OMNIVOROUS HIGH PROTEIN DIETS SUPPORT EQUIVALENT DAILY MYOFIBRILLAR PROTEIN SYNTHESIS RATES AND SKELETAL MUSCLE ADAPTIVE RESPONSES TO HIGH VOLUME RESISTANCE TRAINING IN YOUNG ADULTS.**

MONTEYNE, A.

*UNIVERSITY OF EXETER*

INTRODUCTION: It remains unclear whether non-animal-derived dietary protein sources (and therefore vegan diets) can support resistance training-induced skeletal muscle remodelling to the same extent as animal-derived protein sources.
METHODS: In Phase 1, 16 healthy young adults (m=8, f=8; age: 23±1 y; BMI: 23±1 kg/m2) completed a three-day dietary intervention (high protein, 1.8 g·kg bm-1·day-1) where protein was derived from omnivorous (OMNI1; n=8) or exclusively non-animal (VEG1; n=8) sources, alongside unilateral daily resistance exercise. Resting and exercised daily myofibrillar protein synthesis (MPS) rates were assessed using deuterium oxide. In Phase 2, 22 healthy young adults (m=11, f=11; age: 24±1 y; BMI: 23±0 kg/m2) completed a 10 week, high-volume (5 d/week), progressive resistance exercise programme whilst consuming an omnivorous (OMNI2; n=12) or non-animal-derived (VEG2; n=10) high-protein diet (~2 g·kg bm-1·day-1). Muscle fibre cross sectional area (CSA), DXA whole-body lean mass, MRI thigh muscle volume, muscle strength and muscle function were determined pre, after two (W2) and five (W5) weeks, and post-intervention. Two-way ANOVA and t-tests were used to detect differences in all variables (group × time).
RESULTS: Daily myofibrillar protein synthesis rates were ~12% higher in the exercised compared with rested leg (2.20±0.33 vs 2.46±0.27 %·d-1 and 2.36±0.53 vs 2.62±0.56 %·d-1in OMNI1 and VEG1 groups, respectively; P=0.0005) and equivalent between groups (P>0.05). Resistance training increased lean mass in both groups by a similar magnitude (OMNI2 2.6±0.3 kg, VEG2 3.1±0.8 kg; P>0.05). Likewise, training equivalently increased thigh muscle volume (OMNI2 8±1%, VEG2 8.2±1.4%; P>0.05), and muscle fibre CSA (OMNI2 33±10%, VEG2 32±17%; P>0.05). Both groups increased muscle strength (1-RM) in a variety of multi-joint lifts, to comparable degrees (OMNI2 18±8%, VEG2 29±17%).
CONCLUSION: Omnivorous and non-animal-derived diets can support equivalent rested and exercised daily myofibrillar protein synthesis rates in healthy young adults consuming a high-protein diet. This translates to equivalent skeletal muscle adaptive responses during prolonged high-volume resistance training irrespective of dietary protein provenance.

**MYCOPROTEIN INGESTION WITHIN OR WITHOUT ITS WHOLE-FOOD MATRIX RESULTS IN EQUIVALENT STIMULATION OF POST-EXERCISE MYOFIBRILLAR PROTEIN SYNTHESIS RATES IN HEALTHY YOUNG MEN.**

WEST, S.1, MONTEYNE, A.1, WHELEHAN, G.1, ABDELRAHMAN, D.2, MURTON, A.2, FINNIGAN, T.3, BLACKWELL, J.1, STEPHENS, F.1, WALL, B.1

*1, DEPARTMENT OF SPORT AND HEALTH SCIENCES, UNIVERSITY OF EXETER. 2, DEPARTMENT OF SURGERY, UNIVERSITY OF TEXAS MEDICAL BRANCH. 3, MARLOW FOODS LTD, STOKESLY.*

INTRODUCTION: Ingestion of mycoprotein stimulates skeletal muscle protein synthesis (MPS) rates to a greater extent than concentrated milk protein when matched for leucine content, potentially attributable to the whole-food nature of mycoprotein. We hypothesised that bolus ingestion of mycoprotein within its whole-food matrix would stimulate MPS rates to a greater extent compared with a leucine matched bolus of protein concentrated from mycoprotein following a bout of resistance exercise.
METHODS: Twenty-four healthy young (age; 21±2 y, BMI; 24±3 kg·m2) males participated in a randomised, double-blind, parallel-group trial. Participants received primed, continuous infusions of L-[ring-2H5]phenylalanine and completed a bout of unilateral resistance leg exercise before ingesting either 70 g mycoprotein (MYC; containing 31.4 g protein, 2.5 g leucine, 996 kJ; n=12) or 38.2 g of a protein concentrate obtained from mycoprotein (PCM; containing 28.0 g protein, 2.5 g leucine, 558 kJ; n=12). Blood and muscle samples (vastus lateralis) were taken pre- and (4 h) post-exercise/protein ingestion to assess postabsorptive and postprandial myofibrillar protein fractional synthetic rates (FSRs) and phosphorylation status of key proteins that regulate MPS, in rested and exercised tissue. Two- and three-way ANOVAs were used to detect differences in plasma amino acid kinetics (group × time) and myofibrillar FSRs (group × time × exercise), respectively. When significant interactions were observed, Sidak posthoc tests were performed to correct for multiple comparisons and detect individual differences.
RESULTS: Protein ingestion increased plasma essential amino acid and leucine concentrations (P<0.0001), but more rapidly (both 60 vs 90 min; P<0.0001) and to greater magnitudes (1367 vs 1346 µmol·L-1 and 298 vs 283 µmol·L-1, respectively; P<0.0001) in PCM compared with MYC. Protein ingestion increased myofibrillar FSRs (P<0.0001) in both rested (MYC, ?0.031±0.007%·h-1 and PCM, ?0.020±0.008%·h-1) and exercised (MYC, ?0.057±0.011%·h-1 and PCM, ?0.058±0.012%·h-1) muscle, with no differences between conditions (P>0.05). mTOR phosphorylation increased following protein ingestion, with no difference between groups (P>0.05), or rested and exercised muscle (P>0.05).
CONCLUSION: Leucine matched bolus ingestion of mycoprotein results in equivalent postprandial stimulation of resting and post-exercise MPS rates irrespective of whether it is consumed within or without its natural whole-food matrix. These data support the efficacy of mycoprotein as an effective post-exercise nutritional strategy to support muscle reconditioning, irrespective of whether it is consumed as a whole food or as a (more) isolated protein source.

**COLLAGEN PEPTIDES INCREASE ADAPTIONS OF PATELLAR TENDON MORPHOLOGY FOLLOWING 14-WEEKS OF HIGH-LOAD RESISTANCE TRAINING: A RANDOMIZED-CONTROLLED TRIAL**

JERGER, S.1, CENTNER, C.1, LAUBER, B.1, SEYNNES, O.2, FRIEDRICH, T.1, LOLLI, D.1, GOLLHOFER, A.1, KÖNIG, D.3

*1: UNIVERSITY OF FREIBURG, GERMANY, 2: DEP. OF PHYSICAL PERFORMANCE, NORWEGIAN SCHOOL OF SPORT SCIENCES, NORWAY, 3: DEP. OF SPORTS SCIENCE, INST. FOR NUTRITION, SPORTS AND HEALTH, UNIV. OF VIENNA*

INTRODUCTION: The purpose of this study was to investigate the effect of specific collagen peptides (SCP) supplementation combined with resistance training (RT) on changes in structural properties of the patellar tendon. Furthermore, patellar tendon stiffness as well as maximal voluntary knee extension strength and cross-sectional area (CSA) of the rectus femoris muscle were assessed.
METHODS: In a randomized, placebo-controlled study, 50 healthy male participants completed a 14-week resistance training program (70-85% of 1 repetition maximum) for the knee extensors. While the SCP group received 5g of specific collagen peptides daily, the other group received the same amount of a placebo (PLA) supplement.
RESULTS: The SCP supplementation led to a significant greater ($p < 0.05$) increase in patellar tendon CSA compared with the PLA group at 60% and 70% of the patellar tendon length starting from the proximal insertion. Both groups increased tendon stiffness ($p < 0.01$), muscle CSA ($p < 0.05$) and muscular strength ($p < 0.001$) throughout the intervention without statistically significant differences between the groups.
CONCLUSION: The current study shows that in physically active men, supplementation of SCP in combination with RT leads to greater morphological patellar tendon changes than RT alone. Since underlying mechanisms of tendon hypertrophy are largely undocumented, further studies should investigate potential mechanisms causing the increased morphology adaptions following SCP supplementation.

**DIETARY ANIMAL PROTEIN INTAKE REDUCES THE EFFLUX OF MUSCLE DAMAGE BIOMARKERS, BUT DOES NOT IMPROVE PHYSICAL FUNCTION**

COSIO, P.L., MORENO-SIMONET, L., PORCELLI, A., LLORET, M., FUSTER, J., PADULLÉS, X., PADULLÉS, J.M., CARMONA, G., FARRAN-CODINA, A., CADEFAU, J.A.

*INSTITUT NACIONAL DEDUCACIÓ FÍSICA DE CATALUNYA - UNIVERSITAT DE BARCELONA*

INTRODUCTION: High intensity, eccentric or unaccustomed exercises cause muscle damage, leading to muscle structure and function impairment. Considering that dietary protein intake plays a key role in numerous physiological processes, it is suggested that peri-exercise protein intake may also have a role on facilitating recovery processes. Specifically, higher protein intake decrease muscle soreness (1) and plasma creatine kinase, myoglobin, and lactate dehydrogenase levels (1,2) during post-exercise recovery period but not performance indicators (2). We therefore suggest that dietary protein intake will counteract muscle soreness and muscle damage biomarkers efflux.
METHODS: Healthy males (n=17, 23 ± 0.7 years, BMI 23.7 ± 0.4) and females (n=4, 24 ± 2 years, BMI 21.5 ± 1.2) underwent 10 repeated 40-meters sprints with a 3-minute rest pause between each repetition. Participants recorded their dietary intake during the 3 days following the exercise, and indirect indicators of muscle damage in lower limbs (force generation capacity (FGC), soreness, range of motion (ROM)) and biochemical indicators of muscle damage were tested at baseline and immediately after, at 24-, 48- and 72-hours post-exercise. Participants who did not recover at 72h baseline mtCK values were classified as responders (n=11) and those in which mtCK was unaffected as non-responders (n=6). Two-way repeated measures ANOVA (time x group) followed by a paired t-test with a Bonferroni correction was performed to identify changes from baseline. Unpaired T-test or Mann-Whitney test (decision based on Gaussian distribution) were used to analyse differences in macro and micronutrients intake between groups. The level of significance was set at $p < 0.05$, and data are presented as mean ± SEM.
RESULTS: Repeated sprints resulted in a loss of more than 20% of the FGC and approximatively 20% of the ROM in the most affected leg of the responder group at +24h and remained unrecovered +72h following exercise. No differences were observed between groups for muscle soreness. Serum mtCK increased from baseline (20.0 ± 3.4 ng·mL-1) until a significant peak at +24 h (86.29 ± 14.8 ng·mL-1) and remained significantly elevated at +72h (53.6 ± 10.9 ng·mL-1). Total protein intake during the recovery period differed between groups, accounting for a higher intake by non-responders (MD = 44.7, $p < 0.05$). Moreover, there were no differences between groups in vegetable protein intake ($p = 0.91$), while animal protein intake was the main source of the higher intake of non-responders (MD = 35.4, $p < 0.05$, ES = 1.2).
CONCLUSION: Muscle function (FGC, ROM) remains impaired during the 3-day post-10 repeated 40-meters sprints recovery period in the responder group, while mitochondrial structure and function may have been protected by increased animal protein intake during recovery period.

**THE RECOVERY EFFECTS OF A NEW VEGAN PROTEIN-BASED MULTI-INGREDIENT SUPPLEMENT ON VOLUNTARY MUSCULAR CONTRACTION AND MUSCLE CONTRACTILE PROPERTIES IN PERI-MENOPAUSAL WOMEN, A CASE STUDY.**

PUENTE, J.

*UNIVERSITY OF GREENWICH*

INTRODUCTION: Protein-based multi-ingredient supplements including carbohydrates have been suggested to boost post-workout recovery. The present intervention evaluated the effects of providing post-resistance exercise training supplementation ingesting a vegan protein-based multi-ingredient (MTN) vs. carbohydrate alone (CHO) on the recovery of stimulated muscle contractile properties, voluntary muscle function, psychological perceptions of exertion, and perceived Delayed Onset Muscle Soreness (DOMS) after 3 successive intense resistance workouts.
METHODS: The protocol followed a double-blinded, crossover design. Three recreationally active peri-menopausal women (52.2 ± 5.7 years) completed 2 equal 5-days microcycle periods. For this purpose, the participants performed 3 consecutive days of a circuit-shape resistance training sessions, followed by 2 rest days. After every workout and after the first rest day, the subjects ingested either MTN or CHO. Subsequently, the participants were assessed 1, 24, and 48 hours after the termination of the third training session. The primary outcome was Tensiomyography (TMG) (muscle displacement [Dm], contraction time [Tc], and contraction velocity [Vc]) of the Anterior Deltoids (AD), Vastus Medialis (VM) and Biceps Femoris Long Head (BFLH) muscles. Secondary outcomes were upper- and lower-body performance, DOMS, Self-Perceived Energy Feelings (SPEF), and Sleeping Quality.

RESULTS: Significantly decreased ($p < 0.05$) Dm and Vc were observed for both conditions (Dm: MTN -1.74 ± 1.3, CHO -1.61 ± 1.6 mm; Vc: MTN -0.02 ± 0.03, CHO 0.04 ± 0.04 m·s-1) in the BFLH. At 48 hours, all Tensiomyography variables were recuperated under the MTN and CHO conditions. Maximal Isometric Force, Vertical Jump performance, and Seated Medicine Ball Chest Throw showed a performance decrease after 1 and 24 hours and returned to baseline levels after 48 hours. DOMS showed a higher result in CHO vs MTN after 24 hours but was similar in both conditions after 48 hours. Sleeping Quality and SPEF were slightly superior in MTN vs CHO for the three cases over the course of the week.
CONCLUSION: In a preliminary small sample size of healthy and recreationally active peri-menopausal women, the ingestion of only carbohydrates vs vegan post-workout protein-based multi-ingredient supplementation does not seem to provide further benefits in relation to muscular contractile properties or performance. Conversely, slight improvements in Self-Perceived Energy Feelings, Sleeping Quality and DOMS were observed after a MTN vs CHO consumption.

#### ROLE OF REDOX SIGNALING IN SKELETAL MUSCLE DAMAGE AN ADAPTATION TO TRAINING

GOMEZ-CABRERA, M.

*UNIVERSITY OF VALENCIA*

The contractile function of skeletal muscle is reliant on multinucleated muscle cells (myofibers), which comprise sarcomeres linked by structural proteins. Despite inherent muscle strength and flexibility, the mechanical strain and stress induced by muscle contraction can result in muscle damage. Physical exercise induces mild musculoskeletal injuries that need rapid and efficient repair to preserve muscle homeostasis. Reactive Oxygen Species (ROS) play a role in this damage which is repaired by muscle resident stem cells (satellite cells). Although stem cell-dependent muscle repair has been widely researched, it is unknown whether myofibers are able to self-repair without satellite cell activation. Using in vitro, ex vivo, and in vivo models (animals and humans performing eccentric exercise protocols) of local muscle damage we found that localized injuries, as experienced through exercise, activate a myofiber self-repair mechanism that is independent of satellite cells in mice and humans. The repair mechanism that we have described is preserved in the three models that we have studied and represents a very efficient and highly relevant protection mechanism for minor muscle injuries as those caused by ROS. The muscle injury triggers a signaling cascade involving calcium, Cdc42, and phosphokinase C that attracts myonuclei to the damaged site via microtubules and dynein4. These nuclear movements accelerate sarcomere repair and locally deliver Messenger RNA for cellular reconstruction. Myofiber self-repair is a cell-autonomous protective mechanism and represents an alternative model for understanding the restoration of muscle architecture during exercise.
These results open the way to a better understanding of muscle injury repair both in the field of exercise (a more physiological context) and in the field of disease (more clinical context).

#### THE EFFECTS OF DIFFERENT EXERCISE MODALITIES ON MITOCHONDRIAL FUNCTION IN HUMAN SKELETAL MUSCLE

LARSEN, S.

*UNIVERSITY OF COPENHAGEN*

Mitochondrial function (mitochondrial respiration, mitochondrial content and mitochondrial $H_2O_2$ emission) is improved after an exercise intervention. These improvements are linked to many health parameters such as glucose metabolism. Whether the same magnitude of improvement is seen when it comes to mitochondrial respiratory capacity and mitochondrial content is at the moment debated, and whether different exercise modalities are affecting this. These adaptations are seen after a period of training (2-6 weeks or longer).
Interest has also been on the effect of an acute bout of exercise. It is known that an acute exercise bout leads to a transient increase in $H_2O_2$ emission, and it is speculated that the transient increase in mitochondrial $H_2O_2$ emission is involved in mitochondrial biogenesis. Data suggests that this transient increase in $H_2O_2$ emission is exercise intensity dependent. Whether the increase in $H_2O_2$ emission after an acute exercise bout is beneficial or damaging for a training adaptation depends on different factors (baseline levels of $H_2O_2$ emission and the cellular antioxidant system). This supports the concept exercise-induced hormesis, where to little or too much $H_2O_2$ emitted from the skeletal muscle after exercise leads to no exercise adaptation (mitochondrial biogenesis).
The effects of exercise on mitochondrial function will be discussed focusing on mitochondrial respiration, content and $H_2O_2$ emission, before and after an exercise intervention or an acute bout of exercise.

#### ILLUMINATING ROS/RNS-INDUCED ALTERED SKELETAL MUSCLE FUNCTION IN HEALTH AND DISEASE

LANNER, J.

*KAROLINSKA INSTITUTET*

Strenuous endurance exercise is a potent stimulus to induce beneficial skeletal muscle adaptations leading to increased muscular health and aerobic capacity due to e.g., mitochondrial biogenesis and angiogenesis. Reactive oxygen/nitrogen species (ROS/RNS) increases in skeletal muscle during physical exercise and contributes to the favourable effects of endurance training. At the same time, conditions with prolonged increases in ROS/RNS (such as rheumatoid arthritis, malignant hyperthermia, and in overtraining syndrome and normal ageing) exhibit skeletal muscle dysfunction with altered mitochondrial function and muscle weakness. Thus, increased ROS/RNS production have both beneficial and detrimental effects on skeletal muscle function and the outcome depends on a combination of factors, including the type of ROS/RNS, the magnitude, duration, and location of ROS/RNS production, as well as the defence systems including both endogenous and exogenous antioxidants. In this symposium we will: i) provide mechanism-of-action of how ROS/RNS-induced post-translational modifications interfere directly with actin and the force generation in skeletal muscle without a reduction in muscle mass. ii) Elaborate how molecular pathways involved in exercise-induced mitochondrial biogenesis (e.g. PGC-1α) differs between healthy in diseased conditions and iii) despite previous failed attempts of antioxidant treatments, present why site-targeted antioxidants can be groundbreaking in improving muscle function for patients afflicted with disease-induced muscle weakness.

## OP-BM05 Running and biomechanics

### THE EFFECTS OF HYPOXIA AND RUNNING VELOCITY ON REGULARITY AND FRACTAL DIMENSION OF JOINT ANGLES IN MALE RUNNERS

HUNTER, B.1, GREENHALGH, A.1, KARSTEN, B.2, BURNLEY, M.3, MUNIZ-PUMARES, D.1

*1.UNIVERSITY OF HERTFORDSHIRE, UK, 2. EUROPEAN UNIVERSITY OF APPLIED SCIENCES , BERLIN, GERMANY, 3. UNIVERSITY OF WOLVERHAMPTON, UK*

INTRODUCTION: Previously, running velocity has been implicated with changes to the variability and complexity of movement dynamics (1). However, it remains unclear as to whether movement dynamics are altered because of increased velocity, or because of physiological responses to exercise. Hypoxic environments can accentuate physiological stress when compared to normoxia for any given running velocity (2). Therefore, the aim of this study was to examine the relationship between exercise intensity and movement complexity, separate to running velocity, using moderate hypoxia.
METHODS: Ten healthy male participants (Mean±SD; Age: 28.9±10yrs, height: 1.81±0.07m, mass: 74.0±8.3kg) performed two graded exercise tests (GXT) on a treadmill on separate days until task failure, with one conducted at normoxia (20.9% FiO2; NORM) and the other conducted in hypoxia (15% FiO2; HYP) in a randomised order. Sagittal joint angles of the hip, knee, and ankle were sampled throughout all stages of both GXTs using 3D motion analysis. Regularity and fractal scaling of kinematics of each stage were quantified using sample entropy (SampEn) and detrended fluctuation analysis-α scaling exponent (DFA-α) Two-way repeated-measures ANOVA (condition X velocity) were used to analyse differences in regularity, fractal scaling, and variability on each GXT stage, from the first stage until the last stage common to all participants.
RESULTS: Peak velocity during GXTs were 4.96±0.30 m·s-1, and 4.61±0.32 m·s-1with similar B[La] of 11.1±3.2 and 11.2±4.5 mmol·L-1 for NORM and HYP, respectively. The last common stage for all participants across both conditions was 4.2 m·s-1, with a total of 15 stages used for analysis. A main effect for velocity on SD was evident at the ankle ($P<0.001$), knee ($P<0.001$), and hip ($P<0.001$), with SD increasing as velocity increased. An interaction between velocity and condition was noted for hip SD ($P=0.014$). There was no velocity x condition interaction for DFA-α or SampEn. DFA-α decreased with increasing velocity, indicating a more random movement pattern, at the ankle ($P<0.001$) and hip ($P<0.001$). A difference in DFA-α was evident between NORM and HYP at the ankle ($P=0.02$). SampEn increased, indicating greater complexity, with increased running velocity at the ankle ($P<0.001$), knee ($P<0.001$), and hip ($P<0.001$).
CONCLUSION: As running velocity increased DFA-α decreased, SampEn values increased, and SD increased in both NORM and HYP conditions, suggesting greater complexity and variability change in line with velocity. Temporal profiles of measures of complexity and variability were consistent between NORM and HYP. Therefore, changes in variability and complexity during running are more strongly mediated by running velocity rather than the physiological demand of exercise.

### IMPACT OF SPEED AND SLOPE ON STRIDE VARIABILITY

GODIN, A.1, EUSTACHE, E.2, SAGAWA JR, Y.3, MOUROT, L.1

*1 EA3920 UNIVERSITY OF FRANCHE-COMTE, 2 UNIVERSITY OF NEUCHATEL, 3 EA481 UNIVERSITY OF FRANCHE-COMTE*

INTRODUCTION: Evaluation of variability in stride while running is increasing as some evidences have linked changes in some metrics to fatigue, injury or overreaching (1,2,3). Several kinematic parameters can be used such as stride time (Ts), contact time (Tc), flight time (Tf) or cadence (C) (3). Their variability can be described through different indexes: the amount of stride-by-stride variation (AV), predictability (P), and complexity (Cp) (3,4). However, the impact of running speed or slope on variability of these parameters has not been reported. Hence, our aim was to study the effects of slope and speed on stride variability.
METHODS: 20 recreational runners performed an 11-randomized-conditions treadmill test with 5 conditions derived from preferred running speed (PRS; 80%, 90%, 100%, 110%, 120%) and 6 inclines (-8%, -5%, -2%, 0%, 2%, 5%, 8%) at 90% of the PRS. Ts, Tc, Tf and C were measured with an Optogait system (Microgate, Bolzano, Italy). AV was quantified by coefficient of variation (CV) (3). P and Cp were evaluated using coefficient alpha 1 of detrended fluctuation analysis (aDFA) and Higuchi fractal index (HFI) following recommendations (4). Two separated one-way repeated measures ANOVA were performed to assess the effect of slope and speed.
RESULTS: The effect of slope on AV was significant and similar for the different kinematics . CV was higher for negative slopes than for positive slopes ($p<0.05$) for Ts (at -8%: 3.12%±1.52; at 8%:2.44%±0.41), Tc, Tv and C. There were no differences between the positive slopes and the flat condition for all kinematic parameters studied (e.g. Tf at 0%: 17.96%±6.66 and at 8%: 17.82%±6.82; $p>0.05$). The effect of speed was different depending on the kinematic studied. As speed increased, CV for Tv decreased (80%: 23.16%±7.04; at 100%: 13.18%±4.60; at 120%: 9.18%±2.81; $p<0.05$). CV for Tc was significantly higher at 80% than the other conditions (80%: 2.72%±0.93; at 120%: 2.34%±0.62; $p<0.05$). As regards P, higher values on positive slopes and flat compared with negative slopes were observed for Ts

only (aDFA at -8%: 0.59±0.14; at 0%: 0.65±0.09; at 8%:0.67±0.18; p<0.05). As well P, lower value at 120% than other conditions was observed for Tc only (aDFA at 80%: 0.85±0.09; at 120%: 0.77±0.1). For Cp, no significant changes with slopes were observed for Ts, Tc, Tf and C. On the contrary, lower value at 80% of PRS than other conditions was observed for C (HFI at 80%: 0.93±0.29; at 120%: 1.16±0.9; p<0.05).
CONCLUSION: AV was more sensitive to slope and speed than P and Cp, with low speed and negative slopes having higher CV values. Further studies are required to establish best practices for these indices measure and to study other conditions known to alter running kinematics (e.g., gender, footwear, or age).

## EFFECT OF MIDSOLE HARDNESS ON KNEE ABDUCTION ANGULAR IMPULSE: AN ASCENDANT HIERARCHICAL CLUSTERING IN 123 RUNNERS

GIANDOLINI, M., PLAY, M.C., MILLET, G.Y., ROSSI, J.

*SALOMON SAS*

INTRODUCTION: Forty-two percent of running-related injuries occur at the knee joint, with 46% of these injuries being due to patellofemoral pain (1). Subjects with patellofemoral pain demonstrate increased knee abduction angular impulse (KAAI) compared to healthy subjects during running (2). Mathematically, KAAI represents the integral of knee abduction/adduction moments over the stance phase. Footwear midsole hardness affects running kinematics (3). This study aimed at investigating whether it affects KAAI. It was hypothesized that the effect of midsole hardness on KAAI would be runner-dependent with clusters of runners responding similarly to changes in midsole hardness. Based on this hypothesis, a secondary purpose was to describe these clusters from biomechanical, morphological, and running practice-related variables.
METHODS: Three midsole hardness conditions (Asker C-40, Asker C-55, and Asker C-65, hereinafter called 'soft', 'medium' and 'hard', respectively) were tested in 123 subjects (51 females, 65.4 ± 9.7 kg, 171 ± 8 cm) who ran at their preferred running speed on a motorized treadmill for ten minutes in each condition. Ground reaction forces and 3D lower limb kinematics were collected. Knee abduction/adduction moment was obtained from inverse dynamics, then KAAI was calculated as the integral of the knee abduction/adduction moment signal over the stance phase. KAAIs in the soft and hard conditions were normalized to KAAI in the medium condition. Relative KAAIs were used as the dependent variables to cluster runners using an ascendant hierarchical clustering. Subjects were clustered based on relative KAAIs to ensure classification on the footwear effect rather than on the absolute KAAI magnitude. Age, gender, mass, height, body mass index, fat mass, weekly volume of practice, weekly mileage, experience in running, running speed, and foot strike angle were used as independent variables to describe clusters.
RESULTS: To minimize intra-class variance and maximize inter-class variance, the number of clusters was set at 3. Cluster 1 (n = 16) demonstrated lower KAAI in the medium compared to soft and hard conditions ($p < 0.0001$). Cluster 2 (n = 62) demonstrated greater KAAI in the hard compared to soft and medium conditions ($p < 0.0001$). Cluster 3 (n = 45) demonstrated greater KAAI in the medium compared to soft and hard conditions ($p < 0.0001$). No significant difference in independent variables were observed across clusters.
CONCLUSION: Midsole hardness differently affects KAAI in runners. Half of the present sample increases KAAI with hard midsole; 37% increases KAAI with medium midsole; only 13% decreases KAAI with medium midsole. Despite that the present data do not permit to characterize these clusters, the findings provide insights for the development of running footwear, especially regarding midsole conception.

## EFFECTS OF DIFFERENT PROTOCOLS OF STRENGTH TRAINING ON RUNNING BIOMECHANICS: A SPRING-MASS MODEL APPROACH

STORNIOLO, J.L., BUZZACHERA, C.F., PEYRÉ-TARTARUGA, L.A.

*UNIVERSITÀ DEGLI STUDI DI MILANO*

INTRODUCTION: Heavy and plyometric strength training enhances running performance by eliciting metabolic adaptations such as a lower energy cost (EC) (1). However, little is known about these effects on the mechanical energy saving represented by the spring-mass model. The total mechanical work (Wtot) quantifies the mechanical energy produced by the body during running [summation of external (Wext) and internal (Wint) work denoting the energy variation of the body concerning the environment and from its limbs regarding the body centre of mass] (2). Then, we aimed to analyse the effects of planned heavy and plyometric training on mechanical work parameters in recreational runners.
METHODS: Twenty-four runners were allocated to heavy (HG, n=8), plyometric (PG, n=9), [which added 8 weeks of strength training (twice per week)], and control group (CG, n=7). Runners performed three evaluation sessions (before and after the training period, interspersed by 48h): maximal progressive test, submaximal running test at constant speeds associated with 60 (EC60) and 110% (EC110) of their maximal intensity. A 3D kinematic analysis recorded an 18-markers model (3) to measure mechanical work parameters during the second session. The third session evaluated the 5-km run performance (t5km). Two-way ANOVA with repeated measures was performed to identify probable treatment interactions, and a paired t-test was done to compare intragroup differences pre-and post-training.
RESULTS: The t5km improved for both strength groups (SH: 1430±265 to 1355±208 s, p=0.03; SP: 1464±143 to 1377±156 s, p=0.02) without significant differences for CG (1662±259 to 1637±262 s, p>0.05). Unchanging values of EC60 and EC110 accompanied this performance gain in HG and PG. Concomitantly, Wtot60 maintained similar in HG and PG, but its component, Wint60, increased only for the HG (0.35±0.02 to 0.39±0.01 J.kg-1.m-1, p=0.03). On the other hand, Wtot110 showed a significant increasing pre-to post-training in HG and PG (HG: 2.04±0.06 to 2.33±0.09 J.kg-1.m-1, p=0.006; PG: 2.06±0.07 to 2.21±0.06 J.kg-1.m-1, p=0.02), whereas Wint110 remained similar and Wext110 increased for both groups (HG: 1.39±0.04 to 1.60±0.07 J.kg-1.m-1, p=0.006; PG: 1.39±0.06 to 1.51±0.05 J.kg-1.m-1, p=0.04).
CONCLUSION: The increase in the performance by reducing t5km for both strength training methods reinforces its benefits for running. However, the mechanical work operated differently between the two intensities since Wtot60 kept similar while Wtot110 increased for

both experimental groups. Such behaviour reflected a higher Wext110 despite the unchanged EC110. Our results reveal that heavy and plyometric strength training similarly influences the spring-mass model primarily in high physiological intensities and reflects it in running performance.

**ACUTE EFFECTS OF ELECTROSTATIC CHARGING ON ENDURANCE PERFORMANCE. A DOUBLE-BLIND, RANDOMISED, PLACEBO-CONTROLLED CROSS-OVER DESIGN**

WIESINGER, H., THORWARTL, C., MÜLLER, E., STÖGGL, T.

*UNIVERSITY OF SALZBURG*

INTRODUCTION: Accompanied by paradigm shifts and research gaps, redox-mediated signalling mechanisms are thought to modulate muscle performance, stress-related muscle damage, inflammation, or recovery (1). Interestingly, however, these cellular or subcellular processes seem to be positively influenced by reducing the electrostatic charge of the human body. Accordingly, grounded sleeping has been found to accelerate recovery from stress-related muscle damage (2). However, the potential acute effects of electrostatic charging on endurance performance have never been tested. Here, we propose to evaluate the impact of grounding or sham grounding and thus of electrostatic uncharged or high charged individuals on performance outcomes during incremental treadmill tests until exhaustion.
METHODS: In a cross-over design, nine healthy endurance tests-experienced women (n = 3) and men (n = 6) were randomised to a grounded or sham grounded treadmill test (HP Cosmos Pulsar 3p). The ramp testing (7.0 km·h−1; increment: 1.5 km·h−1 every 5 min, with 30 s recovery between stages, inclination 1%) was separated by one week and comprised absolute maximum oxygen uptake (Cosmed K5 breath-by-breath mode), lactate measures at rest and after each recovery phase, ultrasound-guided near-infrared spectroscopy for vastus lateralis O2 extraction (Moxy), power (Stryd Power Meter), heart rate (Suunto), total running time, and rate of perceived exertion (Borg 6-20 scale). High electrostatic charging was achieved using prototype shoes of pronounced triboelectrification. Voltages were recorded at 5 Hz using a high voltage voltmeter (Kleinwächter HMK 40). Except for total running time, the final two minutes of the last fully completed running stage were analysed. A mixed ANOVA was used.
RESULTS: Individuals absolute V̇O2max was 3.88 ± 0.66 (L·min-1). The sham and grounded groups average electrostatic charging was 6.7 ± 1.4 kV and 0.0 ± 0.1 kV. This charging did not affect measured endurance outcomes ($F < 2.02$, $p > .198$). We observed a learning effect on the lactate ($F$ 17.00, $p = 0.004$) and heart rate ($F$ 13.33, $p = 0.008$) values.
CONCLUSION: Contrary to our hypothesis, these preliminary results suggest that grounding the human body has no acute meaning for intense endurance activities. This statement seems well-found, as similar high triboelectric effects transferred by our prototype shoes are unlikely to occur in the natural environment. The learning effect found in lactate concentration and heart rate but not in other closely related parameters remains challenging. However, it potentially indicates that the latter parameters are more sensitive to detecting changes in the coordination pattern of treadmill running.

### IS-MH06 Hamstring Strain Injury Mitigation in Intermittent Running Sports

**HAMSTRING STRAIN INJURIES: THE EFFECTS OF FATIGUE AND RECOVERY ON MUSCULO-SKELETAL SYSTEM**

CALLEJA-GONZALEZ, J.

*FACULTY OF SPORTS SCIENCES. UNIVERSITY OF THE BASQUE COUNTRY*

Exercise-induced muscle damage (EIMD) is characterized by histopathological muscle tissue changes that originate skeletal muscle damage. The destruction of skeletal muscle fibers causes an inflammatory response that decreases the athlete's physical work capacity and sports performance (Mielgo-Ayuso and Fernández-Lázaro, 2021), specially on hamstrings. Thus, muscle recovery becomes a key role and a priority for top elite athlete. This is evidenced by the significant increase in scientific publications during the last 10 years as teams look to find a competitive edge. Recovery is recognized to be an integral component to assist athlete preparation in the restoration of physical and psychological function, and subsequently, performance in elite team sports athletes (Calleja-González et al. 2021).
This presentation could contribute sensibly and legally to athletes to adequately complement their training to obtain better performance or try "shortcuts" to reach the sport's elite in less time, with treatments and/or prohibited artificial methods that improve their ability to achieve more extraordinary physical performance (Mielgo-Ayuso and Fernández-Lázaro, 2021). In order to achieve optimal muscle recovery, athletes often combine additional recovery strategies (biological, pharmacological, mechanical, and nutritional) in the hope of improving physiological responses and competitive performance However, it is necessary to optimize the consumption of adequate amounts of energy, nutrients, and liquids, methods, timing establishing the correct frequency and associated with the temporality of training and competition.
Finally, all their personal performances should be coordinated and put into practice by the sports team. In this scientific and applied proposal, we primarily dealt with the individual treatment of players in order to improve their personal performance and, consequently, the teams sporting performance and minimizing the risk of injury.

### THE EFFECTS OF FATIGUE ON SPRINT AND COD MECHANICS AND ITS RELATIONSHIP WITH HSI

ALCARAZ, P.

*UNIVERSIDAD CATÓLICA DE MURCIA*

Hamstrings strain injury (HSI) is the most common injury in intermittent running sports such as Australian football, American football, rugby, and football (soccer) (Jones et al., 2019; Mack et al., 2020; Opar, Williams, & Shield, 2012; Orchard et al., 2020; Prieto-Lage, Louzao-Neira, Argibay-González, & Gutiérrez-Santiago, 2020; Ribeiro-Alvares et al., 2019). This type of injury is characterized by acute pain in the posterior thigh with disruption of the hamstrings muscle fibres, where direct external contact with the thigh is excluded as a cause of injury (Liu, Garrett, Moorman, & Yu, 2012; Opar et al., 2012; Poudel & Pandey, 2020). Injury rates are particularly high in football, accounting for 37% of all muscle related injuries (Ekstrand, Hägglund, & Waldén, 2011), and the recurrence rate is also remarkably high (Ekstrand et al., 2020; Martin Hägglund et al., 2013; Heiderscheit, Sherry, Silder, Chumanov, & Thelen, 2010; Woods et al., 2004).Thus, minimizing the risk of first injury is considered a key aspect of overall hamstrings injury reduction strategies. Despite the increasing research focus in this area, the potential injury mechanisms are not well defined (Sun et al., 2015) and injury incidence seems to have increased (Eirale, 2018; Ekstrand, Waldén, & Hägglund, 2016; Martin Hägglund et al., 2013) in recent years
One factor that is known to critically affect injury risk is the level of neuromuscular fatigue (Huygaerts et al., 2020; Lehnert et al., 2017). This fatigue may result from either acute, residual (recovery from competition or training) or chronic physical exercise burden. Epidemiological evidence for an influence of acute fatigue is provided by data showing higher injury rates towards the late stages of a football game (Ekstrand et al., 2011). The accumulation of fatigue across training and competition periods is also linked to injury risk, especially when abrupt increases in total training loads, intensities or high speed running are observed (Green, Bourne, van Dyk, & Pizzari, 2020) or when match density is high, allowing only short recovery between competitive play (Calleja-Gonzalez et al., 2020). However, acute and chronic neuromuscular fatigue might influence risk in very different ways and since player monitoring practices, which are commonly performed and considered a cornerstone of player welfare systems (Matinlauri, Alcaraz, et al., 2019; Taberner & Cohen, 2018), should reduce the risk of chronic fatigue-related injury risk, the current presentation will focus predominately on neuromuscular factors that might trigger an acute hamstring injury event. Specifically, since the majority of HSI occur at maximal or near-maximal running speeds (Sugiura, Sakuma, Sakuraba, & Sato, 2017), the present presentation will describe how acute fatigue could affect mechanical and neuromuscular variables during high-speed running and Change of Directions.

### EFFECTS OF SPRINT, STRENGTH AND MUSCULAR ENDURANCE TRAINING ON THE RISK FACTORS FOR HAMSTRINGS INJURIES

DELEXTRAT, A.

*OXFORD BROOKES UNIVERSITY*

This presentation will address the prevention of hamstrings strain injuries (HSI) in football, which is currently costing a lot to clubs financially and in terms of players' time loss and re-injuries. There are two separate areas that are crucial for this, the first one is working on muscular endurance to ensure that hamstring strength is sustained during the 90-min of a football match. Indeed, it is obvious that injuries occur towards the end of matches, when fatigue takes place. In addition, many authors have shown a greater loss of strength after football matches in the hamstrings (high proportion of fast twitch muscle fibres) compared to the quadriceps (mixed fast and slow twitch fibres), for example (Delextrat et al., 2020; Greig et al., 2008). Several studies have highlighted the benefits of muscular endurance training on performance indicators, but a lot less have looked at risk factors for injuries. For the hamstrings, these risk factors include, for example, the angle of peak torque and the torque-angle relationship. A recent study by our research group has shown that 7 weeks of muscular endurance training reduced the loss of hamstring strength observed at the end of a match in amateur players (Delextrat et al., 2018). The second essential area to focus on is the mechanism of injury itself. The main mechanism of hamstring injury, affecting the biceps femoris, is sprinting, where this muscle is prone to tears in the late swing phase in particular. This has led practitioners to avoid maximal sprints in practice sessions in order to prevent injuries, which is paradoxical, as sprinting is probably what is needed to ensure optimal adaptation of the hamstrings during this specific activity. Indeed, the main limitations of strengthening exercises are that they do not reproduce all the demands placed on the hamstrings during a cyclic activity like sprinting and do not consider this muscle group as a constitutive element of the motor chain. However, there is only limited research on the effects of sprint training on the risk factors for HSI . Freeman et al. (2019) showed that two 4-week training programmes based on NHE and sprint training, respectively, improved hamstring eccentric strength but sprint training resulted in greater improvements (moderate vs. trivial) in maximal speed in recreational team sport players. More recently Mendiguchia et al. (2020) conducted a prospective interventional study comparing the effects of sprint, NHE and football training. Compared to the other types of training, sprint training resulted in a greater increase in the fascicle length of the biceps femoris and greater improvement in sprinting biomechanics, in particular the maximal theoretical horizontal force (F0). These results are of particular importance because F0 has been correlated with hamstrings electromyographic activity during the swing phase and eccentric knee flexor peak torque (Morin et al., 2015).

INTRODUCTION: The difference in muscle size in different regions of the quadriceps muscle may show different relationships with the force-velocity (F-V) relationship, explosive strength and physical performance. However, these relationships are still poorly analysed. This

study evaluated different muscle sizes along the vastus lateralis muscle and their association with the force-velocity (F-V) relationship, the rate of force development (RFD) and the muscle power estimated with the 5 sit-to-stand repetition test.
METHODS: A total of 42 individuals (mean age: 54.7 ± 1.5 years; BMI: 25.8 ± 5.0; 57% woman) from the Toledo Study for Healthy Aging in Middle Age (THSA-ma) were included. Cross sectional area (CSA) of the vastus lateralis muscle was measured at 35%, 50% and 65% of the distance between the proximal border of the greater trochanter and the superior border of the patella (0% = proximal, and 100% = distal). Three transversal panoramic scans of the vastus laterals muscle were obtained for each region using the extended field of view (EFOV) of the scanner. At least 15 minutes of rest in this position were provided for body fluid shift stabilization prior to imaging. The F-V relationship, maximal isometric force (MIF) and RFD were assessed with the leg press exercise, while physical performance was assessed in the 5-repetiton Sit-to-Stand (5-STS) test.
RESULTS: There were significant associations between all the muscle size measures and i) 5-STS mean power (r=0.59-0.79; p<0.05), ii) estimated maximum force at null velocity (r=0-67-0.71: p<0.01); and iii) maximum muscle power (r=0.59-0.76; p<0.01). Both proximal and middle muscle CSA were significantly associated with relative leg press muscle power (r=0.70-0.76; p<0.05), while only proximal muscle CSA was significantly associated with RFD at the first 100, 200, 300 y 400 ms (r=0.66-0.76; p<0.05) and with the MIF (r=0.70, p<0.05)
CONCLUSION: The vastus lateralis muscle CSA appears to be closely related with muscle function at higher forces and lower velocities. Moreover, proximal vastus lateralis CSA showed the highest correlations with the neuromuscular function measures.

**INFLUENCE OF GROWTH AND MATURATION ON THE FORCE-VELOCITY PROFILE IN GIRLS**

SUDLOW, A., GALANTINE, P., PEYROT, N., DEL SORDO, G., DALLEAU, G., RAYMOND, J.J., GAVARRY, O., DUCHÉ, P.
*UNIVERSITÉ DE TOULON*

INTRODUCTION: Sprinting is fundamental to many individual and team sports and relies on maximal force, velocity, and power capabilities (1). During childhood and adolescence these capacities are greatly influenced by growth and maturation (2), but whether differences in between children of different maturity are mainly due to changes in anthropometrics and body composition is unclear. Moreover, research in girls is sparse and merits further attention. Therefore, the primary aim of this study was to determine the influences of growth and maturation on the Force-velocity (F-v) profile in girls.
METHODS: Sixty girls were recruited from local athletics clubs for this study. Body mass (BM), height, and sitting height were measured in order to estimate years to or from peak height velocity (PHV±Y). Subjects were divided into four equal groups according to their maturity status (PHV-4, PHV-2, PHV-0, PHV+2). Whole-body fat free mass (FFM) was calculated via skinfold measurements. Participants performed two maximal 30-m sprints during which raw velocity-time data were measured using a radar device (Stalker ATS II, Texas, USA). Processed speed-time data were used to derive the mechanical parameters of the F-v profile (3). Both maximal force (F0) and power (Pmax) outputs were normalised to BM and FFM. Theoretical maximal velocity (V0) was also examined. One-way ANOVAs were performed to detect differences in mechanical parameters between maturation groups.
RESULTS: Absolute F0 and Pmax were greater for more mature groups in all cases (P<0.001, ES=0.64, P<0.001, ES=0.67 respectively). V0 was also greater for more mature groups (P<0.001, ES>0.66) except for PHV-0 vs PHV+2. When F0 was normalised to BM and FFM force production was similar between groups except for PHV-4 vs PHV-2 (F0/BM: 5.63±0.64 vs 6.34±0.82 N/kg, P<0.05, ES=0.45; F0/FFM: 6.76±0.82 vs 7.88±0.85 N/kg, P<0.001, ES=1.06). When Pmax was normalised to BM power production was similar between groups except for PHV-4 vs PHV-2 (Pmax/BM: 7.51±1.21 vs 9.78±1.51 N/kg, P<0.001, ES=1.19). When Pmax was normalised to FFM power production was similar between groups except for PHV-4 vs PHV-2 (Pmax/FFM: 9.02±1.49 vs 12.2±1.55 N/kg, P<0.001, ES=0.73) and PHV-2 vs PHV-0 (Pmax/FFM: 12.2±1.55 vs 13.9±1.22 N/kg, P<0.01, ES=0.51).
CONCLUSION: Around and post puberty, differences in F0 and Pmax between girls of varying maturity are predominantly due to increases in BM and FFM. For prepubertal girls and especially very prepubertal girls (PHV-4) anthropometric parameters did not account for all differences indicating that neuromuscular development is perhaps more important at this stage. BM and FFM normalisations were applied to attempt to control for changes in body size and composition but may not have fully accounted for the higher levels of force/power required to accelerate with increasing fat mass.

**EFFECTS OF SIX WEEKS ISOKINETIC ECCENTRIC TRAINING (AND DETRAINING) ON PLANTARFLEXOR MUSCLE-TENDON MECHANICS IN OLDER ADULTS**

KAY, A.D.1, FOLLAND, B.1, BAXTER, B.A.1, BLAZEVICH, A.J.3
*1: UON , 2: CU , 3: ECU*

INTRODUCTION: Joint range of motion (ROM) is compromised in ageing and numerous neurological conditions where muscle stretching techniques often provide limited improvements [1]. However, large increases in ROM (10-15°) with concomitant increases in muscle strength have been reported in young adults after eccentric-only training programmes [2]. Therefore, the present study examined the impact of a 6-week isokinetic eccentric plantarflexor and dorsiflexor training programme (and 8 weeks of detraining) on a range of musculoskeletal characteristics in older adults.
METHODS: Maximal isometric and eccentric plantarflexor torque, Achilles tendon and gastrocnemius medialis (GM) stiffness, GM architecture, and dorsiflexion ROM were measured in 11 participants (age [mean ± SD] = 67.4 ± 5.6 y, mass = 70.5 ± 15.6 kg, height = 1.6 ± 0.1 m) before and after the 6-week training programme using dynamometry and sonography. All measures were then re-examined 8 weeks later to quantify detraining effects. Training was performed twice weekly, which consisted of 5 sets of 12 maximal plantarflexor and dorsiflexor isokinetic eccentric contractions, performed at a velocity of 10°·s-1 through 20° plantarflexion to 10° dorsiflexion ROM.
RESULTS: Significant (P < 0.05) increases in isometric (22.4 ± 19.5%) and eccentric (40.1 ± 15.3%) plantarflexor strength, active Achilles tendon stiffness (20.4 ± 6.2%), GM thickness (8.5 ± 5.5%) and fascicle length (7.8 ± 6.1%), alongside decreases in passive muscle-tendon unit (16.4 ± 16.0%) and GM (22.9 ± 19.5%) stiffness were detected immediately after the 6-week training programme. No change in GM pennation angle (0.1 ± 0.8° [0.8 ± 4.6%]) was detected. Eight weeks later, no significant regression in any measure was detected, which remained significantly different to baseline.
CONCLUSION: The concomitant improvements in ROM, tendon stiffness, muscle strength and size after eccentric exercise, with limited regression eight weeks after the cessation of training, is indicative of substantive and prolonged functional benefit. Thus, as older adults are prone to musculoskeletal decline and periods of inactivity, these findings have important implications for clinical exercise prescription.

### ACUTE AND REPEATED BOUT EFFECTS OF SUB-MAXIMAL ISOKINETIC ECCENTRIC EXERCISE ON NEUROMUSCULAR FUNCTION AND PERCEIVED EXERTION IN OLDER ADULTS.

BAXTER, B.A., BAROSS, A.W., RYAN, D.J., WRIGHT, B.H., KAY, A.D.

*UNIVERSITY OF NORTHAMPTON*

INTRODUCTION: The superior muscular adaptations accompanied by lower metabolic demand commonly reported following eccentric exercise make it highly suitable to combat age-related neuromuscular decline [1]. However, acute decreases in strength are often observed alongside muscle soreness following eccentric contractions [2], although these symptoms are usually alleviated following the initial exposure (i.e. “the repeated bout effect” [RBE]). Whilst muscle strength and soreness are commonly examined, few studies investigate other common fall-risk factors. Therefore, the present study examined the acute and RBE of eccentric exercise on neuromuscular fall-risk factors and perceived exertion in older adults.
METHODS: Neuromuscular function (sit-to-stand, timed-up-and-go [TUG], isometric and eccentric strength, explosive capacity, and postural sway) and rate of perceived exertion (RPE) whilst performing functional tasks were measured in 13 participants (age = 67.6 ± 4.9 y) pre- and post-eccentric exercise (0, 24, 48 and 72 h) in bout 1 (acute) and 14 days later in bout 2 (RBE). Eccentric exercise was performed on an isokinetic unilateral stepper ergometer at 50% of maximal eccentric strength for seven minutes (including 1 min warm-up and cooldown) at 18 step/min (126 steps per limb). Two-way repeated measures ANOVAs and post-hoc analyses were conducted to identify any significant ($P < 0.05$) differences.
RESULTS: Eccentric strength significantly decreased in bout 1 at 24 h post-exercise but then recovered; no significant reduction occurred in bout 2. Rate of torque development (0-200 ms) significantly decreased in both bouts at 24 h post-exercise but then recovered; contractile impulse (0-250 ms) did not decrease in bout one but did at 24 h post-exercise in bout 2 and then recovered. No significant reduction occurred in any other neuromuscular function measure in either bout. RPE during sit-to-stand remained significantly elevated for 72 h post-exercise in bout 1 but was only elevated immediately post-exercise (0 h) during bout 2. RPE during TUG remained significantly elevated for 72 h after both bouts of exercise.
CONCLUSION: Sub-maximal eccentric exercise results in minimal disruption to neuromuscular functional characteristics that are commonly associated with falls in older adults after the initial bout, which were eliminated in bout 2, indicative of a protective RBE. Low levels of muscle soreness evident after the initial exposure were also alleviated following the second bout. Despite no change in sit-to-stand or TUG performance, RPE was elevated when conducting these tasks. Nonetheless, the present findings suggest that sub-maximal low-volume eccentric exercise is a safe exercise modality to prescribe to community-dwelling older adults given the minimal impact on fall-risk characteristics.

### PHYSIOLOGICAL AND GENOMIC DATA SUPPORT THE NEURAL CONTRIBUTION TO SARCOPENIA: FINDINGS FROM THE GENOFIT STUDY

PRATT, J., DE VITO, G., PESSANHA, L., WHITTON, L., DOLAN, J., CONROY, J., RYAN, A., SEGURADO, R., NARICI, M., BOREHAM, C.

*UNIVERSITY COLLEGE DUBLIN*

INTRODUCTION: The loss of skeletal muscle strength and mass, termed ‘sarcopenia’, is a deleterious facet of aging, associated with a plethora of negative health consequences in this population. Despite considerable research into sarcopenia, its underlying mechanisms remain poorly understood and prevalence remains high. Further illumination of the regulatory processes underpinning muscle health is needed to help facilitate the refinement of preservative strategies. Although sarcopenia is recognised as a multifaceted disease, emerging evidence suggests neural pathways may be particularly relevant. In this study, we present physiological and genomic data that support the pertinence of neural processes to sarcopenia. Specifically, we report novel associations between plasma levels of neurofilament light chain (NfL), a marker of axonal integrity, and sarcopenia. Secondly, we present findings from a genome wide association study (GWAS) using whole genome sequence (WGS) data that suggest genes involved in neural processes are also linked with skeletal muscle health.
METHODS: For the NfL analysis, we recruited 300 adults aged between 50-83 years (mean age: 64.1 years; 50% female). Body composition was assessed using dual-energy x-ray absorptiometry (DXA), and a skeletal muscle index (SMI) was calculated. Grip strength was assessed with hand dynamometry. Sarcopenia was classified using the European Working Group on Sarcopenia in Older People criteria. Plasma NfL concentration was determined using a highly sensitive ELISA. For the genomic analysis, we performed a GWAS of lean mass, appendicular lean mass (arms and legs) and grip strength using WGS data from 6715 participants aged between 18-83 years (mean age: 44.8 years; 55% female). Body composition and grip strength were also determined using DXA and hand dynamometry respectively.
RESULTS: NfL levels were associated with grip strength and SMI ($p=0.005$, $p=0.045$, respectively) and were significantly elevated in sarcopenic individuals compared to non-sarcopenia participants ($p<0.001$). Overall, individuals with pre-sarcopenia (low grip strength or low SMI) had significantly higher NfL levels, compared to controls ($p=0.001$, $p=0.006$, respectively), although sex-specific differences were observed. NfL concentration demonstrated acceptable diagnostic accuracy for sarcopenia (area under curve=0.726, $p<0.001$). The GWAS revealed genes involved in neuromuscular transmission and neuronal integrity to be linked with skeletal muscle phenotypes relevant to sarcopenia.
CONCLUSION: Together, our findings support the relevance of neural processes to skeletal muscle regulation. Firstly, the associations reported between circulating NfL levels and sarcopenia status demonstrate the link between degrading axonal integrity and sarcopenia. Secondly, the candidate genes identified using WGS further support the pertinence of neural pathways in maintaining skeletal muscle health.

## OP-AP13 Training monitoring

### TRACKING FATIGUE WITH SUBJECTIVE SCALES IN SOCCER REFEREES

FUSCO, A.1, FOSTER, C.2, DI MAMBRO, M.1, CORBO, L.1, CARDINALE, M.3,4, CORTIS, C.1

*1 UNIVERSITY OF CASSINO AND LAZIO MERIDIONALE; 2 UNIVERSITY OF WISCONSIN-LA CROSSE; 3 ASPETAR ORTHOPAEDIC AND SPORTS MEDICINE HOSPITAL; 4 UNIVERSITY COLLEGE LONDON*

INTRODUCTION: Fatigue can have a negative impact on performance, especially when it is not adequately monitored and there is not an appropriate workload to rest ratio [1]. This could result in non-functional overreaching and overtraining not only in players, but also in referees. Therefore, the aim of this study was to investigate the relationship between Hooper index (HI) taken before training session and rate of perceived exertion (RPE) after a submaximal standardized warm-up in soccer referees.
METHODS: After providing their written consent to participate in the study, 23 male referees from the Italian 4th and 5th divisions were followed during two months' soccer pre-season for a total of 244 training sessions. On average, each referee performed 11 trainings (min = 5; max = 24) with a standardized 10-min running warm-up (%heart rate max = 66±9%). Before all training sessions HI was administered [2], while at the end of the warm-up RPE was measured using the Borg category-ratio-10 scale. Intraclass correlation (ICC) was used to assess the internal consistency of the HI and RPE across the first five repeated standard warm-up sessions. High α coefficient (≥0.60) suggests good internal consistency and reliability. Relationship between HI and RPE responses were analyzed via linear mixed model (LMM) using HI and RPE as fixed effects, while the subjects' individual warm-up response as random effects. R-squared (R2) was calculated and Likelihood-ratio test was used to compare the LMM with the linear regression analysis. Significance level was set at 0.05.
RESULTS: The ICC of HI and RPE across the first five repeated training sessions were 0.80 and 0.69, respectively, thus demonstrating good internal consistency. LMM ($p<0.0001$; Wald $chi2=206.62$; $R2=0.48$) had an estimated standard deviation for the random intercepts of 1.61AU (95%CI: 1.18-2.21) with standard error of 0.26. Likelihood-ratio test showed that LMM offered a significant ($Chi2:132.59$; $p<0.0001$) improvement over a linear regression, meaning the intercepts were significantly different between subjects. The relationship between RPE and HI, combining the fixed and random intercepts, can be expressed with the following equation: $HI = 7.080777 + 1.336215*RPE + U0j + \varepsilon i$
CONCLUSION: Results from this study demonstrate that HI and RPE values are directly proportional during a standardized submaximal warm-up in soccer referees. This could indicate that HI and RPE could be valid and practical tools to investigate non-functional fatigue during submaximal warm-ups. Findings from the present study can be used to tailor the workload during period of training and conditioning to avoid non-functional overreaching or overtraining.

### VALIDITY AND RELIABILITY OF FACIAL RATING OF PERCEIVED EXERTION SCALES FOR TRAINING LOAD MONITORING

VAN DER ZWAARD, S., HOOFT GRAAFLAND, F., VAN MIDDELKOOP, C., LINTMEIJER, L.L.

*LEIDEN INSTITUTE OF ADVANCED COMPUTER SCIENCE*

INTRODUCTION: Rating of perceived exertion (RPE) is often used by coaches and athletes to indicate exercise intensity, which facilitates training load monitoring and prescription. Although RPE is typically measured using the Borg Category-Ratio 10-point scale (CR10), digital sports platforms have recently started to incorporate facial RPE scales, which potentially have a better user experience. The aim of this study was to evaluate the validity and reliability of a 5-point facial RPE scale (FCR5) and a 10-point facial RPE scale (FCR10), using the CR10 as a golden standard and to assess their use for training load monitoring.
METHODS: Forty-nine participants (17 untrained, 19 recreationally-trained and 13 trained) completed nine randomly ordered home-based workouts (three intensities × three RPE scales) on the Fitchannel.com platform. Heart rate was monitored throughout the workouts. Participants performed three additional workouts to assess reliability.
RESULTS: Validity and reliability of both facial RPE-scales were low in untrained participants. In (recreationally) trained participants, validity was moderate for FCR5 and good for FCR10 and reliability was rather poor for FCR5 and moderate for FCR10. Reliability was excellent for CR10. In (recreationally) trained participants, session RPE scores were also strongly related to Edward's training impulse scores ($r\geq0.70$, $P<0.001$). User experience was best supported by the FCR10 scale.
CONCLUSION: In conclusion, researchers, coaches and digital sports platforms are encouraged to incorporate the valid and reliable FCR10 and not FCR5 to assess perceived exertion and internal training load of recreationally-trained and trained individuals.

### INJURY RISK CONTROL IN WOMENS ARTISTIC GYMNASTICS THROUGH THE SESSION-RPE METHOD

TRUCHARTE, P., GRANDE, I.

*UNIVERSIDAD POLITÉCNICA DE MADRID*

INTRODUCTION: Nowadays, injuries are one of the most common reasons why athletes have a break in their sports career or end it. The appearance of these injuries is often related to stress or fatigue of the athlete. That is why the control of several variables can help to reduce their appearance. One of the most studied methods to monitor the internal training load is the session-RPE method (sRPE). Depending on the measurement of the internal load, certain calculations can be obtained to help control the risk of injury to our athletes. The most used indices are the ratio between chronic and acute workload (ACWR) (Hulin et al., 2016), training monotony (Tm), and training stress (Ts) (Foster, 1998). Womens artistic gymnastics is considered a demanding sport, and with a high injury rate, proportional to the level of performance of the gymnasts. Therefore, the aim of the present study was to assess the risk of injury in womens artistic gymnastics through the monitoring of the internal load, by means of the sRPE method.
METHODS: From the sRPE, we determined the indices to perform the injury risk control. A total of ten national top-level competitive gymnasts (age: 14.4 ± 2.9 years; height: 1.5 ± 0.1 m; mass: 43.3 ± 12.2 kg) participated in the study. The subjective perception of exertion (SPE) of each gymnast was recorded at a daily basis during four weeks after the end of each training block.

RESULTS: The results obtained from the ACWR index showed that all gymnasts had a moderate risk of injury (ACWR>1.0). In addition, the results of the Tm index showed values between 6.8 and 12.8, increasing in the last weeks of training, the same happened with the Ts index. Gymnasts have a higher risk of injury in the last weeks of training, in which the values of the Tm, and Ts index increase.
CONCLUSION: Our results seem to be in relation with previous studies, in which it is determined that high values of monotony and tension, together with high training loads, increase the risk of injury (Foster, 1998; Delecroix et al., 2019). These findings show that the indexes presented can directly help to establish a quantification of the risk of injury.

### RELATIONSHIP BETWEEN INTERNAL AND EXTERNAL TRAINING LOAD VARIABLES IN ELITE TEAM HANDBALL

LUTEBERGET, L.S., LEKVE, G.M., WIIG, H.
*NORWEGIAN SCHOOL OF SPORT SCIENCES*

INTRODUCTION: Monitoring and managing training load contributes to achieve desired training outcomes. Training load measured independently of internal characteristics is termed external load (e.g. distance, accelerations), while internal load reflects the individual physiological and biomechanical responses to the external load (1). Information about the relationship between internal and external training load has the potential to enhance training prescription and athlete management through a more detailed assessment of training efficacy. In this study we aimed to model the within- and between-player effects of different external load variables on the internal load variable session Rating of Perceived Exertion (sRPE) in elite team handbal
METHODS: Fifteen female team handball players from a team in the Norwegian Premier League were included. We included data from 24 on-field sessions from the in-season period. External load was measured via a tracking-device (Catapult ClearSky T6, Catapult Sports, Australia), which includes a local positioning system and an inertial measurement unit. The variables PlayerLoad™, PlayerLoad2D™, total distance, high speed running distance, very high speed running distance, and high intensity events were used. Players reported their sRPE via an online questionnaire, using a modified Borg CR-10 scale. sRPE was multiplied with session-duration to get sRPE training load (sRPE-TL). Data were analyzed using a linear mixed-effects model, where the external load variables were treated as predictor variables, with separate models for each predictor variable. Player-ID and session-ID were random effects in the models.
RESULTS: The mean±SD sRPE-TL was 425±170 a.u. All external training load variables showed a significant within-player effect on sRPE-TL, where a 2 SD change in external load produced a 17-37% change in sRPE-TL. PlayerLoad™ (Effects size [ES]:1.38), PlayerLoad2D™ (ES:1.24), and total distance (ES:1.19) had the largest effects. None of the external load variables showed a significant between-player effect. The models showed ESs from 0.28 to 0.50 for individual responses (random effect for Player-ID).
CONCLUSION: Our results show that sRPE-TL can differentiate between sessions with differing external load within individual players. sRPE is shown to be closely related to certain external load variables, in agreement with studies from other team sports (2). In contrast to previous research, no between-player effects were found, meaning that players with a typical high or low external load do not differ in their sRPE-TL response to the same external load. However, the individual response effects underline the need for an individual approach to load monitoring. These results contribute to the understanding of the dose-response relationship in handball training for female players.

### ON-COURT DRILLS IN ELITE BADMINTON PLAYERS - IMPACT OF INTERVAL LENGTH ON INTERNAL AND EXTERNAL LOAD

EDEL, A., WIEWELHOVE, T., FERRAUTI, A.
*RUHR UNIVERSITY BOCHUM*

INTRODUCTION: Typical on-court drills aim at different training goals, since the protocol (e. g. number and duration of intervals) has an impact on physiological, physical and performance outcomes. However, due to a lack of evidence regarding individual loads, protocols are prescribed solely following experts' opinion. The aim of the present study was to clarify the impact of drill prescription on loads and technical skill performance in elite badminton.
METHODS: On three experimental days thirteen German professional players (Ten male: 22.2 ± 3.3 years, 180 ± 6 cm, 72.2 ± 6.1 kg; Three female: 20.3 ± 2.5 years, 167 ± 5 cm, 57.7 ± 4.6 kg) completed three different sessions of the so-called "multifeeding drill" in a counterbalanced order (one coach feeds shuttlecocks in randomized direction to one player). The protocols varied in interval duration (10s, 30s and 50s) but were matched for the rally-to-rest-ratio (1:1) and playing time (30min). Cardiorespiratory responses (Portable Spirometry; cortex medical), energy metabolism (Blood Lactate, LA), player´s kinematics (Local Positioning System; kinexon), and technical skill performance (Video Analysis) were measured.
RESULTS: Mean and peak values of heart rate (averagely 160 ± 10 bpm and 179 ± 8 bpm), oxygen consumption (45.0 ± 8.0 ml/min·kg and 72.4 ± 10.6 ml/min·kg), respiratory exchange ratio (0.91 ± 0.04 and 1.15 ± 0.01) and total aerobic energy expenditure (917 ± 210 kcal) did not differ between the protocols. LA was significantly lower in the 10s (3.3 ± 0.9 mmol/l) and similar in the 30s and 50s protocols (5.5 ± 0.8 mmol/l and 6.0 ± 1.0 mmol/l). Striking frequencies (0.59 ± 0.06, 0.60 ± 0.04, 0.59 ± 0.06 shots per second), number of jumps (83 ± 44, 84 ± 36, 80 ± 45) and unforced hitting errors (13 ± 8 %, 17 ± 5 %, 16 ± 3%) did not differ. Overall larger distances were covered during 30min of the 10s protocol, compared to the 30s and the 50s protocol (1579 ± 582 m, 1329 ± 389 m, and 1106 ± 225 m). The average peak accelerations were comparable for the three protocols (3.5 ± 0.7 m/s^2, 3.3 ± 0.5 m/s^2, 3.4 ± 0.9 m/s^2).
CONCLUSION: External loads and technical skill performance are largely similar despite a different interval length and higher anaerobic metabolic loads in the 30s and 50s protocol. Apparently, players can tolerate the higher interval duration to a large extent probably by implementing pacing strategies since the 50s did not lead to higher LA compared to the 30s protocol. As striking frequencies remained equal while players covered less distances in 50s, the coach might feed the shuttlecock easier to reach. From a metabolic point of view the

10s intervals preferably reflect the mean badminton match play requirements. Extending the intervals beyond 30s cannot be recommended for anaerobic training since the metabolic stimulus remains constant.

## Oral presentations

### OP-AP07 Acute response to strength training

#### TIME COURSE OF RECOVERY FOLLOWING WORK-MATCHED STRENGTH-ORIENTED- VERSUS POWER-ORIENTED RESISTANCE EXERCISE BOUTS

VÅRVIK, F.T., BJØRNSEN, T., GRANLI, A., LINDBERG, L.

*UNIVERSITY OF AGDER*

INTRODUCTION: The recovery process is a key aspect for athletes to regain full performance capacity and optimize adaptations. Resistance exercise with high-loads seems to require longer recovery times than lower-load power bouts when volume- or the concentric work is matched (1, 2). However, previous studies have not controlled for the eccentric work. Hence, the aim of this study was to compare the recovery of a strength- versus a power-oriented bout with equal concentric and eccentric work.
METHODS: Nine strength-trained male (n=6) and female (n=3) participants (age: 24¬±2 years, height: 175±8 cm, body weight: 78±13 kg) completed two randomized counterbalanced-crossover training bouts using the smith-machine squat (1RM: 137±27 kg). One strength-oriented (SO: 4 sets x 5 reps at 80% 1RM) and one power-oriented (PO: 6 sets x 5 reps at 40% of body weight [equated ~20-25% 1RM]) session was performed, both with 3-min rest-intervals between sets. Maximal voluntary isometric squat strength (MVC), countermovement jump (CMJ) height and power as well as subjective perceived recovery score was rated prior to, immediately after, 24h- and 48-h after training. Rate of perceived exertion (RPE) was rated immediately after training. A repeated-measure ANOVA with paired-post-hoc tests were conducted for the statistical analysis.
RESULTS: Greater strength loss was observed in the strength-oriented- compared to the power-oriented group (interaction, F=4.23, p=0.010) after training (SO: -9.5% [95% CI: -13.0, -6.1]; PO: -2.6 [-4.7, -0.6]) that was still lower at 24h (SO: -6.7% [-10.7, -2.6], PO: 0.7% [-2.5, 3.8]). CMJ average power decreased more after training in the strength-oriented group (-5.3% [-8.0, -2.7]; PO: -2.2 [-5.2, 0.8]). With no group differences, both groups decreased CMJ height (SO: -11.9% [-17.5, -6.3]; PO: -8.8% [-12.7, -4.9]), and there was a tendency for the strength-oriented group to not be fully recovered at 24h (-5.6% [-11.4, 0.2]). Ratings of perceived recovery was rated lower in the strength-oriented group (interaction, F=4.96, p=0.013), with 2.1-point [0.4, 3.8] lower ratings in the strength-oriented group at 24h. RPE was rated 4.2-points [3.1, 5.4] higher after the strength- versus the power-oriented bout.
CONCLUSION: The strength-oriented bout acutely elicited a more pronounced training stress with greater strength and power loss, higher perceived exertion, in addition to slower strength recovery up to 24h after training and lower overall ratings of perceived recovery, compared to the power-oriented bout. No group-differences were observed in CMJ performance at the 24- and 48h time point; however, this may be due to low statistical power combined with relatively lower sensitivity of the CMJ measurements. More research is needed to provide greater insight into the topic.

#### ACUTE RESPONSES TO DIFFERENT BLOOD FLOW RESTRICTION-RESISTANCE EXERCISE PROTOCOLS DIFFERING IN THE REST TIME BETWEEN REPETITIONS

CORNEJO-DAZA, P.J.1,2, SÁNCHEZ-VALDEPEÑAS, J.1,2, RODILES-GUERRERO, L.1,3, PÁEZ-MALDONADO, J.1, CANO-CASTILLO, C.1, LEÓN-PRADOS, J.A.1,2, PAREJA-BLANCO, F.1,2

*1,2-UNIVERSIDAD PABLO DE OLAVIDE, SEVILLE, SPAIN. 3- UNIVERSIDAD DE SEVILLA, SEVILLE, SPAIN*

INTRODUCTION: Blood flow restriction resistance exercise (BFR-RE) has been shown to induce marked hypertrophic responses and acute metabolic signalling (1,2). On the other hand, the cluster set method (short rest times between repetitions) allows athletes to achieve greater strength, velocity and power in each repetition and lower metabolic stress with respect to traditional training (3,4). However, it remains unknown whether the use of this cluster method in BFR-RE could influence the effects induced by this methodology. Therefore, the aim of this study was to analyze the acute responses to two different BFR-RE protocols that differed in the rest-time between repetitions in the full-squat (SQ) exercise.
METHODS: Twenty resistance-trained young men performed two BFR-RE protocols in the SQ exercise which consisted of 3 sets of 8 repetitions at maximal intended velocity against the 60% 1RM with 2-min rest between sets and a 50% of individual arterial occlusion pressure, but differed in the rest time between repetitions: 30-s rest every 2 repetitions (BFR-Cluster) or traditional repetitions (BFR-Trad). The occlusion was maintained during the entire training session and all repetitions were recorded with a linear velocity transducer and a force platform. In order to analyze the acute responses to these BFR-RE protocols, blood lactate concentration, countermovement jump (CMJ) height, maximal isometric force (MIF) and maximal rate of force development (RFDmax) during a maximal isometric SQ contraction, as well as mean propulsive values of velocity, power and force (MPV, MPP, MPF) against the 60% 1RM load were assessed at Pre- and Post- protocols, in this order. Moreover, MPV, MPP, MPF, percentage of velocity loss (VL) in the set were evaluated in each resistance exercise protocol (average of 24 repetitions) to observe the descriptive characteristics.
RESULTS: Significant “protocol x time” interactions ($p<0.05$) and significant “time” effects ($p<0.05$) were found for lactate concentration and CMJ height. On the other hand, no significant “protocol x time” interactions ($p>0.05$) were found for the rest of the variables analyzed. However, significant “time” effects ($p<.001$) were observed for all parameters. Both protocols showed significant ($P<0.001$) increases in blood lactate and decreases in CMJ height with higher impairments for BFR-Trad ($p<0.05$). Moreover, both protocols resulted in significant ($p<0.01$) decreases in MIF, RFDmax, MPV, MPP, and MPF, these decreases were significantly ($p<0.05$) higher in BFR-Trad in MPV, MPP, MPF. On the other hand, BFR-Cluster resulted in significantly ($p<0.001$) higher values of MPF, MPV, MPP and lower %VL in the training session compared to BFR-Trad.

CONCLUSION: Despite both protocols performed SQ exercise under the same conditions (volume, intensity, rest time between sets and occlusion), the rest time between repetitions with BFR proved to be a tool to induce a lower decrease in mechanical responses and a lower increase in metabolic response even in BFR-RE settings.

### TRAINING BACKGROUND AFFECTS TIME COURSE OF NEUROMUSCULAR FATIGUE DURING POWER AND HYPERTROPHIC LOADING PROTOCOLS

KOTIKANGAS, J., WALKER, S., PELTONEN, H., HÄKKINEN, K.

*UNIVERSITY OF JYVÄSKYLÄ*

INTRODUCTION: Persons with different training backgrounds have specific long-term training adaptations, which may also lead to dissimilar progression of neuromuscular fatigue and strategies to compensate for fatigue during resistance exercises. This study aimed to examine the time course of neuromuscular fatigue during three different resistance exercise loadings, and whether it is affected by the training background.
METHODS: Power athletes (PA, n=8), strength athletes (SA, n=8) and nonathletes (NA, n=7) performed power (PL, 7x6x50% of 1-RM), maximal strength (MSL, 7x3x3-RM) and hypertrophic (HL, 5x10x10-RM) loadings in Smith-machine back-squat. Average power (AP), sEMG amplitude (sEMGRMS) and sEMG mean power frequency (sEMGMPF) were measured during the concentric phases of selected repetitions during all loading sets. For PL and HL, the values of averaged 1st and 2nd repetition (REPIN) were used to represent the first repetition of sets. Blood lactate concentrations (BL) were collected before (PRE) and immediately after (POST) the loadings.
RESULTS: Significantly greater 1-RM and AP at a load of 50% of 1-RM were observed in both PA (144.6 ± 24.2 kg and 664.2 ± 136.6 W) and SA (176.8 ± 31.0 kg and 729.8 ± 112.0 W) compared to NA (106.4 ± 19.8 kg and 450.8 ± 94.9 W) ($p \leq 0.05$). During PL, there was a significantly greater absolute decrease in AP from REPIN of SET1 to the REPs of SET7 in NA (-4.6%) compared to PA (+0.1%) and SA (+4.4%) ($p \leq 0.05$). During MSL, no significant differences were found between groups in any variable. During HL, significantly greater absolute decreases in AP were observed within SET1 and SET5 and from REPIN of SET1 and SET3 to the REPs of SET5 in PA and SA compared to NA ($p < 0.005$). During HL, a significant group×repetition interaction occurred also from REPIN of SET3 to the REPs of SET5 in relative sEMGMPF but the post hoc test did not indicate significant differences between groups. The greatest decreases in absolute AP and relative sEMGMPF and increase in relative sEMGRMS were observed during MSL and HL in all groups. Significant increases in BL from PRE to POST were observed in all groups during all loadings.
CONCLUSION: Training background seemed to affect the progression of neuromuscular fatigue during PL and HL. During PL, the athletes maintained their higher AP levels throughout the loading, which could be due to the changes in the neural activation strategies, but this can not be confirmed by the data of the present study. During HL, the athletes demonstrated clearer absolute decreases in AP, and the training groups may have also demonstrated slightly different strategies to compensate for accumulating fatigue. For instance, within SET1, the increase in sEMGRMS with the concurrent decrease in sEMGMPF was observed in NA, whereas in SA and PA only decreases in sEMGMPF were observed. However, the training background seemed to have a limited effect on neuromuscular fatigue during MSL.

### ACUTE EFFECTS OF SEPARATE UPPER OR LOWER BODY COMPARED TO WHOLE BODY STRENGTH LOADING ON EXPLOSIVE STRENGTH PERFORMANCE

DRAGUTINOVIC, B., FEUERBACHER, J.F., SCHUMANN, M.

*GERMAN SPORT UNIVERSITY COLOGNE*

INTRODUCTION: We have previously shown that not lower body endurance loading alone, but combined lower body endurance and lower body resistance loading induces an acute reduction in upper body explosive strength.1 Whether this reduction is due to the impact of the strength loading or the duration of the combined loading remains unknown. Therefore, it is of particular interest whether an acute strength loading does not only affect the explosive strength in the previously exercised extremity, but also in non-exercised muscles. Thus, the aim of this study was to examine the acute effect of lower and upper body maximal strength loading on upper and lower body explosive strength.
METHODS: Preliminary data of 7 physically active men (age: 24±3, 1RM squat: 120±17 kg, 1RM bench press: 91±12 kg) completed 2 strength training sessions consisting of combined lower (i.e. squat) and upper (i.e. bench press) body maximal strength loading (3×5 followed by 3×3 repetitions at 80% 1RM, for both exercises) was analysed. The session started with either squat (SQ+BP) or bench press loading (BP+SQ). Squat and bench press mean propulsive velocity (MPV) was assessed during the loading as well as in a separate explosive strength assessment (3 repetitions with 60% 1RM) prior to the first loading (T0) and immediately after the first (T1) and the second loading (T2).
RESULTS: No between-condition difference in MPV during the BP and SQ was observed ($p > .05$). Bench press MPV at T1 was only statistically reduced in BP+SQ (BP+SQ: -13.6±9.3%, $p < .001$ and SQ+BP: -5.1±5.6%, $p = .282$), while squat MPV was statistically reduced at T1 in both sessions (SQ+BP: -10.2±4.4%, $p < .001$ and BP+SQ: -7.1±4.0%, $p = .007$). No further decrease was observed between T1 and T2 in both bench press (SQ+BP: -9.7±12.9%, $p = .237$ and BP+SQ: +3.7±17.0%, $p = 1.000$) and squat (SQ+BP: +1.0±6.6%, $p = 1.000$ and BP+SQ: -1.8±14.0%, $p = 1.000$). The decreased bench press MPV at T2 was statistically significant in both sessions (SQ+BP: -14.4±13.4%, $p = .011$ and BP+SQ: -11.5±7.2%, $p = .038$), while squat MPV at T2 only decreased in SQ+BP (SQ+BP: -9.4±5.4%, $p = .033$ and BP+SQ: -8.5±10.3%, $p = .066$).
CONCLUSION: Our preliminary data indicate that upper body high-intensity muscle contractions impair both upper and lower body explosive strength performance, while lower body strength loading does not induce fatigue in the upper body. Whether the reduction in lower body explosive strength after preceding upper body strength loading is due to central or systemic factors remains to be investigated. However, practitioners should be aware of a reduced lower body movement velocity after a preceding upper body maximal strength loading.

**VELOCITY-BASED TRAINING RESULTS IN LESS ACUTE FATIGUING EFFECTS ON JUMP AND SPRINT PERFORMANCE COMPARED TO FAILURE-BASED RESISTANCE TRAINING: A RANDOMIZED CONTROLLED CROSSOVER TRIAL**

DEUTSCH, J.P., HELD, S., RAPPELT, L., DONATH, L.

*INSTITUTE FOR EXERCISE TRAINING UND SPORT INFORMATICS*

INTRODUCTION: Professional team sport is characterized by the interchange of short high-intensity activities and longer low-intensity periods. Strength, power and speed are considered key determinants of success in team sports (Bragazzi et al., 2020; Faude et al., 2013; Suchomel et al., 2016; Yáñez-García et al., 2019). However, the high density of competitions makes the integration of resistance training (RT) very difficult. Due to the short time between competition games and due to the high amount of team training sessions, strength training sessions are therefore often placed in the preparation phase to prepare players for the upcoming demands during the season (Silva et al., 2015). If no further or only insufficient RT sessions are offered after the preparation phase, the performance level will gradually drop again during the course of the season and the risk of injuries increases. This randomized controlled crossover trial investigated whether an acute difference exists between velocity-based RT with maximal10% velocity loss (VL10) and traditional 1RM-based RT to repetition failure (TRF) on jumping and sprinting performance immediately following (POST0) and 24h post (POST24) RT.
METHODS: 15 recreational team sport athletes (23.1±3.5 yr; 1.80±0.06 m; 79.1±7.9 kg , Squat (SQ): 114,8±24,5 kg; Hip-Thrust (HT): 171,1 ± 26 kg) were investigated in this study. The participants could be classified as highly advanced resistance trained males. The subjects completed a load and volume matched VL10 and TRF, in a randomized order with 7 days break in between. Repeated sprint (5x15m), countermovement jump (CMJ) and drop jump (DJ) were measured pre, immediately post and 24h post both RT sessions. Further, heart rate (HR) and lactate were analyzed during the RT sessions.
RESULTS: Statistics revealed significant time*mode interaction effects for CMJ, DJ and 5x15m (rANOVA p≤ 0.001; ηp2≥0.63). Instantly post RT, sprint, DJ and CMJ were less negatively affected (p≤0.03; SMD≥|0.40|) by VL10 vs. TRF. Sprint and CMJ were already recovered 24h post RT and showed no significant differences between TRF and VL10 (p≥0.07; SMD≤|0.21|). At 24h post RT, DJ was still reduced during TRF, but already recovered during VL10 (p=0.01; SMD=|0.70|). TRF resulted in higher lactate, heart rate, and perceived effort compared to VL10 (p≤0.019; ηp2≥0.27; SMD≥|0.68|).
CONCLUSION: Compared to TRF, VL10 seems to be a less demanding RT method and therefore a promising alternative for team sport athletes during in-season training. Future research should focus on implemented VL10 during the regular season in high-level team sport athletes.

**CONCURRENT VALIDITY OF ISOKINETIC LEG PRESS AGAINST SQUAT JUMP POWER-FORCE-VELOCITY PROFILES**

FESSL, I., DIRNBERGER, J., KRÖLL, J., WIESINGER, H.P.

*UNIVERSITY OF SALZBURG*

INTRODUCTION: University of Salzburg (Salzburg, Austria)
Olympic Training Center Salzburg (Salzburg, Austria)
Power-force-velocity profiles expose the sports performance parameters maximum force (F0), speed (v0), power (Pmax), and slope of the F-v relationship (SFV)1. However, unless cohorts are highly jump-experienced3, recent research reports a lack in P-F-v parameter reliability2. Coordinatively less demanding, better standardizeable leg press P-F-v profiles alleviate reproducibility challenges3, but poor agreements to the functional and likely external more valid jump profile raise the question of its suitability as a substitute measure. Here, we compared the performances of vertical squat jump and horizontal leg press P-F-v profile outcomes for the first time in a cohort where all derived parameters can be recorded reliably3.
METHODS: Thirteen male ski jumpers performed a squat jump test on a force plate (CTP Contemplas) followed by an isokinetic leg press test (IsoMed, D&R Ferstl), separated by 20 min. The tests consisted of jumps of five loads from 0% to 80% of body mass or bilateral leg extensions at 0.1, 0.3, 0.7, and 1.2 m·s-1 (ROM: 80° - 130°). Concurrent validity of F0, v0, Pmax, and SFV was obtained using regression validity analysis4 including proportional bias assessments5.
RESULTS: The squat jump (r2≥.96) and the leg press profiles (r2≥.96) revealed highly linear force-velocity relationships. However, the leg press F-v slope was steeper than the squat jump slope, and the F-v parameters did not correlate (F0: r=.48; v0: r=.22; Pmax: r=.69; SFV: r=-.26). F0 was higher in leg press than squat jump P-F-v tests (p<.001), whereas v0 was lower in leg press than squat jump P-F-v tests (p<.001). Significant proportional bias was found for F0: p<.001 and Pmax: p<.001. The typical error in the estimate was for F0: 2.01 N·kg-1, v0: 0.30 m·s-1, Pmax: 1.75 W·kg-1, and for SFV: 0.35 N·s·m·-1·kg-1.
CONCLUSION: Although squat jump and leg press P-F-v profiles revealed linear relationships, they caused different estimations of F0, v0, Pmax and SFV. Hence, multijoint tasks of the lower limb might be coordinatively too complex to be amenable to a single holistic P-F-v assessment. These discrepancies might be explained by biomechanical (e.g. acceleration phases, joint motions and force distributions, punctum fixum – punctum mobile) or neuronal factors and influence F0 and Pmax outcomes depending on performance. The outcomes can differ substantially between approaches as shown by the typical error.

### SINGLE LEG SQUAT TEST REVEALS WHAT DROP JUMP TEST MISSES, DYNAMIC VALGUS TENDENCY EXAMINATION WITH ARTIFICIAL INTELLIGENCE IN ADOLESCENT SOCCER PLAYERS

UHLÁR, Á.

*HUNGARIAN UNIVERSITY OF SPORTS SCIENCE*

INTRODUCTION: The major part of knee injuries and ACL ruptures in sports occurs in dynamic knee valgus position, which means that the knee tilts to the medial side of the body. Usually, this position appears at the landing phase of the jump, during quick direction shift, jumping and squatting. As a consequence of valgus stress the ligaments of the knee are overloaded and overstretched, furthermore above-threshold stimulus they would be ruptured. Movement pattern screening tests can prevent the injury, as revealing the malalignment in the athletes' movement. Instead of FMS and LESS tests the Microsoft Kinect Azure camera can define accurately the major joint of human body and report the movement of lower-limb segments. The Single Leg Squat (SLS), Single Leg Jump (SLJ) and Drop Jump (DJ) as movement pattern screening tests can provide multifunctional feedback about the current status of the athletes.
METHODS: Twelve (Group A; 14.08±0.99 y, 58.91±8.08 kg, 172 ± 9.05 cm) and ten (Group B; 14.7 ± 0.82 y; 61.8 ± 9.28, 174.3 ± 7.31) healthy adolescent soccer players were involved in this study. Group A previously received some special lower-limb corrective exercise on their strength training. However, Group B received traditional strength training exercises. Lower limb performances were examined with Kinect Azure camera during SLS, SLJ and DJ tests. Test results were compared to each other. The knee lateral-medial movement was examined in relation to hip-ankle frontal plane line. The positive numbers mean varus direction, meanwhile the negative numbers mean valgus direction movement.
RESULTS: Average knee positions during SLS; Group A: 0.35±1.32 cm (R) and 0.54±1.18 cm (L), Group B: 0.85±1.19 cm (R) and 0.34±1.1 cm (L). SLJ; Gr A: 1.09±11.27 cm (R) and 1.18±1.45 cm (L), Gr B: 0.58±1.12 cm (R) and 0.72±1.21 cm (L). DJ; Gr A: 4.63±1.53 cm (R) and 5.86±1.77 cm (L), Gr B. 4.26±1.11 cm (R) and 5.03±1.32 cm (L). The differences between group A and B were significant in each case. Based on the Pearson correlation coefficient strong correlation has been found between SLS and SLJ test (r=0.832). However, between SLS and DJ (r=0.296) and SLJ and DJ (r=0.248) weak correlation has been found.
CONCLUSION: It seems that the SLS, SLJ and DJ tests are suitable for dynamic knee valgus screening. Group A showed significantly better results on each movement tests compare to Group B, where no specific lower-limb corrective exercises have given. There was a strong correlation between single leg tasks (SLS-SLJ), however there is no or just weak correlation between single leg tasks (SLS-SLJ) and drop jump test. To conclude beside DJ and LESS test, single leg exercises are recommended when examining athletes' performance. Kinect camera could be a simple, quick and reliable tool for measuring the athlete's current lower limb status.

### ONE-LEGGED VERTICAL JUMP PERFORMANCE IN FEMALE VETERAN VOLLEYBALL PLAYERS IS NOT FACILITATED BY ONE-LEG BALANCE

NIKOLAIDOU, M.E.1, SCHROLL, A.2,3, BARZOUKA, K.1, SOTIROPOULOS, K.1, DRIKOS, S.1, ARAMPATZIS, A.2,3

*1 NATIONAL AND KAPODISTRIAN UNIVERSITY OF ATHENS, GREECE; 2 3 HUMBOLDT-UNIVERSITÄT ZU BERLIN, BERLIN, GERMANY*

INTRODUCTION: It has been shown that the power-velocity potential is a mechanism contributing to vertical jump performance during two-legged counter-movement jumps (CMJ) (1). It can be argued that during one-legged CMJs where the center of mass' (CoM) base of support is reduced, a higher postural balance control would be required. This study aimed at investigating the effect of one-leg balance in the ensuing one-legged vertical jump performance of female veteran volleyball players (VVP). We hypothesized that a higher one-leg balance would facilitate a more vertical displacement of the CoM, thereby creating more favourable force and power conditions of lower leg musculature during jumping.
METHODS: Twenty seven active (ACT: 50±4 years) and 39 non-active (NACT: 51±5 years) female VVP participated in the assessment of one-leg balance during two quiet stance trials with eyes open and of 20 sec duration, while standing barefoot with either left or right leg on a vertical F/P (Wii Biovision, 1000Hz). They also performed two one-legged CMJs per leg and the best trial was chosen. The average of left and right leg in both balance and jump trials was used for analysis. Off-line, the center of pressure (CoP) data was analyzed (Δt=1-16 sec) and one-leg postural balance was determined by the CoP path length, while maximum power and jump height parameters were calculated. Multiple linear regression analyses were used to test if one-leg postural balance and group would be associated with one-legged vertical jump performance.
RESULTS: No significant (P>0.05) differences were found either in one-leg balance (ACT: 69±17, NACT: 75±18 cm) or maximum power (ACT: 17.2±2.2, NACT: 16.1±2.7 W/kg) and jump height (ACT: 3.7±1.4, NACT: 3.5±1.6 cm). Results from the regression analyses showed that a higher one-leg balance in either the ACT or NACT VVP was not significantly associated with a higher maximum power (F(3, 62): 0.99, P:0.405, R2: 0.046) or higher jump height (F(3, 62): 0.54, P:0.661, R2: 0.025).
CONCLUSION: Our results show that one-leg balance did not affect the VVP's ability to perform more efficiently in the one-legged vertical CMJ, thus not confirming our hypothesis. The challenged neuromuscular coordination within the muscle-tendon units of the lower extremities during CMJ (1) may limit the transfer of balance ability to jumping performance. Volleyball training consists of numerous jumps that are executed towards multiple directions and with frequent transitions from horizontal to vertical CoM displacement. These conditions seem to elicit task-specific adaptations in the neuromuscular control of vertical jump performance in female VVP that probably restrain the contribution of one-leg balance.

### BIOMECHANICAL DIFFERENCES OF GENERAL JUMPS AND VOLLEYBALL SPECIFIC JUMPS ON HARD FLOOR AND TWO SAND TYPES

FRESE, C.

*UNIVERSITY OF STUTTGART*

INTRODUCTION: Beachvolleyball is one of the most successful competitive sports in germany besides indoor. Even though kinematic and kinetic differences between indoor and sand condition for different jump types could be proven (1,2), the influence of sand type on those jumps and on injury potential is unknown (3,4). Hence, the aim of this study is to investigate biomechanical variables for the hard floor condition and two sand types differing in degree of hardness.
METHODS: 18 young elite volleyball players (1m/17w) were analyzed. Six different jump conditions including volleyball specific jumps (block, 3 spike forms) as well as standard jumps (CMJ with/without arms) were analyzed on the three grounds. Kinetics and kinematics

were acquired synchronously using insole plantar pressure measurements and IMU-based motion capturing. Kinetic variables include stance time, maximal force and rate of force development (RFD) at takeoff for each limb. Jump height and maximal force for the landing phase were calculated. Kinematic variables include maximal knee flexion angle at takeoff and landing as well as knee flexion at IC.
RESULTS: Kinematic and kinetic differences on the three grounds were not consistent between general and volleyball specific jump types. There was no difference of contact times in the general jumps between grounds, but the closing time in all three spike jump conditions was reduced by 10% in both sand conditions. Contact time of the leading leg didnt differ. The longer contact time of the providing leg goes along with a deeper knee flexion angle of about 15% which wasn't shown in the general jumps. Secondly RFD for both limbs was highest on the hard sand in the general jumps, but highest in hall for the spike jump conditions. Thirdly jump height reduced on the sand conditions in the general jumps by about 3 cm and in all spike jump conditions by about 10 cm. Fourthly players tended to land equally on both legs in the general jumps, but landed primarily on the providing leg after the spike jump on all the grounds. In all jumps maximal forces in the landing phase was highest on hard floor. In contrast in all jump conditions maximal force of the leading leg in the take-off phase was highest in the hard sand condition and lowest in the soft sand condition. Consequently, differences between sand type for take-off was highest.
CONCLUSION: Our results show that general jumps are limited to indicate kinetic and kinematic differences in spike jumps between the three grounds. Furthermore, it has been shown that sand type may have a great influence on maximal force and RFD, but not on knee flexion angle and flight time. Since high maximal forces and high RFDs in the take-off phase might be a risk factor for chronic knee pain in volleyball players (5), further studies should examine the influence of sand type on movement mechanics.

### OP-MH12 Metabolic fitness

#### INFLUENCE OF SLEEP QUALITY AND TIME ON FAT METABOLISM AND LEPTIN LEVELS IN PHYSICALLY ACTIVE YOUNG ADULTS

PONCE GONZÁLEZ, J.G., MARÍN-GALINDO, A., MONTES-DE-OCA-GARCÍA, A., CORRAL-PÉREZ, J., OPAZO-DÍAZ, E., PÉREZ-BEY, A., VELÁZQUEZ-DÍAZ, D., REBOLLO-RAMOS, M., ORELLANA-PECINO, J.I., CASALS, C.

*UNIVERSITY OF CÁDIZ*

INTRODUCTION: A lower fat oxidation at rest (BFox) is associated with a poorer quality of sleep [1]. Only one-night sleep restriction does not influence maximal fat oxidation (MFO) during exercise, but it remains unknown if this restriction maintained over time may affect MFO. The aim of the study was to observe the association between the sleep quality and duration, and the maximal fat oxidation during exercise and blood leptin concentrations in healthy adults.
METHODS: Eighty physically active participants (30 women) 18 to 40 years old were included in this study. Height was measured using height measuring instruments. To evaluate body composition (body weight, fat mass, and fat-free mass) a bioimpedance was used. Pittsburgh sleep quality index (PSQI) scale was used to assess the sleep quality. Indirect calorimetry at rest and during MFO exercise test was measured using the open-circuit gas analyzer (Jaeger MasterScreen). Fasting blood sample for leptin analysis was taken from the antecubital vein and analyzed using the MILLIPLEX® Map kit "Human Metabolic Hormone Magnetic Bead Panel Immunoassay". Simple linear regression models were conducted to examine the independent association of sleep quality with fat metabolism and plasma leptin concentrations. We also conducted multiple linear regression models to test these associations after adjusting by cofounders
RESULTS: We observed no association between sleep latency score and MFO (P>0.05) but we observed an inverse association after including sex and age in the model (all P<0.035). An inverse association was detected between sleep duration score with MFO (P=0.03) even when age was included in the model (P=0.022), but this association disappeared when sex, FMI and VO2max were included (P>0.076). We showed an inverse association between sleep latency with MFO relativized to the lean total mass (MFO-LTM) and leg lean mass (MFO-LLM) (P<0.012), even when the model includes cofounders (P< 0.048). MFO-LTM and MFO-LLM showed an inverse association with sleep duration score in unadjusted model (P<0.019), even when was adjusted by age (P<0.033), but it disappeared when sex, FMI and VO2max were included in the model (P>0.105). PSQI global score was negatively associated with MFO-LTM and MFO-LLM (P<0.041), also when were adjusted for age (P<0.043), but not when adjusted for sex, FMI and VO2max (P>0.138). A direct association was found between PSQI global score with leptin (P=0.037), even when age, sex and FMI were included in the model (P<0.028), but not when was included VO2max (P=0.234)
CONCLUSION: Results suggest that maximal fat oxidation during exercise could improve directly by the quality and quantity of sleep. In fact, it has been reported previously that insomnia or trouble sleeping is associated with obesity, which could be regulated by a reduction in leptin hormone, which suppresses appetite and increase fat oxidation.

#### ASSOCIATION BETWEEN INSULIN RESISTANCE AND FAT OXIDATION KINETICS IN HEALTHY YOUNG ADULTS

MONTES-DE-OCA-GARCÍA, A., VELÁZQUEZ-DÍAZ, D., CORRAL-PÉREZ, J., PÉREZ-BEY, A., REBOLLO-RAMOS, M., OPAZO-DÍAZ, E., MARÍN-GALINDO, A., CALDERÓN-DOMÍNGUEZ, M., CASALS, C., PONCE-GONZÁLEZ, J.G.

*UNIVERSITY OF CADIZ*

INTRODUCTION: Despite the importance of the fat oxidation capacity in metabolic flexibility, which is usually impaired in obese people, and, therefore, its possible impact on insulin resistance, it is unknown how insulin resistance could affect the fat oxidation kinetics (FOK). Therefore, the aim of the present study was to investigate the relationship between insulin resistance and resting fat oxidation (RFO), maximal fat oxidation during exercise (MFO), FatMax (intensity at which MFO is observed) and FOK in apparently healthy young adults.

METHODS: 70 participants (n=26 females; 22.72 ± 4.41 years; Body Mass Index=25.81 ± 5.61 kg · m-2) were enrolled in this cross-sectional study. Fasting glucose and insulin were analyzed in plasma. Body composition was measured by bioimpedance. Different variables related to insulin resistance (HOMA1-IR, HOMA2-IR, HOMA2-%β, HOMA2-%S, HOMA-β and QUICKI) were calculated. RFO and MFO were determined by indirect calorimetry with a gas analyzer, using an incremental exercise protocol of 3-minute steps (15-30W) until RER=1.0 in a cycle ergometer for MFO. Then, after a 5-minute resting period, peak oxygen uptake (VO2peak) test with 1-minute steps (15-30W) was performed until exhaustion beginning at maximum watts of MFO test. A sinusoidal model was used to characterize FOK (dilatation, translation, and symmetry) and to determine the FatMax and MFO during exercise. Linear regression analyzes were performed.
RESULTS: HOMA2-IR was directly associated to MFO (p=0.010) and FatMax (p=0.020), even adjusting for age and sex, body fat or VO2peak in both (p<0.01 in all, p<0.02 in all, respectively). HOMA2-%β was positively associated to RFO (p=0.016), even adjusting for age and sex or VO2peak (p<0.015 in both), MFO only when was adjusted for body fat or VO2peak (p<0.015 in both), and FatMax only when was adjusted for VO2peak (p=0.046). HOMA2-%S was inversely associated to RFO (p=0.041), even adjusting for age and sex or VO2peak (p<0.05 in both), and MFO only when was adjusted for body fat or VO2peak (p<0.03 in both). QUICKI was inversely associated to MFO (p=0.043), even adjusting for body fat or VO2peak (p≤0.03 in both). No significant associations between insulin resistance and fat oxidation kinetics were found (p>0.05).
CONCLUSION: Insulin resistance is directly associated with RFO, MFO and FatMax. However, insulin resistance is not associated with fat oxidation kinetics during exercise. Thus, insulin resistance, due to the inability to use glucose as an energy source, could promote a higher peak of fat oxidation at rest and during aerobic exercise. In fact, due to resistance to this hormone, lipolysis is not inhibited, and this could increase the release of free fatty acids, which could favor fat oxidation. Nevertheless, future research is needed to clarify the association between insulin resistance and fat oxidation kinetics, comparing healthy people and patients with type 2 diabetes mellitus.

### GLYCOLYTIC BEHAVIOR AS A DETERMINING FACTOR IN OLDER FEMALES' MAXIMAL FAT OXIDATION

MONFERRER-MARÍN, J., ROLDÁN, A., MONTEAGUDO, P., BLASCO-LAFARGA, C.

*PHYSICAL PERFORMANCE AND SPORTS RESEARCH GROUP*

INTRODUCTION: The capacity to oxidize fat (FATox) has an impact beyond the oxidative pathway because of its indirect role in lactate production due to the GPR81 action (1), and its association with metabolic flexibility (2). Moreover, recent studies confirm this condition also in chronic exposure to lactate (3). Since there is little knowledge about the metabolic behavior in older women, the present study aims to analyze the relevance of glycolytic behavior in two groups split by Maximal Fat Oxidation (MFO), which are of greater relevance in a population of women over 60.
METHODS: Twenty-four women (67.13±5.31yrs) performed a submaximal incremental cycling test (10W every 315) to the second ventilatory threshold, with gas analysis by indirect calorimetry. FATox and CHOox were calculated by applying the equations of Frayn (1983), with determination of the MFO and peak of CHO (CHOoxpeak). To identify the MFO groups, a neutral band of ±1 was determined about the median (5.01 g/min/kgFFM), being the low MFO group (<4 g/min/kgFFM) and the high MFO group (>6 g/min/kgFFM). Study approved by the scientific ethics committee of the University of Valencia (H105715353921).
RESULTS: Data showed significant between groups differences in Powerpeak (p<0.01), Minpeak (p<0.01) and BLapeak (p=0.01). Other variables such as rFATmax did not reach significance (p=0.14), as well as MinMFO (p=0.47), and CHOox values both at its peak point (p=0.21) and at MFO (p=0.27), showing non-existent differences with respect to the MFO groups.
CONCLUSION: Data confirms BLapeak between MFO-groups differences, despite lactate values were higher in the high-MFO group, unlike indicates the existing literature (3). Since our BLa outcomes were analyzed only post-test, we might assume that the low CHOox rates and power through the test, together with the final BLapeak, might reflect also low lactate outcomes at the MFO point in these women, as suggested by San Millan et al. (3). Moreover, recently a direct association with higher lactate values in those women who obtained a higher MFO was observed (2), indicating that those women who preserved the oxidative pathway, had better maintenance of the glycolytic pathway. Noteworthy, the biggest differences were found with respect to the Powerpeak, confirming the strong association between Powerpeak and fat oxidation in the preliminary phases of this study (2), similarly to the differences found in Minpeak where the highest MFO group is, in turn, the one that performed a longer test. Future studies should analyze the behavior at intensities closer to the maximum in this population to know if these differences are maintained or vary in these markers of interest as well as analyze the lactate behavior in MFO intensities.

### HIGHLY REDUCED ACTIVITY FOR 3 WEEKS IMPAIRS MOOD PROFILE WITHOUT AFFECTING KYNURENINE PATHWAY METABOLITES IN THE BLOOD OF HEALTHY YOUNG INDIVIDUALS

VENCKUNAS, T.1, KAMANDULIS, S.1, SNIECKUS, A.1, BRAZAITIS, M.1, EIMANTAS, N.1, SCHWIELER, L.2, ERHARDT, S.2, WESTERBLAD, H.1,2

*1 - LITHUANIAN SPORTS UNIVERSITY; 2 - KAROLINSKA INSTITUTE.*

INTRODUCTION: Low physical activity is one of the major health risk factors and it may also induce acute and long standing mood disturbances. Kynurenine pathway metabolites have been shown to associate with mood state and also respond to physical exercise. The aim of the present study was to reveal how plasma markers of kynurenine metabolism change in response to two 3-week phases of the intervention – severely limited activity followed by resumed activity plus additional physical exercise – in young healthy individuals.
METHODS: Twenty-four healthy individuals (7 females) aged 25.6 ± 5.6 years volunteered to 6 weeks of intervention. During the first 3 weeks, activity was highly reduced using only forearm crutches for ambulation with one leg suspended (INACT), The following 3 weeks consisted of resumed activity plus additional supervised training sessions (mix of resistance and high intensity interval training, 3 to 6 sessions per week; ACT). At baseline and after both INACT and ACT, blood was collected for subsequent UPLC-MS/MS analysis of eight kynurenine pathway metabolites (Tryptophan, L-kynurenine, KYNA, QUIN, 3HK, Picolinic acid, Niacin, 3-Hydroxy anthranilic acid). Questionnaires for activity (IPAQ), anxiety/depression (HADS) and profile of mood states (POMS, 65 items) were assessed at the same occasions. Activity was monitored with activity bracelets.

RESULTS: During INACT, activity was reduced ~7-fold on average (IPAQ score from 2200 to 300 MET min/week), and increased to ~4000 during ACT; average daily step count was ~1200 during INACT and ~7400 during ACT. During INACT, depression score on HADS scale tended to increase (3.3 to 5.5; p=0.067), while anxiety score did not change; however, HADS anxiety score was reduced with ACT compared to after INACT (p=0.01).
On POMS scale, depression (5.7 to 11.7; p=0.025), fatigue (4.8 to 9.5; p=0.001), confusion (4.8 to 7.0; p=0.029) increased, vigor decreased (18.7 to 15.9; p=0.045) and total mood disturbance (14.0 to 33.4; p=0.020) increased with INACT. Intriguingly, those subjects who developed mood disturbance with inactivity, were more active before the intervention according to their IPAQ report (p<0.05). All POMS scale scores fully restored to baseline with ACT.
None of the eight kynurenine pathway metabolites in the plasma changed significantly with either INACT or ACT. Some subjects developed depression according to HADS scale (mild – 1 case, moderate – 1 case, severe – 2 cases), by the end of INACT, but such developments were not reflected in the concentration of any of the kynurenine pathway metabolites.
CONCLUSION: Severe voluntary restriction of activity for 3 weeks had substantial negative, but transient, impact on mood state in young healthy individuals. These changes were not accompanied by alterations in blood concentrations of kynurenine pathway metabolites.

### EFFECTS OF VITAMIN D DEFICIENCY ON THE ACUTE RESPONSE OF ARTERIAL STIFFNESS TO MODERATE-INTENSITY ENDURANCE EXERCISE IN HEALTHY ADULTS

CHEN, L.Y., WANG, C.W., CHEN, L.A., WANG, S.C., HE, C.S.

*NATIONAL CHUNG CHENG UNIVERSITY*

INTRODUCTION: Cardiovascular disease (CVD) is a disease that causes deaths worldwide. It is estimated that 17.9 million people died from CVD in 2019 (1). The previous study has shown that vitamin D deficiency is associated with CVD and arterial stiffness. Increased pulse wave velocity (PWV) is an indicator of arterial stiffness and a major risk factor for CVD. The peripheral PWV (pPWV) is measured by body limb pulse wave and we used a finger to toe to measure pulse wave velocity (ft-PWV). It is known that moderate-intensity endurance exercise has a positive effect on vascular function (2). The primary objective of this study was to understand the effect of vitamin D status on pPWV following moderate-intensity endurance exercise in healthy adults and the relationship between vitamin D levels and pPWV.
METHODS: Fifty male participants were divided into the 25-hydroxyvitamin D (25(OH)D) sufficiency group (n=28, 25(OH)D ≧50 nmol/L) and deficiency group (n=22, 25(OH)D <50 nmol/L). The acute maximal exercise was performed using an incremental cycling test to exhaustion. The relative exercise intensity was set at 60% VO2peak, and the rotation speed was maintained at 60 revolutions per minute for 120 minutes of continuous riding on a stationary bicycle. And the pPWV and blood pressure (BP) were obtained at rest and 0, 15, 30, 45, 60 minutes after moderate-intensity endurance exercise. The pPWV and BP variables were analyzed with a two-way analysis (ANOVA). Significant interaction and main effects were followed up with post hoc comparisons t-test analysis. Bivariate correlations between 25(OH)D levels and PWV were determined with Pearson product-moment analysis. The accepted level of significance was p <0.05.
RESULTS: The total 25(OH)D concentration from 28 participants classified in the sufficiency group was 60.21 ± 6.75 nmol/L and the total 25(OH)D concentration from 22 participants classified in the deficiency group was 40.28 ± 7.50 nmol/L. T-test analysis revealed that 25(OH)D deficiency group had higher pPWV at post-15 minute (5.41 ± 0.93 vs 4.84 ± 0.75 m/s), post-30 minute (5.30 ± 0.77 vs 4.84 ± 0.75 m/s), post-45 minute (5.56 ± 0.93 vs 5.05 ± 0.68 m/s) than the sufficiency group. In addition, the pPWV decreased significantly from baseline to post-0, 15minute in the sufficiency group. Systolic BP decreases significantly from pre-exercise to post-15, 30, 45 minute in sufficiency group. Diastolic BP was no significant time effect and group effect. The 25(OH)D levels were significantly associated with pPWV at post-15, 30, 45 minute.
CONCLUSION: In this study, we found that adults with sufficient 25(OH)D could have a better vascular function after moderate-intensity endurance exercise. People with sufficient vitamin D status had better vascular regulation and could provide the body with the oxygen needed for endurance exercise.

### EFFECT OF B-COMPLEX SUPPLEMENTATION ON PROFESSIONAL FOOTBALL PLAYERS

CANNATARO, R., BONUCCELLI, A., GATTESCHI, L., CIONE, E., STEFANINI, L., SEMPERBONI, L., BARTOLI, S., ANGELINI, F., CICERO, A.F.

*UNIVERSITY OF CALABRIA*

INTRODUCTION: The use of supplements in professional sport is still a controversial subject; there is a discussion on the advisability of their use regarding the improvement of performance, as well as on the definition of ad hoc ranges that should be different from those of the normal population, which guarantee that there are no deficits and therefore possible pathologies; for example, the RDA of vitamin C guarantees not to have scurvy, but the goal of nutrition applied to the sport should guarantee an optimal value not only to preserve from possible pathological states.
METHODS: 18 Italian professional soccer players being part of a Serie A team received a vitamin B (composition) supplement (B-Dyn®, Metagenics, Milan, Italy ) for 40 days; iDXA, BIA and a battery of biochemical-clinical analyses were performed at the initial time t0 (pre-season preparation), at time t1 (after 40 days) and at time t2 (after 3 months), to evaluate both the quantity of some vitamins (B9, B12 and D) and also the possible effect on the measured parameters of the supplementation.
RESULTS: iDXA and BIA parameters did not show any remarkable change; although the values of vitamin B9 and B12 (value) were within the normal range, the integration intervention recorded an increase which then decreased by interrupting the integration (value); between the values considered the hematocrit shows a significant increase at time t2 (value), as well as the reticulocytes; the VES also shows a similar trend. The other parameters do not show statistically significant changes except for the plasma values of zinc and vitamin D, which both show a decreasing trend over time.

CONCLUSION: In our opinion, although on a limited sample, this work can be a starting point to re-evaluate integration in professional sports. Evaluating a person who does not practice high-level physical activity, supplementation, in particular of vitamin B9 or B12, would not be justified, in this case, it is; on the contrary, it should probably be kept for the whole season or for longer periods (at least 3 months); the delayed improvement of hematocrit values and granulocytes (value linked to hematopoiesis) it might be justified by the fact that hematopoiesis is affected after a longer period of integration. Unfortunately, it is not easy to act on professional athletes during the season, therefore a larger sample and a control group would be useful in subsequent studies.

### VITAMIN D INSUFFICIENCY AMONG INDIAN ATHLETES AND ITS ASSOCIATION WITH CYP2R1 (RS10741657) POLYMORPHISM.

MANJAPPA, K., CHERIAN, K., KOTTURU, S., DURGAM, D., GHOSH, S., YAGNAMBHAT, V.

*ICMR-NATIONAL INSTITUTE OF NUTRITION, INDIAN COUNCIL OF MEDICAL RESEARCH, HYDERABAD, INDIA.*

INTRODUCTION: Vitamin D insufficiency negatively impacts the health and training efficiency of athletes. The growing prevalence of vitamin D deficiency worldwide might be a combined outcome of dietary inadequacy, less exposure to sun, and genetic predisposition. Variations in CYP2R1 gene have been linked by several studies to vitamin D serum concentration. Especially, the rs10741657(G) allele has been associated with lower vitamin D status and thus a potential cause for Vitamin D insufficiency. Although more than 76% of Indians suffer from vitamin D deficiency, currently there are no studies on Vitamin D levels in Indian Athletes and understanding the genetic predisposition to lower vitamin D status. Thus, the aim of this study was to check for an association between CYP2R1 polymorphism and Vitamin D levels of athletes participating across different sporting category.
METHODS: 91 Indian Elite and sub-elite athletes (Male:44 Female:47) participating in different sports categories (Weightlifting (29), Badminton (31), Athletics (14), Rowing (17)) aged 18.61 (SD=4.2) years were included in the study. The blood sample was collected for laboratory analysis. PCR-RFLP of SNP on CYP2R1 (rs10741657) was carried out and vitamin D levels were checked using the ELISA kit method. Chi-square analysis was done to understand the distribution of allele and genotype frequency among gender & sports categories. To find the association between the genotype and vitamin D status ANOVA and Independent sample t-test were carried out.
RESULTS: Majority (92.3%) of the participants were vitamin D insufficient. Vitamin D deficiency was highest among weightlifters and athletics groups (100%), irrespective of gender, followed by female rowers (88%), and Badminton players (64.5%). The genotypic frequency for Wild, Heterozygote and Mutant was 21%, 40% and 39% respectively. The average Vitamin D levels across the Wild, Heterozygote and Mutant genotypes were 27.39 ng/mL, 13.39 ng/mL and 12.41 ng/mL, respectively and it was found significantly different.
CONCLUSION: Vitamin D deficiency is highly prevalent among the athletes in the study. This deficiency may be due to the higher prevalence of alternate allele CYP2R1 polymorphism. Thus, making the genetic makeup a key player in determining the Vitamin D status of athletes.

### HOW CAN SWIMMER'S NUTRITION IMPROVE THE PERFORMANCE: A SYSTEMATIC REVIEW

CAI, Y., ZHOU, C., HUANG, C.

*BEIJING SPORT UNIVERSITY*

INTRODUCTION: Although the nutrition problems of swimmers has been well documented in the literature, still insufficient nutrition existed in swimmers. The aim of this study is therefore to explore how to deal with the problem of insufficient nutrition supplement in swimmers to improve the performance of the athletes.
METHODS: This systematic review was conducted under the guidance of the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) criteria. PubMed, Web of Science, EBSCO and CNKI (Chinese databases) were searched for papers published after 2014. A total of 47 papers were included, and the results of the evidence on age, nutritional criteria, athletic ability and nutrition in the study population were retrieved for systematic evaluation.
RESULTS: Consistent evidence shows that most swimmers currently skip breakfast, with excessive calorie intake in dinner. As for the macronutrients, the problems of both insufficient carbohydrate and fat supplement and excessive protein (especially animal protein) intake exist in swimmers. For the micronutrients supplement, vitamin A, vitamin B1, vitamin B2, vitamin C, vitamin PP, vitamin E, Calcium, Zinc, Potassium and Magnesium are generally insufficient, but Sodium supplement tends to be excessive. The main focus of research on nutritional supplement is on Creatine, Branched-chain amino acids, L-carnitine and Lycopene.
CONCLUSION: Unbalanced energy intake in three meals a day, insufficient carbohydrate and fat supplement and excessive protein intake, lack of certain micronutrients and the improper use of nutritional supplement are the main problems that need to be solved to the performance of swimmers.

### EFFECTS OF DIFFERENT VITAMIN D LEVELS ON BONE MASS AND TURNOVER MARKERS IN FEMALE ADOLESCENT FOOTBALL PLAYERS: A ONE-SEASON STUDY.

LOZANO-BERGES, G., MATUTE-LLORENTE, A., GÓMEZ-BRUTON, A., GONZÁLEZ-AGÜERO, A., VICENTE-RODRÍGUEZ, G., CASAJÚS, J.A.

*UNIVERSITY OF ZARAGOZA*

INTRODUCTION: Vitamin D (Vit D) is a hormone that plays an important role in bone development (Holick 2003). In fact, levels of serum 25-hydroxyvitamin D (25(OH)D) above 30 ng/mL are recommended to maximize calcium absorption and bone mineralization (Holick et al. 2011). To our knowledge, there is only one study that analysed the association between Vit D and bone health finding no correlation between these parameters in female adolescent football players (Brännström et al. 2017). Thus, the aim of this study was to evaluate the influence of different 25(OH)D concentrations on bone health changes during a season in this population.
METHODS: A total of 22 female football players were divided into two groups according to their 25(OH)D concentrations: 11 in deficient/insufficient 25(OH)D group (IVD; <30 ng/mL; 12.6±0.6 y), and 11 in sufficient 25(OH)D group (SVD; ≥30 ng/mL; 12.6±0.6 y). Subtotal body and lumbar spine bone mineral content (BMC), and mean legs areal bone mineral density (aBMD) were measured by dual-energy X-ray absorptiometry (DXA, QDR-Explorer, Hologic Corp). Bone mineral apparent density (BMAD) for the whole body and lumbar spine was calculated using Katzman and Carter equations (Carter, Bouxsein, and Marcus 1992; Katzman et al. 1991). Electrochemiluminescence immunoassays were used to analyse bone biomarkers (procollagen type I N-terminal propeptide, osteocalcin, and C-terminal cross-linked telopeptide) and 25(OH)D. All variables were registered at the beginning and the end of the football season. Serum calcium was measured by colorimetric assay. Analysis of variance for repeated measures was performed to examine body composition differences within players

with IVD and SVD between the beginning and the end of the season and to analyse group by time interactions for normally distributed variables. Mann-Whitney U and Wilcoxon signed-rank tests were used for those that did not show normal distribution.
RESULTS: The increase in legs aBMD and lumbar spine BMAD was higher in players with SVD than those with IVD (n2p were 0.277 and 0.237; p<0.05). Only players with SVD significantly improved whole body BMAD from the beginning to the end of the season (r was 0.63; p=0.001). Both players with IVD and SVD significantly increased subtotal body and lumbar spine BMC (p<0.05). No significant between- and within-group differences were found for bone biomarkers parameters (p>0.05). Moreover, serum calcium levels were reduced in both groups (p<0.05).
CONCLUSION: SVD might cause an extra increase of aBMD and BMAD parameters in female adolescent football players. Moreover, it seems that different serum 25(OH)D concentrations do not directly affect turnover markers in this population.

## OP-SH06 Psychology and education

### VALIDATION OF THE CANADIAN ASSESSMENT OF PHYSICAL LITERACY (CAPL-2) FOR GERMAN AND POLISH CHILDREN

KNISEL, E., LAUDANSKA-KRZEMINSKA, I., WASCHER, L., BREMER, M.

*OTTO-VON-GUERICKE UNIVERSITY OF MAGDEBURG*

Introduction
In recent years physical literacy as a prerequisite of participation in physical activity has attracted researchers' attention worldwide. To measure physical literacy the Canadian Assessment of Physical Literacy, second edition (CAPL-2) with the four domains of Motivation and Confidence, Physical Competence, Knowledge and Understanding, and Daily Behavior is a valid and reliable instrument to assess physical literacy in children. The aim of our study is to translate CAPL-2 (Longmuir et al., 2018) into German and Polish language, adapt it to German and Polish context and to test the measurement properties on German and Polish children 8-12 years old.
Method
CAPL-2 consists of a questionnaire to assess the Knowledge and Understanding and Motivation and Confidence domains. The Daily Behavior domain is assessed from one self-report item of weekly physical activity included in the questionnaire and objectively from step counts during one week. To measure the Physical Competence domain three physical tests are applied. In a first stage the CAPL-2 questionnaire was translated into German and Polish language according to the TRAPD approach (Harkness, 2003), pilot tested and the final two versions of the questionnaire and the final German manual description was produced. So far, the German version of the questionnaire was tested on 113 children (girls=56, mean age=10.77, SD=1.3) and the Polish version on 181 children (girls=94, mean age=11.6, SD=1.1). 71 German children (girls=35, mean age=10.8, SD=1.4) completed CAPL-2 assessments.
Results
The analyses until now show acceptable split-half reliability for the Motivation and Confidence domain. For the total CAPL-2 questionnaire the Mann-Whitney-Test shows no significant differences between the German (M=32.84; SD=5.87) and Polish (M=31.58; SD=5.91) children. The data revealed statistically significant differences in the domain Knowledge and Understanding (p=.000; r=.33) and the item of weekly physical activity (p=.028; r=.14) between the two samples.
Discussion
Following similar procedures adopted in the other CAPL-2 validation studies, confirmatory factor analyses will be performed on full samples of approximately 500 German and 500 Polish children. CAPL-2 total and domain scores will be computed for all children and separately across gender and age groups. The comparison of CAPL-2 scoring of the two samples will show to what extent the different cultural backgrounds and educational systems support the promotion of physical literacy.

### THE DEVELOPMENT AND VALIDATION OF DEPENDENCE AND CRAVING MEASURES SPECIFIC TO ATHLETES WHO USE ANABOLIC-ANDROGENIC STEROIDS

ZOOB CARTER, B.N., BOARDLEY, I.D.

*UNIVERSITY OF BIRMINGHAM*

Background: Anabolic-androgenic steroid (AAS) dependence is estimated to affect approximately 30% of people who use AAS. Presently, measures to assess and diagnose AAS dependence are adapted from scales specific to other forms of drug misuse (e.g., alcohol) and these measures have issues with internal consistency and breadth of construct capture. Alongside this, there are currently no measures to assess AAS craving, which represents a potentially important antecedent to AAS dependence. Therefore, the aim of this study was to develop and provide evidence of validity for measures of AAS dependence and AAS craving.
METHODS: Data were collected from male and female strength athletes who use AAS across two samples (nsample 1 = 206; nsample 2 = 103). Sample 1 completed the new measures alongside instruments assessing theoretically related constructs (Doping Moral Disengagement, Doping Self-Regulatory Efficacy Scale, craving items from the Wisconsin Smoking Withdrawal Scale, AAS adapted Diagnostic and Statistical Manual for Mental Disorder 5th Edition), whereas Sample 2 just completed the new instruments.
Results: Exploratory and Confirmatory Factor Analyses (CFA) were used with data from Sample 1 to determine the factorial structures of the AAS Dependence Scale (AASDS) and AAS Craving Scale (AASCS), as well as the item sets for both measures. The AASDS consists of 15-items across five first-order factors that are represented by one second-order factor. The AASCS consists of 16-items across four first-order factors that are represented by one second-order factor. Evidence supporting the concurrent, convergent and discriminant validity of scores obtained with both scales was provided through their associations with the theoretically related variables. CFA with the data from Sample 2 confirmed the factor structures for both scales.

Conclusions: The AASDS and AASCS are proposed as valid and reliable measures of AAS dependence and AAS craving for use in research with strength athletes who use AAS.

### THE VALIDATION OF AN ORIGINAL CRITERIA-REFERENCED TESTS BATTERY FOR THE ASSESSMENT OF K-8 STUDENTS' FUNDAMENTAL MOTOR SKILLS AND ITS INTEGRATION INTO THE PEDAGOGICAL TEACHING-LEARNING SEQUENCE

IANCU, H.D., PICARD, Y., RICHARD, J.F., BÉLANGER, M., RICHARD, J.

*ÉCOLE DE KINÉSIOLOGIE ET DE LOISIR - UNIVERSITÉ DE MONCTON*

INTRODUCTION: A key role of quality school physical education (PE) is to enable children to learn and master motor skills. The assessment of fundamental motor skills (FMS) therefore becomes essential. Limitations of existing measurement tools include being designed exclusively for clinical and sport contexts, having age restrictions (3 - 10 years old) and not emphasizing, as much as it should, pedagogical purposes of PE learnings. Accordingly, we developed an original battery of 24 representative tests for the evaluation of students fundamental psychomotor (20) and sociomotor (4) skills.
Objective: To assess feasibility, validity and reliability of these 24 FMS tests of the battery.
METHODS: Following established standards for the development of psychomotor tests, we identified the skills to be assessed, developed assessment parameters by focusing on the performance process (quality) rather than the product, and determined the tests procedures. Other experts evaluated the face and content validity of this battery. Testing took place in 7 schools (N = 1584 students). Each test was administered to targeted age groups students (2nd, 5th and 8th grade) to assess the test's feasibility and to refine evaluation parameters. This process was repeated following modifications of testing procedures aimed at improving psychometric properties. Inter-rater reliability and construct validity (more precisely, concomitant validity) were assessed with Pearson correlations, Kappa statistics, Pearsons chi-squared statistics and Cramers V symmetric measurements.
Results: After the first test administration and the first feedback from PE teachers on test parameters, we modified instructions to improve clarity and adjusted the estimated time of administration for some grade levels and the training of raters. Following the 2nd and 3rd school's visits and modifications of testing procedures, acceptable to good indices of inter-rater reliability (Pearson $\chi 2$ = 93,536-136,894; Kappa = 0,654-0,836) and construct validity (Pearsons Khi-square $\chi 2$ = 98.942-148.775; linear by linear association $\chi 2$ = 72.144-89.226; Cohens Kappa = 0.696-0.798 and Cramers V symmetric = 0.806-0.850) were found for final versions of the tests.
Conclusions: Our study shows that the development of this criteria-based test battery following a rigorous methodological process was complex and time intensive (over 5 years). Nevertheless, the statistical analyses led to an appropriate validity and intra-rater reliability. We are continuing to investigate the ability of this criteria-based test battery to identify known group differences. Also, a process of establishing standardized measuring procedures is already in place. This test battery could become a standard measuring tool for assessing the FMS related to the PE learning outcomes, either for diagnostic, formative or summative purposes, within different teaching-learning scenarios of the French school curricula in New Brunswick, Canada.

### EFFECT OF FIVE WEEKS PARTICIPATION IN THE DAILY MILE ON COGNITIVE FUNCTION IN PRIMARY SCHOOL CHILDREN

COOPER, S.B., DRING, K.J., HATCH, L., WILLIAMS, R.A., MORRIS, J.G., SUNDERLAND, C., NEVILL, M.E.

*NOTTINGHAM TRENT UNIVERSITY*

INTRODUCTION: The Daily Mile is an extremely popular school-based physical activity intervention which is currently being implemented in ~14,000 schools in ~80 countries Worldwide. However, the longer-term effects of participation in The Daily Mile on cognitive function in young people are unknown; whilst the evidence from other physical activity initiatives is mixed. Furthermore, it is suggested that changes in physical fitness may moderate changes in cognitive function, given the positive association between fitness and cognition in young people. Therefore, this study examined the effect of five weeks of participation in The Daily Mile on cognitive function and physical fitness in young people.
METHODS: In a quasi-experimental study, two classes were assigned to an intervention group, who completed The Daily Mile every day for five weeks (n=44), or to a control group who continued with their habitual activities for five weeks (n=35). Cognitive function was assessed by a battery of computerised tests, consisting of a Stroop test (executive function), Sternberg paradigm (working memory) and Flanker task (attention). Physical fitness was assessed as distance run on the multi-stage fitness test (MSFT). Baseline and follow-up measurements were completed 48-h before the first, and 48-h after the last, training session respectively. Data were analysed via ANCOVA, examining between group differences at follow-up whilst controlling for baseline values (reported as mean and [95% confidence intervals]).
RESULTS: Response times on the complex level of the Stroop test were faster at follow-up in the intervention group compared to the control group (intervention: 1357 ms [1280, 1400 ms]; control: 1463 ms, [1410, 1523 ms], p = 0.048). There was no effect of The Daily Mile on the simple level of the Stroop test, Stroop test accuracy, or any aspect of performance on the Sternberg paradigm and Flanker test (all p > 0.05). However, physical fitness (MSFT distance) was greater at follow-up in the intervention group compared to the control group (intervention: 880 m, [820, 940 m]; control: 740 m, [680, 800 m], p = 0.002).
DISCUSSION:
Five weeks of participation in The Daily Mile enhanced executive function (as evidenced by faster response times on the complex level of the Stroop task) and physical fitness (as evidence by a greater distance run on the MSFT), when compared to the control group. However, there was no effect on working memory or attention. The findings of the present study suggest that even a relatively short duration implementation of The Daily Mile (five weeks; i.e., over a school half term) has the potential to enhance cognitive function in children, which has implications of schools and policy makers due to the potential beneficial effect on academic achievement.

**EFFECTS OF TWO CONTROLLED PHYSICAL EXERCISE PROGRAMS ON WORK ABILITY, JOB SATISFACTION AND ANXIETY IN THREE SEDENTARY COMPANIES: A PILOT STUDY**

JIMÉNEZ DÍAZ-BENITO, V., ZAFRA DÍAZ, S., SANTACRUZ LOZANO, J.A., CLEMENTE REMÓN, A.L., ESPADA MATEOS, M., MARTÍN RODRÍGUEZ, M., JIMÉNEZ-BEATTY, J.E., BARRIOPEDRO MORO, M.I.

*UNIVERSITY OF ALCALA FACULTY OF MEDICINE AND HEALTH SCIENCES: UNIVERSIDAD DE ALC*

INTRODUCTION: Anxiety is a feeling associated with fear that is related to lifestyle. Moreover, recent studies indicate that it is not only the physical activity itself that brings benefits to work capacity, but also highlight how beneficial it can be to perform it with co-workers. The scientific literature has not yet found the appropriate components of the various intervention programs in order to understand the general state of the question. The objective of this study was to assess the effect of two supervised physical exercise interventions in the workplace on work capacity, job satisfaction and self-perceived anxiety.

METHODS: A pre-experimental study was conducted on workers with sedentary occupations from three different companies and sectors: (1) Renewable energy engineering; (2) Insurance and (3) Infrastructure and services. The participants of the first two were administered a supervised physical exercise program at their corporate headquarters in Madrid (PRODET: n=12; mean age 43.21±7.04 and n=16; mean age 46.59±5.01, respectively). The third company carried out another physical exercise intervention in a single corporate headquarters in Madrid (HASAVI; n=18; mean age 39.25±9.83). A pre- and post-test intragroup analysis was performed on work capacity, job satisfaction and perception of anxiety.

Results: The PRODET program in the company (1) found a significant improvement in work capacity in relation to requirements (p=0.033; ?2=0.24) and an increase in psychic vitality (p=0.037; ?2= 0.23). In this company, a significant increase was found in the overall score of the work capacity index (p=0.045; ?2=0.20). The program also improved the perception of satisfaction in relation to remuneration and benefits (p=0.016; ?2= 0.19), the perception of satisfaction related to the quality of production (p=0.013; ?2=0.21) and the total score of job satisfaction (p=0.016; ?2=0.19). There was also a decrease in trait anxiety (p=0.039; ?2=0.22). No statistically significant differences were observed in the change of values from pre to post in any other company and program (p>0.05).

Discussion: These findings coincide with the results reported by other authors while studies with lower methodological quality found greater effects. Also, recent investigations have focused their interventions on graduate employees, given the presumed ease of access in these organizational contexts. This suggests the existence of considerable barriers for conducting quality interventions in the field of physical activity in the workplace. The PRODET supervised physical exercise program could influence work capacity and job satisfaction in general.

### OP-SH12 Coaching Challenges

**THE INTRINSIC VALUES OF BEING A PARENT COACH IN YOUTH HANDBALL: A 9-MONTH LONGITUDINAL QUALITATIVE STUDY**

JOHANSEN, B.T., KNIGHT, C.J., KJÆR, I.H., SOLSTAD, B.E.

*UNIVERSITY OF AGDER*

Introduction

In Norway, the number of children and adolescents involved in organized sports has grown steadily over the past several decades. Hence, a growing number of parents are coaching their own children. This trend appears to have increased over the past decades. Indeed, it has been estimated that 58 million man-hours are performed in organized sports every year. Because so many parents are involved in coaching their own children, research is warranted to provide insight into why parents choose to stay involved both on and off the court. Therefore, the purpose of the present study was to use a longitudinal qualitative design to gain in-depth insights into parent-coaches' intrinsic values of being a significant adult in youth Norwegian handball.

Methods

Three parent-coaches (n=2 males; n=1 female; all volunteer coaches) who were coaching female handball players (aged 12-13 years) participated in this study. Three focus group interviews (carried out in September, January, and May) were conducted as semi-structured interviews in appropriate settings during a 9-month competitive season. A semi-structured interview guide was developed with the intention of exploring how the participants thoughts and experiences about the intrinsic values of being a parent-coach in youth handball. Thematic analysis was used to analyze the data.

Results

After completion of the thematic data analysis, an overarching theme for the purpose of the study stood out – Enjoyment through being a parent-coach in youth handball. Four different main themes complimented and constituted within the study's overarching theme: (a) the privilege of being a parent-coach; (b) personal growth as a coach; (c) creating progress and mastery experiences; and (d) personal contribution to beneficial socialization processes and friendships between teammates. From the in-depth analysis, results revealed that the sub-themes excitement and variation, from play to performance, and positive feedback stood out under main theme 1. Under main theme 2, the sub-themes receiving support, feeling a sense of autonomy, and use of humor stood out. Under main theme 3, the sub-themes team achievement, personal skills, and performing together stood out. Finally, under main theme 4, the sub-themes team membership, friendships within the team, and personalized team-sport stood out.

Conclusion

The values underlying parent-coaches' thoughts, attitudes, and behaviors are of utmost importance. Our findings showed that the three parent-coaches experienced great enjoyment while staying involved both on and off the court. Additionally, the three parent-coaches expressed feelings of privilege because they appreciated the opportunities of personal growth as a coach, creating experiences of mastery

and progression, and being part of the process of socialization of young handball players. Further research is warranted to understand the role of parent-coaches in organized youth sports.

### LONGITUDINAL EFFECTS OF DIETARY SUPPLEMENT AND MEDICATION USE ON FUNCTIONAL AND MORAL ATTITUDES TOWARDS DOPING

BOARDLEY, I., CHANDLER, M., ZHANG, S.

*UNIVERSITY OF BIRMINGHAM, UNIVERSITY OF DERBY*

Background: Dietary supplement (DS) use has been associated with more favourable doping attitudes (Backhouse et al., 2013; Hurst et al., 2019). However, research to date has been limited to cross-sectional designs. Alongside this, researchers have not differentiated between functional/moral doping attitudes or examined potential effects of medication use on doping attitudes. As such, the aim of this study was to examine the longitudinal reciprocal relations between DS/medication use and functional/moral doping attitudes.
METHODS: Data were collected from male (n = 105) and female (n = 100) student-athletes competing in a range of team and individual sports at three time points across a competitive season. At each time point, participants completed a questionnaire assessing DS/medication use and functional/moral doping attitudes.
Results: Three-wave-cross-lagged panel analysis was used to examine the reciprocal causal effects of DS/medication use and functional/moral doping attitudes. For muscle-building supplements (e.g., protein, creatine), we detected significant weak positive cross-lagged effects from muscle-building supplement use to functional doping attitudes and from functional doping attitudes to muscle-building supplement use between T1 and T2 and T2 and T3. For moral attitudes, significant negative weak-to-moderate effects from muscle-building supplement use to moral doping attitudes were found between T1 to T2 and T2 to T3. No significant effects were detected from moral doping attitudes to muscle-building supplement use. For health and well-being (e.g., vitamins and minerals) and weight-loss (e.g., fat burners, laxatives) supplements, no significant cross-lagged effects were detected for either doping attitude. For medications (e.g., aspirin, paracetamol), we detected significant weak negative cross-lagged effects from medication use to moral doping attitudes and significant weak positive effects from moral doping attitudes to medication use. No significant cross-lagged effects were detected between medication use and functional attitudes.
Conclusions: Representing the first reported research to test the longitudinal effects of DS/medication use on doping attitudes, our findings provide the strongest support yet for a causal link between DS/medication use and favourable attitudes towards doping. Further, muscle-building supplement use appears to be a greater risk factor for doping than other forms of DS use. Our findings also provide some support for effects of attitudes on DS/medication use.

### ATHLETES USING SPORT SUPPLEMENTS MAY BE MORE LIKELY TO DOPE BECAUSE OF A MORE FAVORABLE DOPING ATTITUDE, A GREATER SOCIAL PRESSURE TO DOPE, AND A PERCEIVED EASE IN WHICH TO DOPE

HURST, P., NG, P.Y., UNDER, L., FUGGLE, C.

*CANTERBURY CHRIST CHURCH UNIVERSITY*

Introduction
The use of sport supplements (e.g., creatine, caffeine, and nitrate) is highly prevalent amongst athletes. In the past decade, a body of evidence has shown that sport supplement use may be related to the use of prohibited performance enhancing substances (i.e., doping). The aim of this study was to examine whether the relationship between sport supplement use and doping is mediated by the theory of planned behavior constructs (i.e., attitudes, subjective norms, and doping perceived behavioral control).
Methods
Competitive athletes (N = 443, 46% female, age = 27.0 ± 8.6 years old, years competing = 8.3 ± 3.5) were recruited via social media and completed measures of sport supplement use, doping attitudes, doping subjective norms, doping perceived behavioral control, and doping intention.
Results
Zero-order correlations indicated that sport supplement use was moderately and positively associated with doping attitudes (r = 0.20), subjective norms (r = 0.22), perceived behavioral control (r = 0.22) and intention (r = 0.21). Associations between doping attitudes, subjective norms, perceived behavioral control and intention were large and positive (r range = 0.49 to 0.78). Parallel mediation analysis indicated that sport supplement use was not directly related to doping intention (b = 0.10, 95% CI = -0.22 to 0.42) but instead was indirectly related via doping attitudes (b = 0.23, 95% CI = 0.11 to 0.36, effect size = 0.11), doping subjective norms (b = 0.26, 95% CI = 0.08 to 0.43, effect size = 0.13), and doping perceived behavioral control (b = 0.53, 95% CI = 0.34 to 0.76, effect size = 0.50). Contrast analyses reported no differences for indirect effects for each mediator ($p > 0.05$). Overall, the model accounted for 61% of the variance on doping intention ($F(4, 438) = 171.75$, $p < 0.01$, $R = 0.78$).
Discussion
Our data suggest that athletes who use sport supplements report stronger intentions to dope because of a more favorable doping attitude, a greater social pressure to dope, and a perceived ease in which to dope. For those aiming to in prevent doping in sport, interventions should aim to target attitudinal change towards doping, perceptions of the accepted practice of doping, and decrease perceptions of control.

### POTENTIAL RISKS OF EARLY SPECIALIZATION AND HIGH TRAINING VOLUME AMONG ELITE YOUTH FOOTBALL PLAYERS IN CHINESE SCHOOL FOOTBALL

FENG, R.1, GÓMEZ, M.1, GARCÍA-DE-ALCARAZ, A.2, LI, X.3, LI, C.3

*1 UNIVERSIDAD POLITÉCNICA DE MADRID, 2 UNIVERSIDAD DE ALMERÍA, 3 BEIJING SPORT UNIVERSITY*

INTRODUCTION: With China's commitment to promoting youth football in schools, more and more players engage in more frequent, intensive and organized sports training from a young age despite the controversy over early specialization (ES). Supporters claim that ES

allows players gain advantages in the competition, better training resources and career opportunities, but some literature on youth sports link ES with burnout and injuries. Therefore, this research aims to investigate the correlation between the training volume and ES level of elite Chinese youth players and potential risks of ES.
Method:
A cross-sectional survey study was used. Players who participated in the National School Football Winter Camp were invited to fill out a questionnaire that included the data of ES, sports volume, injury history, and burnout (n=178 children, n=88 boys and n=90 girls).
RESULTS: Confirmatory factor analysis obtain a good overall fit of the model (CMIN/DF=2.016; CFI=.927; RMSEA=.076; GFI=.943; RMR=.041). The internal consistency of the questionnaire were satisfactory (Cronbachs α=.73). The results have shown that 80.3% of the players is high-ES, while 2.8% is low-ES and 16.9% is moderate-ES. Almost all the players (96%) played one sport more than eight months of the year, most of them (75.8%) spent more than twice of the time on organized sport than leisure activities, and 30.3% of them trained exceeding average weekly hours per week based on age in years. In response to the burnout scale, the M±SD values were 1.48±0.65 for emotional/physical exhaustion, 1.64±0.66 for reduced sense of accomplishment, and 1.27±0.55 for sport devaluation. Binomial logistic regression showed the odds of reporting an injury were higher for high ES players compared to players categorized as low and moderate ES (OR=3.046; CI=1.155-8.03; p=.024). It was also higher for high ES players compared to players categorized as low and moderate ES (OR=2.451; CI=1.071-5.61; p=.034) when reporting more injuries. The MANOVA tests showed differences for: (a) burnout by the level of early specialization (F=2.72, p=.046), especially showed significant difference for sport devaluation by the level of early specialization (F=4.99, p=.027); (b) reduced sense of accomplishment by the sports volume (training one sport more than eight months of the year), (F=5.901, p=.016); and (c) emotional/physical exhaustion by the sports volume (the time spent in organized sports is more than twice than leisure activities), (F=8.17, p=.005).
CONCLUSION: The following conclusion can be stated from our findings: (i) high level of ES will increase the odds of injury and lead to sport devaluation; (ii) Excessive training volume is associated with an increased probability of reduced sense of accomplishment; and (iii) Notably, paucity of leisure activities will increase the odds of emotional/physical exhaustion.

**THE EFFECTS OF THE USE OR NON-USE OF LEAGUE STANDINGS AND PLAYOFFS ON PARTICIPATION RATES IN A CHILDREN AND YOUTH SOCCER CONTEXT**

WAGNSSON, S., HÖGMAN, J., AUGUSTSSON, C.
*DEPARTMENT OF EDUCATIONAL STUDIES*

Introduction
Whether or not to use league standings and playoffs (LSPO) in children and youth sports has been a recurring topic for fiery debates. In order to stimulate long-term sports development, enjoyment and continued participation, the Swedish Football Association decided that from 2017 the use of LSPO will be abolished until the year the children turn 13.
Method
In order to study the effect of the use or non-use of LSPO on the participation rate, register data from a specific childrens and youth football context (school class football) were analyzed. This context has the advantage that the conditions have in general been constant several decades until 2017, when keeping official scores, league standings and playoffs were removed for all age groups (7-12 years; Preschool-Grade 5) with the exception for the oldest group (13 years; 6th grade). This makes it possible to study the phenomenon over time in a natural environment and compare groups with each other while at the same time taking reasonable control of confounding factors without intervening or manipulating the groups.
School class football is a phenomenon run by a voluntarily sport club where approximately 3000-3500 children and youths participate annually. In school class football it is the single class that makes up the team and competes against other classes from different schools in the municipality. It is optional for classes to sign up and it is also up to the individual child to participate. The schools are not responsible for their participating classes. Rather, the teams are coached by volunteering parents. School class football is subject to competitive engineering (CE) as rules are modified in several ways (e.g., playing on smaller fields, using smaller goals and footballs, girls and boys playing together, always at least two boys and two girls on the pitch).
Results
Results shows that the participation rate before the removal of LSPO (2015-2017) increased slightly (<1%; from n= 3044 to 3063; n = 19), while a clear increase (20%; from n = 3063 to 3689) could be noted after the removal of LSPO (2017-2021). The increase was particularly noticeable among the girls after the removal of the LSPO (41%; from n = 1102 to 1550). While the increase among the boys was only modest (9%; from n= 1961 to 2139) and in correspondence with the municipality population increase (7 %) in this age group.
Discussion
The results indicate that the removal of league standings and playoffs increases the participation rate of groups of individuals who are usually not considered as competent as other participants. One of the reasons for this may be that a more caring and mastery oriented climate is created where coaches, athletes and parents to a greater extent care that everyone thrives and have fun instead of focusing on winning matches and getting to the playoff.

## Oral presentations

### OP-MH20 Health and fitness in children

**EFFECTS OF 12-WEEK RESISTANCE TRAINING ON NEUROMUSCULAR AND BODY COMPOSITION CHANGES IN PUBERTAL CHILDREN**

RUAS, C.V.1,3, RATEL, S.2, NOSAKA, K.1, GARNIER, Y.2, PINTO, R.S.3
*1 - EDITH COWAN UNIVERSITY, AUSTRALIA; 2 - UNIVERSITÉ CLERMONT AUVERGNE, FRANCE; 3 - FEDERAL UNIVERSITY OF RIO GRANDE DO SUL, BRAZIL*

INTRODUCTION: Children have become less physically active in the last decade, and their muscle force and power levels are lower when compared with the children in ~40 years ago (1). The decrease in physical activity levels seems to have been accentuated due to the COVID-

19 pandemic (2), and dynapenia (i.e., loss of muscle force and/or power) due to muscle disuse is now common in children (3). Thus, effective resistance training (RT) interventions are necessary to increase children's maximal and explosive muscle strength. The present study investigated the effects of 12-week RT on neuromuscular parameters and body composition in pubertal children.
METHODS: Twelve (7 boys and 5 girls) untrained pubertal children (13.4±0.9 y; Tanner stage 3.4±0.6) performed a structured full body RT program consisting of bilateral knee extensions and flexions, bench press, abdominal crunch, back extension, lateral pull-down, elbow flexion, and upright row (60 - 90 minutes a session) twice per week on non-consecutive days; exercises per session for 12 weeks with increasing volume and intensity. Bilateral KE one-repetition maximum test (1-RM) was performed before, post-6 and post-12 weeks of the program. Outcome measures included maximal voluntary isometric contraction (MVIC) torque and rate of force development (RFD) of the knee extensors (KE), electromyographic (EMG) activity of vastus lateralis and rectus femoris muscles (root mean square during MVIC), muscle thickness (MT) and echo intensity (EI) of the whole quadriceps muscle assessed by B-mode ultrasonography, and body composition by dual-energy x-ray absorptiometry. Changes in these measures before and after the training were analyzed by repeated measures ANOVAs and paired t-tests.
RESULTS: KE 1-RM increased (P<0.01) from pre-training (29.1±24.4 kg) to post-6 (48.8±39.4 kg) and post-12 weeks of RT (83.0±65.6 kg). MVIC torque increased (P<0.01) from baseline (134.6±31.6 Nm) to post-training (166.8±47.6 Nm), but RFD and EMG did not change after training (p>0.05). MT increased (p<0.01) from pre- (63.8±9.8 mm) to post-training (78.3±9.1 mm), and EI decreased (p<0.01) from pre- (39.4±8.5 A.U) to post-training (28.5±5.6 A.U). The decrease in EI represents increase in quadriceps muscle quality. Total body fat-free mass (FFM) increased (p=0.01) after the training (39.2±6.5 kg) from the baseline (38.2±7.1 kg), but no changes in body fat percentage, thigh FFM, bone mineral density and content were found (p>0.05).
CONCLUSION: The 12-week RT was effective for increasing MVIC torque (16.3±17.5%) and MT (18.8±5.5%) of the knee extensors in untrained pubertal children. It appears that the risk of paediatric dynapenia can be reduced by the regular RT program, and importantly, the children of the present study enjoyed the resistance exercises and indicated that they wanted to continue the program.

### PRETERM BIRTH IS ASSOCIATED WITH IMPAIRED PHYSICAL FITNESS IN PRESCHOOLERS: A CROSS-SECTIONAL STUDY

MARTÍNEZ-DE-QUEL, Ó.1, MARTÍNEZ-ZAMORA, M.1, ESTEBAN-DÍEZ, I.2, VALENZUELA, P.L.3

*<1> COMPLUTENSE UNIVERSITY OF MADRID. <2> SAN PEDRO HOSPITAL, RIOJA SALUD. LOGROÑO. <3> RESEARCH INSTITUTE OF HOSPITAL 12 DE OCTUBRE. MADRID.*

INTRODUCTION: Preterm birth has adverse consequences in health outcomes later in life. Mounting evidence shows that prematurity is associated with a lower physical fitness in middle childhood, adolescence and adulthood [1]. However, whether these effects are already visible since early childhood remains unknown. We aimed to compare the physical fitness of preterm preschoolers with that of age-matched children born at term.
METHODS: Children aged three to six years old and born preterm (<35 weeks) were recruited from the Neonatal Intensive Care Unit of San Pedro Hospital (Logroño, Spain), and age-matched children born at term (>37 weeks) were included as a control group. A variety of physical fitness indicators (body mass index, waist circumference, upper and lower limbs strength, agility, balance, cardiorespiratory fitness and flexibility) were assessed with the PREFIT battery [2] and the adapted sit and reach test. Demographics and physical activity levels were measured through the PrePAQ questionnaire. Between-group differences were analyzed by one-way ANCOVA adjusting for age, sex, and any other demographic variable differing between groups.
RESULTS: A total of 98 preterm children (gestational age 32.4 ± 2.3 weeks, age 5.1 ± 0.8 years, 45% female) and 74 controls (gestational age 39.9 ± 1.0 weeks, age 4.8 ± 0.9 years, 47% female) were evaluated. Despite similar physical activity levels (p>0.05), preterm children showed an overall poorer physical fitness compared to controls. Specifically, preterm children had a lower handgrip strength (26.4 ± 2.0 vs 7.5 ± 0.2 kg, p<0.001), lower-limb muscle strength (standing long jump: 75.9 ± 2.0 vs 85.2 ± 2.3 cm, p=0.003), agility (4 x 10-m test: 17.6 ±0.2 vs 15.8 ± 0.2 sec, p=0.001), cardiorespiratory fitness (PREFIT 20-m shuttle-run test: 3.2 ±0.2 vs 3.8 ± 0.2 min, p=0.005) and flexibility (adapted sit and reach: 14.6 ± 0.6 vs 17.6 ± 0.6 cm, p=0.001). Conversely, preterm children and controls showed similar results in balance, waist circumference and body mass index.
CONCLUSION: Prematurity seems to impair physical fitness since early childhood, which might support the need for promoting preventive strategies (e.g., exercise interventions or physical activity programs in schools).

### THE EFFECT OF AN ACTIVE BREAKS INTERVENTION ON PHYSICAL HEALTH, COGNITIVE PERFORMANCE AND CLASSROOM BEHAVIOUR: RESULTS FROM THE I-MOVE STUDY

MASINI, A.1, MARINI, S.2, CECILIANI, A.2, BARONE, G.2, LANARI, M.3, GORI, D.1, BRAGONZONI, L.2, TOSELLI, S.1, STAGNI, R.4, BISI, M.C.4, SANSAVINI, A.5, TESSARI, A.5, DALLOLIO, L.1

*UNIVERSITY OF BOLOGNA*

INTRODUCTION: Active Breaks (ABs) intervention involve short bouts of moderate to vigorous physical activity (MVPA) conducted by the appropriately trained teachers and delivered during or between curricular lessons1. The aim of the I-MOVE study was to evaluate the effect of an ABs intervention on physical health and cognitive functioning in primary school children.
METHODS: Two groups were considered: The Active Breaks group (ABsG) performed the I-MOVE protocol three times a day and the control group (CG) continued with normal lessons. The COVID-19 pandemic led to certain design changes in the study so during the lockdown, the ABs protocol was conducted through distance learning. Cognitive performance was assessed using working memory test and physical health was monitored through Actigraph accelerometers, motor fitness test and anthropometric evaluation. Classroom behaviour was monitored using an "ad Hoc questionnaire".

RESULTS: The percentage of children in the overweight/obesity category increased in CG and decreased in ABsG (CG pre:43.6% post:46.2% vs ABsG pre:28.4% post:25.9%, p=0.02). The 6 minutes Cooper test was significantly different between-group with adjustment for baseline values (ABsG change:1.77±136.03 vs CG change:-156.42±187.53; p<0.05). For the standing long jump no statistically, significant differences were found between the two groups over time. Working memory performance increased significantly more ABsG (change:1.30±1.17) than in CG (0.96±1.20), p<0.05. Actigraph results show that the weekly time spent in MVPA and minutes spent in vigorous and moderate PA increased in both groups with no statistically significant difference between groups, only ABsG increased in light PA. The time spent in sedentary behaviour significantly increased both in ABsG and CG, +1208.29±1077.07, p=0.001 respectively, but without significant differences from baseline to follow-up when comparing the groups. Almost the entire sample of children wanted to continue with the intervention in the following year. Children reported improvements in their quality of school life including feeling better in class 75.40% and in school 82.50% when using active breaks. There were also improvements in their time on task behaviours: 52.90% reported they work easily in class, 58.80% reported they can stay seated easily, 52.90% said they could listen more clearly, and 59.60% said they learned better and were more focused after ABs. The same results were confirmed by the teachers.
CONCLUSION: The program has proven to be very effective on the childrens cognitive and cardio-fitness performance, anthropometric measures and classroom behaviour. As the intervention presents these positive effects, its implementation in schools can have a positive, sustainable and long-term impact on childhood health.

### IS-PN07 Metabolomics in sports and exercise science

#### METABOLOMICS IN APPLIED SPORT SCIENCE RESEARCH

OWENS, D.

*LIVERPOOL JOHN MOORES UNIVERSITY*

In the applied sports setting, new methods to profile athletes with some predictive power are constantly sought. Whether this be injury prediction, recovery status or maximizing performance. For example, large scale projects have been set up to identify genetic genomics-based biomarkers in athletes with an adequate predictive power (Pitsiladis et al., 2016). However, profiling the genome of athletes is only the tip of the iceberg as the proteome and transcriptome also influence the phenotype of the athlete. As well as the aforementioned 'omics' approaches, metabolomics is an exciting discipline as unlike genes and proteins, metabolites are the direct outcome of biochemical reactions, thus can be insightful and reliable factors in physiological profiling of athletes.
In this symposium presentation, an overview of studies that describe how metabolomics is being utilised in applied sport science studies will be given. A spotlight will be put on data from two exemplar studies from the presenter's research group that have profiled i) endurance and ii) strength and power athletes. To balance use case for metabolomics in applied sports scenarios, attention will be paid to limitations of the technique with suggested do's and don'ts of applied sports metabolomics research.
In summary, this symposium presentation will demonstrate how metabolomics can reveal novel insights allowing practitioners to develop appropriate interventions to influence performance and recovery whilst raising critical considerations for study design.

#### CAN METABOLOMICS REVEAL NOVEL METABOLITES AND METABOLIC PATHWAYS ASSOCIATED WITH MUSCLE HYPERTROPHY?

BAUMERT, P.

*TECHNICAL UNIVERSITY OF MUNICH*

Resistance training is an attractive and low-cost intervention to increase muscle mass and function in various populations including athletes and elderly. Several studies show that resistance training not only increases muscle size and strength but also additionally improves glycaemic control (Yang et al., 2014), and increases glucose uptake (Colberg et al., 2016) as well as insulin sensitivity (Ibañez et al., 2005), suggesting metabolic adaptations. However, whilst mTORC1 has been identified as a key mediator of the protein synthesis, which increases post resistance exercise and during chronic overload, there are still many gaps in our understanding of the metabolic adaptations following muscle hypertrophy.
Thus, I will firstly present own data about the effect of muscle growth stimulation on metabolic changes in differentiated murine skeletal muscle stem cells in vitro and in hypertrophied mouse muscles in vivo. I will then put my results into the context to the limited published literature (e.g. Fazelzadeh et al., 2016) and I will present a systematic review of metabolic changes in muscle hypertrophy for the first time as part of a symposium. In this regard, I will explain the outcomes and that the identification of pathways associated with muscle hypertrophy is more important to advance this new field than only detecting changes of individual metabolites. Lastly, I will discuss the limitation of metabolomics analysis in muscle tissue and, as a consequence, the current incomplete coverage of global metabolic changes during muscle growth. The objectives of this presentation are to facilitate the understanding of the omics-based systems approach for gaining a comprehensive insight in metabolic adaptation following muscle hypertrophy, and to elicit debate of the future direction of this field, how discoveries of novel biomarkers will help to develop efficient training regimes for athletes.

**METABOLOMICS FOR IN VITRO AND IN VIVO EXERCISE SCIENCE**

LAUTAOJA, J.

*UNIVERSITY OF JYVÄSKYLÄ*

Exercise-like electric pulse stimulation (EL-EPS) of differentiated skeletal muscle cells, i.e., myotubes, evokes contractions that mimic intra- and extracellularly many of the physiological responses produced by in vivo exercise1. Besides EL-EPS, other in vitro exercise models, such as pharmacological compounds2 and myotube stretching3, exist. Strength of the in vitro exercise models is exclusive examination of the muscle cells without the interference of other cell types. This is not the case with in vivo studies. Overall, both in vivo and in vitro approaches are valuable tools in skeletal muscle and exercise research.
Different omics approaches, such as metabolomics4,5, are commonly used to examine exercise-induced changes in vivo. However, the number of in vitro EL-EPS metabolomics studies is small6,7. Additionally, although nutrition is known to have a great impact on exercise performance in vivo8, this aspect has remained understudied in vitro7,9.
We applied low-frequency EL-EPS under high- and low-glucose conditions to understand how myotube contractions and carbohydrate availability affect the C2C12 myotube, media and cell-free media metabolomics7. We observed contraction-induced uptake of glucose and release of lactate, acetate, 3-hydroxybutyrate and branched-chain fatty acids. Others have studied the effects of high- and low-frequency EL-EPS6 and stretching10 on the C2C12 myotube and media metabolomes, respectively. These studies demonstrated that high-frequency EL-EPS induced greater responses on the myotube metabolome than low-frequency EL-EPS, at least after short-term stimulation6 and that the cessation of the myotube stretching promoted myotube atrophy observed as increased media amino acid content10.
Metabolic disturbances promote exercise-induced adaptations in vivo and these responses can further be augmented by carbohydrate restriction8. When we cultured myotubes in low-glucose conditions, both the cells and the media were almost completely depleted from glucose after EL-EPS. This was not the case in high-glucose conditions. Interestingly, many of the contraction-induced responses observed in the myotube and media metabolomes were of lower magnitude in low-glucose conditions. This demonstrates that EL-EPS does not replicate all the in vivo responses to skeletal muscle contractions. That being said, in vitro exercise models improve constantly. For example, 3D muscle cell models and optimization of the cell microenvironment (e.g., hypoxia, nutrition and media flow) are being developed. Finally, it is important to keep in mind when interpreting in vitro data that the origin- and donor-specific characteristics of the skeletal muscle cell lines influence the obtained results11.

### IS-EX01 JSPFSM-ECSS exchange: Benefit of Maternal Exercise and Physical Activity on Childrens Health

**THE RELATIONSHIP BETWEEN PHYSICAL ACTIVITY IN PREGNANCY AND CHILD HEALTH: AN EPIDEMIOLOGICAL PERSPECTIVE**

MATSUSHITA, M.

*TOKAI UNIVERSITY*

World health organization guidelines on physical activity and sedentary behaviour recommend an active lifestyle for pregnant women. These guidelines are based on cohort studies targeting maternal and fetal health outcomes, such as low birth weight of the offspring, preterm births, and a variety of child health. I will provide an overview of East Asian and Japanese birth cohort studies. Physical inactivity during pregnancy is prevalent. To provide more practical recommendations, physical activity assessment requires several unidentified information such as 1) practical exercise intensity information, 2) type of physical activity such as commuting, chores, leisure, and sports, and 3) the influence of pre-pregnancy physical activity are necessary. Cohort studies considering the above information are still lacking. Wearable sensors using ICT technologies may potentially benefit future cohort studies.

**PLACENTAL SUPEROXIDE DISMUTASE 3 MEDIATES BENEFITS OF MATERNAL EXERCISE ON OFFSPRING HEALTH**

KUSUYAMA, J.

*TOHOKU UNIVERSITY*

INTRODUCTION: Poor maternal diet increases the risk of obesity and type 2 diabetes in offspring, fueling the worldwide epidemic of these diseases. Recent animal studies have shown that maternal exercise improves the metabolic phenotype of offspring in adulthood, including improved glucose tolerance and liver function (1). Here, we demonstrated the molecular mechanisms responsible for these critical effects of maternal exercise on glucose metabolism in offspring. METHODS: 8-weeks-old C57BL/6 female mice were fed a chow or high-fat diet and housed in cages with (trained) or without (sedentary) running wheels for 2 weeks before breeding and during gestation. Offspring were sedentary and chow-fed. RESULTS: Maternal exercise improved glucose metabolism and liver function, characterized by glucose tolerance test, hepatocyte glucose production, RNA-sequence of the liver in adult offspring. Beginning at embryonic day 13.5, maternal exercise increased expression of the tricarboxylic acid cycle and fatty acid oxidation genes in offspring liver, and increased DNA demethylation at promoters of these hepatic genes. Next, we identified a novel maternal exercise-induced AMP-activated protein ki-

nase(AMPK)/isocitrate dehydrogenase/alpha-ketoglutarate/ten-eleven translocation (TET) methylcytosine dioxygenases axis in offspring liver controlling DNA demethylation. Primary hepatoblasts treated with serum from trained dams, but not sedentary dams or trained non-pregnant females stimulated this signalling pathway, suggesting the effects of maternal exercise on offspring stem from a placenta-derived serum factor(s). Proteomics of serum and RNA-sequence of the placenta from trained dams identified this factor as superoxide dismutase 3 (SOD3). Recombinant SOD3 treatment of mouse and human hepatoblasts increased AMPK-TET signalling and hepatic gene expression. The effects of maternal exercise to increase liver AMPK-TET signal, alter liver DNA methylation and gene expression, and improve offspring glucose tolerance in vivo were ablated in placenta-specific Sod3 KO mice. By utilizing the transcriptome of the placenta and reporter analysis of Sod3 promoter, we demonstrated that maternal exercise-induced expression of vitamin D receptor (VDR) and vitamin D signalling mediate placental Sod3 expression, and normal vitamin D levels are necessary for the beneficial effects of maternal exercise on offspring liver gene expression. Finally, SOD3 was increased in serum and placenta from highly physically active pregnant women. CONCLUSION: SOD3 is an exercise-induced, placenta-derived protein that improves glucose homeostasis via epigenetic changes in offspring liver, defining a novel mechanism for the beneficial effects of exercise on metabolic health (2). These findings may lead to novel therapeutic approaches to limit the transmission of metabolic disease to the next generation. **MATERNAL OBESITY AND EXERCISE; EVIDENCE AND ISSUES**

ELLIOTT-SALE, K.

*MANCHESTER METROPOLITAN UNIVERSITY*

Pregnancy has been identified as a risk factor for the development of obesity, with long lasting consequences for both maternal and child health that last years/decades. As such, managing maternal obesity is of major public health interest. The pregnancy and postpartum periods are 'teachable moments' due to the heightened awareness about health and positive attitude towards lifestyle interventions. However, there are also a number of barriers to maintaining a healthy lifestyle during this time, which makes weight management difficult. Understanding these barriers and developing mitigation strategies is essential for the design and delivery of successful exercise-based interventions. I will (i) provide an overview of current exercise-based interventions for weight management during and following pregnancy and (ii) suggest future research directions. At present, physical activity interventions that provide choice and support and involve women in their design seem to be most successful at influencing body mass and markers of health.

### OP-PN13 Ergogenic Aids I

**BEETROOT JUICE SUPPLEMENTATION DOESN´T AFFECT TO VERTICAL JUMP PERFORMANCE IN COMPETITIVE FEMALE VOLLEYBALL PLAYERS.**

LÓPEZ-LEÓN, I., MORENO-LARA, J., MUÑOZ-LÓPEZ, A., RICO, E., GUZMÁN-NEBRO, J.A., SÁNCHEZ-OLIVER, A.J., MUÑOZ-LLERENA, A., DOMÍNGUEZ, R.

*UNIVERSITY OF SEVILLE*

INTRODUCTION: Volleyball is characterized by explosive efforts and it demands agility, jumps, and blocks for athletes. Jumping ability is one of the key elements of volleyball performance (1). Vertical jumps are related to blocking, spiking, and serving abilities (2). Sports supplements that include nitrate (NO3-) rich beetroot juice (BJ) (3) has been suggested as an ergogenic aid in sport. Based on the absence of studies analysing the possible ergogenic effect of BJ on female volleyball players, this study aimed to analyse the effect of BJ on vertical jumps in female competitive volleyball players.
METHODS: 11 competitive female volleyball players with more than six years of experience who competed in the second Spanish national league (age: 22.45 ± 3.13 years; weight: 72.25 ± 7,1 kg; height: 175.64 ± 6,7 cm) participated in this study. 150 minutes before each testing session, the players ingested a total 140 mL of BJ (~12.8 mmol NO3-), or 140 mL of a NO3depleted BJ as placebo (PLA), on a radomised assignment. The players executed three different types of vertical jumps: countermovement jump (CMJ), block jump (BJ), and attack/spike jump (AJ). Between-group differences were analysed using a Studen t-test. The effect size (ES) was used for qualitative assessment. We set the statistical significance level at $p<0.05$.
RESULTS: There were no significant between-groups differences in any of the vertical jumps: CMJ (30.95 ± 2.27 vs 30.67 ± 2.83 cm; $p = 0.638$; ES = 0,11 [-0,79 - 1,00]), BJ (31.72 ± 2.52 vs 31.93 ± 2.87 cm; $p = 0.721$; 0,07 [-0,96 – 0,81]), and AJ (40.25 ± 4.60 vs 39.31 ± 4.42 s; $p = 0.324$; ES = 0,20 [-0,69 – 1,09]).
CONCLUSION: BJ supplementation has been suggested as an ergogenic aid in explosive (4) and high-intensity efforts (5). Our results did not agree with previous results. Future studies must analyse the effect on other key parameters of this sport as agility or speed. In addition, it´s necessary to analyse the possible effect of a chronic supplementation protocol.

**EFFECTS OF BEETROOT JUICE SUPPLEMENTATION ON AGILITY IN COMPETITIVE FEMALE VOLLEYBALL PLAYERS**

MORENO-LARA, J., LÓPEZ-LEÓN, I., MUÑOZ-LLERENA, A., GUZMÁN-NEBRO, J.A., RICO, E., SÁNCHEZ-OLIVER, A.J., MUÑOZ-LÓPEZ, A., DOMÍNGUEZ, R.

*UNIVERSITY OF SEVILLE*

INTRODUCTION: Inorganic nitrate (NO3-), which is abundant in some green leafy vegetables and beetroot, is sequentially reduced to nitrite (NO2-) and nitric oxide (NO) following ingestion. Dietary NO3- supplementation has been reported to have ergogenic effects on improving

endurance (1), high intensity (2), and explosive efforts (3). However, the majority of the studies included only male athletes. The objective of this study was to analyse the influence of the acute supplementation with NO3rich beetroot juice (BJ) on the subsequent performance of professional female volleyball players agility ability.
METHODS: 11 female professional (second Spanish national league) volleyball players with an experience higher than six years competed in the second Spanish national league (weight: height: 175.64 ± 6,7 cm; 72.25 ± 7,1 kg; age: 22.45 ± 3.1 years) articipated in this study. The study followed a randomised double-blind cross-over design. Before each testing session, the players ingested 140 mL of NO3rich BJ (~12.8 mmol NO3-) or a NO3depleted BJ (PLA), 150 minutes before. The players executed the 0-5-0 agility test and a modified T-test in each session. We assessed the differences between BJ and PLA using a Student t-test. The effect size (ES) was also calculated. We set the statistical significance as $p<0.05$.
RESULTS: There were no significant differences between BJ and PLA for the 0-5-0 test (2.92 ± 0.16 vs 2.85 ± 0.17 s; $p = 0.046$; ES = 0.41 [-0.49 – 1.31]) nor the modified T-test (6.37 ± 0.28 vs 6.25 ± 0.35 s; $p = 0.320$; ES = 0.36 [-0.53 – 1.26]).
CONCLUSION: Acute supplementation with NO3rich BJ was not effective in increasing performance in the agility ability of female volleyball players. The absence of significant differences could be attributed to a gender effect due to a reduction of NO2- to NO blunted, based on a greater oxidative skeletal muscle phenotype than males (4). Therefore, future studies are necessary to detect possible differences in response to NO3- in females compared to males.

### SODIUM CITRATE OR SODIUM BICARBONATE INGESTION? A COMPARISON OF GASTROINTESTINAL SYMPTOMS AND BLOOD ALKALOSIS.

URWIN, C., SNOW, R., CONDO, D., SNIPE, R., WADLEY, G., CONVIT, L., CARR, A.

*DEAKIN UNIVERSITY*

INTRODUCTION: Ingestion of either sodium citrate (SC) or sodium bicarbonate (SB) can induce blood alkalosis, some gastrointestinal symptoms (GIS), and exercise performance improvement (1). However, direct comparisons of these supplements to-date have been limited and equivocal (REFS). Investigating the timing and magnitude of blood alkalosis and GIS responses to SC and SB supplementation may allow more evidence-based recommendations to athletes as to how and when these supplements may be used prior to exercise. This study aimed to compare the recommended dose of SC (500 mg.kg-1 BM) and SB (300 mg.kg-1 BM) supplementation for induced blood alkalosis (blood pH and [HCO3-]) and GIS (number and severity).
METHODS: Using a repeated-measures, double blinded, cross-over design, 16 healthy and active male (n = 8) and female (n = 8) completed two experimental testing sessions, with 500 mg.kg-1 BM SC or 300 mg.kg-1 BM SB ingested in gelatine capsules alongside a carbohydrate-rich meal over a 15 min period. Forearm venous blood samples were collected and immediately analysed for blood pH and [HCO3-] at baseline, immediately after ingestion, and then every 30 min for 300 min post-ingestion. GIS questionnaires were completed at the same time-points (2). Time-course and session value (i.e. peak and time to peak) comparisons of SC and SB supplementation were performed using linear mixed models.
RESULTS: Peak blood pH and [HCO3-] were similar for SC and SB ($p = 0.729$, 0.308), as were delta blood pH and [HCO3-] ($p = 0.654$, 0.478). Blood [HCO3-] was ≥ 6 mmol.L-1 above baseline from 180-240 min post-ingestion for SC, significantly later than for SB (120-180 min, $p < 0.001$). GIS were mostly minor, and peaked 80-90 min post ingestion for SC, and 35-50 min post ingestion for SB. There was no significant differences for the number or severity of GIS reported ($p > 0.05$ for all parameters).
CONCLUSION: When comparing SC and SB, similar blood alkalosis and GIS was observed post-ingestion with regards to peak and total values. However, the time-course of these responses did differ, as had previously been suggested (3). Specifically, for SC (500 mg.kg-1 BM), blood alkalosis peaks and GIS subside by 180-240 min post-ingestion. For SB (300 mg.kg-1 BM), the same occurs by 120-180 min post-ingestion. For both supplements, the most frequently reported GIS were bloating, belching and flatulence, although all were relatively infrequent and of minor severity. Therefore, to maximise alkalosis and minimise GIS, our findings suggest SB should be ingested 2-3 hours prior to exercise, and SC 3-4 hours prior to exercise.

### DIETARY INORGANIC NITRATE AS AN ERGOGENIC AID: AN EXPERT CONSENSUS DERIVED VIA THE MODIFIED DELPHI TECHNIQUE

SHANNON, O.M., ALLEN, J.D., BESCOS, R., BURKE, L., CLIFFORD, T., EASTON, C., GONZALEZ, J.T., JONES, A.M., JONVIK, K.L., LARSEN, F.J., PEELING, P., PIKNOVA, B.

*LEAD INSTITUTIONS: NEWCASTLE UNIVERSITY, UK ; MID-SWEDEN UNIVERSITY, SWEDEN ; UNIVERSITY OF PAVIA, ITALY*

(co-authors) Siervo, M., Vanhatalo, A., McGawley, K., Porcelli, S.
INTRODUCTION: Dietary inorganic nitrate is a popular nutritional supplement, which augments nitric oxide bioavailability and may enhance exercise performance. Despite considerable research exploring the effects of dietary nitrate during exercise, there is currently no expert consensus on how, when and for whom this compound could be recommended as an ergogenic aid. Additionally, there is no consensus on the safe administration of dietary nitrate as an ergogenic aid.
METHODS: In this study, we used the modified Delphi technique to establish the views of 12 expert panel members on the use of dietary nitrate as an ergogenic aid. Over three iterative rounds (two via questionnaire and one via videoconferencing), the expert panel members voted on 222 statements relating to the use of dietary nitrate as an ergogenic aid. Consensus was reached when > 80% of the panel provided the same answer (i.e., yes or no). Statements for which > 80% of the panel cast a vote of insufficient evidence were categorised as such and removed from further voting. These statements were subsequently used to identify directions for future research.
RESULTS: The 12 panel members contributed to voting in all three rounds. A total of 39 (17.6%) statements reached consensus across the three rounds (20 yes, 19 no). In round one, 21 statements reached consensus (11 yes, 10 no). In round two, seven further statements

reached consensus (4 yes, 3 no). In round three, an additional 11 statements reached consensus (5 yes, 6 no). The panel agreed that there was insufficient evidence for 134 (60%) of the statements, and were unable to agree on the outcome of the remaining statements.
CONCLUSION: This study outlines the current expert consensus on dietary nitrate as an ergogenic aid, which may be of value to athletes, coaches, practitioners and researchers. Findings suggest that the effects of dietary nitrate are reduced in individuals with higher aerobic fitness (V̇O2peak > 60 ml/kg/min) and therefore aerobic fitness should be taken into account when considering use of dietary nitrate as an ergogenic aid. It is recommended that athletes hoping to benefit from dietary nitrate supplementation should consume 8–16 mmol nitrate acutely or 4–16 mmol/d nitrate chronically (with the final dose ingested 2–4 hours pre-exercise) to maximise ergogenic effects. From a safety perspective, athletes may be best advised to increase their intake of nitrate via vegetables and vegetable juices. Acute nitrate supplementation up to ~ 16 mmol is believed to be safe. However, the safety of chronic nitrate supplementation requires further investigation. The expert panel agreed that there was insufficient evidence for most of the appraised statements, which highlights the need, and considerable scope, for additional research in this area.

**EFFECT OF NITRATE SUPPLEMENTATION AND HYPOXIC TRAINING ON OXIDATIVE STRESS AND NITRIC OXIDE METABOLISM IN ENDURANCE ATHLETES**

SOUSA, A., CHAMBION-DIAZ, M., VIANA, J.L., MILHEIRO, J., REIS, V.M., CARIN, R., MILLET, G.P., PIALOUX, V.
*CLAUDE BERNARD UNIVERSITY LYON 1*

INTRODUCTION: Hypoxic exercise was shown to increase the oxidative stress through overproduction of reactive oxygen species (ROS). But, chronic aerobic exercise training decrease the oxidative stress at rest and post- exercise by improving the antioxidant enzymatic efficiency. However, little is known regarding the effects of several weeks of HIIT performed in hypoxia on the oxidative stress and antioxidant systems. In other hand, nitrates supplementation is a strategy used to improve exercise performance when microvascular perfusion may be one of the limiting factors. The benefits of nitrates supplementation rely partly on the increases in nitric oxide bioavailability and in subsequent muscular microvascular perfusion. Moreover, NO has antioxidant properties and thus nitrate supplementation may modulate the OS resulting from high-intensity exercise in hypoxia. The goal of this study was therefore to assess the effects of nitrate supplementation during HIIT performed in normobaric hypoxia on oxidative stress and antioxidant systems.
METHODS: 30 subjects trained in endurance were randomised in 3 groups: hypoxic training + nitrate supplementation (HNO); hypoxic training + placebo (HPL); normoxic training + placebo (NPL: control, CON). Participants completed 4 weeks with 3 sessions per week performed in hypoxia or in normoxia. Participants ingested nitrates or placebo 2h30/3h before the beginning of each session. Blood tests were done at rest in pre- and post-intervention (i.e., one week before the training period and one week after). Antioxidant enzymes activity (SOD; GPX; catalase), NO metabolites (NOx), ferric reducing antioxidant power, myeloperoxidase activity (MPO), advanced oxidation protein products (AOPP), Malondialdehyde (MDA), nitrotyrosine and uric acid were measured in plasma
RESULTS: In post-training, nitrates (p=0.07) and NOx (p=0.06) were higher in HNO, compared to CON group. HNO increased both nitrates (p=0.1, +32%) and NOx (p=0.09, +33%) from pre- to post-intervention, whereas HPL and NPL did not. GPX increased during the training period (time effect p=0.025) independently of the group. However only CON group significantly increased GPX (p=0.017, +20%), while HPL and HNO groups did not change. Similarly, MDA increased during the training period (time effect p=0.0003). Both HNO (p=0.001, +60%) and CON groups increased (p=0.023, +30%) while HPL did not change.
CONCLUSION: Our results confirm in trained subjects that normoxic HIIT increases GPX as already observed in untrained subjects. The addition of hypoxia blunts this increase, maybe by a lower metabolic stimulus during hypoxic sessions. Hypoxia seems limit the MDA increase observed in CON group and could result to lower mitochondrial ROS generation during hypoxic sessions. The increase in MDA in HNO group is intriguing; however, nitrate supplementation could allow develop higher power during hypoxic sessions. The reported low effects of supplementation on OS markers may come from the moderate circulating increase in NOx.

## Invited symposia

### IS-AP06 Flywheel resistance exercise: rationale, current evidence, and practical applications

**ACUTE AND CHRONIC PERFORMANCE CHANGES WITH FLYWHEEL RESISTANCE EXERCISES**

BEATO, M.
*UNIVERSITY OF SUFFOLK*

The concept of flywheel training has been developed in the recent past with the first evidence supporting its efficacy as a conditioning method dating back to the early 1990's (Colliander and Tesch, 1990). Flywheel training was initially studied and implemented to mitigate the negative effects of the absence of gravity on astronauts during space travels (Norrbrand et al., 2008). Later, practitioners understood the advantages offered by this methodology and they started to use flywheel training for the performance development of athletes (Maroto-Izquierdo et al., 2017).
Previous studies have described the mechanical advantages of these devices and attempted to clarify the neurophysiological mechanisms, morphological adaptations and training effects induced by flywheel exercise (Beato and Dello Iacono, 2020; Norrbrand et al., 2008). In detail, flywheel exercise is characterized by the combination of both concentric and eccentric contractions, which offers neural patterns and mechanical responses that have important implications for both acute changes and chronic adaptations (Beato et al., 2019; Petré et al., 2018).
While the acute enhancement of athletic performance using traditional resistance exercises has been extensively investigated, evidence supporting flywheel exercises for such a purpose is still limited (Cuenca-Fernández et al., 2018; Beato et al., 2020). Preliminary findings suggest implementing flywheel exercises to elicit acute performance enhancement may be a viable alternative to traditional protocols; however, there is no evidence about what conditioning activity (flywheel vs. traditional protocols) may be superior in enhancing athletic performance (Beato et al., 2019). About the use of flywheel training to obtain chronic adaptations, previous evidence reported that significant increases in muscle volume and cross-sectional area (Petré et al., 2018) and in sport-specific parameters can be expected following >6 weeks of training (de Hoyo et al., 2015; Allen et al 2021).

However, the effect of flywheel training is associated with some factors such as training load components, which will determine the specificity of stimuli, as well as, the user's familiarization level, which is important to optimize the effect of the exercises, e.g., when specific eccentric strategies are needed to decelerate the movement at the desired joint angles (Beato and Dello Iacono, 2020). Additionally, from a methodological point of view, the choice of the exercises (e.g., training variation), training intensity, volume, and frequency, provide the desired stress to achieve the sport-specific adaptations in line with the program objectives. Therefore, this presentation aims to better understand the motivations of some adaptive responses (i.e., acute and chronic) and to summarize studies that elucidate how to better implement flywheel technology into strength training protocols.

### MUSCLE ACTIVATION, BIOMECHANICAL LOADING AND HYPERTROPHY WITH FLYWHEEL RESISTANCE EXERCISE

NORRBRAND, L.

*KTH ROYAL INSTITUTE OF TECHNOLOGY*

The gravity-independent flywheel exercise device was first developed for use in space to counteract muscle loss in astronauts during long-duration space flights (Berg and Berg, 1993, Berg and Tesch, 1994), and has been used in many training programs and research studies ever since. The flywheel exercise device allows for varying loading throughout the repetitions, and this talk will cover some of the differences between flywheel resistance exercise and traditional weight training.

Traditional weight training commonly provides constant load and therefore often call for submaximal muscle activation during the eccentric actions, and maximal or near maximal muscle activation around the so called "sticking point" in the concentric actions. During flywheel resistance exercise, the force applied to the strap in the concentric phase is transformed to kinetic energy of the rotating flywheel, and by decelerating the flywheel rotation over a short time in the last part of the eccentric action, it is possible to produce eccentric overload (Fernandez-Gonzalo et al., 2014). The subsequent high muscle activation during the concentric and parts of the eccentric action of flywheel resistance exercise (Pozzo et al., 2006) may promote a more efficient resistance training, rather than being restricted at a submaximal level as in traditional weight training (Norrbrand et al., 2008, Maroto-Izquierdo et al., 2017).

Previous flywheel studies have demonstrated substantial eccentric overload during open-loop knee extensions, and consequently high muscle activation during the eccentric action (Norrbrand et al., 2010). However, eccentric overload was not always apparent in closed-loop leg-extension exercises (Alkner and Tesch, 2004, Norrbrand et al., 2011, Sjöberg et al., 2021), possibly due to that the concentric peak force commonly occurs where muscle mechanics are favourable, i.e. at relatively extended knee and hip angles, whereas the peak eccentric force is produced in the unfavourable flexed position close to the turning point (Sjöberg et al., 2021). Thus, depending on which type of workout that is performed, e.g. body positioning, lever arms, and muscle length will affect the force output throughout the flywheel repetitions.

Furthermore, flywheel resistance training was proven effective counteracting muscle atrophy during 90 days of bed rest (Alkner and Tesch, 2004), induced substantial hypertrophy following only 5-7 weeks of resistance exercise (Seyennes et al., 2007, Norrbrand et al., 2008, Lundberg et al., 2013), and was reported to induce an overall greater hypertrophy response than traditional weight-stack resistance training (Maroto-Izquierdo et al., 2017).

In summary, the present talk will cover the muscle activation and the biomechanical loading during flywheel resistance exercise, and the resulting hypertrophy response following flywheel resistance training.

### FLYWHEEL RESISTANCE TRAINING METHODOLOGICAL APPLICATIONS

MUÑOZ LÓPEZ, A.

*UNIVERISTY OF SEVILLE*

Coaches and practitioners may benefit from a proper combination of important training variables such as loading intensity and training volume in resistance training. What is more, the percentage of velocity loss along repetitions (i.e., velocity-based training) can be helpful to decide the desired fatigue level While there is extensive knowledge on how to implement traditional resistance training exercises on programs. (González-Badillo and Sánchez-Medina, 2010, Pareja-Blanco et al., 2017), only over the last years the methodology know-how of flywheel resistance training devices is being developed.

Different technologies can be used to monitor the loading intensity using flywheel devices (Muñoz-López et al., 2021b). Recently, some research showed progressive overloading while the moment of inertia is increased (McErlain-Naylor and Beato, 2021). Furthermore, there are interesting differences in the overload profile if men are compared to women (Martinez-Aranda and Fernandez-Gonzalo, 2017), highlighting the importance of considering an individualized approach when using flywheel devices. Recent research also applied the velocity-based training approach in these devices (Muñoz-López et al., 2021c; Sabido et al., 2018). In particular, it has been shown that a minimum of 3-4 repetitions are required at the beginning to establish a target training zone. (Sabido et al., 2018). Indeed, the mechanical loss differs from the mechanical output used (Muñoz-López et al., 2021c). Interestingly, the mechanical loss in flywheel devices is more likely curvilinear than linear. For example, executing more than 20 repetitions on the leg extension exercises did not show more mechanical decrements (Muñoz-López et al., 2021c).

Finally, during this talk, I will also cover an important concept surrounding the use of flywheel resistance training devices: the so-called "eccentric overload" (Berg and Tesch, 1998). A recent meta-analysis showed that most of the research using flywheel devices did not prove if an eccentric overload was achieved or not (Muñoz-López et al., 2021b). Usually, practitioners link the eccentric overload training with the simple use of flywheel devices, but it has been proved that it is not mandatory (Núñez et al., 2020). First, a proper definition of the eccentric overload in flywheel devices remains to be defined. Secondly, important methodological aspects such as the familiarization (Tous-Fajardo et al., 2006), the moment of inertia used (McErlain-Naylor and Beato, 2021), the mechanical variable monitored (Muñoz-López et al., 2021b), or the flywheel shaft type (Muñoz-López et al., 2021b) could affect the eccentric overload measurement. In summary, this talk will highlight how to effectively manage important methodological considerations in the daily practice of using resistance training devices based on scientific evidence.

## OP-AP10 Endurance Running

### RELATIONSHIP BETWEEN PHYSIOLOGICAL PARAMETERS AND TIME TRIAL PERFORMANCE OVER 1, 2 AND 3 KM IN WELL-TRAINED RUNNERS

SCHWARZ, Y.M., NOLTE, S., FUCHS, M., GEHLERT, G., SLOWIG, Y., SCHIFFER, A., FOITSCHIK, T., ABEL, T., QUITTMANN, O.J.
*GERMAN SPORT UNIVERSITY COLOGNE*

INTRODUCTION: Middle distance running is unique due to its proximity to sprint running. Athletes competing over these distance display various physiological profiles [1]. Due to increasing anaerobic energy supply and altered muscular demands of high velocity running, differences become more pronounced with distances bordering sprint events [2]. Previous research has focused on comparing physiological measures in different groups of athletes specialized in distinct running distances [3]. However, within-group comparisons of athletes participating over various distances are rare. Therefore, it was the aim of this study to assess the relationship of physiological variables and running performance over 1-, 2- and 3-km time-trials (TT) close to the sprint-endurance divide in a single cohort of athletes.
METHODS: Twenty well-trained male sprinters, middle- and long-distance runners/triathletes performed several laboratory tests (incremental test, ramp test, sprint test, constant load tests) to determine V̇O2max, running economy (RE), fractional utilization of V̇O2max at maximal lactate steady-state (%V̇O2max), maximal fat oxidation (MFO) and maximal lactate accumulation rate (V̇Lamax) [4]. As performance tests, TT over 1, 2, and 3-km were performed on an outdoor track. Relationships between physiological parameters and TT velocity as well as 100-m performance (v100) were assessed by correlation coefficients and confidence intervals (CI).
RESULTS: Participants completed the 100-m and 1-, 2-, and 3-km TT in 12.8 ± 0.8, 173.0 ± 10.6, 383.9 ± 24.7 and 606.0 ± 45.5 seconds, respectively. V̇O2max showed the highest positive relationship with performance over all TT distances ($p < 0.001$) from 1 to 3 km ($r = 0.66$, $r = 0.80$, $r = 0.84$, respectively), while no significant correlation was present with v100 ($r = -0.03$, $p = 0.90$). Despite overall lower correlation coefficient and broader CI, MFO showed similar results. V̇Lamax and RE were positively correlated with v100 and displayed increasingly negative correlation for TT, whereas no significant correlation was found for 1000-m. %V̇O2max was not significantly correlated with TT nor v100.
CONCLUSION: In line with previous research, aerobically determined variables become increasingly relevant with growing running distance [1]. In contrast, anaerobic power expressed as V̇Lamax, has increasingly negative influence on competitions exceeding ~3 min. Hence, running durations of 1.5-3 min seem to represent the divide of sprint and endurance running . Based on these results, practitioners should focus on enhancement of aerobic measures even for distances close to the sprint-endurance divide. Training emphasizing anaerobic power should be progressively reduced with increasing competition duration due to growing negative influence of anaerobic metabolism.

### INTERVAL TRAINING SESSION DESIGN, INTENSITY CONTROL AND THE EFFECTS ON ACCUMULATED TIME ABOVE 90% VO2MAX

SKOVERENG, K.1, APPELHANS, D.2
*1NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY, 2TECHNICAL UNIVERSITY OF MUNICH*

INTRODUCTION: The accumulation of time above 90% of VO2max (t>90%VO2max) has been suggested as a potentially important stimulus for endurance adaptation [1]. Multiple factors of methodological (e.g. session design) and physiological (e.g. anaerobic threshold in % of VO2max) nature can be the reason for the large variation in t>90%VO2max observed in recent studies [2,3]. Therefore, this study aimed to investigate how two different interval sessions with two methods of controlling intensity influenced time accumulated above 90% of VO2max.
METHODS: Twelve well-trained cyclists and triathletes (VO2max: 68±6.3 and maximal aerobic power (MAP): 4.9±0.5 W/kg) performed preliminary testing of VO2max, anaerobic threshold and time to exhaustion at MAP. Subsequently, the athletes performed a short interval session (SI) consisting of 3 rounds of 13 repetitions of 30 seconds effort with 15 seconds rest and a long interval session (LI) consisting of 6 rounds of 5 minute efforts with 2.5 minutes rest. Both interval sessions were completed two times. In the fixed condition the intensity was set to 84 [2] and 100% [4] of MAP for SI and LI respectively while an effort-based approach was used for the free intensity condition (i.e. the participants were instructed to aim to achieve the greatest possible average work rate over all intervals). Session RPE was recorded 30 minutes after the end of each session.
RESULTS: The average work rate was greater ($p < 0.01$) in the free (SI: 316±42W & LI: 323±44W) compared to the fixed (SI: 296±42W & LI: 300±43W) condition. In the fixed condition, SI led to grater t>90%VO2max compared to LI ($p < 0.01$ SI: 420±259sec & LI: 178±159sec). However, there was no statistically significant difference ($p = 0.32$) in t>90%VO2max between SI (1130±204) and LI (1016±312). The SI sessions had statistically significantly ($p < 0.01$) higher ending blood lactate concentrations compared to LI in both the fixed (SI: 5.83±1.86 & LI: 4.68±1.56) and free (SI: 8.57±2.03 & LI: 7.73±2.19) conditions. Finally, there was no statistically significant difference ($p = 0.28$) in the session RPE between the SI and LI but the free intensity was rated harder ($p < 0.01$) compared to the fixed.
CONCLUSION: While the fixed intensities led to differences in t>90%VO2max between the SI and LI sessions, the effort-based approach resulted in no such differences which demonstrates the importance of details in the design of exercise sessions. Although using the effort-based approach made both SI and LI sessions harder (i.e. as demonstrated through lactate and session RPE), which must be accounted for in daily training practice, and likely requiring experienced athletes, the method may provide a better way of intensity control when comparing different exercise sessions.

### EFFECT OF PERFORMANCE LEVEL ON CHANGES IN ECONOMY DURING PROLONGED RUNNING

ZANINI, M., FOLLAND, J., BLAGROVE, R.

*SCHOOL OF SPORT, EXERCISE, AND HEALTH SCIENCES, LOUGHBOROUGH UNIVERSITY*

INTRODUCTION: Running economy (RE) is an important determinant of endurance running performance [1]. Although RE is known to be sensitive to fatigue during prolonged running [2,3], the pattern of this deterioration may be mediated by training status, which currently remains unexplored. The aims of this study were to quantify the changes in RE during a prolonged run and compare changes between sub-populations of male endurance runners.
METHODS: Thirty-four well-trained distance runners (maximal oxygen uptake (VO2max) 62.7±7.3 ml/kg/min; 10km time 35:57±4:24) completed two treadmill trials separated by 5-10 days. The first trial involved an incremental test to determine lactate threshold (LT) and VO2max. The second trial involved a 90 min run at the speed corresponding to LT (sLT). Respiratory gases were collected at 15 min intervals for 5 min, and blood lactate (BLa) was measured at 15, 60, and 90 min. Subsequently, two subgroups of 12 athletes were identified based on 10km race time as high-performers (HP; 10km <33:00, VO2max 70.0±5.0 ml.kg-1.min-1) and low-performers (LP; 10km 38:00-45:00, VO2max 56.7±4.4 ml.kg-1.min-1) A two-way repeated measures ANOVA with Bonferroni post-hoc corrections was used to detect changes over time and between groups, and effect sizes (ES) were calculated as Cohen's d. Significance was defined as $p<0.05$.
RESULTS: The athletes ran at 14.3±1.5 km/h, corresponding to 79.8±2.9 % of VO2max, and mean RE was 212.6±12.0 and 220.6±13.7 ml/kg/km at 15 and 90 min, respectively. Compared to the 15 min time-point, RE remained unchanged at 30, 45 and 60 min but was significantly elevated after 75 min (1.8±2.6%, $p=0.003$, $d=0.30$) and 90 min (3.6±2.9%, $p<0.001$, $d=0.57$). Between 15 and 90 min, the respiratory exchange ratio (RER) remained unchanged (0.92±0.03 vs 0.91±0.03), but BL increased from 1.7±0.3 to 2.5±0.6 mMol/L ($p<0.001$, $d=0.62$). The two subgroups did not differ in RE after 15 min (HP: 214.3±10.6 ml/kg/km, LP: 212.1±10.0 ml/kg/km), and although the difference in RE change after 75 min wasn't significant, there was a large effect of performance level on it (HP: 1.5±2.7, LP: 3.3±2.6%, $p=0.06$, $d=0.81$). The between-group difference in RE change at the 90 min time-point was also not significant (HP: 3.7±2.0, LP: 5.0±3.6%, $p=0.29$, $d=0.44$).
CONCLUSION: During a 90 min run at sLT, RE remains stable until 60 min before deteriorating significantly in well-trained male runners. BLa also increases as the exercise progresses, whereas RER remains stable. The performance level of endurance runners didn't significantly influence changes in RE between the two groups, although a moderate effect was reported. More data is required to clarify the possible differences depending on performance level.

### SEX DIFFERENCES IN PERFORMANCE FATIGABILITY DO NOT AFFECT THE HALF-MARATHON PACING STRATEGIES OR PERCEIVED EXERTION IN RECREATIONAL TRIATHLETES

QUAGLIAROTTI, C.1, VILLANOVA, S.2,3, COLOSIO, M.3,4,5, PASTORIO, E.3, PILOTTO, A.6, MARCIANO, A.2,3, GATTI, M.3, PAPETTI, G.3, ROMAGNOLI, R.1, PORCELLI, S.2,3, PIACENTINI, M.F.1,7

*<1>UNIVERSITY OF ROME 'FORO ITALICO' <2>UNIVERSITY OF THE WEST SCOTLAND <3>UNIVERSITY OF PAVIA <4>NATIONAL RESEARCH COUNCIL <5>UNIVERSITY OF MILAN <6>UNIVERSITY OF UDINE <7>VRIJE UNIVERSITEIT BRUSSEL*

INTRODUCTION: Many factors have been shown to affect the pacing adopted by athletes during endurance events, such as perceived exertion and performance fatigability[1]. Alterations in muscular function after a prolonged running race have already been reported[2], with greater impairment of muscle contractile properties as the distance increases[3]. Moreover, sex differences have been reported in both pacing[4] and the maximal voluntary isometric contraction (MVIC) force decrease after long-distance races[5]. During triathlons, athletes run after swimming and biking and pacing is affected by the previous portions of the race[4]. Therefore, the purpose of the present study was to investigate the effects of MVIC force loss during a triathlon race on the sex differences in pacing strategies and rating of perceived exertion (RPE) during running. We hypothesize that a decrease in MVIC force would be correlated to a positive pacing and a faster increase in RPE.
METHODS: Seventeen recreational triathletes, 8 females (F; age: 43.3±10.4 y) and 9 males (M; age: 46.6±7.8 y) were tested in an official triathlon race (1.9 km swim, 90 km bike and 21.1 km run). Knee extensors MVIC force was assessed at pre-race (Pre) and immediately before the running section (T2) and the strength decrease from Pre to T2 (ΔS) was calculated. Pacing data were obtained by individual GPS tracking devices. The RPE (CR-10 scale) of each triathlete was collected at 15 equal-distant points during the half marathon. Non-parametrical statistical analysis was performed to assess between and within sex groups differences in MVVIC, ΔS, pace and RPE.
RESULTS: Higher absolute MVIC force at Pre (M: 491.4±120.9 N; F: 357.9±83.0 N) and T2 (M: 381.1±93.3 N; F: 310.9±74.1 N) were found in M compared to F ($p<.05$), but F showed a lower ΔS (M: -23.1±1.6 %; F: -15.3±2.6 %; $p<.001$). No sex differences were observed in the average running speed (M: 362.7±88.5 s/km; F: 383.8±58.9 s/km; $p=.736$), and speed decrement from the 8th km (M: from 331±55 s/km to 387±59 s/km; F: from 347±55 s/km to 409±59 s/km) with an overall positive pacing strategy. RPE increased from the 16th km to the end of the race (from 7±2 to 9±1 in both M and F; all $p<.05$) with no difference between sexes.
CONCLUSION: Despite a larger decrease in the MVIC force of the knee extensors prior to running, M showed similar decrease in speed or increase in RPE to F throughout the following half-marathon. These results suggest that the pacing strategy adopted by athletes during triathlons is dependent on the complex interplay of physiological and psychological factors that can contribute to fatigability and thus to overall performance.

**PHYSIOLOGICAL CHARACTERISTICS OF WORLD-CLASS KENYAN RUNNERS – MAXIMAL AEROBIC CAPACITY AND RUNNING ECONOMY**

KNOPP, M.1,3, MUNIZ-PARDOS, B.2, WACKERHAGE, H.3, SCHÖNFELDER, M.3, PITSILADIS, Y.4, RUIZ, D.1

*1 ADIDAS AG; 2 GENUD RESEARCH GROUP, UNIVERSITY OF ZARAGOZA; 3 EXERCISE BIOLOGY GROUP, TECHNISCHE UNIVERSITÄT MÜNCHEN; 4 SCHOOL OF SPORT AND HEALTH SCIENCES, UNIVERSITY OF BRIGHTON*

INTRODUCTION: Kenyan middle and long-distance runners have become a major research interest over the past years and even more recently with the new flood of world records in such events since 2016 [1-3]. Such performances depend on three main physiological factors: an athletes' maximal oxygen uptake or VO2max; their ability to sustain a high percentage of that VO2max for long periods of time; and an athletes' ability to move efficiently at submaximal speeds, representing a good running economy [4,5]. While the first two factors respond to training, technological advances such as new running shoes can improve running efficiency [3,6]. The aim of this study was to measure the VO2max and running economy on a lab treadmill in world-class Kenyan distance runners at two different intensities. We then compared this data to the literature in an attempt to explain the recent flurry of world records.
METHODS: Seven world-class male Kenyan runners (age: 22.7 ± 3.2 years; weight: 59.9 ± 4.8 kg; height: 174 ± 5 cm) who had an official mean personal record for the half-marathon of 59:30 ± 0:48 min:s, and a 10 km personal best of 27:33 ± 0:41 min:s) were recruited and completed maximal and submaximal laboratory-based tests (adidas AG, Herzogenaurach, Germany). Assessments included a maximal rate of oxygen uptake test and submaximal steady state running economy trials on a treadmill related to both marathon (75% vVO2max) and 10km pace (90% vVO2max) during three separate visits.
RESULTS: The measured VO2max of the world-class runners was 75.9 ± 3.5 mL/kg/min which can be classified into the top range of values found in previously published literature for a similar population, which overall ranged from 60.7–85.3 mL/kg/min with an average of 71.9 mL/kg/min [7,8]. The submaximal running economy showed large inter-subject variability and at 75% vVO2max was 192.3 ± 8.1 mL/kg/km or 54.5 ± 2.0 mL/kg/min, and at 90% vVO2max was 184.1 ± 10.1 mL/kg/km or 61.9 ± 3.3 mL/kg/min, both of which are in the middle of the range of previously reported values for a similar population [9].
CONCLUSION: This study found the obtained physiological values from world-class runners to be in line with those already published suggesting the recent improvements leading to a new flood of world records might not be physiological, but other factors such as novel shoe designs may play an important role in terms of running economy as previously suggested [3,10].

INTRODUCTION: Hypogonadism in men is considered a clinical syndrome manifesting with low testosterone levels (TT), associated with a decline in muscle mass, muscle strength, increased adiposity, and visceral obesity, altogether leading to various alterations in the metabolism of these patients. The overall muscle atrophy during hypogonadism is particularly important, as it is one of the major contributors to normal physical function. However, there is still a lack of studies dealing with the effect of regularly performed physical activity on hypogonadism. The study aimed to examine the effect of a 12-week resistance training programme on body composition, muscle strength and skeletal muscle cell parameters in hypogonadal men, and determine their skeletal muscle tissue quality both, on the macroscopic and microscopic levels.
