METHODS: In the study, we compared the effect of resistance training (RT) on hypogonadal patients without hormonal therapy (HP: n=6; age:48.41±6.38 years; body weight: 95.25±13.90 kg; TT level =7.9±1.75 nmol/L), and treated hypogonadal patients (HPT: n=8; age:43.00±3.19 years; body weight: 99.09±26.53 kg; TT level= 12.85±3.44 nmol/L), with control group of eugonadal males (EM: n=8; age:49.31±5.84 years; body weight: 85.97±7.49 kg; TT level =15.81 ±3.99 nmol/L). Within 12 weeks subjects performed RT twice a week. The training program consisted of 6 exercises at an intensity from 60-80% of 1RM. Body composition was measured by DXA and muscle strength was measured by predicted dynamic leg press 1RM from multiple repetition maximum. To compare the effect of 12-week training on the skeletal muscle composition, percutaneous muscle biopsies from Vastus Lateralis were performed both, before and after the intervention. Immunohistochemical analyses (IHC) were used to determine the muscle morphology variables of slow-twitch (type I) and fast-twitch (type II) cross-sectional area (CSA), myonuclear number and satellite cell (SC) density.
RESULTS: A significant increase in lean mass was observed both, in HP ($p<0.05$) with an average increase of 2.73 kg, and HPT ($p<0.05$) group. HM also showed a trend to increase muscle mass on average by 2.27 kg ± (d=0.53). Muscle strength of lower limbs increased in all three groups ($p<0.01$). When subjects were merged, a negative correlation between TT and body mass ($p<0.01$) and a positive correlation

between TT and lean mass (p<0.05) was found before and after the intervention, in both groups The increase in CSA, myonuclear number and SC was in all groups after the intervention.
CONCLUSION: In conclusion, the study proved significant improvement in muscle strength and positive changes in muscle mass regardless of the overall levels of testosterone. There were also positive changes on the microscopic level of the skeletal muscle tissue. The outcomes might be useful for their clinical relevance in the hypogonadal males treatment
The study was funded by the VEGA no. 1/0714/16. Trial registration: ClinicalTrials.gov: NCT03282682

**CORRELATION BETWEEN DIFFERENT MEASURES OF EXERCISE CAPACITY AND QUALITY OF LIFE IN COPD**

REUVENY, R.1, JONES, A.M.3, WILKERSON, D.3, KADOSH, S.2, BAIDATS, Y.2, VELNER, A.2, VAGNER, R.2, SEGEL, M.J.2
*1) PHYSICAL THERAPY DEPARTMENT, UNIVERSITY OF HAIFA, ISRAEL 2) PULMONARY INSTITUTE, SHEBA MEDICAL CENTER, ISRAEL 3) SPORT AND HEALTH SCIENCES, UNIVERSITY OF EXETER, EXETER, UK*

INTRODUCTION: Airflow obstruction and impaired exercise capacity are the main clinical characteristics of chronic obstructive pulmonary disease (COPD). It is unclear whether physiological impairments are reflected by functional impairments in daily life or other aspects of health status and dyspnea evaluation. In this prospective cross-sectional study, we explored the relationship between different measures of exercise capacity, and symptoms and quality of life (QoL) in patients with COPD.
METHODS: 42 patients with moderate to severe COPD participated. Measures of exercise capacity included: oxygen consumption (VO2) at the anaerobic threshold (AT) and at peak exercise (peak VO2) during a maximal cycle ergometer test; endurance time (ET-hiCWR) at a high intensity constant work rate (70% of peak work-rate (WR) achieved in the maximal test); the time constant for VO2 kinetics (tau) in a moderate intensity constant WR exercise test; and 6-minute walk distance (6MWD). Patient reported outcome measures (PROMs) of health impairment were obtained by: St. George Respiratory Questionnaire (SGRQ), divided into 3 domains (symptoms, activity, and impacts) scored 0 to 100 (higher score = worse impairment), from which a total score was calculated; and Baseline Dyspnea Index (BDI), a 24 item multidimensional measurement of dyspnea during daily activities. Correlations between measures of exercise capacity and PROMs were calculated by Spearmans test.
RESULTS: 36 patients with COPD (23 males, FEV1 = 43±10%pred.) completed all evaluations. No correlation was found between pulmonary function at rest and PROMs. Peak VO2 correlated with SGRQ total score (r=-0.507, p= 0.002) and domain scores, and with BDI (r=0.619, p=0.0001). 6MWD correlated with the activity domain score of SGRQ (r= -0.517, p=0.013). No other correlations were found between 6MWD, tau, ET-hiCWR, AT and SGRQ total or domain scores or BDI score.
CONCLUSION: In a cohort of patients with moderate to severe COPD, peak VO2 was the only measures of exercise capacity that correlated with PROMs of QoL and dyspnea. 6MWD, tau, ET-hiCWR and AT were not significantly correlated to PROM scores. These results shed light on the relationship between metrics related to the physiological responses to exercise and the quality of life in COPD patients.

**A 12-WEEK CONCURRENT TRAINING INTERVENTION IMPROVED MUSCLE DYSFUNCTION BUT NOT SYSTEMIC OXIDATIVE STRESS AFTER 1 YEAR OF TRAINING CESSATION IN OLDER PEOPLE WITH COPD.**

BALTASAR-FERNANDEZ, I., LOSA-REYNA, J., CARRETERO, A., RODRIGUEZ-LOPEZ, C., ALFARO-ACHA, A., GUADALUPE-GRAU, A., ARA, I., ALEGRE, L.M., GOMEZ-CABRERA, M.C., GARCÍA-GARCÍA, F.J., ALCAZAR, J.
*UNIVERSITY OF CASTILLA-LA MANCHA*

INTRODUCTION: Skeletal muscle dysfunction is a major problem in patients with chronic obstructive pulmonary disease (COPD), affecting both ventilatory and non-ventilatory muscles (1). Muscle dysfunction is characterized by a decreased proportion of type I muscle fibers and oxidative enzyme capacity and a reduced exercise tolerance (2). Concurrent training combining power-oriented resistance training (RT) and high-intensity interval training (HIIT) has been shown to improve both muscle dysfunction and systemic oxidative stress in the short term (3), however, the long-term effects remain poorly known. This study aimed to assess the effects of a 12-week concurrent training program composed of power-oriented RT and HIIT on physical performance, quality of life, pulmonary and neuromuscular performance, and systemic oxidative stress in older adults with COPD after 1 year of training cessation.
METHODS: A total of 29 older adults with COPD were randomly divided into intervention (INT; n=14) or control (CON; n=15) groups, of which 21 completed the 1-year detraining follow-up (INT, n=8; CON, n=13; 76.9±6.8 years). Primary outcomes were Short Physical Performance Battery (SPPB), health-related quality of life (EQ-5D-5L), vastus lateralis muscle thickness (MT; ultrasonography), peak oxygen volume (VO2peak) and peak work rate (Wpeak) (incremental cardiopulmonary exercise test), rate of force development (RFD; force platform), leg press maximum power (Pmax; force-velocity relationship) and systemic oxidative stress and antioxidant activity (protein carbonylation and malondialdehyde levels, and catalase activity, respectively). Assessments were performed at baseline and 1 year after completion of training. Mixed model repeated measures ANOVA with Bonferroni's post hoc tests was used.
RESULTS: INT group improved SPPB (Δ=1.0 point; p<0.05), quality of life (Δ=0.07 points; p<0.05), MT (Δ=0.06 cm; p<0.05), VO2peak (Δ=1.3 ml·kg-1·min-1; p<0.05), Wpeak (Δ=10.3 W; p<0.05), RFD (Δ=834 N·s-1; p<0.05) and Pmax (Δ=62.2 W; p<0.05) while no changes were observed in the CON group (all p>0.05). No changes in systemic oxidative stress were observed in either group in the long term (all p>0.05).
CONCLUSION: Twelve weeks of concurrent training were enough to improve physical performance, quality of life, exercise tolerance and neuromuscular performance but not systemic oxidative stress in older adults with COPD after 1 year of training cessation.

### OP-PN23 Hypoxia II

**EFFECTS OF PRE-TERM BIRTH ON THE CARDIO-RESPIRATORY RESPONSES TO HYPOXIC EXERCISE IN CHILDREN**

NARANG, B.J., MANFERDELLI, G., KEPIC, K., SOTIRIDIS, A., OSREDKAR, D., BOURDILLON, N., MILLET, G.P., DEBEVEC, T.
*JOŽEF STEFAN INSTITUTE*

INTRODUCTION: Pre-term birth is associated with numerous long-term physiological sequelae which appear to impair exercise capacity. However, preliminary evidence suggests a cardio-protective effect of pre-term birth on hypoxia-induced physiological impairments. Further

evidence is required to corroborate this theory, and there is as yet no data to investigate the relationships between prematurity, hypoxia and exercise capacity in children. Therefore, the aim of this study was to assess the cardio-respiratory responses to an incremental exercise test in pre-term children, relative to their full-term counterparts, under normoxic and hypoxic conditions. The pre-term children were hypothesised to display a lower exercise capacity in normoxia than a full-term control group, and this difference was hypothesised to be attenuated in hypoxia.
METHODS: Fourteen prematurely-born (PREM) (Mean ± SD; gestational age 29 ± 2 weeks; age 9.1 ± 0.6 years), and fifteen physical activity-matched full-term children (CONT) (gestational age 39 ± 1 weeks; age 9.5 ± 0.9 years) visited the laboratory on three occasions. They first performed a baseline lung function test (spirometry), and then underwent two incremental exercise tests to exhaustion in normoxia (FiO2 = 20.9%) and normobaric hypoxia (FiO2 = 13.2%) on a cycle ergometer. Gas exchange, capillary oxygen saturation and haemodynamic parameters were continuously recorded using a metabolic cart, fingertip pulse oximetry and impedance cardiography, respectively.
RESULTS: Forced vital capacity ($p = 0.971$) and forced expiratory volume in one second ($p = 0.428$) were similar between groups. However, PREM demonstrated a lower peak expiratory flow rate than CONT (3.46 ± 0.89 vs. 4.24 ± 0.95 L/min; $p = 0.031$). Peak power output was higher in normoxia than hypoxia (103 ± 17 vs. 77 ± 18 W; $p < 0.001$), with no difference between CONT and PREM (94 ± 23 vs. 86 ± 19 W; $p = 0.154$). Peak oxygen uptake was significantly higher in normoxia than hypoxia in CONT (50.8 ± 7.2 vs. 43.8 ± 9.9 ml/kg/min; $p < 0.001$) but not in PREM (48.1 ± 7.5 vs. 45.0 ± 6.8 ml/kg/min; $p = 0.137$; interaction $p = 0.044$). Higher peak heart rate (187 ± 11 vs. 180 ± 10 bpm; $p = 0.005$) and lower stroke volume (72 ± 13 vs. 77 ± 14 ml; $p = 0.004$) were observed in normoxia relative to hypoxia in CONT, with no such differences observed in PREM ($p = 0.218$ and $p > 0.999$, respectively).
CONCLUSION: Pre-term children demonstrated greater expiratory flow limitations despite no differences in vital capacity. A hypoxia-induced decrease in peak oxygen uptake was only apparent in the full-term group, suggesting that pre-term birth (and/or associated neo-natal treatments) could protect against the negative effects of hypoxia on exercise capacity. This is a promising finding for prematurely-born individuals wishing to engage in physical activity at altitude. Further research is however required to consolidate these findings, and to identify the limiting factors to normoxic and hypoxic exercise capacity in this population.

## ACUTE PERFORMANCE, PHYSIOLOGICAL, AND PERCEPTUAL CHANGES IN RESPONSE TO REPEATED CYCLING SPRINT EXERCISE COMBINED WITH SYSTEMIC AND LOCAL HYPOXIA IN YOUNG MALES

BEHRENDT, T., BIELITZKI, R., BEHRENS, M., SCHEGA, L.

*OTTO-VON-GUERICKE-UNIVERSITY MAGDEBURG*

INTRODUCTION: Studies have shown that sprint training in combination with systemic or local (i.e., with blood flow restriction, BFR) hypoxia is an effective training method to improve sport-specific physical performance compared with the same training in normoxia. Since systemic and local hypoxia create different intrinsic stimuli, it is important to determine the performance, physiological, and perceptual changes in response to these conditions to gain insights into the adaptive mechanisms and to maximize training-induced adaptations. Thus, this study investigated motor performance fatigue (i.e., decrease in peak and mean power output) and the associated physiological adjustments (e.g., muscle oxygen saturation (SmO2) and muscle activity) during repeated cycling sprint exercise in local and systemic hypoxic as well as normoxic conditions. Moreover, perceived fatigue and its potential determinants (i.e., effort and physical strain perception) were quantified.
METHODS: Fourteen active males (24.2±2.0yrs, 80.9±10.0kg, 1.8±0.1m) participated in a randomized cross-over study. Subjects performed repeated cycling sprints (i.e., six intervals of 10s with 30s rest in between) in normoxia (NOR), systemic normobaric hypoxia (14.4% O2, HYP), and with BFR (40% of individuals' arterial occlusion pressure). Mean and peak power output, SmO2 of vastus lateralis as well as muscle activity of vastus medialis and lateralis were assessed during each interval. Percentage decrement score (Pdec) was calculated to quantify motor performance fatigue. Perceived fatigue, effort perception, and perceived physical strain were also queried immediately after each interval. SmO2 was normalized to the data recorded at rest over 30s prior to exercise. Before and immediately after exercise termination, peripheral blood lactate concentration (BLC) and oxygen saturation (SpO2) were recorded. Data were analyzed with repeated measures ANOVAs (time×condition).
RESULTS: Pdec for mean and peak power output was higher in HYP and BFR compared to NOR (all $p<.009$). SmO2 increased over the course of exercise in NOR and was higher compared to the BFR condition only in set 6 ($p<.001$). Muscle activity was not different between conditions. In the BFR condition, muscle activity of vastus medialis was reduced in set 5 and 6 compared to set 1 and 2 (all $p<.033$). Perceived fatigue, effort perception, and perceived physical strain progressively increased without differences between conditions. In parallel with lower SpO2, greater BLC was observed in HYP immediately after exercise compared to BFR and NOR (all $p<.001$).
CONCLUSION: HYP and BFR resulted in an exacerbated motor performance fatigue development but did not differentially influence perceived fatigue, effort and physical strain perception as well as muscle activity compared to NOR during 'all-out' repeated cycling sprint exercise. The lower oxygen availability in HYP and BFR might have impaired the contractile function of muscles resulting in a reduced repeated sprint ability performance.

## THE EFFECT OF COMBINED ARM AND LEG EXERCISE TRAINING IN HYPOXIA ON PHYSICAL PERFORMANCE, AND BIOMARKERS OF CHRONIC FATIGUE IN BIATHLON JUNIOR ATHLETES

ZEBROWSKA, A., SIKORA, M., ZWIERZCHOWSKA, A., MIKOLAJCZYK, R., MANOWSKA, B.

*DEPARTMENT OF PHYSIOLOGICAL AND MEDICAL SCIENCES, ACADEMY OF PHYSICAL EDUCATION*

INTRODUCTION: Biathlon is a complex sport discipline, that in addition to a high endurance capacity and efficient skiing technique, demands accurate shooting performed directly after intense exercise. Scientific evidence suggests that hypoxia training increases exercise performance and high altitude acclimatization. The physiological mechanisms responsible for these benefits include improvements in cardiovascular hemodynamics, oxygen transport and beneficial changes in immune system. The aim of the present study was to examine the acute effect of endurance training under normobaric hypoxia on physical functioning and biomarkers of muscle fatigue in biathlon junior athletes.
METHODS: Twelve biathlon junior athletes (aged 16.4 ± 2.1 years) completed a 3-week training programme in normobaric hypoxia (HypTr) (FiO2=15.2 %). HypTr sessions consisting of an arm cycling exercise with an intensity of 150.0 ± 34.0 Watts (SkiErgo Cocept 2 USA) and running intervals (13.0 ± 1.0 km/h) (Matrix Jeager HP, Cosmos, Germany) with intensity calculated individually for each athletes. Spiroergometry and biomarkers of muscle fatigue were performed before and after the end of the training protocol.
RESULTS: An increase in maximal oxygen uptake (55.6 ± 8.8 vs. 58.5 ± 8.5 mL/kg/min) and the absolute power output during arm exercise test (257.0 ± 63.5 vs. 272.5 ± 60.2, $p<0.01$) were observed in response to exercise training in hypoxia. HypTr has significant effect on hemo-

globin (F=5.0 p<0.05), myoglobin concentrations (F=4.8 p<0.05), creatine kinas activity (F=7.4 p<0.01) and transforming growth factor β levels (F=8.2 p<0.01). Training in hypoxia has little effect on antioxidant status with a favourable changes in proinflammatory cytokines levels.
CONCLUSION: Exercise training in normobaric hypoxia had a significant positive effect on the physical performance and concentration of the specific fatigue biomarkers, therefore it may play a crucial role in the physiological adaptive mechanisms in biathlon junior athletes.

## COMPARISON OF THE AUTOMATIZED AND THE OPTIMIZED CARBON MONOXID (CO) REBREATHING METHOD MEASURING HAEMOGLOBIN MASS

KELLENBERGER, K., STEINER, T., WEHRLIN, J.

*SWISS FEDERAL INSTITUTE OF SPORTS MAGGLINGEN*

INTRODUCTION: A high haemoglobin mass (Hbmass) is a prerequisite for a high maximum oxygen uptake and hence, a high endurance performance. The most commonly used method to measure Hbmass is the optimized carbon monoxide (CO) rebreathing method (oCO) that is athlete-friendly and highly reproducible [1]. Recently, a new automated CO rebreathing method (aCO) was introduced [2]. The aCO method uses the same CO dilution principle as the oCO method, but there are some small methodological differences. Until now estimated Hbmass has never been compared between the new aCO method and the oCO method. The aim of this study was therefore, to quantify the difference between Hbmass estimated with the oCO with capillary blood samples (procedure oCOc) and the aCO method with venous (procedure aCOv) or with capillary blood samples (procedure aCOc).
METHODS: 18 healthy subjects (9 male, 9 female) participated in the study. Hbmass was estimated with both CO rebreathing METHODS: The oCO method was based on the standard protocol (procedure oCOc) [1], with minor modifications [2]. The aCO method, using the automated OpCO system (Detalo Instruments, Denmark), is described by Fagoni et al. [3]. Briefly, subject inhaled CO for 10 minutes in a supine position. Venous (procedure aCOv) and capillary blood samples at the right earlobe (procedure aCOc) were taken simultaneously at the same time points
RESULTS: Overall, Hbmass was different between the three measurement procedures (F = 57.55, p<0.0001). Hbmass was lower (p<0.0001) for the oCOc procedure (737 g ± 179 g lower) than for the aCOv procedure (825 g ± 189 g, -9.3%) and for the aCOv procedure (835 g ± 189 g,-10.6%). There was no difference (p = 0.12) for Hbmass estimated with the aCOv and the aCOc procedures.
CONCLUSION: Hbmass estimations with the oCO method (procedure oCOc) were about 10% lower than for the aCO method (procedures aCOc and aCOv). This difference is relevant and should be taken into account when the oCO method is replaced with the aCO method in a laboratory and individual longitudinal comparisons of the measured Hbmass are important and when comparing Hbmass results of studies using either the oCO or the aCO method. Possible reasons for this difference could come from different calculations for Hbmass including CO flux from blood to myoglobin for the oCO method compared to the aCO method and other influences yet to be discovered.

## NEAR-INFRARED SPECTROSCOPY ASSESSMENT OF SKELETAL MUSCLE OXIDATIVE CAPACITY: METHODOLOGICAL CONSIDERATIONS

RASICA, L., INGLIS, E.C., IANNETTA, D., MURIAS, J.M.

*UNIVERSITY OF CALGARY*

INTRODUCTION: The assessment of skeletal muscle oxidative capacity through near-infrared spectroscopy (NIRS) has gained popularity within the past 10 years. Different approaches have been used by several research groups in terms of exercise modality, intensity and duration of the exercise employed, number of occlusions performed, NIRS signals investigated, muscles assessed, and equations used to correct for blood volume shifts.
This study aimed to compare the use of different NIRS signals with and without blood volume correction equations for the assessment of NIRS-derived oxidative capacity. Additionally, this study explored the simultaneous evaluation of the vastus lateralis (VL) and tibialis anterior (TA) muscles in two groups of young healthy participants of different fitness levels.
METHODS: Thirty-six participants, eighteen chronically trained (CT: 14 males, 4 females) and eighteen untrained (UT: 10 males, 8 females), were recruited for this study. Maximal O2 consumption (V̇O2max) was assessed during a cycling incremental test to exhaustion. NIRS-derived oxidative capacity was assessed at rest, after 20 leg extension movements with ankle weights (1 s extension and 1 s flexion), performing 20 transient arterial occlusions (5 s occlusion every 10 s). Two trials were performed with 2 minutes of rest in between. Muscle oxygen consumption (V̇O2m) was estimated by calculating the slope of each occlusion period from both the deoxygenated hemoglobin signal (HHb) corrected for changes in blood volume following the Ryan [(2), HHbR] and Beever [(1), HHbB] equations, and the oxygen saturation signal (StO2 ). V̇O2m values were then fit using a monoexponential function and the time constant Tau was taken as the measure of muscle oxidative capacity. These analyses were performed in both the VL and TA muscles.
RESULTS: V̇O2max was significantly greater in CT compared to UT (58.2±4.8 vs 43.0±4.9 mL/kg/min, P<0.0001). The goodness of the monoexponential fits for V̇O2m was excellent for all variables investigated (r2 0.94±0.05). Tau estimated from HHbR and HHbB were not different while Tau estimated using StO2 was significantly smaller (27.3±7.1 vs 27.3±7.1 vs 23.2±6.2 s, respectively; P<0.0001). HHbR Tau values were significantly smaller in CT compared to UT in both VL and TA (CT: VL 23.5±5.8 and TA 24.3±4.4 vs UT: VL 31.1±8.3 and TA 29.4±7.3; P<0.0001). No differences were detected between VL and TA within the same group (P>0.05).
CONCLUSION: This study showed that within the same muscle, HHb and StO2 signals result in different Tau values, although different blood volume correction strategies for HHb do not impact Tau. Additionally, no differences were detected across muscles for the same NIRS signals suggesting that the TA muscle is suitable for investigating skeletal muscle oxidative capacity and able to identify fitness level differences.

## OP-BM12 Monitoring

### LONGITUDINAL SWIMMING PERFORMANCE AND TECHNIQUE MONITORING DURING TRAINING BASED ON A SINGLE IMU -A PILOT STUDY TRACKING CHANGES IN STROKE EFFICIENCY AND SPATIO-TEMPORAL PARAMETERS

BOUVET, A.1,2,3, DELHAYE, E.1,2, ALBERT, S.1, MARBAC, M.3, EL-KOLEÏ, S.3, BIDEAU, N.1,2

*1M2S LABORATORY , UNIVERSITY RENNES 2, ENS RENNES, FRANCE; 2MIMETIC - ANALYSIS-SYNTHESIS APPROACH FOR VIRTUAL HUMAN SIMULATION, INRIA RENNES, FRANCE; 3CREST, ENSAI, FRANCE*

INTRODUCTION: Ongoing monitoring of swimmers becomes a coachs major duty, evaluating their performance and providing feedbacks for their improvement [1]. Inertial Measurement Units (IMU) became more readily available in sport to allow performance and technical assessments. Thus, previous applications of such sensors during in-situ swimming training showed their relevance to automatically quantify spatio-temporal metrics [2, 3]. However, these studies were restricted to short period of time, and led to limited insights as regards to training process. The aim of this study was to assess the sensitivity of IMU-derived performance and kinematical variables over the first part of the 2022 season to monitor technical abilities.
METHODS: Four regional swimmers performed 5 monitoring trials (T1, T2, T3, T4, T5). They consist in 4x100m in front crawl at 400m pace starting each 2 minutes with an IMU (Cometa WaveTrack, Italy) on the sacrum. A deep-learning model allowed to compute lap by lap speed (SP), stroke rate (SR), stroke length (SL) and jerk cost (JC) [4]. Smallest Worthwhile Change (SWC) [5] were used to detect changes in metrics for the whole training group. An ANCOVA and SWC were used to assess changes in estimated linear regression coefficients (B0 and B1) between SP and JC to track modification in smoothness and stroke efficiency across the season. Significance was set at $p<0.05$ and meaningful change at 1xSWC.
RESULTS: Meaningful variations over time were found with an increase of JC at T2 (1.29xSWC), a decrease at T4 (-1.18xSWC) and a decrease of SR (-1.45xSWC) coupled with an increase of SL (1.18xSWC) at T5. ANCOVA revealed a significant global interaction effect of B1 ($F(4.27)=5.27$; $p<0.01$) and significant differences in B0 ($F(4)=4.11$; $p<0.01$) according to monitoring trials. It was confirmed by meaningful changes in B1 at T2 (-2.43xSWC), T4 (5.20xSWC) and T5 (-3.10xSWC) and in B0 at T4 (-4.40xSWC) and T5 (4.43xSWC).
CONCLUSION: This pilot work showed that regression coefficients between SP and JC were modified across the training period that allows longitudinal significant data-driven feedbacks on swimming technique. Whereas no meaningful change in performance was quantified, a lower jerk cost associated with same speed was highlighted. This leads to a better swimming efficiency reflected by the increase in regression coefficients. This result may be linked to modification in kinematics reflected by SL increase and SR decrease. Finally, on-field single IMU-based monitoring of swimming can provide useful data for training regulation. Nevertheless, such analysis needs to be expanded to high level swimmers and over a full training season.

### INDIVIDUALISED BALL SPEED PREDICTION IN BASEBALL PITCHING BASED ON IMU DATA

GOMAZ, L.1,2, VEEGER, D.2, VAN DER GRAAFF, E.3, VAN TRIGT, B.2,3, VAN DER MEULEN, F.1

*1, 2 DELFT UNIVERSITY OF TECHNOLOGY, 3 VRIJE UNIVERSITEIT AMSTERDAM*

INTRODUCTION: The optimal pitching motion displays a sequential activation of body parts, also known as the kinetic chain, in which the pelvis and trunk play an essential role. Enhancing pitching technique through the optimal positioning and timing of proper pitching mechanics can result in a fast and accurate throw and reduce the injury risk [1,2,3]. Therefore, estimating ball velocity based on IMU data can be a step towards assessment of the pitching technique.
METHODS: Twenty-five youth baseball pitchers performed ten fastball pitches with maximal effort. Ball velocity was measured by a radar gun (Stalker Radar, Plano, TX, USA). Two 9-DOF IMUs (MPU-9150, Invensense, San Jose, CA, USA, Accelerometer: 16 g, Gyroscope: 2000 deg/s) were rigidly attached to participant's pelvis and sternum. Peak angular velocity of pelvis (PAP) and trunk (PAT) were calculated by taking the Euclidian norm [4]. We developed three multilevel Bayesian regression models to predict the ball velocity: (I) complete pooling model (Observations), (II) two-level varying-intercept model (Personal) and (III) two-level varying-intercept, varying-slope model (Full). Each model was evaluated by the predictive performance defined as the expected log-predictive density (elpd). Comparing the developed models determines the contribution of the kinematic parameters related to pitching mechanics and pitcher's body height to predictive performance. We used leave-one-out (LOO) cross-validation for a model selection.
RESULTS: The Full model was a preferable model ($R2 = 0.975$), followed by the Personal ($R2 = 0.973$) and the Observations model ($R2 = 0.137$). The Full model was better than the Observations model by 308.3 (SE = 13.5) and better than the Personal model by 5.5 (SE = 3.3) of log predictive probability values.
CONCLUSION: Ball velocity can be estimated with a low accuracy with only IMU data. However, by including an additional level, we introduce the group participation that makes a distinction between pitchers of a different height. This results in a significantly improved predictive performance of the model that includes PAP and PAT on an individual-level when including pitcher's height on a group-level. Therefore, IMUs, that can be easily used in every situation, can provide an input for ball velocity predictions without use of a radar gun. Our results demonstrate the added value of a pitcher's height to predictive performance and use of proposed method represents a potential for predictions of future throwing speed when pitchers grow taller.

### CONCURRENT VALIDITY OF THE STRYD POWER METER DURING WALKING AT DIFFERENT SLOPES AND BACKPACK LOADS.

PINEDO-JAUREGI, A., GARCIA-TABAR, I., CÁMARA, J.

*UNIVERSITY OF THE BASQUE COUNTRY*

INTRODUCTION: Mountain rescuers, wildland firefighters and military personnel could be treated as elite athletes because the success of accident rescues might often depend on their physical performance. Therefore, training load quantification is of paramount importance in order to improve physical performance of rescue teams. In recent years, some inertial measurement units have been designed to quantify training load during some physical task, such as running [1]. In this sense, the Stryd device has been validated to measure power output during running [2] but not during walking [3]. Walking, either at different slopes or with load carriage, is one of the main activities that rescue personnel have to face during rescues[3]. Accordingly, the aim of this research was to measure the concurrent validity of the Stryd power during walking at different slopes and with different backpack loads without slope during level walking.
METHODS: Seventeen participants from a mountain rescue team performed 8 walking trials. Each trial consisted of 5 minutes walking at 3.6 km/h at different positive slopes (1%,10% and 20%) and with different backpack loads (0%, 10%, 20%, 30% and 40% of body mass) without slope. During the trials, the internal load indicators of oxygen uptake (VO2), minute ventilation (VE), heart rate (HR) and rate of perceived exertion (RPE) were registered. Concurrent validity of the Stryd's power output was assessed by checking its linearity with the internal load indexes. Pearson´s correlation coefficients (r) were used to evaluate the direction and magnitude of the linear relationships. Significance was set at $P<0.05$.
RESULTS: Results showed significant ($P< 0.05$) positive correlations between power (W) and the internal load indicators (VO2 ml/kg/min r= 0.91; VE L/min r= 0.95; HR r= 0.92; %VO2max r= 0.92; %HRmax r= 0.89 and RPE r= 0.83) during walking at 1%, 10% and 20% slopes. The relative power (W/kg) also showed a significant ($P< 0.05$) positive correlation with these measures (VO2 ml/kg/min r= 0.96; VE l/min r= 0.93; HR r= 0.93; %VO2max r= 0.94; %HRmax r= 0.92 and RPE r= 0.89). During walking with different backpack loads, the results showed positive correlations between power and relative power against all the physiological and perceptive variables measured (range r= 0.52 to 0.75).
CONCLUSION: This is the first research that assessed the concurrent validity of the Stryd Power Meter device during walking. Our findings indicate that measurements of power (W) and relative power (W/kg) provided by Stryd device units show concurrent validity. We suggest that the Stryd device may be useful and valid to measure power in walking activities at different slopes and backpack loads. This project was supported by the Basque Country Government (PRE_2019_2_0102).

### DESCRIPTION OF THE THERMAL PATTERN OF 950 ATHLETES USING THERMOGRAPHY TO MEASURE SKIN TEMPERATURE.

ESCAMILLA-GALINDO, V., DEL ESTAL-MARTÍNEZ, A., ARNAIZ-LASTRAS, J., SILLERO-QUINTANA, M., FERNÁNDEZ-CUEVAS, I.

*THERMOHUMAN*

INTRODUCTION: Infrared thermography is a fast technology that allows non-invasive measurement of skin temperature. This tool has been applied in the scientific literature for the control of training workloads and the prevention of injuries, since it allows detecting the body regions that present the greatest risk of injury. This has been shown, especially when thermal asymmetries are used in the analysis (Carmona P. et al. 2020; Corte A. et al. 2019). The objective of this study was to identify and describe the distribution of thermal asymmetries in athletes in order to describe normal values and be able to establish individualized profiles.
METHODS: 950 athletes measured by the same observer were analyzed including only thermography images in a basal state, according to the indications of the Glamorgan protocol (Ammer K. et. al. 2008). The images were taken with a FLIR T530 camera (Flir Teledyne systems, Sweden) and analyzed using the automatic ThermoHuman software (Pema Termo Group, Spain), scientifically validated for this purpose (Requena-Bueno L. et al. 2020). Thermal analysis was performed anonymously, extracting data from 80 regions of interest (ROI) using an artificial vision algorithm and displaying the average, minimum, and maximum temperature results for each ROI. The system automatically compared the ROIs of both sides to obtain the mean asymmetry metric, that is, the difference between the mean temperature of one ROI and its contralateral.
RESULTS: The asymmetry values showed a mean difference of (0.004ºC ± 0.66ºC) in all ROIs. When the ROIs were analyzed individually, the most stable with the least mean asymmetry were: the ROI of the chest (0.007ºC ± 0.16ºC), the trapezius in its frontal view (0.008ºC ± 0.24ºC), the lower back region (0.007ºC ± 0.26ºC) and the vastus medialis (0.003ºC ± 0.27ºC). While the greatest differences were found in the foot in the posterior view (0.37ºC ± 3.73ºC), the wrist in both anterior and posterior views (0.16ºC ± 0.72ºC; 0.09ºC ± 0.65ºC), the shoulder in the posterior view (0.09ºC ± 1.47ºC) and the vastus lateralis (0.09ºC ± 0.40ºC). In addition, the regions with the greatest variability were: the neck (0.03ºC ± 2.10ºC; 0.01ºC ± 2.04ºC) and the foot (0.005ºC ± 2.26ºC; 0.37ºC ± 3.73ºC), both in its anterior and posterior views.
CONCLUSION: A normality profile of athletes using thermography to analyze the skin temperature of the ROIs was established. This allows the comparison of a new athlete with the database of the 950 athletes. In addition, as has been verified with the descriptive analysis of this sample, the ROIs show a degree of similarity very close to symmetry when a large number of evaluations are included, even without knowing the factors of influence. This facilitates the generation of individualized thermal profiles that can improve the understanding and usefulness of thermographic analysis.

### CAN BODILY SELF-CONSCIOUSNESS AFFECT TRAINING IN VIRTUAL REALITY WHEN IDENTIFYING TO AN AVATAR?

PRATVIEL, Y., DESCHODT-ARSAC, V., LARRUE, F., ARSAC, L.M.

*UNIVERSITÉ DE BORDEAUX*

INTRODUCTION: The growing development of Virtual Reality (VR) technologies offers appealing opportunities for athletes to train in simulated environments [1]. Coupled with motion capture, VR grants the possibility to see oneself from a third-person perspective, embodying an avatar, which offers new perspectives for movement training and visualization. However, several aspects of brain perception-action may distinguish interactions in real world and in VR. When manipulating an avatar, a critical aspect is the consciousness of a self, anchored in a physical body, as a construct of multisensory integration [2]. The aim of this study was to evaluate how visuomotor performances evolve from a first person to a third person (avatar) perspective, and to assess the modulating role of bodily self-consciousness.

METHODS: Thirty-one sport students (thirteen females) performed a visuomotor task in virtual reality (VMVR) which consists in hitting as quickly as possible buttons spatially arranged around concentric circles on a vertical board (120x120cm). In the first-person condition (1PP), buttons are successively lit up after being reached by the hand-held VR controllers. In the third-person condition (3PP), the buttons are reached using the hands of an avatar created with motion capture, displayed two meters in front of the participant and following its movements. The task was performed seeing the avatar from the back (0°), or with a viewpoint positioned to the left (-60°) or to the right (60°) to stimulate perspective taking. A questionnaire and specific VR tasks evaluated components of bodily self-consciousness: self-identification, self-location and perspective taking.
RESULTS: A repeated measures ANOVA showed no differences between 1PP and 3PP scores whatever the viewpoint : 0°, 60° or -60° ($F(3,123) = 1.29$, $p = 0.28$), which shows that participants were able to maintain similar visuomotor performances while manipulating the avatar. In addition, we show that participants take full advantage of the far-from-target viewpoint (two meters away) in avatar conditions, reaching lower reaction times for peripheral stimuli in 3PP compared to 1PP ($F(3,123) = 5.98$, $p = 8x10\text{-}4$). A Principal Component Analysis indicated orthogonality between 1PP/3PP response times and measures of self-identification, self-location and third-person perspective, which confirms the lack of impact of bodily-self-consciousness on visuomotor performances when manipulating an avatar.
CONCLUSION: This study demonstrates the ability of a population of young athletes to instantly manipulate a third-person avatar in VR, without interferences due to bodily self-consciousness. The performances obtained facing the avatar's back or by adding a 60° angle - which implies perspective taking and mental rotations, are unaltered. Thus, manipulating an avatar in VR can be used to exploit rich cognitive-motor stimulating environments for athletes training.

#### VALIDATION OF AN OPEN SOURCE AMBULATORY ASSESSMENT SYSTEM FOR PHYSICAL ACTIVITY MEASUREMENT

GABRYS, L.1, HÖLZEMANN, A.2, VAN LAERHOVEN, K.2

*1. UNIVERSITY OF APPLIED SCIENCES OF SPORT AND MANAGEMENT POTSDAM, 2. UNIVERSITY OF SIEGEN*

INTRODUCTION: Inertial-based trackers have become a common tool in data capture for ambulatory physical activity assessment and for physical activity promotion. Most commercially available systems use black-box aggregation algorithms, often resulting in data that are locked into proprietary formats and metrics that make later replication or comparison difficult (Brondin et al. 2020). For physical activity and health promotion strategies and interventions the accurate recording and appropriate feedback to the user seems essential for intervention success and data interpretation. The aim of the presented study is to further develop and evaluate an open source ambulatory assessment system that produces data which can be complemented and compared against later. This consists of generic software and open algorithms for capturing physical activity, with a special focus on persons with non-communicable diseases (diabetes, cardiovascular diseases), which can be used for research questions as well as health promotion strategies.
METHODS: The aim of the study is to validate an open-source ambulatory assessment system that consists of an open source smartwatch (Bangle.js), algorithms, and software components (smartphone app) against a reference tool (ActiGraph GT9X). Two validation experiments were performed, one lab-based treadmill study (3, 5, 7 km/h) to define activity cut-offs (light, moderate, vigorous) and step validation in a convenience sample of 16 volunteers (7m, 9w) with a mean age of 45.4 years (±6.8 SD) and one 'in vivo' study with 28 volunteers (14m, 14w) suffering from diabetes or cardiovascular disease with a mean age of 65.6 years (±13.2 SD). All code for the analysis was written in Python and is made available online.
RESULTS: A comparison between data from ActiGraph GT9X trackers and our proposed system reveals the original inertial sensor signals at the wrist strongly correlate (Pearson correlation coefficients for raw inertial sensor signals of 0.97 in the controlled treadmill-walking setting). The obtained classification accuracy for distinguishing between low-moderate or moderate-vigorous activity is 97.5% and 86.7%, respectively under labaratory conditions. The estimated steps from the open-source wrist-based detection approach strongly correlate with the hip-worn ActiGraph output (average Pearson correlation coefficients of 0.81 for minute-wise comparisons of detected steps) in day-long ambulatory data.
CONCLUSION: Recording inertial sensor data in a standardized form and relying on open-source algorithms on these data form a promising methodology that ensures datasets can be replicated or enriched long after the wearable trackers have been decommissioned.

#### RESEARCH ON THE HIGH-QUALITY DEVELOPMENT OF CHINAS SPORTS FITNESS APPS UNDER THE DIGITAL BACKGROUND

WANG, Y.F.1, LIU, X.H.2, ZHI, Z.X.3

*CHINA INSTITUTE OF SPORT SCIENCE*

INTRODUCTION: By analyzing the main problems of current Chinas sports fitness apps, exploring the new opportunities for app development under the digital background, and proposing targeted strategies for promoting the high-quality development of Chinese sports fitness apps.
METHODS: literature method, logical analysis method
RESULTS: Dilemma: 1. In China, the user information of sports fitness platform is at risk of leakage , the existence of loopholes in network technology and the lack of corresponding supervision and management mechanisms of platforms may make users privacy stolen by criminals and seriously affect network information security; 2. Platform fitness function is single and homogenization is serious, most platforms compete viciously for their own interests and get more customers by playing price war, 3. The profit model is backward, currently many fitness guidance apps are using implanted advertising or part of the course fees to obtain profits, but this requires extremely high number and loyalty of users ,too much advertising and paid courses will often cause the loss of users.
Opportunity:
1.Policy support: In China, the government has issued a series of policies to help the digital transformation of the sports industry, such as the "National Fitness Plan 2021-2025", which provides endogenous impetus for the development of "digital + sports"; 2. Market prospect:

The epidemic situation in COVID-19 is still grim, home isolation has become the normal state of peoples lives, The public awareness of fitness is increasing day by day, and the "cloud fitness" based on digital technology is very hot. 3. Technical support: digital technology can promote the transformation and upgrading of APP to create a more immersive experience for the audience; 4. Economic foundation: the GDP per capita of Chinese residents is growing year by year, the public demand is changing to a higher level, and sports, as a public service, can meet peoples spiritual, physical and psychological needs and become the first choice for many people.
CONCLUSION: Countermeasures: 1. Improve the platform supervision and management mechanism: use digital technology to upgrade the user information protection system; increase the punishment for leaking user information and other acts, and form a supervision and management circle with government, society and platform as a whole; 2. Improve platform services and functions, and create a sports service platform that meets the fitness needs of different age stages; 3. innovating profit model: accurate advertising times, optimization of paid service course quality, free placement of basic service courses, and free value-added services for loyal customers.

### A JUST-IN-TIME ADAPTIVE INTERVENTION TO ENHANCE PHYSICAL ACTIVITY AFTER INACTIVE PHASES IN CHILDREN AND ADULTS.

FIEDLER, J., SEIFERTH, C., ECKERT, T., WOLL, A., WUNSCH, K.

*KARLSRUHE INSTITUTE OF TECHNOLOGY*

INTRODUCTION: Just-in-time adaptive interventions (JITAIs) are promising technology-based interventions for behavior change (Wunsch et al., 2022). This study aimed to evaluate if a JITAI can enhance physical activity in the subsequent hour depending on whether the JITAI trigger has been answered (JITAI condition) compared to when the trigger was not answered (control condition).
METHODS: Data of the three-week intervention period of the SMARTFAMILY2.0 trial which aimed to promote physical activity in families (Wunsch et al., 2020) was used for analysis. A total of 80 participants with 907 JITAI triggers were included in this study. A JITAI was sent when the participant has been inactive for at least 60 minutes (indicated by accelerometry). Two multilevel models were calculated (outcomes: metabolic equivalents (MET) and step count) using RStudio with measurements (level 1) nested in participants (level 2) under consideration of several covariates (i.e. weekday/weekend, time of the day, adult/child).
RESULTS: Results indicated significantly higher MET and step count in the JITAI condition com-pared to the control condition within-persons (level 1). Participants in the JITAI condition recorded 5.52 higher MET ($\beta = 0.08$, $p = .014$) and 113.16 more steps ($\beta = 0.08$, $p = .022$) in the following hour compared to participants in the control condition.
CONCLUSION: The inactivity JITAI implemented in the SMARTFAMILY2.0 trial indicates promising results concerning physical activity enhancement in the subsequent hour. Here, the inclusion of further factors like the availability of the participant or the inclusion of affective variables into the design of the JITAI might further enhance the effect in future studies.

### HEALTH EFFECTS OF A 12-WEEK WEB-BASED LIFESTYLE INTERVENTION FOR PHYSICALLY INACTIVE ADULTS: A RANDOMIZED CONTROLLED CLINICAL TRIAL

BRAME, J.1, KOHL, J.1, CENTNER, C.1, GOLLHOFER, A.1, KÖNIG, D.1,2

*1 UNIVERSITY OF FREIBURG; 2 UNIVERSITY OF VIENNA*

INTRODUCTION: Physical inactivity has been identified as an important health risk factor, especially for non-communicable diseases. Web-based lifestyle interventions have become of great research interest to promote a physically active lifestyle. Previous research on such interventions indicates health-promoting effects, but further research is needed. Therefore, the aim of the present study was to investigate the health effects of a web-based health program (TK-HealthCoach) offered by a national health insurance fund (Techniker Krankenkasse, TK).
METHODS: The study was designed as a randomized controlled clinical trial in which n = 189 physically inactive adults (48.07 ± 12.01 years, 73.50% females, 25.56 ± 3.66 kg/m2) were included and randomly assigned to a 12-week interactive (TK-HealthCoach) (intervention group) or non-interactive (control group) web-based health program using permuted block randomization. Cardiorespiratory fitness was set as the primary outcome. Musculoskeletal fitness, physical activity and dietary behavior, anthropometry, blood pressure, blood values, and vascular health were defined as secondary outcomes. All outcomes were assessed before and after the 12-week intervention and after a 6- and 12-month follow-up. Complete case (CC) and intention-to-treat (ITT) analyses were performed using robust linear mixed models (RLMM).
RESULTS: CC analysis (n = 96) showed significant time effects for the primary and most secondary outcomes ($p < 0.05$). Significant interaction effects were observed for single secondary outcomes of blood pressure, blood levels, and vascular health ($p < 0.05$), but mainly in favor of the control group. ITT analysis (n = 189) revealed significant time effects for the primary outcome and single secondary outcomes of physical activity, anthropometry, and blood values ($p < 0.05$). There was a significant interaction effect for blood pressure outcomes favoring the control group ($p < 0.05$). No other effects were observed.
CONCLUSION: This study demonstrated that participation in a 12-week interactive or non-interactive web-based health program can induce health effects in physically inactive adults. However, no evidence was found for the superiority of the interactive web-based health program. Thus, more research is needed to clarify the findings of this study within the available evidence on web-based lifestyle interventions.

## OP-BM22 Central and / or spinal drive I

### SPINAL REFLEX MECHANISMS IN ANTICIPATED AND NON-ANTICIPATED ROTATIONAL AND TRANSLATIONAL POSTURAL PERTURBATIONS

WÄLCHLI, M., EGGER, S., TAUBE, W.

*UNIVERSITY OF FRIBOURG*

INTRODUCTION: It is assumed that stretch reflex responses are functionally modulated, meaning that reflex reactions to toe-up rotations are counterproductive to regain balance and are therefore suppressed, whereas in translational backward perturbations they have a supporting function and are facilitated (Nashner, 1976). However, previous studies have compared rotations and translations that led to different ankle movements and therefore may evoke the muscle spindles differently. Here, we matched the rotations and translations in terms of the ankle angle properties and additionally analyzed the spinal excitability by means of the H-reflex technique. It was hypothesized that the spinal reflex activity in the anticipated conditions should be decreased in rotations and increased in translations when compared with the equivalent non-anticipated conditions.
METHODS: Muscular responses to external induced anticipated (blocked) and non-anticipated (random) rotations and translations were analyzed by comparing the EMG root mean square signal of the m. soleus within the short-latency response (SLR; 30-60ms after perturbation) in 24 healthy adults. H-reflexes were evoked shortly before (30ms; preparatory setting) and after (45ms; during the SLR) the onset of perturbation. Biomechanical effects of the perturbations were assessed with the maximal ankle angle movement and the time to the maximal ankle angle.
RESULTS: Rotations and translations were shown to induce different muscular activities during the SLR, i.e. noticeably less activity in translations ($p < .001$). In anticipated rotations, the SLR was suppressed ($p = .015$) and H-reflex amplitudes were facilitated ($p = .044$) when compared to the non-anticipated condition. In translations, neither an effect of the stretch reflex response nor the H-reflex could be seen between anticipated and non-anticipated perturbations. Biomechanical effects of the perturbations were not different between rotations and translations and anticipated and non-anticipated perturbations.
CONCLUSION: In line with our hypothesis, muscular activity during the SLR in anticipated rotations were adequately decreased to diminish unnecessary reactions. In contrast, H-reflexes elicited in rotations were increased in anticipated compared to non-anticipated perturbations. It is known that stretch reflex responses and H-reflexes are differently sensitive to the influence of presynaptic inhibition (Morita et al., 1998). However, this cannot explain contradictory behavior of stretch and H-reflex responses as seen in this study. Therefore, it is assumed that the fusimotor system is differently activated in anticipated and non-anticipated postural perturbations and that the muscle spindles have an important role in the feedforward control of postural perturbations.

### EFFECTS OF A PERCUSSIVE MASSAGE ON PASSIVE TORQUE AND REFLEX ACTIVITY OF PLANTAR FLEXOR MUSCLES

DATOUSSAID, M., GUISSARD, N., BAUDRY, S.

*UNIVERISTÉ LIBRE DE BRUXELLES*

INTRODUCTION: Handheld percussive massage treatment has gained popularity in the therapeutic and athletic communities in the last few years, although evidence of its efficacy is still lacking. A recent study showed that a 5-min handheld percussive massage of the calf muscles increased the ankle dorsiflexion range of motion (Konrad et al. 2020). This may reflect a decrease in muscle stiffness or in the responsiveness of the muscle spindle pathway. The purpose of this study was to investigate the effect of percussive massage on passive torque and reflex activities of the ankle plantar flexors (PF).Handheld percussive massage treatment has gained popularity in the therapeutic and athletic communities in the last few years, although evidence of its efficacy is still lacking. A recent study showed that a 5-min handheld percussive massage of the calf muscles increased the ankle dorsiflexion range of motion (Konrad et al. 2020). This may reflect a decrease in muscle stiffness or in the responsiveness of the muscle spindle pathway. The purpose of this study was to investigate the effect of percussive massage on passive torque and reflex activities of the ankle plantar flexors (PF).
METHODS: Eleven healthy young adults participated to this study [mean (SD); 24 (2)yrs]. Before and after a 5-min handheld percussive massage (TheragunTM Massager pro 4th Gen; PERCU session) or effleurage massage (SHAM session), the maximal amplitude of the Hoffmann reflex (Hmax), maximal M-wave amplitude (Mmax) and tendon tap reflex recorded in the soleus, and the passive torque of PF muscle-tendon unit were measured. Hmax and Mmax were evoked in the soleus by stimulating the tibial nerve (1-ms duration) while tendon tap were triggered by precutting the Achilles tendon with a percussion hammer at 90° ankle angle (Guissard et al., 1988). The passive torque was recorded during ankle dorsiflexion (2.5°/s) from 90° to 60° ankle angle.
RESULTS: The passive torque during ankle dorsiflexion changed neither after PERCU nor CON. Similarly, the Hmax did not change after PERCU [before: 43 (12) % Mmax); after: 40 (19) % Mmax] or SHAM [before: 43 (13) % Mmax); after: 44 (13) % Mmax]. In contrast, the tendon tap reflex amplitude increased after [27(1) % Mmax] compared with before [21(6) % Mmax; $p = 0.02$] PERCU, while no change was observed for SHAM.
CONCLUSION: In the absence of change in passive torque and Hmax, the increase in tendon tap reflex suggests an enhanced muscle spindle sensitivity. This may reflect the thixotropic property of intrafusal muscle fibers (Gregory et al. 1998; Nakajima et al. 2009), providing only a transient effect which should be abolished by muscle contraction. Overall, our results did not demonstrate a salient effect of percussive massage on the plantar flexors neuromechanics.

### WIDE-PULSE HIGH-FREQUENCY NEUROMUSCULAR ELECTRICAL STIMULATION DOES NOT INFLUENCE THE H-REFLEX PATHWAY

THEODOSIADOU, A., PLACE, N., BAUDRY, S.

*LABORATORY OF APPLIED BIOLOGY & RESEARCH UNIT IN APPLIED NEUROPHYSIOLOGY INSTITUTE OF SPORT SCIENCES AND DEPARTMENT OF PHYSIOLOGY*

INTRODUCTION: Wide-pulse high-frequency (WPHF) neuromuscular electrical stimulation is characterized by high stimulation frequencies (>80 Hz) and long pulse durations (1ms), which preferentially depolarize Ia afferents compared to motor axons (1). Accordingly, some motor units are recruited via the Ia-afferent pathway in the physiological recruitment order (2). However, repetitive activation of the Ia afferent pathway may alter its functioning (3), but it remains unknown whether WPHF transiently modifies presynaptic mechanisms associated with this pathway. This study investigated the effect of a 20-min bout of WPHF on the soleus Hoffmann (H) reflex, and two mechanisms which presynaptically modulate its efficacy to recruit motor units [homonymous postactivation depression (HD) and Ia presynaptic inhibition (PSI)].
METHODS: Twelve healthy young adults (19-25yrs; 3 women) participated to one control session (no stimulation train; CON), and one session during which twenty 20-s WPHF stimulation trains (1-ms pulse duration; 100 Hz; 40-s rest between trains) were applied on triceps surae. The stimulus intensity produced an initial force corresponding to 5% of the participant's maximal force. Before and after the WPHF or the 20-min control period, 20 soleus H reflexes were evoked by stimulating the tibial nerve with an intensity producing an M wave of 10% of the M-wave maximal amplitude (Mmax). HD was assessed by evoking two H reflexes with an interval of 0.5 s. PSI was assessed with the D1 method which consists of conditioning the H reflex by an electrical stimulus of the common peroneal nerve delivered 20 ms prior to the tibial nerve stimulus. Two-way ANOVAs [session (CON vs. WPHF) x time (before vs. after)] were used to analyse the data.
RESULTS: The Mmax amplitude did not change, regardless of the session (p=0.28). The H-reflex amplitude did not differ between sessions before [mean(SD); WPHF: 51(19)% Mmax; CON: 45(21)% Mmax] and after the intervention [WPHF: 45(19)% Mmax; CON: 50(17)% Mmax; p=0.15]. Similarly, HD (p=0.85) and PSI (p=0.23) did change neither in WPHF nor CON session.
CONCLUSION: The lack of change in H-reflex amplitude after WPHF indicates that the efficacy of the synaptic transmission between Ia afferents and motor neurons was not altered. This contrasts with previous work showing a decrease in H-reflex amplitude (4), differences between studies may depend on participants characteristics. The absence of change in HD and PSI suggests that presynaptic mechanisms were not influenced by WPHF (5). Overall, the results suggest that WPHF could be used in rehabilitation to induce a more functional activation of motor units without altering the muscle spindle pathway.

### H-REFLEX AND HOMOSYNAPTIC POST-ACTIVATION DEPRESSION MODULATION DURING LOW- AND HIGH-INTENSITY SUBMAXIMAL ISOMETRIC FATIGUING CONTRACTIONS

KALC, M.1,2, URH, F.3, KRAMBERGER, M.3, FRANCIC, A.3, VOGRIN, M.1,4, HOLOBAR, A.3

*1 UNIVERSITY OF MARIBOR, FACULTY OF MEDICINE, 2 SCIENCE AND RESEARCH CENTRE KOPER, 3 FACULTY OF ELECTRICAL ENGINEERING AND COMPUTER SCIENCE, UNIVERSITY OF MARIBOR, 4 UNIVERSITY MEDICAL CENTRE MARIBOR*

INTRODUCTION: One of the possible mechanisms accounting for fatigue is the reflex inhibition of the motoneuron mediated by group III and IV afferents sensitive to by-products of the fatiguing contraction. The H-reflex can serve as a probe to assess a complex interplay between central and peripheral fatiguing mechanisms. H-reflex is also sensitive to previous stimuli, resulting in the decrement of the reflex response, which is attributed to homosynaptic depression of Ia afferents (HPAD). The examination of HPAD represents a tool to gather insight into the integration of central and peripheral mechanisms that regulate muscle output during fatiguing contractions. It has been recently shown, that HPAD is modulated during high intensity (60% MVC) fatiguing intervention (1). However, it is not clear how contraction intensity affects HPAD during fatigue. Thus, the study aimed to investigate the effects of continuous isometric contractions of two intensities on H-reflex and HPAD.
METHODS: Twelve males (age 26.8 ± 8.1 years) were instructed to isometrically contract the plantar flexors, maintaining 25% (CON25) or 65% (CON65) of their MVC until volitional failure. The tibial nerve was stimulated in the popliteal fossa with an electrical stimulator (NeoStim1; EMF Furlan, Slovenia) PRE, during and POST intervention. Ten submaximal paired stimuli (interstimulus interval 8 s) elicited a test (Htest) and a conditioned reflex response (Hcond) 0.5 s later. The EMG signal was collected from the muscle soleus using a 64 channels matrix electrode (GR08MM1305, OT Bioelettronica, Italy). Peak-to-peak amplitudes were extracted from the electrically elicited responses. Data were analysed using repeated measures nested linear mixed effect models.
RESULTS: Hcond was significantly ($P < 0.001$) lower than Htest at PRE (CON25: -37.7%; CON60: -42.6%) and POST (CON25: -36.6%; CON60: -42.4%), resulting in no significant interaction between the effect of time, intervention intensity and previous stimulation on the H-reflex at rest. However, during the fatiguing contraction, there were no statistically significant differences between Htest and Hcond, suggesting a drop in HPAD. Both Htest and Hcond dropped significantly during CON25 intervention by -38.6% and -32.1% respectively ($P = 0.028$; $P = 0.065$) and stayed statistically unchanged during CON60 ($P = 0.573$; $P = 0.66$), resulting in a significant interaction between time and intervention intensity ($P = 0.014$).
CONCLUSION: The results of this study showed that HPAD diminished during muscle contraction compared to rest. However, the drop of both reflex responses (Htest and Hcond) during CON25 suggests that contraction intensity plays an important role in motoneuron output modulation during a fatiguing task. Further analysis of the data from the matrix electrodes is required to gain insight into the effects of fatigue on the modulation of motor unit firing rates.

**ISCHEMIC PRECONDITIONING DID NOT AFFECT CENTRAL AND PERIPHERAL FACTORS OF MOTOR PERFORMANCE FATIGUE AFTER SUBMAXIMAL ISOMETRIC EXERCISE**

BEHRENS, M., SCHEGA, L., MITTELMEIER, T., HUSMANN, F.

*OTTO VON GUERICKE UNIVERSITY MAGDEBURG*

INTRODUCTION: Ischemic preconditioning (IPC) involves repeated, short-term periods of vascular occlusion with subsequent reperfusion and has been shown to increase human performance if applied to the exercising limb prior to physical activity. Studies have found that IPC has an ergogenic effect on a variety of endurance exercise modalities including running, cycling, swimming, and sustained submaximal isometric contractions. The present study was designed to provide further insight into the mechanistic basis for the improved exercise tolerance during submaximal isometric exercise following IPC by investigating key-determinants of motor performance and perceived fatigue.
METHODS: Using a randomized, counterbalanced, single-blinded, sham-controlled, crossover design, 16 males performed an isometric time-to-exhaustion (TTE) test with the knee extensors at 20% maximal voluntary torque (MVT) after an IPC and a sham treatment (SHAM). Those who improved their TTE following IPC performed a time-matched IPC trial corresponding to the exercise duration of SHAM (IPCtm). Neuromuscular function was assessed before and after exercise termination during each condition (IPC, IPCtm, and SHAM) to analyse the impact of IPC on motor performance fatigue and its central and peripheral determinants. Muscle oxygenation (SmO2), muscle activity, and perceptual responses (effort and exercise-induced muscle pain) were recorded during exercise. Motor performance fatigue as well as its central and peripheral determinants were quantified as percentage pre-post changes in MVT (ΔMVT) as well as voluntary activation (ΔVA) and quadriceps twitch torque evoked by paired electrical stimuli at 100 and 10 Hz (ΔPS100 and ΔPS10/PS100-ratio), respectively.
RESULTS: TTE, motor performance fatigue, its determinants, muscle activity, SmO2, and perceptual responses during exercise were not different between IPC and SHAM. However, six participants improved their TTE by >10% following IPC compared to SHAM ($P < 0.001$, $d = 3.23$). Based on effect sizes ($\eta p^2$, d), the time-matched comparisons (IPCtm vs. SHAM) for these 'responders' indicated that motor performance fatigue, its determinants, and SmO2 were not affected, while effort perception seemed to be lower ($\eta p^2 = 0.495$) in the IPCtm condition. The longer TTE in the IPC condition (IPC vs. SHAM) was also accompanied by a lower effort perception ($\eta p^2 = 0.380$) and larger impairments in neuromuscular function, i.e. larger ΔMVT, ΔVA, and ΔPS10/PS100 ($d = 0.71$, 1.0, 0.92, respectively).
CONCLUSION: IPC did neither affect TTE, motor performance fatigue, as well as its central and peripheral determinants, nor muscle activity, SmO2, and perceptual responses during submaximal isometric exercise. However, IPC seemed to have an ergogenic effect in a few subjects, which might have resulted from a lower effort perception during exercise. These results support previous findings that there are 'responders' and 'non-responders' to IPC.

**DIFFERENCES IN BIOLOGICAL MATURITY STATUS AND PREDICTED ADULT HEIGHT BETWEEN SELECTED AND NON-SELECTED PLAYERS: AN INVESTIGATION OF MALE AND FEMALE ATHLETES IN YOUTH ELITE BASKETBALL**

LEYHR, D.1, ROESCH, D.1, VILLMETER, F.2, HÖNER, O.1

*1 UNIVERSITY OF TUEBINGEN, GERMANY; 2 GERMAN BASKETBALL FEDERATION , GERMANY*

INTRODUCTION
The influence of biological maturity on talent identification in physically demanding sports is critically debated within both, research and practice. Especially during adolescence, maturity-related performance differences within the same age group may cause greater chances of being selected and promoted for early-maturing athletes (Malina et al., 2019). Though increasing interest is dedicated to maturity-related parameters in talent identification and development in general, evidence of its impact for talent identification in Basketball is still scarce. However, particularly in Basketball, maturity-related indicators (e.g., body height) are considered relevant for performance. Accordingly, the aim of the present study was to analyze differences in the biological maturity status and predicted adult height between selected and non-selected male and female youth basketball players for the German U15 and U16 youth national teams.
METHODS
Male U15 (N=71) and female U16 (N=50) elite youth basketball players were investigated who participated with regional associations squads in a selection tournament for the youth national teams. Just before the start of the tournament, height, weight, biological maturity status (maturity offset, MO; Mirwald et al., 2002), and predicted adult height (PAH, Khamis & Roche, 1994) for each player were assessed. After the tournament, 28 male and 15 female players were selected for the extended squad of the respective youth national teams. Separately for each gender, independent samples t-tests were utilized to analyze differences in the assessed outcomes between selected and non-selected players. Cohen's d served as effect size.
RESULTS
In the male sample, selected players were significantly taller ($p<.01$; $d=0.65$), heavier ($p<.05$; $d=0.44$), and showed significantly higher MO ($p<.05$; $d=0.44$) when compared to their non-selected counterparts. Regarding PAH, selected male players were predicted to get significantly taller than non-selected counterparts ($p<.01$; $d=0.70$). Regarding anthropometric characteristics in the female sample, selected players were taller ($p<.01$; $d=0.70$) while no differences in body weight were present ($p=.08$). Also, significantly higher MO ($p<.01$, $d=0.78$) and PAH ($p< .001$; $d=1.02$) could be observed in selected females.
DISCUSSION
Generally, evident advantages regarding maturity-related parameters in selected male and female players highlight the necessity for their consideration within talent identification procedures. However, future studies are required to allow for more differentiated analyses of the influence of biological maturity on talent selection within elite youth basketball. Among others, the evaluation of benefits of using bio-banded teams within selection tournaments may display a promising approach.

### THE IMPACT OF BIOLOGICAL MATURITY, BODY SIZE, AND BODY COMPOSITION IN RELATION TO RELATIVE AGE IN TALENT SELECTION AMONG FEMALE HANDBALL PLAYERS

TRÓZNAI, ZS., UTCZÁS, K., PÁLINKÁS, G., JUHÁSZ, I., SZABÓ, T., PETRIDIS, L.

*HUNGARIAN UNIVERSITY OF PHYSICAL EDUCATION AND SPORT SCIENCE*

INTRODUCTION: Our previous studies have shown that talent selection based on sport-specific tasks is affected by the relative age effects among adolescent handball players. Relatively older players are more likely to be selected than relatively younger ones, which is typically attributed to differences in maturity and body size. In this study we examined the differences in body dimensions, body composition, and biological maturation of selected and not-selected players during a talent selection process in relation to their relative age.
METHODS: Talent selection included N = 264 adolescent female handball athletes who were born in 2008-2009. 106 players were selected for the next stage and 158 were excluded. The selection was based only on sport-specific tasks. The players underwent anthropometric, body composition, and bone age measurements on the day of the selection. Body height was measured with an anthropometer (DKSH Switzerland Ltd, Zürich, Switzerland) to the nearest 0.1 centimetre. Biological age was estimated from bone age with an ultrasound-based device (Sunlight Medical Ltd, Tel Aviv, Israel). Body weight and body composition was determined with an Inbody 720 bioimpedance instrument. We examined relative age effects based on the month of birth in quarter-year intervals (from Q1 to Q8). Differences in maturity, body size and body composition between Q1 to Q8 groups were examined by one-way analysis of variance (with a Scheffe post hoc test), Cohen d was used to compare selected and not-selected groups. We used SPSS 25.0 (IBM) for the statistical analysis.
RESULTS: Selected players were taller than not-selected players (164.7±6.6 vs 161.5±5.5 cm; d=0.54), biologically more developed (13.7±1.1 vs. 13.1±1.0 years; d=0.58) and had larger muscle mass (25.2±3.2 vs 23.5±3.2 kg; d=0.50). When analyzing the results in relation to the relative age groups separately for the selected and not-selected players significant differences between quartiles were evident only for maturity, with older players being more developed than their younger counterparts. There were no differences for body size or body composition.
CONCLUSION: Relative age effects affect selection chances in youth sport. Based on the existing literature, we assumed that the advantage of relative older in talent selection is attributed to differences in maturity, body size, and physical capabilities. Talent selection here was based only on sport-specific tasks and skills. Although there were differences between selected and not-selected players in maturity and body dimensions, the results did not confirm the superior body size and body composition for the relative older players. As expected, relative age groups differed only in maturity, but not in any other measure, suggesting that the advantage of the relative older, and thus more mature, players is not connected to their physical attributes. Rather it seems to affect performance in technical and tactical skills.

### THE IMPORTANCE OF SOCCER-SPECIFIC MOTOR COORDINATION IN ELITE SOCCER ACADEMY PLAYERS' AGILITY TESTING

ZINNO, R., DI PAOLO, S., GAVIOLI, S., LUCA MILANDRI, L., BARONE, G., PINELLI, E., BRAGONZONI, L.

*UNIVERSITY OF BOLOGNA*

INTRODUCTION: The assessment of agility performance is a priority for soccer academy coaches since it fosters training optimization and talent identification. The majority of agility tests used in soccer players evaluation accounts for the physical aspect of agility only. Despite their wide use, these tests do not assess soccer-specific performances. Recently, the introduction of soccer-specific motor coordinative (SSMC) elements e.g., the capacity to manage a ball while sprinting, has been claimed to improve tests sensitivity for performance and maturation. The aim of the present study was to compare the outcomes of a generic agility test with a modified version including soccer-specific skills in a cohort of young elite soccer players.
METHODS: One-hundred forty elite male academy soccer players (U6, n=12; U8, n=28; U10, n=25; U12, n=24; U14, n=24; U16, n=27) participated in the study. Each player performed two tests: standard Illinois Agility Test (IAT) and Modified Illinois Agility test with ball (IATm). All tests were performed after pre-season training, during one regular training session for each category. The execution time for each test was recorded by a single operator through a handled digital stopwatch to the nearest 0.01s. The execution time for each player in each test was averaged among the three trials. The "SSMC gap" was defined as the difference between IATm and IAT execution time. IAT and IATm times were compared through the Repeated Measures ANOVA.
RESULTS: The execution time of IAT and IATm decreased with players' category ($F(5,134)=113.4$, $\eta^2p=0.81$, $p<0.001$), showing performance improvement. A substantial time decrease was noted up to 10 years old, while a lower decrease was found from U10 category on. The SSMC gap also decreased from 25.0 ± 4.9s (U6) to 4.6 ± 1.2s (U16). The SSMC gap for U6 and U8 was significantly higher than the other categories ($p<0.001$, large effect). From U10 category on, no differences in SSMC gap were found (post-hoc p-value $p<0.05$, Cohen's $d<1.94$).
CONCLUSION: The difference between IAT and IATm outcomes (SSMC gap) effectively tracked players' maturation and agility performance. The SSMC gap and SSMCI could provide valuable insights regarding players' skills. Soccer academy coaches should consider the combined use of generic and soccer-specific tests to optimize agility performance assessment at an early age.

### PHYSICAL PERFORMANCE DIFFERENCES IN FEMALE AND MALE GERMAN ELITE YOUTH BASKETBALL PLAYERS ACCORDING TO SELECTION STATUS

ROESCH, D.1, HÖNER, O.1, HUTH, M.2,3, LEYHR, D.1

*1 UNIVERSITY OF TUEBINGEN, GERMANY; 2 GERMAN BASKETBALL FEDERATION , GERMANY; 3 ALBA BERLIN BASKETBALLTEAM, GERMANY*

INTRODUCTION
Within talent identification in sports, test batteries assessing physical abilities and skills are commonly used to assist coaches in their efforts to identify promising young players (Johnston & Baker, 2020). For basketball particularly though, there is only limited evidence for the relevance of physical parameters in predicting future performance, especially as it pertains female youth players (Johnston et al., 2018; Mancha-Triguero et al., 2019). Therefore, the aim of the present study was to compare physical performance indicators of selected and non-selected female and male elite youth players competing at the national selection tournament of the German Basketball Federation.
METHODS
The study samples consisted of N = 46 female U16 and N = 68 male U15 elite youth players who were invited to participate in the initial selection tournament for the German youth national basketball teams. In advance of the tournament, players passed a standardized physical performance test battery (10m-sprint, counter movement jump, standing long jump, modified agility T-test). After the tournament, n = 13 female and n = 27 male players were selected for the extended roster of the respective youth national teams. Independent samples t-

tests and associated Cohen's d were calculated for each gender separately to compare the test results between selected and non-selected players.
RESULTS
Considering descriptive statistics, selected players outperformed their non-selected counterparts in all investigated tests (except for male players in the 10m-sprint). Within the female sample, selected players outperformed non-selected players in the 10m-sprint ($p < .05$, $d = 0.68$) and the modified agility T-test ($p < .05$, $d = 0.67$). However, comparisons just failed to reach significance with respect to counter movement jump ($p = .08$) and the standing long jump ($p = .07$). For males, t-tests confirmed significant advantages for selected players in counter movement jump ($p < .05$; $d = 0.49$), while no statistically meaningful advantages were found regarding 10-m sprint ($p = .29$), standing long jump ($p = .15$), and the modified agility T-test ($p = .42$).
DISCUSSION
The present findings show that some of the conducted tests may assist coaches in identifying promising youth basketball players. However, there seem to be gender differences with regards to the abilities that differentiate selected from non-selected players. Thus, while speed abilities seem to be more relevant for identifying talented female basketball players, vertical jumping abilities may be a focus in male players. Future research is needed to examine such gender differences more closely.

**YOUTH INTERNATIONAL EXPERIENCE IS A LIMITED PREDICTOR OF SENIOR SUCCESS IN FOOTBALL: THE RELATIONSHIP BETWEEN U17, U19, AND U21 EXPERIENCE AND SENIOR ELITE PARTICIPATION**

HERREBRØDEN, H., BJØRNDAL, C.T.
*UNIVERSITY OF OSLO / NORWEGIAN SCHOOL OF SPORT SCIENCES*

Introduction
Athlete participation in youth international competitions is often regarded as crucial to the attainment of future success. However, the link between participation and performance in sports at youth levels and senior levels is unclear at best. To understand this relationship better we conducted two studies of male football players.
Methods
A total of 1,482 players who had national football team experience at either the U17, U19, U21, or senior levels were included in our studies. These were players from six different nations, distributed across the various playing positions. In Study 1, we examined adult performance at the upper levels of football using a factor analysis and identified the characteristics that define what we termed a 'Super Elite' level, which is the highest level of participation. This outcome measure was used in Study 2 to explore further the link between youth international experience and Super Elite experience via regression models.
Results
In Study 1, the factor analysis suggested that participation in a senior national team, the Champions League, and the Europa League was highly related and could be grouped together as a Super Elite level. In Study 2, our results indicated that youth international experience is a limited predictor of participation at the Super Elite level of football. Participation at the U21 level was the strongest, most consistent predictor of Super Elite level participation. U17 participation was found to be either an insignificant or a negative predictor of subsequent participation in international football. The effect of U19 participation on later participation was partly significant, but weaker than the effect of U21 participation, and depended on national context and playing position.
Discussion
Investments in association-based youth talent identification and selection systems in football may not be useful because such participation does not appear to be a strong predictor of later international elite football participation. Our findings indicate that sport governing bodies need to re-consider their strategies for talent identification and development: before players reach adulthood, fewer resources could be spent on helping a limited number of selected players gain competitive international team experience. This may mean, instead, that the limited economic and human resources that are available should be re-allocated to more local activities that promote recruitment, participation, and development at the grassroots level. Doing so could achieve broader benefits without compromising the development of elite sport.

### OP-SH16 Psychology: Motivation

**PRIOR SELF-CONTROL EXERTION AND REPEATED CYCLING SPRINT PERFORMANCE**

BOAT, R., HUNTE, R., SUNDERLAND, C., COOPER, S.B.
*NOTTINGHAM TENT UNIVERSITY*

INTRODUCTION: The exertion of self-control has been associated with impaired performance on a number of subsequent physical tasks also requiring self-control, including endurance performance, skill-based tasks, and isometric tasks (Hunte et al., 2021). However, it remains unknown whether repeated sprint exercise performance is negatively affected by the prior exertion of self-control. Therefore, this study explored whether prior self-control exertion reduces subsequent performance on a repeated sprint cycling task and potential mechanisms for these effects.
METHODS: Nineteen physically active males (21.2±2.2 y) completed a repeated sprint cycling task (Wattbike) on two occasions. The repeated sprint exercise task involved 5 x 6 s sprints, with a 24 s passive recovery between each sprint. Prior to the repeated sprint cycling task, participants completed a congruent Stroop task (non-self-control exertion) or an incongruent Stroop task (self-control exertion) for 4 min. Participants RPE and motivation (measured via a Visual Analog Scale) were recorded following each sprint.

RESULTS: Repeated measures ANOVAs (self-control * time) revealed that there was no significant interaction effect for peak power (p = .625), average power (p = .862), distance covered (p = .441), and cadence (p = .984) during the repeated sprint cycling task. Furthermore, there was no significant interaction effect for motivation (p = .960). However, there was a significant main effect of self-control for RPE (p = .030), whereby RPE was higher in the self-control exertion trial (M = 11.32, 95% CI = 10.08, 12.57) compared to the non-self-control exertion trial (M = 10.57, 95% CI = 9.53, 11.60).
DISCUSSION:
The findings suggest that the prior exertion of self-control leads to higher RPE during a repeated sprint cycling task. However, despite the higher perceptions of exertion, there was no difference in performance on the repeated sprint cycling task between the self-control and non-self-control exertion trials.

### ASSOCIATIONS BETWEEN SELF-REGULATION AND THE ADOPTION OF RECOVERY STRATEGIES IN SWIMMERS

POIGNARD, M.1, BOSQUET, L.2, PLA, R.3, RUFFAULT, A.1,4

*1 LABORATORY « SPORT, EXPERTISE, AND PERFORMANCE » , FRENCH INSTITUTE OF SPORT , PARIS, FRANCE ; 2 LABORATOIRE MOVE , FACULTY OF SPORT SCIENCES, UNIVERSITY OF POITIERS, POITIER*

Introduction
Recovery is an important factor that allows swimmers to limit the training-induced fatigue and achieve continuous performance. Nutrition intake, hydration and sleep constitute primordial elements of the recovery process, as well as cooling strategies (e.g., cold-water immersion [CWI], contrast water therapy [CWT] and whole-body cryotherapy [WBC]), which have positive effects to reduce muscle soreness, improve the quality and quantity of sleep, and enhance performance. The benefits of these recovery strategies are now widely promoted. However, recent studies reported that swimmers' recovery behaviours differ from the actual recommendations. Exploring the specific determinants of self-regulation (i.e., self-control, motivation, self-efficacy) could allow to better understand the adoption of recovery strategies. Hence, we aimed to explore the associations between self-regulation and the adoption of the swimmer's recovery strategies.
Methods
A total of 780 competitive swimmers (41.5% female; age: 33 ± 15 years old) participated in a cross-sectional study. After providing information regarding their expertise and training status, participants were invited to fill in the sport motivation scale (SMS-II) assessing six motivational regulations from the Self-Determination Theory (intrinsic motivation, integrated, identified, introjected, and external regulation of extrinsic motivation, and amotivation). Self-efficacy and self-control were then respectively assessed with the Generalized Self-Efficacy Scale (GSES) and the Self-control scale (SCS). Additionally, participants stated whether they adopt the "recovery foundations" (nutrition, hydration, sleep hygiene) and/or "cooling strategies" (CWI, CWT, WBC). Due to non-normal distributions in the SMS-II, GSES, and SCS scores, non-parametric analyses were performed to compare participants who adopted or did not adopt recovery strategies.
Results
Statistical analyses were performed on 212 participants, excluding those with missing data. Group comparisons showed a higher score of amotivation (p=0.01) for swimmers who did not adopt recovery foundations, while swimmers who adopted recovery foundations had a higher score of intrinsic motivation (p=0.05). We observed tendencies of a higher score of integrated regulation (p=0.06) for swimmers who adopted cooling strategies, and of a higher score of introjected regulation (p=0.06) among swimmers who did not adopt cooling strategies.
Discussion
The results of this study suggest that swimmers who adopt recovery strategies are more intrinsically motivated to swim than those who do not; and that swimmers who do not adopt recovery strategies are more extrinsically motivated to swim. One limitation could be the "trait" measures of self-control and self-efficacy. Future studies could focus on motivation to swim and the formation of beliefs that underpin swimmer's recovery behaviours.

### HEART RATE VARIABILITY AND PRE-EJECTION PERIOD AS PHYSIOLOGICAL MEASURES OF EFFORT ENGAGEMENT DURING THE DEPLETING TASK IN A SEQUENTIAL TASK PROTOCOL

LORCERY, A., AUDIFFREN, M., BENRAÏSS, A., PINGAULT, M., MIRABELLI, F., ANDRÉ, N.

*UNIVERSITY OF POITIERS*

INTRODUCTION: The strength model of self-control (Baumeister et al., 1998) suggests that the deployment of effort in a first effortful task results in the impairment of performance in a subsequent effortful task. This phenomenon is known as ego-depletion effect. In the past few years, this phenomenon has been criticized due to replication failures or theoretical underpinnings. The aim of the present study was to replicate the ego depletion effect using an adequate sequential task protocol. Since the Model of Neurovisceral Integration, Thayer and Lane (2000) proposed a heart-brain connection; i.e., a direct link between mental effort and the autonomous regulations over the heart. Heart rate variability and pre-ejection period, two measures of the autonomous regulation of the heart can be viewed as biological markers of cognitive resource mobilization. Measuring this resource mobilization could help us to study the link between effort engagement in the depleting task and the size of the ego depletion effect.
METHODS: We used a counterbalanced within-subjects design. Participants completed two experimental conditions (control vs. depleting). We used a modified 30-min Stroop task involving two executive functions (inhibitory control and cognitive flexibility) as the depleting task, a sub-maximal time-to-exhaustion handgrip task as dependent task, and watching a documentary as control task. On session 1, participants (N = 43) familiarized with the depleting task and the dependent task. At sessions 2 and 3, participants performed the control or the depleting task and then the endurance handgrip task. To measure the ego depletion effect, we compared the performance in the endurance handgrip task after the depleting or control task. The evolution of effort engagement during the control and depleting tasks was indexed by the activity of the sympathetic nervous system obtained by heart rate variability and pre-ejection reactivity. Participants perception of pain and effort was recorded every 30 sec during the endurance handgrip task.

Results: We replicated the ego depletion effect. Participants performed worse in the endurance handgrip task after the Stroop task compared to the video task ($p < 0.05$). Participants demonstrated a higher sympathetic activity during the Stroop task than during the video task ($p < 0.001$). Moreover, the sympathetic activity decreased from the beginning to the end of the Stroop task compared to the video task ($p < 0.001$). These results suggest a higher effort mobilization and a decrease over time during the Stroop task.
Discussion: These results confirm that a difficult effortful task is detrimental to a subsequent endurance performance. This study also highlights that the ego depletion effect is accompanied by an effort disengagement over time during the depleting task. Taken together these results show the pertinence of using physiological measures to control effort engagement in sequential task protocols.

## AUTONOMOUS MOTIVATION INFLUENCES ENDURANCE PERFORMANCE VIA EMOTIONAL RESPONSES TO DISRUPTIONS IN GOAL PURSUIT

TAYLOR, I.M., HUNTE, R.

*LOUGHBOROUGH UNIVERSITY*

Introduction
The degree to which endurance activity is congruent with one's sense of self (i.e., autonomous) is positively associated with endurance performance. This effect has been explained by hedonic and reflective motivational disturbances during the endurance activity. However, it has also been theorized that autonomous motivation leads to more effective emotional regulation, especially when endurance goal pursuit is disrupted, which subsequently leads to superior performance. Two studies examined this hypothesis by focusing on participants' degree of frustration when endurance activities became unexpectedly more difficult.
Method
Study 1 involved 40 participants (45% female, Mean age = 22.65, SD = 2.61) completing a ten-minute cycling task and Study 2 involved 30 participants (40% female, Mean age = 21.63, SD = 1.94) completing an increasingly effortful cycling task until voluntary exhaustion. In both studies, autonomous motivation was measured prior to the task and the task was made unexpectedly more difficult during the trail. In study 1, feelings of frustration were measured at the end of the task and the performance outcome was distance covered. In Study 2, frustration was repeatedly measured throughout the task and the performance outcome was time until task cessation. Mediation analysis (Study 1 & 2) and multilevel modelling (Study 2) were employed to analyse the data.
Results
In study 1, a standardized indirect effect of autonomous motivation on performance via frustration was observed (B = 0.16, 95% CIs = .01 - .32). In study 2, autonomous motivation predicted slower increases in frustration over the course of the trial (B = -.01, p = 0.01). Slower increases of frustration were also characteristic of better performance (B = -.03, p = 0.01). Furthermore, a standardized indirect effect of autonomous motivation on performance via mean levels of frustration was observed (B = 0.24, 95% CIs = .04 - .46).
Discussion
Across two studies, consistent evidence demonstrated that autonomous motivation influences endurance performance via self-regulatory emotional responses to goal disruption. As such, this process should be considered alongside motivational dynamics that explain the performance benefits of autonomous motivation. It is likely that this process occurs because autonomously motivated individuals typically perceive goal disruptions as lower threats to self and adaptively respond to such disruptions.

## I WANT MY TO EXPERIENCE EMOTIONS THAT HELP ME PERFORM BETTER!!! AN INVESTIGATION RE-ANALYSISING OF BBC LAB UK DATA

LANE, A.M.

*UNIVERSITY OF WOLVERHAMPTON*

Emotions have a profound effect of thoughts and behaviour. Learning effective emotion regulation skills via use of psychological skills could have benefits for behaviour and health. Recent research has demonstrated that delivering psychological online improved performance and lead to adaptive emotional states among a large sample of over 44,000 participants (Lane, Totterdell et al., 2016). The present study uses the same database but focused on meta-beliefs that emotions helped performance, with the logic that interventions designed to regulate emotions should strengthen this relationship.
The online study was developed in conjunction with the BBC Lab UK and fronted by former Olympian Michael Johnson. Using data from 72,204 participants we tested 13 interventions comprising 3 different techniques (imagery, if-then planning, self-talk) that were targeted towards 4 different foci (outcome, task, process, arousal control), with a 13th group who were an active control group (N = 4383), who received instructions from Michael Johnson to play again. A 14th group of participants who voluntarily skipped the intervention video (N = 13265).
Repeated measures ANOVA was used to analyse changes in the intensity of beliefs that emotions helped performance over 4 rounds of competition. The performance measure was an online concentration grid where the goal was to complete as fast as possible, and beat an opponent matched against their time in the practice round. Baseline data was gathered in Round 1 and after which participants were grouped and then followed one of 12 interventions or a control. A 14th group comprised participants who skipped the instructional video. Participants then completed Round 2, with the same intervention followed again and then completed Round 3. ANOVA results indicated that participants who skipped the intervention reported lower meta-beliefs that emotions helped performance from the outset. Of the interventions, interventions that focused on improving skill, that is giving instructional information, had the weakest effect and were similar effect to skipping the interventions. In contrast, interventions that focused on managing emotional arousal, focusing on process goals and achieving an outcome goal had the strongest positive effects. In addition to Lane, Totterdell et al. (2016), findings from the present study emphasise the utility of focusing interventions on emotional arousal. Findings from the present study are showing that are useful in developing meta-emotional beliefs that emotions help performance. Further, the present study shows insight into developing a scalable method teaching and assessing the effects of brief video delivered interventions.

### UCLMUÉVETE PROJECT: USE OF GAMIFICATION AND DIGITAL APPLICATIONS TO PROMOTE ACTIVE BREAKS ON UNIVERSITY WORKERS

MARIN FARRONA, M.

*UNIVERSITY OF CASTILLA-LA MANCHA*

INTRODUCTION: Occupational risk prevention programs targeting unhealthy habits are increasing in interest because they do not only improve workers health but also reduce absenteeism and increase productivity (Fazen et al., 2020). To do so, these programs usually target physical inactivity (PIA), sedentary lifestyles, social isolation, or stress. However, cost-effectiveness of these programs at are still unclear. Programs based on active breaks within the occupational time are promising approach because they increase physical activity (PA) levels of workers and break long-time sitting behaviour. On the other hand, digital applications and gamification seem to increase adherence to newer behaviours by providing social support, group cohesion and commitment (Haque et al., 2020; Mamede et al., 2021. Thus, combining these three elements in a healthy occupational program (#UCLMuévete) might result in a high cost-effectiveness that increase productivity and reduce absenteeism of internal clients (Grimani et al., 2019). Aims: This work aimed to 1) pilot-test the effectiveness of the #UCLMuévete program on university workers health, productivity and work relationships; 2) to analyse the practice adherence to this program.
METHODS: #UCLMuévete is a mixed quasi-experimental project that includes a 2-months pilot intervention. This project has been developed according to the TIDieR guideline and reporting checklist. The pilot intervention was applied at the University of Castilla-La Mancha by the time this abstract was submitted to the ECSS 2022. A total of 71 university workers voluntarily participated in this project. Participants were gathered into teams and received the indications of perform one active break every working day. Three types of active breaks were delivered to the participants under the gamification methodology using a app. So, anytime a participate completed the active break its team got a point. The team with the highest score at the end of the challenge won different rewards. The data collection was conducted before and after the 2-months intervention. The variables measured were (1) health parameters: cardiorespiratory fitness level, lower body strength, body composition; (2) productivity parameters measured through Heart Rate Variability, a variable that provides information of stress; (3) parameters related to work relationship; and (4) practice adherence.
Expected results: Significant improvements are expected to be observed in (1) cardiorespiratory parameters, lower body strength levels, and body fat; (2) productivity; (3) work relationship; and (4) practice adherence. In addition, a positive association between productivity and worker health is expected.
Conclusion: #UCLMúevete might increase university workers productivity by increasing their health through an innovative program that includes a gamification methodology and active breaks. TIDieR guidelines facilitate this project can be expanded to other sports organizations

### OP-MH21 Health and adolescents

### THE EFFECTS OF DIFFERENT CORE STABILITY TRAINING ON TRUNK STABILITY AND ATHLETIC PERFORMANCE IN ADOLESCENT FEMALE BASKETBALL PLAYERS

LIANG, I.J., LIN, L.L.

*INSTITUTE OF PHYSICAL EDUCATION, HEALTH &LEISURE STUDIES, NATIONAL CHENG KUNG UNIVERSITY, TAINAN, TAIWAN*

INTRODUCTION: Trunk position is not only related to the performance of the physical fitness but important for the balance, stability and helping to progressively build fitness levels and improve athletic performance. This study aimed to investigate the effects of trunk stability and athletic performance after 2 types of core muscle training in adolescent female basketball players.
METHODS: Fifty-one of the top four elite female basketball players (age: 14.76± 1.84yrs, BMI: 21.41± 1.96 kg/m2) in the high school basketball league in Taiwan, were randomly assigned to control, TRX and Swiss ball groups using the total ranking of the pre-test scores. All were free from musculoskeletal injuries, vestibular dysfunction, and concussion within three months before the experiment and during data collection. All participants performed a progressive program consisting of 3*8 sessions twice-a-week unstable core muscle training for 8 weeks during the pre-season. Participants engaged in a total workout of 60 minutes with 10 minutes warm-up, 40 minutes main exercises (3*8 sessions: 40-second workout with 20-second rest between each exercise), and 10 minutes cool-down. The plank test for core muscle ability, jumping, speed, agility, and the ankle proprioception test were evaluated in one week before and after the training.
RESULTS: The score of the plank test increased in both TRX and Swiss ball groups, yet no significant difference was observed between the two groups. In terms of athletic performance, no significant change among the three groups after decreasing training volume converts into core muscle training.
CONCLUSION: Both TRX and Swiss ball training can increase core muscle ability without regressing athletic performance. Moreover, core muscle training could help players gain improved power transmission ability and also prevent injury. Thus, we suggested that adding core muscle training, instead of doing original/traditional training, would be an effective strategy for injury prevention.

### RELATIONSHIPS BETWEEN LOAD, WELLNESS AND INJURY IN ELITE JUNIOR AUSTRALIAN FOOTBALL: IT MAY NOT BE THE LOAD BUT HOW WELL YOU COPE THAT MATTERS.

GASTIN, P.

*LA TROBE UNIVERSITY*

INTRODUCTION: Elite junior Australian football players experience high loads across levels of competition and training [1]. High loads have been linked to the risk of injury, either in a linear or curvilinear (U-or J-curve) fashion [2]. Few studies have adjusted for variables that may influence the load-injury relationship such as how well players respond or cope with the physical and mental stresses of their sport [3]. The purpose of this study was to investigate the relationships between player load, wellness and injury. We hypothesised that player wellness would mediate and/or moderate the load-injury relationship.
METHODS: Data were collected and analysed from 280 Australian football players from nine under-18 state league clubs across one season. Internal load was measured via session rating of perceived exertion (sRPE) for training and competition. Week and month-based

absolute and relative load measures were then calculated. Player wellness was reported three times per week for sleep duration and ratings (1-5) of sleep quality, fatigue, soreness, stress and mood. Principal Component Analysis factor loadings were used to identify distinct covariates (6 components, 17 load and wellness variables). Injury was defined as 'any injury leading to a missed training session or competitive match', with only new injuries included in the analysis. Associations between covariates and injury risk (yes/no) were determined via logistic Generalised Estimating Equations.
RESULTS: Univariate analysis indicated that load was associated with injury in the form of a non-linear relationship. Further, wellness as a composite measure, as well as individual factors of stress, soreness and fatigue demonstrated direct relationships with injury. Modelling indicated evidence of mediation where increased soreness amplified the relationship between stress and injury, while increased sleep duration reduced the relationship. A significant interaction term between load and wellness on injury was found (OR= 0.76 95% CI 0.62 to 0.92, P<0.01), indicating the regression weight of load on injury varied as a function of wellness (i.e., wellness acting as a moderator, with poor wellness at high loads further increasing the risk of injury). Including wellness as a mediator or moderator in the analysis suggests that injury risk increases substantially at a 1-week load of 3750 au and beyond.
CONCLUSION: Internal measures of training and competition load are associated with injury risk. This relationship is further influenced by player subjective wellness and sleep, which when poor can amplify the risk of injury at high loads. There is also evidence that higher stress is linked with injury and that soreness and sleep can mediate this relationship. Efforts to monitor and manage load and to support positive adaptive responses may reduce the risk of injury, with perceptions of stress, soreness and sleep relevant in this cohort.

**ASSOCIATION BETWEEN WORKING MEMORY PERFORMANCE AND CARDIOVASCULAR FITNESS IN YOUNG HEALTHY ADULTS**

LOOSER, V., LUDYGA, S., PÜHSE, U., GERBER, M.

*UNIVERSITY OF BASEL*

INTRODUCTION: Aerobic exercise and cardiovascular fitness have been shown to be beneficial to working memory. Empirical data mainly covers developmental changes in children and older adults leaving a research gap on the association in young adulthood. As memory performance reaches its peak in young adulthood, the lack of evidence in this age group may be attributed to the expectation of ceiling effects.
METHODS: The present study addresses this research gap by assessing the association between working memory performance at increasing difficulty and cardiovascular fitness and in young adults. The presented cross-sectional study examined the association between visual working memory performance and cardiovascular fitness and in N = 98 (57% female) healthy adults aged 18 to 35 years (M = 23.8, SD = 3.6). Cardiovascular fitness was assessed by estimation of maximal oxygen consumption (VO2max) from the Åstrand submaximal bicycle ergometer test (Nordgren et al., 2014). Working memory performance was assessed using the modified Sternberg task with increasing difficulty, using set-sizes 3 and 6 (Ludyga et al., 2018).
RESULTS: Estimated relative CRF (VO2max) was put into relation with accuracy and mean reaction time and the inverse efficiency score (RT/ACC) at low and high memory load using linear regression. The results showed no significant association between relative VO2max and working memory performance in young adults.
CONCLUSION: In conclusion, young adulthood may be a period, during which working memory performance may not be benefited by increased cardiovascular fitness.

**THE POTENTIAL IMPACT OF EXERCISE UPON SYMPTOM BURDEN IN ADOLESCENTS AND YOUNG ADULTS UNDERGOING CANCER TREATMENT.**

MUNSIE, C.

*UNIVERSITY OF WESTERN AUSTRALIA*

INTRODUCTION: Adolescents and young adults (AYAs), in comparison to younger and older cohorts, are reported to experience the greatest symptom burden resulting from cancer treatment-related toxicities (TRTs). Growing evidence supports integrated exercise to mitigate several TRTs in other cohorts, however in AYAs specifically this is yet to be explored. This study sought to evaluate the impact of an exercise intervention on TRTs in AYAs undergoing cancer treatment.
METHODS: A prospective, randomised controlled trial allocated participants to a 10-week exercise intervention (EG) or control group (CG) undergoing usual care within an outpatient hospital setting. Participants undertook weekly blood tests and telephone interviewing to capture haematological and patient-reported TRTs throughout the intervention. All TRTs were graded per the Common Terminology Criteria for Adverse Events (CTCAE V5.0). Toxicities were then categorised for analysis into the maximal worst grade experienced as per standard clinical trial toxicities reporting. Further, novel exploratory longitudinal analysis was conducted to capture the trajectory of toxicities experienced over time between groups.
RESULTS: Forty-three (43) participants (63% male, mean age 21.1 years) were enrolled. The maximal worst grade toxicity experienced for haematological and patient-report TRTs (Grade 0, Grade 1-2 and ≥Grade 3) demonstrated no significant differences between groups ($p>0.05$). However, exploratory longitudinal analysis of the four most common toxicities (fatigue, pain, nausea and mood disturbances) revealed a decrease in the frequency of severe fatigue, nausea and mood in the EG, compared with the CG. Additionally, there was an increased incidence of severe pain toxicity in the EG compared with the CG. All exploratory analyses were not statistically significant ($p>0.05$).
CONCLUSION: While no group differences were apparent when utilising standard toxicity reporting, it appears that the longitudinal analysis of toxicities provided the greatest insight into the toxicity profile of AYAs undergoing cancer treatment. This novel approach revealed potentially clinically relevant differences between the two groups over time which would have been otherwise been missed using traditional analysis methods. As such, the exercise intervention appeared to provide benefit in terms of reducing the severity of fatigue, nausea

and mood disturbances in this cohort. While these trends must be interpreted with caution due to their lack of statistical significance, they provide insight into the possible reduction of symptom burden and should be investigated in a larger homogenous sample.

### EFFECTS OF ISOMETRIC RESISTANCE TRAINING AND SUBSEQUENT MAINTENANCE DOSE ON AMBULATORY BLOOD PRESSURE AND MORNING BLOOD PRESSURE SURGE IN YOUNG NORMOTENSIVES

BAROSS, A.W., JAY, G., STOODLEY, L.

*UNIVERSITY OF NORTHAMPTON*

INTRODUCTION: Hypertension, a modifiable risk factor for cardiovascular disease (CVD) is associated with approximately one third of deaths globally each year. Diurnal blood pressure (BP) variability and more specifically morning blood pressure surge (MBPS) are associated with increased risk of stroke, end-organ damage and are considered to be destabilising factors for atherosclerotic plaques. Isometric resistance training (IRT) has been shown to reduce ambulatory BP and MBPS following 8-10 weeks of training. However, there is no data at present which has established the dose of training needed to maintain these reported reductions following the initial IRT period. Therefore, the purpose of this study was to determine the effects of IRT on ambulatory BP and the MBPS in young normotensives following (i) 8 weeks of IRT and (ii) 8 weeks of a once a week maintenance dose.
METHODS: Twenty-five normotensive individuals (15 men, age=21±4 years; 10 women, age=22±3 years) were randomly assigned to a training-maintenance (TRA-MT, n=13) or control (CON, n=12) group. Ambulatory BP and MBPS were measured prior to, after an 8-week (3 days/week) training period and following an 8-week maintenance period (1 day/week) of bilateral leg IRT using an isokinetic dynamometer (4 x 2-minute contractions at 20% MVC with 2-minute rest periods). A two-way repeated measures MANOVA was used to assess the within and between groups changes in ambulatory BP and MBPS. MBPS was calculated as: mean systolic BP 2 hours after waking, minus the lowest sleeping 1-hour mean systolic BP.
RESULTS: There were significant reductions in 24-h ambulatory systolic BP following IRT (pre-to-post training, -7±5 mmHg, p=0.001) and these reductions remained after the maintenance period (pre-to-post maintenance, -6±4 mmHg, p=0.000). There were significant reductions in daytime BP (pre-to-post training, -5±5 mmHg, p=0.034) which remained following maintenance (pre-to-post maintenance, -5±5 mmHg, p=0.02), but there was no change in night-time systolic BP (pre-to-post training, -2±5 mmHg, p=0.685) or post maintenance period (pre-to-post maintenance, 1±6 mmHg, p=0.94). Additionally, there were significant reductions in the MBPS (pre-to-post training, -9±10 mmHg, p=0.005) which were maintained post maintenance period (pre-to-post maintenance, -8±11 mmHg, p=0.014). Additionally, significant correlation was identified between the magnitude of the change in MBPS and the magnitude of changes in mean SBP 2-h after waking (r = 0.78, P=0.002).
CONCLUSION: These results provide further evidence that IRT causes significant reductions in MBPS in addition to the previously reported reductions in ambulatory BP. Additionally, these reductions seem to be maintained with a reduced exercise dose. These findings may also have important clinical implications, the significant reductions in the MBPS offer the potential for meaningful CVD and stroke risk reduction, provided these effects can be demonstrated in those who are at risk.

### IS-PN10 The microbiome-diet-host interactions: Implications for health and exercise performance

### THE INFLUENCE OF DIET AND ORAL MICROBIOME ON NITRIC OXIDE HOMEOSTASIS AND CARDIOVASCULAR HEALTH

VANHATALO, A.

*UNIVERSITY OF EXETER*

Imbalances in the oral microbial community, and poor dental health, have been associated with impaired cardiovascular health and the role of the oral microbiota as a potential modulator of human health is a growing area of multidisciplinary research. One mechanism that may link the oral microbiota to good health is the nitrate-nitrite-nitric oxide (NO) reduction pathway. This, for its first step, crucially relies on the reduction of nitrate, which is ingested through diet, to bioactive nitrite by anaerobic bacteria residing in the mouth. Among many other physiological roles, NO regulates vascular endothelial function, and therefore blood pressure. Epidemiological studies show that a high dietary nitrate intake (such as in the vegetable-rich 'Mediterranean' or '≥5 a day' diets) may reduce the risk for adverse cardiovascular events, and several studies have shown that dietary nitrate supplementation significantly reduces blood pressure in both young and older adults. Differences between individuals in the ability to reduce nitrate to nitrite and in the effects on blood pressure indicate that the benefits derived from a high nitrate diet may be contingent on individuals having the right oral microbiota. The ability to produce NO in the body through the classical pathway involving nitric oxide synthase (NOS) enzymes is impaired in older age, leading to a gradual increase in blood pressure and associated comorbidities. The nitrate-nitrite-NO pathway has significant potential to compensate for dysfunctional NOS in older age and recent research has concentrated on how the symbiotic relationship between the human host and the oral microbiota might change with ageing and how the oral microbiota might be optimised to maintain cardiovascular health during ageing. This presentation will discuss recent advances in elucidating the role of the oral microbiome in the maintenance of NO homeostasis, and highlight the therapeutic potential of oral prebiotic and probiotic interventions for improving cardiovascular health in older age.

### FERMENTABLE DIETARY FIBRE AND ASSOCIATED EFFECTS ON THE GUT MICROBIOME, HEALTH, AND PERFORMANCE

TORQUATI, L.

*UNIVERSITY OF EXETER*

Specific types of dietary fibre escape digestion and reach the colon, where they are fermented by beneficial bacteria to produce short chain fatty acids. These organic acids have potent anti-inflammatory effects and maintain gut barrier integrity. In recent years SCFA have been identified as the mechanistic link between gut microbiome and its systemic effects on the nervous (gut-brain axis), cardiovascular, and

immune system. There is emerging data pointing at the association between gut microbiome and exercise, with potential effects on muscle metabolism and performance.
This presentation will focus on one of the most studied and characterised fermentable fibre (inulin) and discuss the effects of inulin supplementation in health and performance outcomes. It will provide practical implications and recommendations for conducting such studies in real-world settings, including methodological implications and controlling for confounders. Our target audience includes those interested in healthy aging, non-communicable diseases, and performance, including researchers and practitioners (sports nutritionists, exercise physiologists)
The first part will discuss the mechanistic link between gut microbiome and cardiovascular and immune functions. This will include the ability of inulin supplementation of increasing the abundance of specific beneficial bacteria and metabolites, and how these affect vascular and immune markers both in the general population and athletes. This part will also discuss novel studies that combine inulin and exercise interventions or exercise alone, and how these differ in terms of gut microbiome changes and clinical outcomes.
The second part will focus on performance outcomes, and how inulin supplementation might improve this from mice to human studies. This part will present up-to-date evidence on the mechanistic role of specific gut microbiome metabolites (acetate and butyrate) on muscle metabolism and endurance capacity.

**THE EFFECTS OF DIETARY PATTERNS ON ORAL AND GUT MICROBIOMES AND IMPLICATIONS FOR EXERCISE PERFORMANCE IN ELITE ENDURANCE ATHLETES**

BURKE, L.

*AUSTRALIAN CATHOLIC UNIVERSITY*

The macronutrient content of the diet has a major influence on the composition of the microbiome in the mouth and throughout the gastrointestinal tract. The impacts of dietary patterns on the oral and gut microbiomes have been recently investigated in cohorts of elite endurance athletes who follow extremely specialised diets such as high carbohydrate (CHO) or periodised high-CHO diet, and the ketogenic low-CHO high-fat (LCHF) diet. The macronutrient composition of the diet may influence host physiology via metabolic outputs of bacteria (e.g. production of short chain fatty acids) and via alterations to the quantity of bacteria or composition of the microbial community (e.g. changes in abundances of nitrate-reductase bacteria). In a series of studies we examined the diet-microbiota interactions potentially affecting the physiology and/or metabolism of healthy, highly trained human subjects. The first comprehensive investigation of the effects of high-CHO and LCHF diets on the gut microbiome of elite endurance athletes revealed that LCHF diet significantly increased the relative abundances of key bacterial taxa (Bacteroides and Dorea spp.) that correlated with impaired exercise economy and fat oxidation. We subsequently showed that three weeks of LCHF diet in elite race walkers resulted in alterations in abundances of oral bacterial taxa (Haemophilus, Prevotella and Neisseria) that considered to be key nitrate-reducers in the enterosalivary nitrate-nitrite-nitric oxide (NO) pathway within the oral cavity. This lecture will highlight the most recent research findings suggesting that dietary patterns appear to exert a significant impact on the gut and oral microbiotas of endurance athletes. It is important that commonly used dietary approaches that are applied to enhance athletic performance are carefully monitored and managed to ensure that the microbiota is appropriately nurtured to maximise the available benefits from nutrition.

## Invited symposia

### IS-EX02 ACSM-ECSS exchange: Blood glucose regulation during exercise

**THE EFFECT OF TRAINING ON INSULIN SECRETION**

DELA, F.

*UNIVERSITY OF COPENHAGEN*

Physical training improves insulin sensitivity in skeletal muscle. This effect is present regardless of the modality of training, being endurance exercise, strength training or high-intensity interval training. Likewise, the effect is present in healthy individuals, young as well as old, and it is present in patients with insulin resistance, e.g. obese patients and/or patients with type 2 diabetes.
However, glucose homeostasis is balanced by not only insulin action but also by insulin secretion from the pancreatic ß-cells. Perhaps as a consequence of the training-induced improvement in skeletal muscle insulin sensitivity, the □-cell secretory capacity diminishes. This has been described as the hyperbolic relationship between insulin secretion and sensitivity.
Diminished insulin response to a given stimulus (e.g. glucose, arginine) is prudent in a situation with enhanced increased insulin action. If the adaptive insulin response is not present, the risk of hypoglycemia increases.
The hyperbolic relationship between insulin secretion and sensitivity is important in healthy individuals, but it may not be advantageous in patients with type 2 diabetes. These patients suffer from a relative insulin deficiency, i.e. the insulin secretory capacity does not match the prevailing insulin sensitivity and hyperglycemia succeeds. In this situation, a decrease in insulin secretion, elicited by a training-induced increase in insulin sensitivity, will not be beneficial for glucose homeostasis.
Some studies indicate that patients with type 2 diabetes display an opposite β-cell response after aerobic physical training, i.e. the insulin secretory capacity increases in contrast to the decrease seen in healthy individuals. The enigma hidden here is the mechanism behind the opposite β-cell responses to the same stimuli.
β-cell secretory function is typically measured by a hyperglycemic clamp or an intravenous glucose tolerance test. This is done in the resting state with 1-2 days since the last training bout. Yet, the pancreatic □-cells are somehow able to sense the training status of the body and respond accordingly. Thus, a "memory" in the β-cells or elsewhere has been introduced by the exercise training. The nature of this "memory" is yet unresolved.
In the presentation, new data on β-cell adaptation to training in patients with type 2 diabetes will be presented. This will include responses to endurance training with and without simultaneous pharmacological antidiabetic treatment. Furthermore, an experimentally based hypothesis on the introduction of β-cell "memory" will be presented.

### THE PRECIOUS 5 GRAMS OF BLOOD GLUCOSE DURING EXERCISE: ROLES OF THE GLUCOSE SHUNT AND LACTATE SHUTTLE

BROOKS, G.

*UNIVERSITY OF CALIFORNIA*

Physical exercise typically demands major increases in energy demand, particularly is exercise intensity is high and prolonged. As exercise intensity exceeds 65% of maximal oxygen uptake carbohydrate energy sources predominate. However, relative to the meager 5 g (one teaspoon) of blood glucose (1 g L x 5 L blood  20 kcal), carbohydrate oxidation rates of 20 kcal/min can be sustained in a fit person for an hour, if not longer. And while glucose rate of appearance (i.e., production, Ra) from splanchnic sources in a post absorptive person can rise 2-3 fold over rest during exercise, working muscle and adipose tissue glucose use must be restricted otherwise hypoglycemia would result in less than a minute during hard exercise because blood glucose disposal rate (Rd) could easily exceed glucose production (Ra) from hepatic glycogenolysis and gluconeogenesis and rapidly. While during rest most body glycolysis is from blood glucose, during exercise, use is glucose as body CHO fuel is restricted, shunted to working muscles even as working muscle glucose uptake is limited. Hence, glycogen in working muscle becomes the major CHO energy source in working muscle. As well, glycogen in working muscle and other depots (non-contracting muscles and adipose) produces lactate, the major gluconeogenic precursor in liver and kidneys. As well, lactate releases from glycogen depots can directly fuel heart, working red muscle and brain. In this presentation the integration of physiological, neuroendocrine, circulatory and biochemical mechanisms necessary for euglycemia to be maintained during sustained hard exercise are discussed. Among these are the integrated regulation of insulin, the sympathetic nervous system, other glucoregulatory hormones and competitiveness among energy substrates.

## Oral presentations

### OP-PN12 Energy availability

### SEMI-PROFESSIONAL RUGBY UNION PLAYERS MAY BE AT RISK OF LOW-ENERGY AVAILABILITY

ROBERTS, C., BEAVEN, C., POSTHUMUS, L., GILL, N., SIMS, S.

*UNIVERSITY OF NORTHAMPTON*

INTRODUCTION: Rugby players should aim to consume enough food to meet energy, macronutrient and micronutrient requirements. Failure to do so can negatively impact performance, recovery, health, well-being, cognitive function and may increase injury risk. Provincial academy players in New Zealand typically present congested schedules; alongside developmental rugby athletes will train and play at the local club level and balance study and work commitments. As such, monitoring and management of dietary intake is crucial.
METHODS: Nine semi-professional developmental rugby union players (age = 20.6 ± 1.7 years; height = 186.3 ± 9.0cm; body mass = 102.4 ± 18.2kg; fat free mass = 82.9 ± 12.1kg) recorded dietary intake over a 4-week pre-season using the remote food photography method. Body composition was assessed via three-dimensional optical scanning.
RESULTS: A total of 76 days were sufficiently logged. A large variability in daily total nutrient intake was observed (Energy = 2550 ± 914 kcal, protein = 135 ± 50 grams, carbohydrate = 270 ± 122 grams, fat = 97 ± 42 grams). Energy intake relative to fat free mass (FFM) was 31 ± 11 kcal.kg FFM. Relative to total body mass, protein intake was 1.3 ± 0.4 grams and carbohydrate intake 2.6 ± 1.3 grams. Requirements for protein and carbohydrates were not met on 49.4 and 96.6% of eating occasions, respectively.
CONCLUSION: Energy intake relative to FFM did not meet the proposed threshold of 40kcal.kg FFM to ensure optimal energy availability for physiological functions in male athletes [1]; previous research has demonstrated that high-level rugby players may expend 61 kcal.kg FFM daily [2]. Failure to meet the optimal threshold may result in physiological and metabolic dysfunction [3], impairment to adaptive responses to exercise and performance [1,3], increased risk of injury or illness [1,3] and a failure to meet macronutrient and micronutrient requirements [3]. Indeed, relative protein intake was at the low end of recommendations for athletes, potentially compromising FFM during periods of energy deprivation, which may be further exacerbated by inadequate energy intake [1]. Similarly, carbohydrate intake did not meet best-practice sports nutrition recommendations for rugby players.
Developing rugby players should take care to consume a high-quality diet that meets energy and macronutrient requirements to tolerate the demanding nature of the sport, promote adaptation and optimal health and decrease injury risk.

### COMPARISON OF PHYSIOLOGICAL AND CLINICAL MARKERS FOR CHRONIC SPRINT-INTERVAL TRAINING EXERCISE PERFORMED EITHER IN THE FASTED OR FED STATES AMONG HEALTHY ADULTS

TAN, A.

*CHANGI GENERAL HOSPITAL*

INTRODUCTION: Sprint-interval training (SIT) and intermittent fasting are effective independent methods in achieving clinical health outcomes. However, the impact of both modalities when performed concurrently is unclear. The aim of this study was to compare the effects of 6 weeks of SIT performed in the fasted versus fed state on physiological and clinical health markers in healthy adults.
METHODS: Thirty recreationally-active participants were equally randomised into either the fasted (FAS; 4 males, 11 females) or the fed (FED; 6 males, 9 females) group. For all exercise sessions, FAS participants had to fast ≥10 h prior to exercising while FED participants had to consume food within 3 h to exercise. All participants underwent three sessions of SIT per week for 6 weeks. Each session consists of repeated bouts of 30-s Wingate Anaerobic cycle exercise (WAnT). Pre- and post-training peak oxygen uptake (VO2peak), isokinetic leg strength, insulin sensitivity, blood pressure and serum lipid levels were assessed.

RESULTS: There were no differences in baseline physiological and clinical measures between both groups (all $p > 0.05$). VO2peak improved by 6.0 ± 8.8% in the FAS group and 5.3 ± 10.6% in the FED group (both $p < 0.05$), however the difference in improvement between groups was not statistically significant ($p > 0.05$). A similar pattern of results was seen for knee flexion maximum voluntary contraction at 300◦/s. SIT training in either fasted or fed state had no impact on insulin sensitivity (both $p > 0.05$). There was significant reduction in diastolic blood pressure (8.2 ± 4.2%) and mean arterial pressure (7.0 ± 3.2%) in the FAS group (both $p < 0.05$) but not FED group (both $p > 0.05$).
CONCLUSION: A lack of significant change in the VO2peak gains between FAS and FED groups after six weeks of SIT could be due to mismatch in fuel source for SIT, whereby the body's preferred energy source during SIT type of exercise is creatine phosphate and anaerobic glycolysis of muscle glycogen, rather than FFA oxidation as seen in fasting. Improvement seen in knee flexion MVC at 300◦/s was likely secondary to neural adaptation to WAnT training. The two different mechanisms elicited by fasting (increased production of nitric oxide (NO) through reduced oxidative stress to endothelial cells and upregulation of pathways (e.g. tyrosine phosphorylation and AMPK/PI3K/Akt/eNOS) via metabolic switching with increased uptake of FFA by the body) and SIT exercise (increases availability and production of NO by increasing endothelial nitric oxide synthase activity and reducing endothelin-1 levels to improve endothelial function and reduce arterial wall stiffness and peripheral vascular resistance) could have combined to amplify the positive effects on BP.
In conclusion, VO2peak and leg strength improved with SIT regardless of whether participants trained in the fasted or fed state. Chronic SIT in the fasted state may potentially reduce blood pressure to a greater extent than the same chronic SIT in the fed state.

### ADDITION OF FRUCTOSE TO A CARBOHYDRATE-RICH BREAKFAST IMPROVES CYCLING ENDURANCE CAPACITY IN TRAINED CYCLISTS

PODLOGAR, T., CIRNSKI, S., BOKAL, Š., VERDEL, N., GONZALEZ, J.
*UNIVERSITY OF BIRMINGHAM*

INTRODUCTION: The importance of high carbohydrate (CHO) availability for optimal performance in endurance sports is well established and thus strategies have been developed to optimise CHO availability before, during and after exercise sessions. It has been demonstrated that fructose-glucose based CHO mixtures are superior in achieving high CHO availability if ingested during exercise and in recovery. During the latter, ingestion of fructose-glucose-based carbohydrates led to superior liver and similar muscle glycogen synthesis as compared to glucose-based CHO. After an overnight fast, liver glycogen stores are reduced, and based on this we hypothesised that addition of fructose to a glucose-based breakfast would lead to improved subsequent endurance exercise capacity.
METHODS: 8 trained male cyclists took part in this double-blind cross-over randomised study (VO2max: 62.2 ± 5.4 ml.kg-1.min-1). participants completed 2 experimental trials consisting of two exercise bouts. In the afternoon of Day 1, they completed a cycling interval training session aimed to normalise glycogen stores after which a standardised high carbohydrate diet was provided for 4 hours. After an overnight fast on Day 2, participants received 2 g.kg-1 of carbohydrates in the form of glucose and rice (GLU+RICE) or fructose and rice (FRU+RICE), both in a CHO ratio of 1:2 (fructose:glucose based CHO). Two hours later they commenced a cycling exercise session at the intensity of the first ventilatory threshold until task failure, during which blood glucose and lactate as well as substrate oxidation rates were assessed every 15 minutes.
RESULTS: Exercise capacity was higher in FRU+RICE (137.03 ± 22.72 min) as compared to GLU+RICE (130.06 ± 19.87 min; $p = 0.046$). Blood glucose and blood lactate remained stable throughout the trials and did not differ between conditions ($p>0.05$). Oxidation rates of CHO decreased, and fat increased over time with no differences between conditions ($p>0.05$).
CONCLUSION: Present data demonstrates that addition of fructose to a glucose-based CHO source at breakfast improves endurance exercise capacity, possibly as a result of higher CHO availability due to improved carbohydrate storage in the form of liver glycogen. It could therefore be recommended that athletes ingest a breakfast containing both fructose- and glucose-based CHO. Further studies are required to determine the optimal dose and ratio and to better understand the mechanisms.

## Invited symposia

### IS-AP07 How good are we in quantifying Training/Competition Load, Fatigue and Performance? – New insights

### UP-COMING BLOOD-BASED BIOMARKERS FOR MONITORING LOAD, FATIGUE, AND RECOVERY

HALLER, N.
*JOHANNES-GUTENBERG-UNIVERSITY MAINZ*

Blood biomarkers are routinely used in elite sports settings. They can play an important role in individualizing the workload of athletes by providing an objective measure of internal load, health, or recovery processes to reduce injury risk and maximize performance. Currently, many established biomarkers such as creatine kinase, while convenient and quick to measure, have drawbacks and are of limited use to coaches in managing athlete workload, especially when measured in the absence of further variables. Researchers have therefore increased their efforts to identify novel robust surrogate biomarkers to help in monitoring training load, fatigue, and recovery.
This lecture will provide an overview of emerging load-sensitive biomarkers and multi-marker approaches that should be considered in future research. A variety of such innovative markers (e.g., heat shock proteins, cell-free DNA, blood cell ratios) have shown meaningful and pronounced increases after standardized exercise settings or even correlations with performance traits. However, most of these markers have not been extensively studied, and the cost, time, and effort associated with measuring these variables on a regular basis remain high, making them unsuitable for monitoring purposes to date. Due to evolving technology, these innovative markers will likely become relevant to sports practitioners very soon. Finally, the section on practical applications will focus on statistical considerations and ideas for standardized study designs to help identify and establish new biomarkers.

### MODERN METHODOLOGIES AND CONCEPTS FOR TRAINING AND COMPETITION LOAD MONITORING: POSSIBILITIES AND CHALLENGES

STÖGGL, T.

*UNIVERSITY OF SALZBURG*

The quantification of training and competition load is of high relevance in modern load monitoring and management concepts. The provided data should serve to control the training, prevent injuries and overload and lead to the proper training stimulus and consequently the targeted adaptations to maximize performance. Various methodologies and concepts for quantification of the external and internal load are already applied in sport practice and science. Further, the trend towards miniaturization of measurement hardware and its integration into sports gear starts to allow an even more microscopic insight into physiology and biomechanics of human motion from a more global (E.g. heart rate, oxygen uptake, blood lactate) to local perspective (E.g. loading of single muscles). The introduction of novel sensor data as NIRS, power meters, sensor patches (E.g. glucose, lactate) but also modern training software applications open up a new world in the field of performance diagnostics and training load management. However, the greater possibilities and more microscopic view on the human body in motion leads also to novel challenges.
The presentation will provide insight into to date applied sensor technologies, methodologies and concepts for quantification of training and competition load in science and sport practice in elite endurance- and team sports. Challenges, pitfalls, possibilities and perspectives will be demonstrated on selected examples like concepts about the energy expenditure of training (E.g. energy expenditure during various endurance training concepts – isocaloric training), competition and training analysis based on wearable technology (e.g. heart rate, vs. high-end GNSS vs. NIRS), concepts about the quality of motion (E.g. acting forces, technique feedback, equipment behaviour) and the discrepancy of various concepts when aiming on quantification of the distribution of the training intensity and training volume. Further, concepts and ideas how to determine the total training load when it comes to mixed training content like endurance plus strength/speed training will be presented and discussed.

### RELATIONSHIP BETWEEN PHYSIOLOGICAL CHARACTERISTICS AND PERFORMANCE/FATIGUE IN INTERMITTENT AND CONTINUOUS SPORTS

WAHL, P.

*GERMAN SPORT UNIVERSITY COLOGNE*

The overall aims of performance diagnostics are prescribing individualized training intensities, monitoring athlete's development, and predicting performance/fatigue in competition. For this purpose, the identification of physiological performance determinants as well as performance assessment under valid conditions seems to be essential. However, the various sports differ greatly in their load structure and are characterised by either a more continuous (e.g., running/cycling) or an intermittent load (e.g., soccer). It can therefore be assumed that the different types of sports also differ in their physiological requirements, and thus the physiological determinants. The lecture will give an overview of the relationship between physiological determinants/training load measures and performance/fatigue in continuous and intermittent sports. The data presented are from controlled trials and translational approaches.
Continuous exercise: In the last decades, research has helped to identify key metabolic, neuromuscular, and mechanical determinants of distance running performance or cycling time-trail performance. Indeed, several studies have revealed that maximum oxygen consumption, lactate thresholds and maximal speed/peak power output during incremental tests predict different lengths of running or cycling time trial performances. However, it remains unclear whether or how the relationship between laboratory test parameters changes over the course of short-, middle-, and long-distance performances, especially regarding the physiological profile of an athlete. The comparison of a runner's velocity-profile or a cyclist's power-profile with physiological and neuromuscular performance indicators could enable a better explanation of a measured performance, which considers the complex interplay of different physiological systems and allows specific training description. Accordingly, the assessment of the relationship between established laboratory test parameters and performance outcomes over different durations is of great practical relevance. This part of the talk will focus on the relationship between velocity-profiles of runners or power-profiles of cyclists and their physiological characteristics.
Intermittent exercise: One sport that has been studied quite extensively in the context of intermittent sports is football). The physical demands in football are characterized by a high total running distance, which is interspersed with short and repeated bouts of high-intensity running. Many studies deal with the question of quantifying the load and the associated metabolic and neuromuscular requirements. Due to the unpredictability of the game, there are large inter-individual differences in demands that make it difficult to systematically study stress and fatigue on an individual basis. This part of the talk will focus on the quantification of load/fatigue and their relationship with physiological determinants including laboratory and field data.

## Oral presentations

### OP-MH10 Health promotion and behaviour

### WHAT PREVENTS PEOPLE WITH SEVERE MENTAL ILLNESS FROM SITTING LESS AND MOVING MORE? PERCEIVED BARRIERS TO IMPLEMENT "SIT LESS, MOVE MORE" INTERVENTIONS IN OUTPATIENT MENTAL HEALTH CARE SETTINGS

JABARDO-CAMPRUBÍ, G.1, GUARDIA-SANCHO, A.1,2,3, SANTOS-LÓPEZ, J.M.2,3, BORT-ROIG, J.1, PUIG-RIBERA, A.1

*<1> UNIVERSITAT DE VIC - UNIVERSITAT CENTRAL DE CATALUNYA; <2> OSONAMENT - OSONA PSYCHOPEDAGOGICAL MEDICAL CENTER; <3> VIC UNIVERSITY HOSPITAL*

Introduction
Patients living with severe mental illness (SMI) live on average 10 to 20 years less than the general population partly due to pathologies linked with sedentary behaviour and physical inactivity. The health-benefits of reducing and breaking up sedentary behaviour in patients living with SMI are acknowledged, yet few interventions have focused on tackling sitting less and moving more in this population. Thus, knowing the patients' barriers to sit less and move more remains basically to promote effective interventions to reduce sedentary behaviour in people living with SMI.

Methods
Patients living with SMI and health care professionals (HCP) were recruited during November 2017 from the mental health care center "Osonament", located in the city of Vic (Barcelona). Qualitative data were gathered from five focus groups in an outpatient mental health care setting. Three groups were conducted with patients with SMI and two with HCPs. Participants in each group were purposely allocated on the basis of age, gender, and duration of illness to ensure some homogeneity. Inductive thematic analysis was used for data analysis.
Results
The main overarching theme was that patients and HCPs understand and experience the illness from different points of view. These different points of view impaired their mutual ability and communication to address patients' sedentary behaviour within outpatients´ mental health settings. First, HCP reify and view the pathology from a purely biological point of view, looking for the exact location of the pathology to treat it. Second, patients living with SMI live their illness as a global whole that affects their daily life in all its dimensions.
Discussion
Our findings suggested that in order to improve current practice for HCPs to promote sitting less and moving more in patients with SMI it is necessary the following issues. First, to understand that patients´ sedentary behaviour was not only a biological-related behavioural risk factor, but a lifestyle (i.e. sociocultural construction) with social implications and repercussions that also needed to be addressed. Second, socialization (e.g. with groups rather than individuality) may be a key strategy for dealing with sedentary behaviour. Thus, while for HCP it is important to sit less and move more, for patients living with SMI it is more important with whom they do and share this "sitting less and moving more" time. While for HCP is important to reduce sedentary behaviour to improve health, for patients with SMI are more important the social implications that might have reducing sedentary behaviour by being involved in active-based-social tasks. Targeting these aspects could hold promise for effective interventions in this population.
This work was cofounded by Osonament (Osona Psychopedagogical Medical Center) and the Industrial Doctorate Program funded by the Government of Catalonia [grant number 2015 DI 024].

**GOALS AND BARRIERS TOWARDS PHYSICAL EXERCISE IN PEOPLE WITH SEVERE MENTAL ILLNESS. THE PSYCHIACTIVE PROJECT 2.0.**

LÓPEZ MORAL, A., BUENO ANTEQUERA, J.

*UNIVERSIDAD PABLO DE OLAVIDE*

INTRODUCTION: Physical inactivity is a major public health issue in people with severe mental illness (SMI). Exercise can improve clinical outcomes in SMI but poor adherence to exercise is often reported in this population [1]. Understanding and controlling the factors that affect physical exercise programs could improve the prevention and treatment of these patients. The aim was to study the goals and barriers towards physical exercise in people with SMI.
METHODS: A cross-sectional study was carried out in 61 adults (♀ = 13, 20-60 years) with SMI. Participants completed "The barriers self-report questionnaire for the practice of physical exercise" (ABPEF) and the "Goal Content for Exercise Questionnaire" (GCEQ). The ABPEF comprises 17 items related to four different subscales (body image/ physical and social anxiety; fatigue/ laziness; obligations/ lack of time; environment/ facilities), each item is measured according to a Likert scale from 0 ("Unlikely reason") to 10 ("Likely reason"). The GCEQ comprises 20 items measured on a seven-point Likert scale, from 1 ("Nothing important") to 7 ("Very important"). Each item is related to five different subscales (social affiliation; image; health management; social recognition; skill development) where the first, third and fifth factors are intrinsic, and the second and fourth factors represent extrinsic exercise goal content. The mean and the standard desviation for each factor were calculated.
RESULTS: Health management was the highest self-reported physical exercise goal for active (5.72±0.32) and inactive (5.63±0.22) men, as well as active (6.38±0.63) and inactive (6.05±0.43) women. Regarding the barriers to exercise, active men reported fatigue/ laziness (3.52±0.48) as the main barrier to exercise, as did inactive men (4.55±0.42). On the other hand, active women reported obligations/ lack of time (3.88±0.98) as the main barrier to exercise. Finally, the inactive woman reported fatigue/ laziness (5.02±0.50) as the main barrier to physical exercise.
CONCLUSION: Current findings suggest that physical exercise programs for people with SMI should be designed to improve intrinsic goals. Providing the necessary professional supervision would help overcome your barriers, improve exercise adherence, and enhance the effects of physical exercise on your health and physical recovery.

**CHANGES IN TOTAL, MODERATE-INTENSITY AND VIGOROUS-INTENSITY PHYSICAL ACTIVITY ARE ASSOCIATED WITH ALL-CAUSE MORTALITY AMONG 87,302 ADULTS: THE LIFELINES COHORT**

BAKKER, E.A., LEE, D.C., ORTEGA, F.B., HOPMAN, M.T.E., THIJSSEN, D.H.J., EIJSVOGELS, T.M.H.

*RADBOUD INSTITUTE FOR HEALTH SCIENCES*

INTRODUCTION: Regular physical activity (PA) reduces the risk of all-cause mortality (1) with greater risk reductions at higher exercise intensities (2). However, an important limitation of most studies is that they examined the association between PA and mortality at a single time-point, whereas PA volumes change over time. We examined the effects of changes in PA volumes on all-cause mortality, and explored the role of exercise intensity on the association.
METHODS: Data was used from the Lifelines Cohort (N=87,302). Self-reported PA volumes at baseline and follow-up were presented as Metabolic Equivalent of Task (MET) minutes per week. Changes in PA were calculated by subtracting MET-min/week of the first from the second assessment (median interval 3.8 years), and study participants were categorized into 5 groups; large reduction (<-2000 MET-min/week), moderate reduction (-2000 to -500 MET-min/week), no change (-500 to 500 MET-min/week), moderate improvement (500 to 2000 MET-min/week) and large improvement (>2000 MET-min/week). Activities with a MET between 3-6 were defined as moderate-intensity PA and ≥6 as vigorous-intensity PA. All-cause mortality was retrieved from the Dutch national death registry. Cox regression was used to calculate hazard ratios (HR) with 95% confidence intervals (CI).
RESULTS: Participants were 45±12 years old and 40% was male. After a median follow-up of 7 years [IQR 6-8], 848 (1%) individuals died. After adjustment for confounders and baseline PA, individuals with a moderate to large improvement of total PA had a lower risk of death (HR 0.70 [95% CI 0.55-0.89] and HR 0.65 [95% CI 0.52-0.81], respectively) compared to individuals with no change in PA. Intensity specific analyses showed that moderate and large improvements in vigorous-intensity, but not moderate-intensity, PA were associated with a

reduced risk (HR 0.65 [95% CI 0.51-0.83] and HR 0.75 [95% CI 0.60-0.95], respectively). A large reduction in total PA resulted in a higher risk of death, but this was not statistically significant (HR 1.17 [95% CI 0.93-1.46]). Moderate and large reductions in moderate-intensity, but not vigorous-intensity, PA resulted in a significantly increased risk of death (HR 1.37 [95% CI 1.14-1.65] and HR 1.34 [95% CI 1.05-1.72], respectively) compared to no change in PA.
CONCLUSION: Increasing total PA, especially increasing vigorous-intensity PA and maintaining moderate-intensity PA, is an important and effective strategy to reduce the risk of premature death in the general population.

**ASSOCIATIONS BETWEEN PHYSICAL ACTIVITY, LUNG FUNCTION AND E-CIGARETTE USAGE IN YOUNG ADULTS.**

MOSS, S., TAMULEVICIUS, N., MARTINISEK, M.
*NORTH-WEST UNIVERSITY*

INTRODUCTION: Regular physical activity (PA) is a key component of a healthy lifestyle and the prevention of future chronic conditions. The risk of developing lung conditions when smoking tobacco from an early age is increased. However, the association between smoking of electronic cigarettes and lung function and the role of regular physical activity is not clear. We aimed to determine the associations between self-reported physical activity, lung function and electronic cigarette usage in young adults.
METHODS: An availability sample of 100 young adults (21.7 ±2.9 years) who signed informed consent were included in the study. Demographic characteristics age, gender, weight, height and ethnicity were self-reported by the participants. All participants then performed a peak expiratory flow rate assessment (Easy One spirometer). The international physical activity questionnaire (IPAQ) was completed by each participant to calculate physical activity in MET.min/week. A self -developed smoking survey was completed online to record the smoking habit and electronic cigarette usage. A partial correlation analyses was performed on the data, with adjustments made for confounders, smoking behavior, BMI and gender. The level of statistical significance was set at p≤0.05.
RESULTS: The average physical activity levels of males (n=50) were significantly higher (8188.00±7005 MET.min/week) than those of females (6060.40 ± 4620 MET.min/week; p<005) (n=50). Males maintained their physical activity levels regardless of smoking habits, whereas females who smoked reported lower physical activity levels. Males had an overall higher peak expiratory flow rate (9.22 ± 189 L/min) compared to females (6.32± 1.79 L/min; p <0.001). A non-significant correlation was found between self-reported physical activity and peak expiratory flow rate (r = 0.191; p = .057), even when adjusted for smoking behavior, BMI and age (r = .121; p=.235).
CONCLUSION: Our study found that the associations investigated between physical activity, lung function and the smoking habit were not statistically significant, but trends were observed that persons with higher physical activity levels tend to produce higher flow rates, while adjustment for the smoking habit removed the trend. Longer periods of engagement with smoking might be needed before detrimental effects are observed in lung function.

### OP-SH02 COVID-19: Psychological well being and motivation

**POSITIVE AND NEGATIVE LEISURE ACTIVITIES AND THEIR RELATIONSHIP WITH ANXIETY AND DEPRESSION, DURING THE COVID 19 PANDEMIC**

AGUILAR CORTEZ, L., PEREZ, V.F.
*UNIVERSIDAD DEL FUTBOL Y CIENCIAS DEL DEPORTE*

Positive and negative leisure activities and their relationship with anxiety and depression, during the Covid 19 Pandemic
Introduction
Participation in positive and negative leisure activities were related to levels of anxiety and depression in individuals from Mexico who were in social isolation during the Covid 19 pandemic.
Methods
Quantitative, correlational and longitudinal research, two measurements were applied that were carried out online during Phase 2 and Phase 3 of the COVID-19 pandemic; that is, during the peak of the epidemic; where the population was called to stay at home, restricting activities that the health authorities declared non-essential, two self-administered questionnaires were applied, the first called Leisure activities, from Cuenca (2000) validated at the Leisure Studies Institute. the University of Deusto, and the second Goldberg and Hillier questionnaire. (1979) in search of symptoms and/or signs of anxiety and depression, applied to 764 subjects of both sexes in Mexico
Results
Anxiety and depression was found during phase 2 in the total population represented by 67.26%, being higher in women than in men, with a significant difference, age, as well was significant, it turned out to be significant in tounger men and women suffered from more anxiety and depression than older men and women.
The negative leisure activities that presented higher levels of anxiety and depression were: Dedicating too much time to work at home and to housework. Surf the internet for a long period of time (check social networks). Watch TV for a long periods of time (more than 2 hours). Behave passively or as a spectator in family leisure activities. Feeling that you are wasting your time when you dont go to work.
The positive leisure practices that presented lower levels of anxiety and depression were: Listening to the radio. Doing physical activity. Taking care of plants. reading books. Helping the family. Listening to music. Helping with housecore. playing games. Buy online. Take care of animals. Watch movies. Take an online course. Eat as a family. Play with the family. Organize the days activities.
Discussion
Negative leisure activities are related to not knowing what to do and boredom with an increase in leisure time in social isolation. A longer periods of time that increased anxiety and depression for not knowing what to do with it. On the other hand, positive leisure practices are

activities that cause satisfaction and have an autotelic meaning , that is, they have an end in themselves, are more structured.. They are also found in which positive leisure activities refer to those that are a means for personal training and recovery and health prevention. As a main conclusion, the data indicated that the greater the positive leisure, the less depression, the effect of positive leisure is much lower on anxiety and only occurs with autotelic leisure. It can also be observed that the greater the negative leisure, the greater the

**A SEVEN-DAY REMOTE INTERVENTION TO MANAGE FOOD CRAVINGS AND EMOTIONS DURING THE COVID-19 PANDEMIC**

DEVONPORT, T.J., CHEN-WILSON, C.H., NICHOLLS, W., ROBAZZA, C., CAGAS, J.Y., FERNANDEZ-MONTALVO, J., CHOI, Y., RUIZ, M.C.

*UNIVERSITY OF WOLVERHAMPTON*

Due to the physical and aesthetic demands of sport, elite athletes must pay meticulous attention to functional eating, with emphasis on adequate and nutritionally appropriate food. However, it is increasingly recognised that food may also be consumed in response to emotions, known as emotional eating. In the context of elite sport, emotional eating may compromise functional eating goals, as the use of food to regulate emotions is associated with a failure to maintain weight management goals. On March 11th 2020, the World Health Organisation declared COVID-19 a pandemic. Exposure to stress during the pandemic, and the subsequent potential for unpleasant emotions had the potential to influence poor eating habits during the pandemic. Notably, increased calorie consumption derived largely through consumption of foods high in fats and sugars, thus leading to weight gain. Targeting eating behaviour through provision of remote interventions is, therefore, a critical strategy to ameliorate the impact of COVID-19 and is the focus of this research. This study examined the effectiveness of two brief remote interventions targeting the general population that aimed to help individuals deal with food cravings and associated emotional experiences. Participants (n = 165) completed a seven-day intervention that involved two groups, a daily food craving diary or a daily food craving diary and mindful eating practice. Repeated measures MANOVA indicated significant differences in the experience of emotions by Measurement (T1 through T7). Follow-up analysis indicated significantly lower experience of unpleasant emotions across time. Group (food craving diary vs. food craving diary and mindful eating practice) effect was not significant. Repeated measures MANOVA also revealed significant decrease in experience of food cravings by Measurement but not by Group. Participants reported significantly less eating and enhanced wellbeing at T7 vs. T1. Qualitative feedback from participants indicated that they perceived completion of the food craving diary to be an easy task, and mindful eating practice to be a strategy that some intended to continue using. Our findings offer support for a growing body of research which indicates that many individuals experienced an increase in unpleasant emotions during the COVID-19 pandemic. Significantly less eating and better wellbeing were reported after both intervention conditions. The completion of a 7-day food diary was effective in reducing food cravings (i.e., frequency of craving experienced, giving into craving, and difficulty resisting), as well as the intensities of unpleasant emotions experienced at the time of the highest food cravings. Following mindful eating guidelines alongside a food diary for the same time period was no more effective than completion of the diary alone. The results from this study support the use of remote interventions to encourage healthy eating behaviours. Implications for elite athlete populations are discussed.

**OVERWEIGHT, OBESITY AND HEALTHY HABITS IN CHILDREN IN THE CITY OF MADRID DURING THE COVID-19 PANDEMIC: THE LONGITUDINAL ASOMAD STUDY.**

PORTALS-RIOMAO, A., QUESADA-GONZÁLEZ, C., NEHARI, A., LÓPEZ-SEOANE, J., PANTOJA-ARÉVALO, L., CHIESA, I., PALAZZO, S., GESTEIRO-ALEJOS, E., MARTÍNEZ DE QUEL PÉREZ, O., GONZÁLEZ-GROSS, M., ZAPICO, A.G.

*UNIVERSIDAD POLITÉCNICA DE MADRID*

INTRODUCTION: Overweight and obesity seem to be increasingly widespread in children over the last few years. Furthermore, COVID-19 has seriously affected the quality of life of the scholar population due to the restrictions imposed since its inception, the city of Madrid has been one of the most restrictive spots in Europe. Few studies have evaluated lifestyle changes throughout the pandemic. Thus, the aim of this study was to analyze the evolution of healthy lifestyle levels during the course of the pandemic in Madrid school-aged children.
METHODS: This is a part of a longitudinal study from 2020 to 2023 that is currently taking place in Madrid city which was carried out with a representative sample of children aged 8 to 14 living in the City of Madrid. Body composition was measured by BIA (TANITA DC-240MA, Japan). Diet quality, physical activity (PA), sleep measurements, and emotional well-being were measured by validated questionnaires (KIDMED Index, PAU-7S, BEARS9/SHSA8 and KIDSCREEN-10, respectively). Data were collected twice, 1 year apart, winter 2020/21 and winter 2021/22.
RESULTS: PA levels improved as the restrictions of confinement have been eased ($p<0.01$) mainly due to increased light PA. Similarly, mean adherence to Mediterranean diet improved in 2022 compared to 2021 ($p<0.01$). However, excess weight according to the International Obesity Task Force (IOTF) affected 32% (22.4% overweight and 9.6% obese) of children in 2021 and 35.3% (19.1% overweight and 16.2% obese) in 2022. Screen time during the week and sleep time on weekends increased without significance, meanwhile screen time on weekends and sleep time during the week did not improve significantly. Well-being did not differ statistically between 2021 and 2022, even 49 % of children indicated to be sad in 2021 and 52% in 2022. Loneliness improved from 36% in 2021 to 28% in 2022.
CONCLUSION: Between the two analysed periods, overall physical activity, adherence to Mediterranean diet and feeling lonely improved. Percentage of children with excess body weight, weekly screen time and sleep time during weekends increased. A careful follow-up is needed in this population to promote a recovery from the effects of the pandemia and improve their quality of life.
Funding: Agreement between UPM and Area Delegada de Deportes, Ayuntamiento de Madrid.

**A VIRTUAL EXERCISE PROGRAM THROUGHOUT PREGNANCY DURING THE COVID-19 PANDEMIC MODIFIES MATERNAL SMOKING HABITS AND BIRTH WEIGHT. RANDOMIZED CLINICAL TRIAL**

SILVA-JOSE, C., MOTTOLA, M., BARAKAT, R.

*FACULTAD DE CIENCIAS DE LA ACTIVIDAD FÍSICA Y DEL DEPORTE - INEF - UPM*

INTRODUCTION: The intrauterine environment is key to the health of the newborn and infant in the short and long term. Birth weight is an important indicator of fetal health and is related to maternal variables that may influence the fetal environment due to epigenetics. Considering the current situation of COVID-19 and the lack of physical activity, in parallel with higher levels of stress affecting smoking patterns and the physical and emotional health of the pregnant population, establishing non-invasive approaches to maintain the health of future generations is crucial.

METHODS: A randomized clinical trial (NCT04563065) was conducted. One-hundred and ninety-two pregnant individuals without obstetric contraindications were assigned to the intervention (IG) or the control group (CG). A supervised virtual program of moderate exercise was developed throughout pregnancy based on the Barakat Model and following the recommendations of international clinical guidelines. Study adherence was sealed at 80%. Data on maternal and neonatal outcomes were collected from hospital records
RESULTS: Overall, there were no differences in the mean of birth weight between IG and CG (3197.85 ± 423.95 g vs. 3187.75 ± 462.37 g; p= 0.896; respectively). However, significant differences were found between the study groups when strategized by birth weight ($\chi 2$ (7) = 6.610; p = 0.037) with low birth weight and macrosomia found more often in the CG (4% vs 14% and 3% vs 9%, respectively) and higher admissions to the neonatal intensive care unit ($\chi 2$ (4) = 5.075; p = 0.024) in the CG (20/28.6%) compared to the IG (9/13.0). Smoking during pregnancy was also found more often in the CG (12/17.1%) compared to the IG (3/4.4%) (p = 0.016).
CONCLUSION: A virtual program of supervised exercise throughout pregnancy during the ongoing pandemic could help to maintain adequate birth weights, modify maternal smoking habits, and lower admissions to the neonatal intensive care unit.

**THE INFLUENCE OF ABSENT CROWDS ON NATIONAL RUGBY LEAGUE MATCH PLAYER STATISTICS AND RUNNING METRICS**

FAZACKERLEY, L., GORMAN, A., MINETT, G., CAIA, J., KELLY, V.

*QUEENSLAND UNIVERSITY OF TECHNOLOGY*

INTRODUCTION: The novel strain of coronavirus disease, COVID-19, was first identified in 2019, and due to its highly contagious nature, many elite sporting competitions were suspended and/or postponed. Sporting events that could continue, whether immediately or delayed, implemented strict bio-safety precautions to minimise the risk of spreading infection. Consequently, in many cases, crowds were prohibited from attending games. Research suggests that the presence or absence of a crowd may exert a social facilitation effect on players and officials in elite sport, which in turn might affect performance. Along with social facilitation theory, a related phenomenon known as the home advantage, suggests that the home team typically wins more games and scores more points than the away team. Research suggests that supportive crowds are social representatives of their players and encourage the home team to play well. However, minimal research has investigated the interaction between crowd (present or absent) and match location (home or away) on sport performance.
METHODS: This study used a retrospective observational design to investigate the influence of the crowd and match location in the National Rugby League (NRL) by comparing player statistics (attacking or defending) and Global Positioning System (GPS) metrics between season 2020 Round 1 (crowds) and Round 2 (no crowd). Data were obtained for 203 professional NRL players. A linear mixed model with a random intercept (Player ID) was used to assess the relationship between crowd removal and match location on performance indicators and GPS metrics. Effect sizes (ES) were also calculated to determine the magnitude of change.
RESULTS: The effect of a crowd and match location were trivial to small (ES range: -0.213 to 0.224). Attacking statistics suggest that NRL players engaged in more decoys (p=0.022, ES=0.162), increased post-contact metres (p=0.020, ES=0.206), and decreased support runs (p=0.005, ES=-0.184) in the absence of a crowd. When defending, the number of missed tackles increased (p=0.018, ES=0.213) in the absence of a crowd. GPS running metrics suggest that players had higher maximal velocities (p=0.027, ES=0.155), however, lower relative acceleration loads (p=<0.001, ES=-0.224), in the absence of a crowd. When playing away from home, athletes spent more time in the high-speed running thresholds (p=0.020, ES=0.072).
CONCLUSION: The findings suggest that the absence of a crowd had minimal effect on players' performance indicators. Further, findings also showed that the HA was largely unaffected by the removal of the crowd in the sample of professional rugby league games examined in the present study. Any changes were more likely to result from the score margin and other contextual factors. Potentially, the removal of the crowd may have reduced the advantage toward the home-team. However, it appears that elite rugby league athletes can maintain optimal physical performance without a crowd.

### OP-PN25 Cardiovascular II

**CEREBRAL BLOOD FLOW RESPONSE TO GRADED EXERCISE IN MIDDLE-AGED MEN AND WOMEN: THE TOLEDO STUDY FOR HEALTHY AGING IN MIDDLE AGE**

MUÑOZ-MUÑOZ, M.1,2, SOTO-PANIAGUA, H.1,2, GARCÍA-AGUIRRE, M.1,2, RODRÍGUEZ-LÓPEZ, C.1,2, ALEGRE, L.M.1,2, LOSA-REYNA, J.1,2, ARA, I.1,2, GARCÍA-GARCÍA, F.J.2,3

*1. GENUD TOLEDO RESEARCH GROUP, UCLM, TOLEDO ; 2. CIBER OF FRAILTY AND HEALTHY AGEING , MADRID ; 3. HOSPITAL VIRGEN DEL VALLE, TOLEDO*

INTRODUCTION: Cerebral blood flow (CBF) regulation is vital for proper delivery of O2 and energy supply to the brain (1). Although brain's blood demand is relatively constant, exercise represents a challenge for the cerebral vasculature (2). During exercise, skeletal muscle blood flow response is usually greater in women; however, it is unclear whether this sex-specific difference occurs in CBF as well (3,4). Therefore, the main goal of this investigation was to assess sex-specific differences in CBF responses to maximal graded exercise during middle age.
METHODS: Twenty-six participants (15 females and 11 males, 54.8±1.5 years old) completed a progressive incremental exercise test (GXT) on an electromagnetically braked cycle-ergometer (800X, Ergoline, Germany). All subjects completed 5-min resting and 5-min warm-up (women: 15 W; men: 30 W) stages. Thereafter, power output increased 3 and 4 W every 12 s for women and men, respectively, until volitional fatigue or inability to maintain proper cadence (≥60 rpm), while receiving intense verbal encouragement. Afterwards, a verification test was performed. Ventilation and pulmonary gas exchange were assessed using a breath-by-breath system (Oxycon Pro, Jaeger, Germany) and heart rate was continuously measured (GEH-ECG-1200, General Electric Company, Spain). Middle cerebral artery mean blood flow velocity (MCAv) was continuously measured via quality transcranial doppler during the GXT (Multi-Dop T, DWL Compumedics, Germany). When possible, both left and right MCA were recorded and data were averaged together.
RESULTS: Men achieved greater peak power (Wmax) (2.81±0.63 vs 1.74±0.35 W/kg, p<0.001) and VO2max (33.9±7.5 vs 24.5±3.7 ml/kg/min, p<0.001) during GXT in comparison with women. There was no difference in resting MCAv between men and women (52.69±11.24 cm/s vs 59.39±14.28 cm/s, p=0.210). MCAv kinetics was similar between men and women during the different stages of GXT.

The most pronounced rise in MCAv was recorded from resting to warm-up (+3.48 cm/s in men; +2.55 cm/s in women). During low to moderate intensity exercise (25-75% Wmax) MCAv increased slightly (1.64 cm/s in men; 1.83 cm/s in women), and then (from 75 to 100% Wmax) MCAv declined slightly in men (-2.89 cm/s) and reasonably in women (-7.74 cm/s) (all p>0.05).
CONCLUSION: Despite the sex-differences in VO2max and Wmax, these differences were not present for the middle to middle cerebral artery mean blood flow velocity. Ultimately, this work will need to be continued to identify mechanisms of cerebrovascular responses and sex-specific differences that may occur.

## RESTING RIGHT VENTRICULAR SYSTOLIC FUNCTION PARAMETERS ARE NOT ASSOCIATED WITH PEAK EXERCISE CARDIORESPIRATORY FUNCTION IN HEALTHY ADOLESCENT ELITE MALE ATHLETES

WILLIAMS, C.A.1, DOROBANTU, D.M.1,2, WADEY, C.1, RYDING, D.3, MCNALLY, S.3, PERRY, D.3, STUART, A.G.2, PIELES, G.E.2,4

*<1> CHERC, UNIVERSITY OF EXETER; <2> UNIVERSITY OF BRISTOL; <3> MANCHESTER UNITED FOOTBALL CLUB; <4> ASPETAR ORTHOPAEDIC AND SPORTS MEDICINE HOSPITAL*

INTRODUCTION: The relationship between right ventricular (RV) systolic function and cardiorespiratory fitness is complex, especially during exercise, when cardiac output and oxygen uptake (VO2) change in relation to one another. Previous small studies have alluded to a possible correlation between resting RV function and peak VO2 in young athletes. The aim of this study was to investigate this relationship using a large cohort of healthy elite adolescent football players.
METHODS: Adolescent male players from an elite football club were included, undergoing a minimum of 12 h per week training and game time. All players underwent a comprehensive cardiac evaluation, including cardiopulmonary exercise test (25 W or 50 W step increments) and baseline resting echocardiography. Relative VO2 was calculated at peak VO2, gas exchange threshold (VO2@GET) and at respiratory compensation point (VO2@RCP). The following RV systolic function parameters were calculated at rest: free wall longitudinal strain (RV-FW Sl), strain rate (RV-FW SRl), fractional area change (RV-FAC), peak tricuspid annular systolic velocity (RV-S') and tricuspid annular plane systolic excursion (TAPSE). Associations were explored using the Pearson's correlation coefficient (r) and linear regression R-squared. RV-FW Sl and SRl are negative by convention, with higher negative values denoting better function.
RESULTS: A total of 81 participants were included, mean age 14.5 ±1 y (range 12.6-16.6 y). All athletes had been screened for cardiac disease and cleared for sport participation. None had noted abnormalities, and all had cardiac normal RV function. Mean peakVO2 was 46 ±6.3 mL•min-1•kg-1,, mean VO2@GET 2 8±4.8 mL•min-1•kg-1 and mean VO2@RCP 40.6 ±5.8 mL•min-1•kg-1 . Mean RV-FW Sl was -27.7±3.6%, mean RV-FW SRl -1.5 ±0.3 s-1.
RV-FW Sl showed weak or moderate correlations with oxygen uptake measurements: with peakVO2, r= -0.35, R2 = 0.13, (p=0.003); with VO2@GET, r=-0.36, R2=0.13 (p=0.002); with VO2@RCP: r=-0.11, R2=0.01 (p=0.4). RV-FW SRl showed weak or moderate correlation with oxygen uptake measurements: with peak VO2, r= -0.33, R2=0.11 (p=0.006); with VO2@GET, r= -0.27, R2=0.08 (p=0.02); with VO2@RCP, r= -0.07, R2=0.006 (p=0.6). Weak associations were also observed between other RV function parameters and oxygen uptake measurements (r range from 0.001-0.31, p value range from 0.006-0.95, of which TAPSE showed the strongest correlation).
DISCUSSION & CONCLUSION: In healthy adolescent elite footballers, RV myocardial function at rest shows weak or moderate correlation to oxygen uptake at different physiological thresholds during a max exercise test. RV longitudinal function at rest explained at most 13% of observed variation in peak VO2 and GET and had no association with VO2@RCP This supports the hypothesis that cardiorespiratory fitness is not well predicted by resting cardiac function in healthy individuals, but rather by RV myocardial function responses during exercise.

## METHODS: RESULTS: CONCLUSION: COMPARISON OF LEFT VENTRICULAR MYOCARDIAL FUNCTION BEFORE AND AFTER SPORTS SEASON IN PROFESSIONAL MALE ADOLESCENT FOOTBALL PLAYERS

DOROBANTU, D.M.1,2, WADEY, C.1, RYDING, D.3, MCNALLY, S.3, PERRY, D.3, STUART, A.G.2, PIELES, G.E.2,4, WILLIAMS, C.A.1

*<1> CHERC, UNIVERSITY OF EXETER, <2> UNIVERSITY OF BRISTOL, <3> MANCHESTER UNITED FOOTBALL CLUB, <4> ASPETAR ORTHOPAEDIC AND SPORTS MEDICINE HOSPITAL*

INTRODUCTION: Professional athletes undergo intense and rigorous training regimens during sporting seasons, and whether there are any post-season changes in cardiac function, beneficial or detrimental to performance e.g., cardiac fatigue, is not well known. The aim of this preliminary study was to compare left ventricular (LV) myocardial function before and after a competitive season in a group of adolescent elite football players, using state-of-the-art echocardiographic exercise testing.
METHODS: Adolescent male players from an elite football club were recruited. They had a minimum of 12 h per week training, game time and selection, actively participating in international competitions. All players underwent comprehensive cardiac evaluations, including exercise echocardiography, with images being acquired (Artida/Aplio i900 machine, Canon Medical Systems, Japan) at rest, 0, 50, 100, 150 W, 2 minutes, and 6 minutes recovery, pre- and post-season. LV myocardial function was analysed using speckle tracking echocardiography (STE) and expressed as LV longitudinal strain (Sl) and strain rate (SRl), LV circumferential strain (Sc) and strain rate (SRc). A two-way repeated measures ANOVA was used, with pre-/post- season timing and exercise test steps as repeated measures.
RESULTS: A total of 25 participants were included, mean age 14.1±0.7 y at pre-season visit (range 12.7-16.1 y). All were cleared for participation, none had cardiac conditions, and all had normal baseline cardiac function.
Exercise step test had a significant effect on LV Sl ($F(6, 66)=10.7$, $p=<0.001$, $\eta2=0.5$), SRl ($F(3,36)=100$, $p<0.001$, $\eta2=0.9$), basal Sc ($F(6,54)=15.2$, $p<0.001$, $\eta2=0.6$) and basal SRc ($F(6,60)=87.8$, $p<0.001$, $\eta2=0.9$), with a gradual increase up to 150 W, and return to baseline in recovery for all parameters.
There were no statistically significant effects of pre-/post- season timing on LV Sl ($F(1,11)=2.3$, $p=0.2$, $\eta2=0.2$), SRl ($F(1,11)=0.003$, $p=0.9$, $\eta2=0$), basal Sc ($F(1,9)=5$, $p=0.8$, $\eta2=0.01$) or basal SRc ($F(1,10)=0.2$, $p=0.6$, $\eta2=0.02$). In addition, there were no statistically significant effects of pre-/post- season and exercise test step on LV Sl ($F(6,66)=0.7$, $p=0.6$, $\eta2=0.06$), SRl ($F(6,66)=1.3$, $p=0.3$, $\eta2=0.1$), basal Sc ($F(6,54)=0.8$, $p=0.6$, $\eta2=0.1$) or basal SRc ($F(2,23)=1.5$, $p=0.2$, $\eta2=0.1$). Analyses were repeated for baseline to stage 100 W (missing data mostly at 150 W) with similar results, of no significant effect of pre-/post-timing on any of the LV function parameters.

CONCLUSION: Resting LV cardiac function, as well as myocardial strain dynamic changes during exercise stages and recovery remain unchanged between pre- and post-season in adolescent footballers. These findings show that intense training periods such as that of professional sports season are not associated with "cardiac fatigue," or other major changes in LV function. More research is needed into the differing effects of teams sports compared to ultra-endurance training, as well as differing impacts on the right ventricle.

### HEART RATE VARIABILITY: OBTAINING THE STRESS SCORE FROM SDNN VALUES

SALAZAR-MARTÍNEZ, E., SARABIA-CACHADIÑA, E., NARANJO ORELLANA, J.

*CENTRO DE ESTUDIOS UNIVERSITARIOS CARDENAL SPÍNOLA - CEU / UNIVERSIDAD PABLO DE OLAVIDE*

INTRODUCTION: Heart Rate Variability (HRV) is a feasible tool for quantifying training loads and physiological stress (1). Its feasibility appears in Apps and devices which comprise HRV parameters as recovery index. Usually, these Apps use linear parameters like the Standard Deviation of Normal Sinus Beats (SDNN). The Stress Score (SS) is a new measure of sympathetic stress (2) calculated from the Poincaré plot, which is not performed by most of the existing Apps, so they cannot incorporate this stress index. However, we know that there is a close relationship between SD2 and SDNN (2), so it would be possible to obtain SD2 estimating it from SDNN (ESD2) and using it to estimate SS (ESS). Thus, the aim of the present study was to prove that is possible to obtain de SS from the SDNN.
METHODS: 16 active males (25.17±5.84 years; 178.37±8.77 cm; 70.2±12.73 kg) performed 2 exercise treadmill running tests on separate days; one incremental until exhaustion, and other at constant load (70% of maximal aerobic velocity). All subjects underwent 5' HRV analysis: a) seated pre-test, b) during both exercise tests, and c) seated post-test at 3 intervals (0-5', 5-10' and 10-15'). From those analysis, SDNN and SD2 were selected. For the validation, the regression line between SDNN and SD2 was obtained, and it was used to calculate ESD2 from SDNN values. Then, ESS was calculated from ESD2 values, and it was compared with the SS obtained from the real SD2. Given that the SS is calculated as 1/SD2*1000, the ESS was set as 1/ESD2*1000. The reliability of the use of the ESS (versus the SS) was evaluated using a Bland-Altman analysis. Bias, limits of agreement (LoA), standard deviation of difference (SDD), intra-class correlation (ICC) and Person's coefficient were calculated.
RESULTS: Bias and upper-lower LoA were 1.23 (16.16, -13.71). The SDD was 7.62. Bland-Altman plot showed a good correlation without systematic error when comparing SS with ESS measurements. SD2 and SDNN showed a positive linear relationship (r2=0.981) in all conditions (n=147). Both SS and ESS were highly correlated (Pearson´s coefficient > 0.9) (significant agreement ICC > 0.9) and low variation (CV < 10%) during all conditions (pre-test, during test, and post-test). SS and ESS described a positive linear relationship (r2=0.97) in all conditions measured (n=147).
CONCLUSION: ESS provides values very close to SS, so obtaining it from SDNN (which is present in most of the current Apps and devices for training loads control) is a valid alternative.

### HRV DYNAMICS: FROM INDIVIDUAL PROFILES TO INTERPERSONAL COORDINATION IN ATHLETES

BOFFET, A., ARSAC, L.M., PRATVIEL, Y., DESCHODT-ARSAC, V.

*IMS - LABORATOIRE DE L'INTÉGRATION DU MATÉRIAU AU SYSTÈME*

INTRODUCTION: Interpersonal coordination is the term used to describe how several individuals synchronize their activity. Recent studies have explored the level of coordination based on correlations between physiological signal outputs [1], although this has not been documented to date in athletes.
Based on a conceptual network that governs brain-heart interactions, recent works have shown the potential of heart rate variability (HRV) to monitor psychophysiological modulations when tasking [2,3]. This approach could yield promising results in the study of interpersonal coordination.
The objective of the present study was twofold: first, by using a clustering approach, we established psychophysiological profiles of athletes confronted to a prolonged cognitive task designed to induce mental fatigue. Then, to show how these psychophysiological profiles can influence interpersonal coordination, causal interactions between athletes HRV dynamics were explored through Granger causality computations.
METHODS: To establish clusters, HRV metrics (RMSSD, LF, HF entropy) were obtained in 52 sport students (20.7 ± 2.9 years, 27 males) while performing 20-min of Continuous Vigilance Task (CVT) as a source of mental fatigue. Unsupervised clustering analysis (k-means) was used to determine individual psychophysiological profiles.
To determine interpersonal coordination while performing cooperative tasks on a computer, similar HRV metrics were collected in 12 dyads of athletes (20.9 ± 1.3 years, 17 males) before and after CVT. Granger causality computed on each HRV metric (RMSSD, LF, HF entropy) provided the quantitative coordination.
RESULTS: The clustering analysis revealed three clusters wherein all subjects showed similar levels of fatigue and task performance but exhibited distinct profiles of cardiac autonomic control (RMSSD, LF, HF entropy).
Granger causality showed effective autonomic interactions between subjects within dyads. Most importantly, individual behaviors within a dyad depended on the cluster the athlete was belonging. Athletes with high autonomous power had a lower propensity to synchronize with a partner and conversely.
CONCLUSION: This study shows that distinct cardiac autonomic control responses lead to similar levels of mental fatigue and task performance. Moreover, interpersonal coordination within dyads of athletes is strongly influenced by their autonomic behavior. Grangers causality may be a useful tool for managing groups of athletes, especially when dealing with mental fatigue.

### WHY ARE PLAYERS WITH A PREVIOUS ACL INJURY AT ELEVATED RISK OF SUSTAINING A NEW SECONDARY ACL INJURY?

MAUSEHUND, L., KROSSHAUG, T.

*NORWEGIAN SCHOOL OF SPORT SCIENCES*

INTRODUCTION: About 25% of the ball/team sports athletes who return to play after an anterior cruciate ligament (ACL) injury end up with a new, secondary ACL injury. To make return to these sports safer we need more knowledge of injury causation. Also, ACL injuries typically occur during single-leg landings or cutting maneuvers, which is why such movements should be in the center of research attention. The purpose of this study was to investigate whether knee biomechanics during sidestep cutting maneuvers differ between athletes with and without a history of ACL injury.
METHODS: 751 female elite handball and football players, 72 of which with a history of ACL injury, performed sport-specific cutting tasks while 3D kinematics and kinetics were measured. We compared seven knee related variables between both the previously injured leg and the uninjured leg of players with an ACL injury history with legs of injury free players.
RESULTS: For the previously injured leg, we found that players with an ACL injury history had significantly lower peak knee valgus angles (MD, 1.3°; 95% CI [0.0, 2.6]) and lower valgus angles at initial contact (MD, 1.2°; 95% CI [0.1, 2.3]) as compared to injury free players. Also, they showed significantly lower peak knee flexion moments (MD, 0.31 Nm/kg; 95% CI [0.16, 0.45]), knee abduction moments (MD, 0.27 Nm/kg; 95% CI [0.13, 0.41]) and knee internal rotation moments (MD, 0.06 Nm/kg; 95% CI [0.00, 0.11]). For the non-injured leg and for knee flexion angles, no differences were found.
CONCLUSION: 3.7 years after an ACL injury, female elite athletes still, unintentionally or intentionally, unload their previously injured leg. These loading alterations might be part of the explanation for why players with previous ACL injury are at elevated risk of sustaining a new secondary ACL injury.

### ASSOCIATIONS BETWEEN VELOCITY AT DIFFERENT RELATIVE INTENSITIES IN THE SQUAT EXERCISE, PHYSICAL PERFORMANCE, AND TENSIOMYOGRAPHY.

BACHERO-MENA, B.1, ALCAZAR, J.2, PÁEZ-MALDONADO, J.1, CORNEJO-DAZA, P.J.3, SÁNCHEZ-VALDEPEÑAS, J.3, RODILES-GUERRERO, L.1, SÁNCHEZ-MORENO, M.1, PAREJA-BLANCO, F.3

*<1> UNIVERSITY OF SEVILLE; <2> UNIVERSIDAD DE CASTILLA-LA MANCHA; <3> UNIVERSIDAD PABLO DE OLAVIDE*

INTRODUCTION: The force-velocity (F-V) relationship in the squat (SQ) exercise has recently increased its popularity since it provides a unique means of viewing the whole individual performance spectrum in a single action (1,2). This study aimed to compare the relationships between velocity at the different percentages of one-repetition maximum (%1RM) in SQ and physical performance and muscle contractile properties.
METHODS: One hundred and seven strength-trained men (≥2 years of experience in the SQ) participated in the study. Tests were performed in the following order: 1) tensiomyography (TMG) measurements of the vastus lateralis (VLA) and medialis (VME) muscles at rest; 2) countermovement jump (CMJ); 3) maximal voluntary isometric contraction (MIF) in SQ; and 4) progressive loading test in SQ. The relationships between variables were determined using Pearson's coefficients (r) and 95% CI. Velocity values described for each %1RM correspond to mean propulsive velocity.
RESULTS: Significant correlations ($p<0.001$) were found between velocity at different %1RM, being the highest associations between velocities at near %1RM. No correlations were found between velocity at low %1RM (0-30%) and velocity at high %1RM (80-100%) (all $p>0.05$), while velocities at medium %1RM (40-70%) were associated to those observed at low (r=0.28-0.84) and high %1RM (r=0.38-0.98) (all $p<0.05$). Significant correlations were found between velocity at low and medium %1RM and CMJ (r=0.23-0.48, $p<0.01$). Regarding maximal strength, significant correlations were found between velocity at low %1RM and 1RM (r=0.23-0.45), MIF (r=0.22-0.34), and RFDmax (r=0.27-0.35) (all $p<0.05$). In addition, significant relationships were observed between velocity at any %1RM and velocity reached against 20 and 60 kg (r=0.31-0.92; all $p<0.05$), showing a decreased correlation as %1RM increased. No associations were observed between velocity at any %1RM and tensiomyography data of the VLA and VME muscles (all $p>0.05$).
CONCLUSION: Our findings suggest that velocity at which a specific %1RM is lifted is related to velocity with loads at near %1RM, but as it gets further from this %1RM, the correlation disappears. In this sense, the performance achieved against a specific load (i.e low load) does not seem to be explained by the same factors that would explain performance with another different load (i.e high load). In addition, the physical performance variables analyzed were more related to velocity at low %1RM (0-30%).

### DEVELOPMENT AND EVALUATION OF A HORIZONTAL SQUAT JUMP TEST TO MEASURE THE PEAK PUSH-OFF VELOCITY IN ACYCLIC LOWER LIMB EXTENSION

VOLK, N.R., FERRAUTI, A.

*RUHR UNIVERSITY BOCHUM*

INTRODUCTION: The restricted range of velocity measures during vertical force-velocity profiling has been questioned [1, 2]. Lower limb extension velocities assessment beyond 60%V0 have been examined using customized force plates on a wall [3] or a modified leg press [4]. Therefore, this study aimed to assess the reliability and validity of the horizontal squat jump push-off (HoPu) with a linear velocity transducer (LVT) to make it accessible for the practitioner.
METHODS: 28 healthy male (n=18) and female (n=10) sports students volunteered in a test-retest design. Participants were placed supine on a roller device, maintaining an individual preferred knee angle with their feet against a perpendicular wall before maximal lower limb extension. Peak push-off velocities were measured on a typical indoor sports floor using a double pulley with an LVT (100Hz). Further, a motorized resistance device (MRD, 333Hz) was attached parallel to the board to obtain peak velocity and peak force values. Additional

assessments of vertical squat jump (SJ) and maximal isometric force output (MVIC) matching the HoPu push-off position were performed. Repeated measures ANOVA was used to account for relative within-session (ICC2,5), relative between-session (ICC2,1), and absolute (SEM, CoV) test-retest reliability. Peak velocity measurements of both devices were compared (100 Hz vs 333Hz) for external validity.
RESULTS: Both the MRD and the LVT showed an excellent within-session (ICC2,5: 0.95-0.98 [0.92-0.99]; SEM-MRD: 0.08, SEM-LVT: 0,02, CoV: 2%) and a good-to-excellent between-session (ICC2,1: 0.79-0.86 [0.61-0.93]; SEM-MRD: 0.08, SEM-LVT: 0,03, CoV: 3%) reliability. Between-device comparison for mean peak velocity from both devices demonstrated no significant difference with a mean bias of 0.005 m*s-1. HoPu resulted in significantly higher take-off velocities compared to SJ (+34%), very close to V0. Force values were maximized during MVIC and lowest during the HoPu.
CONCLUSION: Both devices were able to measure peak push-off velocities accurately. The results point to sufficient reliability and construct validity of the HoPu for assessing the maximal acyclic lower limb velocity extension capacities with both an MRD and an LVT combined with a pulley hoist. The HoPu demonstrates a possibility to quantify the ability of the neuromuscular system to develop force at extremely high lower limb contraction velocities. This information can extend the possibilities of force-velocity profiling, notably of force production capabilities at high velocities.

### KNEE AND HIP JOINT ANGLES DURING SQUAT EXERCISE IN NATURAL AND ARTIFICIAL GRAVITY

AVILA-MIRELES, E.J., BABIC, J., MEKJAVIC, I.B., SORRENTINO, R., FISHER, J., MCDONNELL, A.C.
*INSTITUT JOZEF STEFAN*

INTRODUCTION: Long duration space flight-induced muscle atrophy is a major concern during prolongued space missions. Replacing the loss of the natural gravity (NG) vector with centrifugal forces generated by a short arm human centrifuge (SAHC) has been proposed as a viable muscle atrophy mitigation strategy. SAHCs allow squatting by means of an adjustable sliding sledge. This study investigated the biomechanical differences between squatting under normal (NG) and artificial (AG) gravity conditions.
METHODS: The study was conducted at the ESA Ground Base Facility »PlanHab« (Rateče-Planica, Slovenia). A total of 10 subjects performed 3 sets of 6 timed squats in the upright position (NG), and in the supine position on a bespoke sledge system on the SAHC (AG) with 1 minute rest between sets. The total time of centrifugation was 10 minutes per subject with the AG set at 1.5G at heart level. An Xsens Awinda motion capture system was used to record subjects movements at a rate of 60Hz, and the joint angles of the knees and hips extracted and analysed.
RESULTS: During NG, the joint trajectories of both knees and hips were consistent during all of the squatting sets. However, for the first squat under AG, the knee and hip joint angles presented oscillations of up to 2° during the flexion. Further, at the deepest squat position, the joint angle oscillations were 14° at the knee and 13° at the hip just prior to initiating extension. These oscillations were not present during the extension movement, nor at any other stage of the movement from the third squat on. The average knee joint (15° to 101°) and hip joint angles (19° to 84 for left hip, and to 88° for right hip) for the remaining squats indicate a shortening of the overall movement pattern. While in the NG condition, the joint angles for the knee ranged between 3° to 119° and from 6° to 123° for the hip.
CONCLUSION: The joint oscillations present on the first AG squat may be attributed to a transient adaptation to the distortion of subjects center of mass displacement induced by a novel gravity vector and possibly the movement interference caused by the sledge. The main differences were present during the lowering phase of the squatting movement. The difference between the left and right hip trajectories may be a consequence of the load difference due to Coriolis forces and spin direction. Development of an exercise strategy on the SAHC requires further analysis of muscle activation during the exercise.
This study was supported, in part, by the European Space Agency and the Slovene Research Agency.

### DOES MOVEMENT SMOOTHNESS DURING WALKING DIFFER BETWEEN POLYNEUROPATHY PATIENTS AND AGE-MATCHED HEALTHY CONTROLS?

WALZ, I.D.1, WAIBEL, S.1, HUCKER, P.2, LIPPI, V.1,4, GOLLHOFER, A.3, MAURER, C.1
*1, 2, 4 MEDICAL CENTER – UNIVERSITY OF FREIBURG, FACULTY OF MEDICINE, UNIVERSITY OF FREIBURG, FREIBURG ; 3 UNIVERSITY OF FREIBURG, FREIBURG, GERMANY.*

INTRODUCTION: Walking is a complex sensorimotor behaviour, which is usually characterized by spatio-temporal and rhythmic parameters, while the quality of movement execution, e.g. smoothness, has rarely been considered [1]. Smooth movements might reflect a well-coordinated neuromuscular activity and are particularly economical regarding energy expenditure [2]. In order to separate movement smoothness from effects of movement amplitude and velocity covered by conventional gait parameters, some authors suggest corrections for amplitude and velocity effects, leading to e.g. smoothness spectral arc length (SPARC), or log-dimensionless jerk (LDLJ) [3,4]. Our study's purpose is to evaluate smoothness aspects of gait in patients with sensorimotor dysfunctions, i.e. polyneuropathy (PNP).
METHODS: We recorded whole-body movements of 20 PNP patients and a matched healthy control group (CG, n=20) during fast walking (≤10 steps) via a marker-less, vision-based motion capture system. We calculated movement smoothness of 11 segments (left/right ankle, knee, hip, shoulder, elbow, center of mass (COM)) using SPARC and LDLJ. Mean values of step cycles were statistically analysed (non-parametric testing). Subsequently, conducted a principal component analysis (PCA) including all segments for both groups.
RESULTS: Compared to CG, PNP patients' movements are less smooth in terms of LDLJ as they showed a significantly higher LDLJ in all segments ($p<.023$). Concerning SPARC, the PNP group was less smooth at COM ($p<.001$), right knee ($p=.005$), and right hip ($p=.001$). LDLJ values across segments correlated highly, which corresponds to the first principal component (PC) covering ≤89% of the entire variance of data. SPARC variance across segments, both in CG and PNP, converged to three major PCs with the first covering about 40%. In CG, rotated PC 1 accounted for lower limbs, COM, left elbow, but without the left knee and ankles. PC 2 accounted for upper limbs and left knee. In PNP, PC 1 accounted for all upper joints and COM. PC 2 accounted for lower limbs and COM without ankles. PC 3 in CG and PNP covered both ankles.
CONCLUSION: Since PNP patients' proprioceptive feedback is impaired, it seems plausible that their movement execution is less smooth compared to CG. The parameters SPARC and LDLJ appear to address different dimensions of smoothness. LDLJ characterizes overall smoothness differences between PNP and CG while SPARC seems to uncover different movement patterns in terms of segmental coupling. More specifically, PCA of SPARC in PNP reveals a smoothness pattern along the body axis (upper limbs, proximal lower limbs, and ankles),

while for CG, PCA delivers a diagonal pattern. Thus, analysing smoothness patterns reveals movement abnormalities in PNP, which are not covered by spatio-temporal and rhythmic parameters.

### PROBING THE LINK BETWEEN CORTICAL INHIBITORY AND EXCITATORY PROCESSES AND MUSCLE FASCICLE DYNAMICS

LAUBER, B.

*UNIVERSITY OF FRIBOURG*

INTRODUCTION: Goal-directed voluntary human movements require refined levels of neural drive generated by the interplay between the activity of cortical excitatory and inhibitory neurons. This neural drive is descending from the motor cortex via the corticospinal pathway to the motoneurons ultimately activating the muscle(s) resulting in muscle fiber shortening. Previous studies either concentrated on neural or on mechanical aspects but information about the relationship of neural activation and muscle fiber behavior is scarce. This study investigated cortical excitatory and inhibitory processes in relation to muscle fascicle dynamics during isometric explosive contractions.
METHODS: Fourteen adults performed submaximal and maximal explosive dorsiflexions. Single and paired pulse transcranial magnetic stimulation of the tibialis anterior (TA) was applied during rest, the activation and deactivation phase of submaximal explosive contractions to test for short- (SICI) and long-interval intracortical inhibition (LICI) and intracortical facilitation (ICF). Furthermore, to relate the measures of cortical activity with muscle fascicle behaviour, B-mode ultrasound images were taken during submaximal as well as maximal explosive contractions to measure muscle fascicle dynamics of the superficial (TASF) and deep (TADP) TA compartments.
RESULTS: The results show significantly greater maximal shortening velocities ($p = 0.003$) and greater maximal fascicle shortening ($p = 0.003$) in TASF than TADP during submaximal dorsiflexions. Significantly lower SICI levels during activation compared to deactivation ($p = 0.019$) and at rest ($p<0.0001$) were observed. ICF was significantly greater during activation ($p = 0.03$) than during rest while LICI did hardly modulate. Maximal TASF but not TADP shortening velocity was associated with SICI levels at activation ($p = 0.06$) and correlated with the rate of torque development ($p = 0.02$).
CONCLUSION: The present results suggest a strong coupling between SICI and TA muscle fascicle behavior. the present study shows movement-phase dependent modulations in cortical excitatory (ICF) and inhibitory processes (SICI, LICI) during explosive isometric dorsiflexions. Noteworthy, GABA-A mediated inhibition (SICI) shows the strongest modulations. Furthermore, we show that a reduction in the level of GABA-A mediated cortical inhibition is associated with the fascicle dynamics of the superficial compartment of the TA.

### EFFECT OF COMBINED ELECTRICAL STIMULATION AND MUSCLE LENGTHENING ON TORQUE DEVELOPMENT

PINEAU, A., MARTIN, A., LEPERS, R., PAPAIORDANIDOU, M.

*LABORATOIRE INSERM U1093 - CAPS*

INTRODUCTION: Neuromuscular electrical stimulation (NMES) can elicit muscle contractions through peripheral and central pathways. Peripheral pathways consist of motor axons' depolarization, whereas central pathways involve depolarization of sensory axons. The use of wide-pulse duration delivered at low stimulation intensities results in contractions mainly originating from a central pathway and gives rise to the phenomenon of extra torque (ET), which is characterized by an additional torque of what would be developed through peripheral pathways (1). The reflex activation of spinal motoneurons likely proceeds to a more physiological motor units' recruitment following Henneman's size principle and may hence be promising in rehabilitation since it can induce less fatiguing contractions (2). However, the occurrence of ET is not present for all subjects (3). Combining a technique that enhances the activation of these afferent pathways, such as muscle lengthening (LEN) (4), could facilitate ET generation. The study aimed to evaluate the effect of the combination of these two modalities (NMES + LEN) on torque development and to examine the associated neuromuscular changes.
METHODS: Fourteen subjects participated in a unique experimental session consisting of 20-s stimulation trains delivered over the tibial nerve at 20 or 100 Hz (1-ms pulse duration, intensity set to initially evoke ~10% of maximal voluntary contraction). During these stimulation trains, the ankle joint was either moved (180°/s) from a stretched position (80°) to the reference position (90°) (shortening, SHO), either from a shortened position (100°) to the reference one (lengthening, LEN) or maintained constant at 90° (isometric, ISO). For all stimulation trains, the torque-time integral (TTI) was calculated (TTILEN, TTISHO, TTIISO) and was expressed as a percentage of the TTI of ISO condition. Spinal excitability, assessed by the maximal H-reflex (Hmax) normalized with respect to the maximal M-wave (Mmax), was evaluated at rest, before and after each stimulation train.
RESULTS: Results showed that TTILEN was significantly higher than TTISHO during low-frequency NMES ($P<0.05$), while there were no significant differences during high-frequency NMES. Spinal excitability remained unchanged after the stimulation trains for both frequencies.
CONCLUSION: These results indicate that low-frequency NMES combined with LEN increases the developed torque, while there is no effect of superimposed LEN with high-frequency NMES. A possible explanation is that the combination of LEN with high-frequency NMES induced a saturation of the afferent pathways limiting further torque increase. The unchanged spinal excitability suggests that inhibitory and facilitatory phenomena at the spinal level were similarly modulated by both low and high frequencies.

### MODULATION OF TORQUE INDUCED BY WIDE-PULSE, HIGH-FREQUENCY NEUROMUSCULAR ELECTRICAL STIMULATION: IMPLICATION OF PERSISTENT INWARD CURRENTS?

POPESCO, T., ANDREOTTI, G., DULAC, L., DONNELLY, C., PLACE, N.

*UNIVERSITY OF LAUSANNE*

INTRODUCTION: Wide-pulse high-frequency neuromuscular electrical stimulation (WPHF NMES) favors a reflexive recruitment of motor units at the spinal cord level by the depolarization of large diameter sensory afferents at low stimulation intensity. WPHF NMES has been observed to evoke a progressive increase in torque during the stimulation ('extra torque' (ET)), which occurs in ~60% of individuals (Wegrzyk et al., 2015). However, the mechanisms responsible for ET production remain largely unknown. The main hypothesis is the potential contribution of persistent inward currents (PICs), which are depolarizing currents that can amplify motoneuronal synaptic inputs (Heckman & Enoka, 2012). Similarities between the development of PICs and ET in response to WPHF NMES support the hypothesis of a link between the two mechanisms.
Thus, any intervention aiming at modulating ET production in response to WPHF NMES should also modulate PIC strength. The aim of this study is to test the hypothesis that a remote contraction (i.e. contraction of an unrelated muscle) would increase ET during WPHF NMES of the plantar flexors because of enhanced PIC strength.
METHODS: Twenty five healthy volunteers (26 ± 6 years, 7 women and 18 men) took part to the protocol. Participants were asked to perform an isometric triangular contraction with their plantar flexors (0-20-0% of maximal voluntary contraction (MVC) torque). The intensity of stimulation necessary to evoke 10% of MVC torque using WPHF NMES (1 ms, 100 Hz) was determined with 1-s stimulation trains and trains of 20 s of WPHF NMES were delivered at this intensity. High-density electromyography (HD EMG) of the gastrocnemius medialis (GM) and the soleus (SOL) muscles was recorded. The experiment was performed in two conditions: Control and Remote condition, where the participants sustained an isometric elbow flexion at 20% of MVC torque.
ET was calculated as the variation (%) between the last s and the first s torque during WPHF NMES. Participants with a positive ET value were considered as 'responders'. Estimates of PICs were calculated using HD EMG recordings with the DeltaF technique (Gorassini et al., 2002).
RESULTS: ET was lower in Control compared to Remote (median ±SD: +15 ±113 and +55 ±180%, p=0.003). The percentage of responders increased from 60 (Control) to 80% (Remote) of the tested sample. DeltaF was not different between Control and Remote for SOL (mean ±SD: 1.40 ±1.39 and 0.74 ±1.90 Hz, p=0.278) and GM (1.12 ±1.34 and 0.96 ±2.47 Hz, p=0.721).
CONCLUSION: Our results show that WPHF NMES ET can be enhanced by a remote contraction and that the occurrence of responders can be increased, which supports the central origin of ET in WPHF NMES. Although these findings may open new therapeutic strategies, our results do not support a direct link between PIC estimates and ET in response to WPHF NMES.

### NON-INVASIVE MUSCLE BIOPSY: ESTIMATES OF MUSCLE FIBER SIZE FROM A NEUROMUSCULAR INTERFACE

CASOLO, A.1,2, MAEO, S.3,4, BALSHAW, T.G.4, NUCCIO, S.5, MORO, T.1, PAOLI, A.1, FELICI, F.5, FOLLAND, J.P.4, FARINA, D.2, DEL VECCHIO, A.6

*1 UNIVERSITY OF PADUA; 2 IMPERIAL COLLEGE LONDON; 3 RITSUMEIKAN UNIVERSITY; 4 LOUGHBOROUGH UNIVERSITY; 5 UNIVERSITÀ DEGLI STUDI DI ROMA FORO ITALICO; 6 FRIEDRICH-ALEXANDER UNIVERSITY*

INTRODUCTION: The gold-standard technique to assess fiber size and composition is muscle biopsy. However, although safe and reliable, it is characterized by some degree of invasiveness, and more importantly it provides morphological information dissociated from the neural control of the sampled muscle fibers (1). Due to its purported linear relation with muscle fiber diameter, motor unit conduction velocity (MUCV) may be adopted as an alternative physiological parameter to assess muscle fiber properties non-invasively in humans. This relation has been assessed in animal models (2), in humans through intramuscular EMG and electrically-stimulated contractions (3-4), or it has been mathematically-derived from separate datasets, as in Stålberg's seminal work (5). Here we systematically explored the relation between MUCV of large and representative populations of motor units (MU) and muscle fiber diameter derived from muscle biopsies.
METHODS: Twenty-nine healthy volunteers (age: 21.9±3.2yr; body mass: 82.1±13.9kg) completed linearly increasing isometric elbow flexions at forces up to 70% of maximum, whilst high-density surface EMG signals were recorded from biceps brachii and in turn decomposed into MU discharge timings. The mean (MUCVmean), minimum (MUCVmin), and maximum (MUCVmax) MUCV value of 701 MU was estimated in the ascending phase of the ramp contractions. The diameters of 5619 muscle fibers (MFDmes) were derived from muscle biopsies. We fitted Stålberg's original equation (5) with our experimentally-derived MFDmes data and estimated muscle fiber diameters (MFDest). In particular, we iteratively changed the two normalization parameters of the original equation and computed the Euclidean distance between the two distributions, which were fitted with gaussian distributions
RESULTS: Correlation analyses revealed positive linear associations between the minimum, maximum and mean MFDmes and minimum ($r=0.75$, $P < 0.001$), maximum ($r=0.80$, $P < 0.001$) and mean ($r=0.81$, $P < 0.001$) MFDest at the individual subject-level. Additionally, when we pooled data from all participants with a different training status, the proposed novel methodology was able to predict with high accuracies the distribution histograms of the MFDmes (90.8 ± 19.6 µm) from the MFDest (90.8 ± 19.7 µm) estimated from MUCV values.
CONCLUSION: We revealed the possibility to predict with high accuracy the minimum, maximum and mean muscle fiber diameter from an EMG-derived parameter, i.e. MUCV, at the individual subject level in healthy individuals. Thus, MUCV may be considered a novel non-invasive marker of muscle fiber size that could be adopted as an alternative to the more invasive biopsy sampling, therefore opening new avenues for research in aging, training and neuromuscular diseases.

**LOWER EXTREMITY MUSCLE ACTIVITY DURING WALKING AT DIFFERENT SPEEDS: THE QUADRICEPS CHANGE MOST**

KAWAKAMI, Y., WU, J., AOKI, R., SHIOTANI, H.

*WASEDA UNIVERSITY*

INTRODUCTION: Impairment of walking performance is linked to the loss of mobility of the elderly, and caused by the deterioration of muscle strength in the lower extremity [1]. To know the muscles responsible for walking performance, we need to clarify the loads imposed on the muscles engaged. In the present study, muscle loading was evaluated for the thigh and lower leg during walking under a wide variety of speed.
METHODS: Twenty healthy adults (10 women and 10 men, 24 ± 3 yr) voluntarily participated. Each subject walked on a treadmill (level surface) at the speed from 0.6 to 2.0 m/s (increased by 0.1 m/s). During walking, the subject reported her/his most preferrable walking speed. Surface electromyogram (EMG) was recorded from the vastus lateralis (VL) and medialis (VM), rectus femoris (RF), biceps femoris (BF, long head), semitendinosus (ST), tibialis anterior (TA), gastrocnemius medialis (GM) and lateralis (GL), soleus (Sol) of the right side. Each EMG amplitude was normalized to the value at the preferred speed. Pressure sensors on the right shoe insole detected the heel contact and toe off in the stance phase, and the walking cycle was divided into early and late stance, and swing phases. Repeated measures (speeds) and factorial (muscles) ANOVA was applied to detect the main effect and interaction with $p<0.05$ being significant, and Bonferroni corrected multiple comparisons were performed where applicable.
RESULTS: The preferred walking speed was 1.16 ± 0.16 m/s and 1.22 ± 0.18 m/s for women and men, respectively with no significant difference. There was a significant main effect of speeds as well as muscles, and their interaction was also significant in all (early stance, late stance, and swing) phases of walking. When EMG data were pooled for women and men, their amplitudes showed exponential increases. Its magnitude was largest / smallest for VM (404%@2.0m/s) / GM (169%) in the early stance phase, VM (572%) & RF (612%) / MG (190%) in the late stance phase, and VM (350%) / Sol (216%) in the swing phase, respectively. At speeds lower than preferred, the above tendency was reversed and VM, VL and RF showed smaller activities.
CONCLUSION: Results suggest that the increase in walking speed is achieved by systematic but inhomogeneous increases in muscle activity in the lower extremity. At higher speeds, the quadriceps (VM in particular) are activated remarkably and vice versa at lower speeds, indicating that these muscles sensitively change their activation in response to the motor command to control walking speed. It is therefore likely that in daily normal walking at preferred or slower speed, the quadriceps are not adequately activated, which can be associated with the specific atrophy of these muscles in the elderly [2]. In contrast, the quadriceps come into play during brisk walking, and this type of exercise would favor prevention of sarcopenia and health promotion in the elderly.

**NEURAL AND CONTRACTILE DETERMINANTS OF BALLISTIC (BURST-LIKE) CONTRACTIONS OF KNEE EXTENSORS**

DEMANUELE, S.

*UNIVERSITY OF VERONA*

INTRODUCTION: Human locomotion has been described as generated by an impulsive (burst-like) excitation of muscle groups (1). The activation profiles are Gaussian-shaped curves (2) without any holding phase. The timing and shape of force production during ballistic contractions is crucial. To elucidate the neuromuscular determinants of rate of force development (RFD) some studies adopted ballistic contractions with various durations from ≈1 to 3 s (3, 4). Neural and contractile determinants of purely explosive contractions (≈ 200 ms) without holding phase are unknown although it is relevant in human locomotion and also for sporting tasks and daily activities.
The aim of this work is to investigate the neural and contractile determinants of time-locked force (50, 100, 150 ms) and in RFDpeak in burst-like isometric knee extensions through High Density surface Electromyography (HDsEMG) and electrically evoked contractions to elicit the maximum RFD.
METHODS: 24 (5 females) healthy adults performed 10 purely explosive isometric knee extension interspersed with 3 s rest. Voluntary sequential force (50 ms epochs), RFDpeak and maximal voluntary force (MVF) were assessed. HDsEMG was recorded from vastus lateralis and medialis muscles with two grids of 64 electrodes. We evaluated the contractile and EMG responses in voluntary and electrically evoked stimulation with twitch and octets (8 stimuli delivered at 300 Hz). Pearsons correlation and linear stepwise regression analysis were used to assess the significant determinants of force in the various time blocks of voluntary contractions (F50, F100, F150) and for RFDpeak.
RESULTS: For F50 the adjusted R2 was 0.361 ($p=0.001$) explained by RMS. For F100 was 0.646 ($p<0.001$) explained by RFD octet and for F150 was 0.711 ($p<0.001$) explained by MVF and 0.061 ($p=0.016$) by RFD octet. For RFDpeak the adjusted R2 was 0.518 ($p<0.001$) explained by the MVF and another 0.074 ($p = 0.036$) explained by RMS.
CONCLUSION: Accordingly with previous evidence (3,4), the present findings suggest that the burst-like isometric force production exhibited different neural and contractile determinants depending on the considered force-time intervals. The first 50 ms of a purely explosive contraction are explained by neural determinants, at 100 ms by contractile determinants and at 150 ms the combination of both. Moreover, the RFDpeak is explained for the most part by contractile determinants and to a small share by neural determinants.

### COACHING JUDO FOR OLDER ADULTS: RESULTS FROM SEVEN NATIONAL FOCUS GROUPS

CIACCIONI, S.1, CAPRANICA, L.1, PALUMBO, F.1, SACRIPANTI, A.2, TESSITORE, A.1

*1.UNIVERSITY OF ROME "FORO ITALICO"; 2.INTERNATIONAL JUDO FEDERATION ACADEMY FOUNDATION, MALTA.*

(co-authors) Forte, R., Galea, E., Kozsla, T., Milne, A., Lampe, N., Lampe, S., Jelusic, T., Bradic, S., Lascau, M., Rodica-Borza, A., Camacho Pérez, R., Diéguez Rodríguez-Montero, F., Kapan, M., Gezeker, K.

Introduction

To counteract the negative secular trend of global sedentary behaviours the promotion of novel interventions of physical activity in advancing age are needed [1]. A crucial aspect of coaching is to ensure health and safety of participants, especially those experiencing age-related functional declines [2]. The purpose of this study was to provide eminence-based knowledge on judo coaching for older adults.

Methods

Between May and October 2021, seven focus groups were organized in Croatia, Italy, Malta, Romania, Slovenia, Spain, Turkey encompassing a four-step process: 1) definition of research questions, procedures, data processing; 2) purposeful experts' sampling of the scientific/judo communities; 3) participants recruitment through invitation letter and informed consent; 4) data gathering, analysis, summary, collation. Seventy-eight (F=29.5%) academic and technical experts in geriatrics, psychology, physiology, nutrition, medicine, kinesiology, and combat sports volunteered for the study.

Results

The 262 collected items were organized in five themes: 1) judo benefits (N=83, 31.7%); 2) training information (N=58, 22.1%); 3) risk prevention/management (N=50, 19.1%); 4) older practitioner groups definition criteria (N=33, 12.6%); 5) tools/tests/measurements (N=38, 14.5%). The items deemed most important were related to physical (N=16, 3%; e.g., fitness, constitution, limitations), tests (N=16, 3%; e.g., technical, balance, stress), and social (N=9, 2%; e.g., family, environment, relations) aspects. For health issues, other relevant aspects (N=12, 4.6%) were: diabetes, bone, and blood pressure. Other significant information involved training (N=6, 2.3%; e.g., safety, adjustments, intensity), status (N=11, 4.2%; e.g., psychophysical and social), and sports (N=5, 1.9%; e.g., lifetime sport participation).

Discussion

The present cross-national qualitative study synthesized the experts' perspectives about the most relevant content of an educational programme for judo coaches of older practitioners. These findings will be used to create a sound educational content for judo coaches to ensure optimal supportive programmes for individuals approaching judo with advancing age [3].

### AN INVESTIGATION INTO THE GAIN IN KNOWLEDGE OF, ATTITUDES TOWARDS AND CONFIDENCE TO DELIVER A GAMES-BASED PHYSICAL LITERACY CONCEPT IN PRACTITIONERS ACROSS THE UK

WING, K., DE STE CROIX, M., ROBERTS, W., BAKER, C.

*UNIVERSITY OF GLOUCESTERSHIRE*

INTRODUCTION: It is well recognised that practitioner education could impact on a learners Physical Literacy (PL) and subsequent Physical Activity (PA) throughout life [1]. Boing is a workshop-based programme that aims to help practitioners develop children's PL through active play. However, the impact on practitioners is unknown. Therefore, the aims of this study was to explore current knowledge of, attitude towards, and confidence to deliver PL and investigate changes following the programme.

METHODS: 926 practitioners (coach educators, teachers, coaches, volunteers and other facilitators) from 45 organisations were recruited. Two sequential validated questionnaires exploring perceived knowledge, attitude towards and confidence to deliver the Boing programme were completed prior to and immediately post a 90-minute interactive online workshop. Variables were scored on a Likert scale (1-very poor, 5-very good). Potential changes elicited were assessed using Wilcoxon signed-rank tests for non-parametric data. Rank-biserial correlation [r] was utilised to calculate the effect size based on existing criteria [2]. Chi-square tests explored differences between organisations. The alpha level was set at 0.05 a priori.

RESULTS: 738 participants completed both questionnaires (community focused n=337, sport/sporting governance n=130, education providers n=125, wider facilitators of physical activity n=146). Perceived knowledge and confidence before the workshop were poor across all organisations (2.2±1.1; 2.4±1.2) however attitude was apathetic (3.0±1.2). Significant differences in attitude between organisational groups before training was evident (p=0.01) whereby sporting organisations frequently reported more positive attitudes towards PL. The majority of practitioners (82%) were not aware of any programmes to develop PL. Participants on average agreed strongly that they needed a greater understanding of exercises and games that can improve physical activity (87%); how to implement PL into sessions (77%); and how to design fun games (88%). Increases pre/post were statistically significant ($p<0.001$) with large positive effect sizes: knowledge ($r= 0.99$ [95% CI = 0.98 – 0.99]), confidence ($r= 0.98$ [95% CI = 0.98 – 0.99]) and attitude ($r= 0.96$ [95% CI = 0.95 – 0.97]). The majority of participants (90%) reported intention to implement the programme.

CONCLUSION: Given that current knowledge, confidence, and awareness of PL among practitioners is poor; intervention is needed. Current attitude differed between organisations however this was not reflected in knowledge and confidence. Practitioners clearly identified a need for education. It is evident the workshop developed knowledge, confidence and attitude which was reflected in intention to implement. Follow-up is needed to explore if the positive changes in practitioners' confidence and intention translates into impacting on learners PL and subsequent PA.

## EFFECTS OF A SCHOOL-BASED PHYSICAL EDUCATION INTERVENTION ON INCREASING PHYSICAL ACTIVITY LEVELS IN CHILDREN FROM MARGINALIZED COMMUNITIES IN SOUTH AFRICA

ARNAIZ, P., DOLLEY, D., JOUBERT, N., MÜLLER, I., WALTER, C., PÜHSE, U.

*UNIVERSITY OF BASEL*

INTRODUCTION: While non-communicable diseases (NCDs) tend to appear in adulthood, most risk factors develop at a young age and are preventable through healthy, active lifestyles (1). Results from South Africa (SA) show that many children, particularly from marginalized communities, do not achieve the minimal requirements of physical activity (PA) (2). Moreover, physical education (PE) is no longer a stand-alone school subject in SA. Thus, primary schools present unique opportunities for interventions to increase PA among schoolchildren and decrease their risk for NCDs (3).
METHODS: Within "the KaziBantu model (Healthy Schools for Healthy Communities)" we developed KaziKidz, an educational toolkit to bring PE to public primary schools. KaziKidz was implemented between February and October 2019 as a clustered randomized controlled trial in 8 primary schools from low resourced settings in the Eastern Cape of SA. Children between 8 and 13 years of age wore the ActiGraph automated accelerometry device (wGT3X-BT) around the waist for 7 consecutive days to assess the effect of the intervention on PA levels. Repeated measures analyses of variance (rANOVAs) were performed to examine changes in the outcome variables from baseline to post-intervention.
RESULTS: Baseline results showed that 35.6% of children did not meet the WHO recommended daily 60 minutes of moderate to vigorous PA (MVPA). During the school day, a significant decrease in sedentary behaviour was observed both for the control ($F(1, 435)=44.32$, $p<0.001$, $\eta2 = 0.09$) and intervention ($F(1, 425)=18.57$, $p<0.001$, $\eta2 = 0.04$) groups. Interestingly, while a moderate significant increase was observed for the control group in light PA ($F(1, 435)=30.65$, $p<0.001$, $\eta2 = 0.07$) but not for the intervention group ($F(1, 425)=0.43$, $p=0.513$, $\eta2 = 0.01$), the intervention group showed a significant increase of large effect size on MVPA ($F(1, 425)=72.24$, $p<0.001$, $\eta2 = 0.15$) that was only moderate for the control group ($F(1, 435)=53.11$, $p<0.001$, $\eta2 = 0.11$). However, between-group analyses showed no statistically significant differences between the control and intervention groups post-intervention both for sedentary ($p=0.67$) and MVPA ($p=0.07$).
CONCLUSION: While PA levels increased throughout the study population, the KaziKidz intervention appears to promote daily minutes in MVPA during the school hours compared to light PA observed in the control schools. With increase in MVPA being associated with health benefits, it is important to identify opportunities throughout the day to promote MVPA in children, especially in disadvantaged settings where PA opportunities outside of school are scarce.

## MOTIVATIONAL MODELING OF SPORTS, EXERCISE, PHYSICAL ACTIVITY BEHAVIOURS AND SEDENTARY LIFESTYLES IN UNIVERSITY STUDENTS

SOOS, I., TEGLASY, G., WHYTE, I., BOROS, SZ.

*UNIVERSITY OF PHYSICAL EDUCATION AND SPORT SCIENCES, BUDAPEST; NATIONAL INSTITUTE OF HEALTH CARE OF SPORTS, BUDAPEST; INTERNATIONAL NETWORK OF SPORT AND HEALTH SCIENCES ; EÖTVÖS LORAND UNIVERSI*

Introduction
Motivational modeling of sports, exercise, physical activity behaviours, and sedentary lifestyles of young people are explained by varous theories, models and approaches. Amongst those, the Self-Determination Theory (SDT) and the Theory of Planned Behavior (TPB) are the most commonly used theories in the international literature. Our aim was to identify patterns of sports, regenerative/recreational exercise, and leisure-time physical activity in university sports students, and what motivational factors influenced their activities.
Material and method
Following ethical approval, 100 university students (60 female) were recruited. Thirteen identified as elite athletes and/or competitive athletes and 87 as recreational athletes and/or bodybuilders. Respondents ranged in age from 19 to 24 years (mean age = 21.4 years). Among them, 71 people played individual sports and 29 team sports, training 1-8 times per week for between 30 and 150 minutes per day. Motivational orientation was measured utilising seven-point validated Likert scales using 2 items from each of autonomy, competence and relationships from the SDT, and attitude, perceived behaviour control, and subjective norms of the TPB. IBM SPSS v.25 software package was employed to determine descriptive statistics.
Results
During the study period, the elite/competitive athletes trained 2-8 times a week and spent a mean of 105 minutes per day in training or competition. The recreational athletes/bodybuilder group, spent an average of 55 minutes per day on physical activity, with 30% doing it alone and 70% with peers, family or friends. Leisure-time physical activity was undertaken on average 3-4 days a week (mean 33 minutes per day). With respect to motivation, competence (mean = 5.27) was most important for regenerative/recreational exercise, with autonomy support (5.05) and relationship factors (4.75) being second and third respectively. Reviewing the information obtained from the Theory of Planned Behavior (contributions to the behavioural effect) perceived behavioral control (mean = 6.06) scored first, with attitude being second (5.52). Third rated was subjective norm resulting from the environmental influence (4.89). Young university athletes, reported that they received most support from their family (mean = 5.82), with support from friends (5.80) and coach (3.71) being the next most important respectively.
Conclusions
Young sports students in our sample were engaged in sports, exercise and physical activity in accordance with international recommendations, but we suggest that there is still a need to reduce the amount of time spent in sedentary activities. From a motivational perspective, it is important for their regenerative/recreational exercise to maintain competence, promote a positive attitude, and continue to receive autonomy support from family, friends, and coaches.

### THE IMPACT OF A YOGA TRAINING PROGRAM ON MUSCLE CONTRACTILE PROPERTIES IN ELITE SOCCER PLAYERS

PEREIRA, A., MADEIRA, R., MONTEIRO, L.

*UNIVERSIDADE LUSÓFONA DE HUMANIDADES E TECNOLOGIAS*

INTRODUCTION: Yoga challenges the body in many ways, and being a very different methodology to normal training, it can be an important complementary technique for more extensive training or even replace traditional methods, with a highly positive impact on football practice and training [1]. Considering the results showing the potential of Yoga to reduce perceived propensity to reduce injuries and general fatigue, its integration into football training can be considered [2]. Our hypothesis is that Football players undergoing additional Yoga training, improve the lower limbs muscles contractile properties[3,4].
METHODS: Twenty-one professional football players from the 1st Portuguese Football League, senior levels under-23 and B, voluntarily participated, divided into two groups: Intervention (IG), Control (CG), all of them being assessed by tensiomyography before training and after 12 weeks. IG practiced Yoga at the end of the training, during 12 weeks, 2 weekly Yoga sessions, 60 minutes/each, guided by a certified teacher with 40 years of experience. Yoga techniques were selected and ordered according to the objectives of the study: pránáyáma (breathing techniques), ásana (psychophysical techniques), yoganidrá (relaxation), samyama (concentration, meditation and so on).
RESULTS: Comparing the two groups after 12 weeks Yoga: IG and CG, verified statistically significant differences for the variables: left biceps femoris muscle (LBF): Time Contraction, Tc (ms), $t(14) = 2.690$, $p = .018$, (-13.06 vs 0.29); Time Delay, Td (ms), $t(14) = -2.593$, $p = .008$, (-1.16 vs 1.54); Displacement, Dm (mm), $t(14) = 3.879$, $p = .018$, (-2.17 vs 2.99); Contraction Velocity, BFE_Vc (mm/s), $t(14) = -3.851$, $p = .012$, (72.18 vs 12.91) with the evolution being significantly greater in GI. In the remaining muscles contractile properties there were no significant differences between the groups.
CONCLUSION: Results showed when comparing the two groups: the GI after Yoga shows a significantly higher evolution, contributing to the growing understanding of the impact Yoga can have on muscle contractile properties, allowing for hypothesis testing in future work.

### EFFECTS OF JUDO TRAINING ON WORKING MEMORY CAPACITY IN CHILDREN WITH ADHD

LUDYGA, S.1, LEUENBERGER, R.1, BRUGGISSER, F.1, MÜCKE, M.

*DEPARTMENT OF SPORT, EXERCISE & HEALTH, UNIVERSITY OF BASEL, BASEL, SWITZERLAND*

INTRODUCTION: Background: Children with ADHD show deficits in working memory capacity that affect academic performance and the ability to learn. Skill acquisition in judo places demands on visuospatial working memory and has the potential to promote related functions. We investigated the effects of 12 weeks of judo training on behavioral and neurophysiological indices of working memory capacity in children with ADHD. Method: 57 children with ADHD (aged 8-12 years) were randomized to a judo training group, who completed 120 min of judo per week over 12 weeks, and a wait-list control group. Before and after the intervention period, patients completed a Change Detection task demanding visuospatial working memory. Using electroencephalography, the contralateral delay activity elicited by the task was assessed as proxy for working memory capacity. Additionally, patients completed a motor test battery to measure balance and manual dexterity.
Results: In comparison to the control group, patients in the judo training group showed a higher K-score (indexing the number of items hold in working memory) following the intervention, when pretest scores were accounted for. Similarly the posttest contralateral delay activity was higher in the judo training group than the control group, after accounting for its amplitude prior to the intervention. In contrast, no differences between groups were observed in balance and manual dexterity.
Conclusion: A short judo training program promotes the ability to maintain visuospatial information in working memory in children with ADHD. An increase in the effectiveness of working memory processes seem to underlie these improvements in behavioral performance.

### METHODS: RESULTS: CONCLUSION: COMPARATIVE STUDY OF MOTOR PROFICIENCY AND COGNITIVE ABILITY IN ADOLESCENTS WITH AND WITHOUT LEARNING DISABILITY.

KLAVINA, A.

*LATVIAN ACADEMY OF SPORT EDUCATION*

Introduction.Development and maturation of body movements play a critical role in cognition of adolescents. Motor competence serves as a foundation for cognitive functioning in childhood and adolescence. This study aimed to explore motor proficiency and cognitive ability in adolescents with and without learning disability (LD). Methods. Participants were 17 adolescents with (LD) (13 males, age:13.21±2.01 years), and 28 adolescents without LD (9 males, age: 13.59± 1.42 years)
Motor abilities were assessed with the four subtests from Bruininks- Oseretsky Test of Motor Proficiency (BOT-2) including bilateral coordination, balance, strength, agility and running scores. The Vienna Test System's six subtests (Adaptive Matrice test, Cognitron, Determination test (DT), Figural Memory (FM) test, Stroop test and Reaction time (RT) test) were used to assess general intelligence, concentration, attention, stress tolerance and reaction time, respectively.
Results and Discussion.

Analysis of BOT-2 scores revealed significantly higher performance of adolescents without LD in balance and body coordination (p =.037 and p = .003, respectively). Regarding cognitive abilities, adolescents without LD had significantly higher results in General intelligence test (p = .047), in overall Cognitron test scores (p = 0.00 to .002), in short and long term memory test outcomes (p = .00) and Stroop test (p = .00). However, significant difference between the two groups were not found in stress tolerance and reaction speed test outcomes. Analyses of correlations between motor proficiency and cognitive ability scores revealed that 14 of a total of 32 correlations reached statistical significance for adolescents without LD. The strongest positive correlations were between DT scores presenting stress tolerance and ability correctly react under complex stimulus conditions and BOT-2 total scores (r = .441 to .501, p < .05). The moderate significant negative correlations were between reaction time and errors in reaction to stimuli and total BOT-2 scores, indicating that adolescents with higher motor proficiency scores needed less time and made fewer errors in RT test (r = -.495 to - .468, p <.05).
For adolescents with LD only 4 of a total of 32 correlations reached statistical significance including variables that indicates errors or incorrectly performed tasks, for example, in concentration performance negative significant correlation was between mean time spent on incorrect responses and BOT2, indicating that those students who in short time made more errors in the Cognitron test had better motor proficiency scores (r = -.527, p <.05). Regarding reaction to complex stimuli those students with LD who omitted more tasks had better BOT2 scores (r = - .580, p <.05).
Conclusions.
The data demonstrated that motor proficiency was positively correlated with several aspects of cognitive functions in adolescents without LD, while such relationships were not found in adolescents with LD.

**PROMOTING EXECUTIVE FUNCTIONS BY LINDY HOP DANCE TRAINING IN ADULTS**

BIRKLBAUER, J., PANKOTAI, C., MÜLLER, E.
*UNIVERSITY OF SALZBURG*

INTRODUCTION: Early development and lifelong promotion of executive functions (EF) have been identified as important goals of children's education and better aging. In young and older people, dance-based interventions have shown to be effective training programs to accomplish these objectives (e.g. 1, 2) as dancing poses demands on physical, cognitive and social functions by multisensory stimulation in an enriched environment. In this vein, we examined the efficiency of a 10-week Lindy Hop dance training on multi- and single-component measures of EF in healthy adults, which is an underrepresented cohort when additive cognitive benefits are concerned.
METHODS: In the experimental study with physically active adults aged 22-56 yrs (half females), 3 dance groups (n=39) practiced, on average, 3.5 h/wk Lindy Hop (half in teaching classes, half in free training) while matched controls (n=20) did not undergo any dance training. Beginners with little or no prior knowledge were instructed on the basic techniques and moves of Lindy Hop, intermediates that had already attended at least one basic class learned new moves and refined their basics while advanced dancers aimed to further improve and perfect their technique by new inputs and feedback. Pre- and post-performance on EF were assessed by 3 well-known assessment tools.
RESULTS: Planned contrasts (one-way ANOVA) on change scores from pre- to post-test revealed significant improvements of the 3 dance groups in contrast to the control group in the performance of the Design Fluency Task with 9.4%p more attempted designs (p=.004; d=2.62) and 8.2%p more correct designs (p=.041; d=1.62). Medium to large training effects were also found in the Trail Making Task but without conclusive evidence (total time part B-A: p=.232; d=0.83 and number of errors part B: p=.175; d=0.88). The intervention did not systematically affect the Stop-Signal Task performance (p=.990; d=0.01). Planned comparisons between beginners, intermediate and advanced dancers indicate similar intervention effects across dance levels in all three EF tasks (p>.330; d<0.41).
CONCLUSION: Our results extend the findings in children and elderly as they provide valuable indications that dance training like Lindy Hop dancing is a promising recreational activity for the improvement of EF even in healthy adults. This is particularly remarkable since the studied cohort consisted of already previously physically active subjects with a high level of education and a pre-test performance on the DFT of about 1 SD above the norm. In contrast to the aggregated measure of EF, performances on specific tests of cognitive flexibility and inhibitory control were not significantly advanced by the dance intervention, suggesting that generally fit adults already exhibit efficient processing on core EF or need longer intervention periods to improve single EF components.

**EFFECTS OF DAYTIME NAPPING ON PHYSICAL AND COGNITIVE PERFORMANCES IN OLDER ADULTS**

SOUABNI, M., SOUABNI, M.J., HAMMOUDA, O., ROMDHANI, M., TRABELSI, K., AMMAR, A., DRISS, T.
*PARIS NANTERRE UNIVERSITY*

INTRODUCTION: Napping is common among older adults [1]. This systematic review aimed to: 1) determine how studies evaluated napping behavior in older adults (frequency, duration and timing); 2) explore how napping impacts perceptual measures (i.e., sleepiness, fatigue and alertness), cognitive and psychomotor performances, night-time sleep and physiological parameters in the elderly.
METHODS: This systematic review was conducted in accordance with the preferred reporting items for systematic reviews and meta-analyses (PRISMA) guidelines. Four bibliographic databases were searched from database inception to December 2021. Primary research published in peer-reviewed journals, conducted with older adults (i.e., ≥ 55 years of age) and investigating the effect of napping on cognitive and/or physical performance were included. The quantitative assessment tool 'QualSyst' was used to assess the risk of bias of each study.
RESULTS: The predefined search strategies yielded a preliminary pool of 738 possible papers, 41 of which remained after duplicates had been excluded and titles and abstracts had been screened. After a careful review of the 41 full texts, eleven articles were included, as well as four additional records identified through the screening of the references and related citations from other journals via Google Scholar lists of included articles. In total, fifteen studies met our inclusion criteria with a mean age ranging from 60.8 to 78.3 years and a cumulative sample size of n=326. Daytime napping had an overall positive impact on subjective measures (i.e., sleepiness and fatigue), cognitive and psychomotor performances (i.e., reaction time and accuracy) and learning abilities (i.e., declarative and motor learning). Further, studies investigating acute and chronic effects of daytime napping on nighttime sleep showed (i) consistency between nap and control conditions regarding sleep duration, efficiency and latency, and proportion of sleep stages, and (ii) increase of 24 h sleep duration with nap compared to control condition. Based on the findings of the present review, there is minimal evidence to indicate that napping is detrimental for older adults' nighttime sleep.

CONCLUSION: The findings of the present systematic review are meaningful for understanding the impact of daytime napping on the life of older adults. Because short sleep is associated with cognitive impairment in older adults across ages, and given the huge beneficial effect of napping on perceptual measures, physical and cognitive performances, and declarative and procedural learning, a diurnal daytime nap opportunity could be proposed as a solution to improve older adults' health and daily performance. Nonetheless, considering the long-term impact of long sleep on cognitive performance, researchers, geriatric specialists and doctors should be careful about which nap duration to propose to older adults in order to not exceed the recommended duration of sleep.

### ASSOCIATIONS BETWEEN MUSCULAR STRENGTH AND MENTAL HEALTH IN COGNITIVELY NORMAL OLDER ADULTS. A CROSS-SECTIONAL STUDY FROM THE AGUEDA TRIAL

BELLON, D.1, RODRIGUEZ-AYLLON, M.2, MORA-GONZALEZ, J.1, SCLAFANI, A.1, MARTÍN-FUENTES, I.1, RIVAS-NAVAS, D.3, CABANAS-SÁNCHEZ, V.R.4, LUBANS, D.5, CATENA, A.6, SOLIS-URRAA, P.1, ESTEBAN-CORNEJO, I.1

*UNIVERSITY OF GRANADA.1; ERASMUS MC UNIVERSITY MEDICAL CENTER ROTTERDAM.2; VIRGEN DE LAS NIEVES UNIVERSITY HOSPITAL GRANADA.3; CEI UAM+CSIC MADRID.4; UNIVERSITY OF NEWCASTLE.5; UNIVERSITY OF GRANADA.6*

INTRODUCTION: Over 38% of European individuals are affected by mental disorders, which in turn, contribute to other physical health problems and high morbidity. Muscular strength has been associated with lower mortality risk in older people. Nevertheless, its role in mental health is not clear yet at this age range. Therefore, the aim of the present cross-sectional study was to examine the associations between muscular strength and mental health (i.e., psychological distress and well-being) in a sample of older adults.
METHODS: In the present cross-sectional study, we used a sample of 82 cognitively normal older adults aged 65-80 years (59% female) who were participating in the AGUEDA randomized controlled trial (https://profith.ugr.es/agueda). Absolute muscular strength (i.e., the maximum amount of force exerted in kg, regardless of muscle or body size) was evaluated using the handgrip strength test (TKK 5101 Grip dynamometer). Additionally, relative muscular strength (the amount of strength/body size) was expressed per kg of body weight. The test was performed twice for each hand and, the average of the highest score of each hand was used. Satisfaction with life was assessed by the Satisfaction With The Life Questionnaire (SWLQ), self-esteem by the Rosenberg Self-Esteem scale (RSE), anxiety by the Hospital Anxiety and Depression Scale (HADS), depression by the Geriatric Depression Scale (GDS), loneliness by the University of California, Los Angeles Loneliness (UCLA-L) scale, and stress by the Perceived Stress Scale (PSS). First, linear regression models, adjusted for sex, age, and years of education (model 1) were performed to explore the relationship of absolute and relative muscular strength (predictor variables) with mental health outcomes (dependent variables). Secondly, we entered cardiorespiratory fitness into the model to examine whether cardiorespiratory fitness attenuated the association of muscular strength with mental health outcomes (model 2).
RESULTS: Relative muscular strength was positively associated with self-esteem in model 1 (β= 0.414, p= 0.004) and model 2 (β= 0.384, p= 0.018). However, absolute muscular strength was not associated with self-esteem in models 1 (β=0.383, p=0.06) and 2 (β=0.310, p=0.152). Furthermore, muscular strength was not associated with any other psychological distress or well-being indicator (all p > 0.08).
CONCLUSION: We observed a positive association between relative muscle strength and self-esteem that was independent of cardiorespiratory fitness and other confounding factors. However, muscular strength may not influence any other mental health indicator in cognitively normal older adults. Large scale experimental studies are needed to decipher the temporality of the associations.

### ASSOCIATIONS BETWEEN PHYSICAL ACTIVITY AND GRAY MATTER VOLUME IN COGNITIVELY NORMALOLDER ADULTS. A CROSS-SECTIONAL STUDY FROM THE AGUEDA TRIAL.

SCLAFANI, A.

*UNIVERSIDAD DE GRANADA*

INTRODUCTION: The practice of physical activity is associated with a better physical and mental health, especially physical activity of moderate-to-vigorous intensity seems to increase gray matter volume, or at least, slow down gray matter atrophy during aging. This might imply numerous benefits in terms of working memory, attention, executive function, and other brain function, as well as the prevention of the neurodegenerative disease, which is common in older adults. The aim of the present study was to examine the association between moderate-to-vigorous physical activity and gray matter volume in cognitively normal older adults.
METHODS: A total of 79 cognitively normal older adults (45 females; average age =71.2 ± 3.73 years) were included in this cross-sectional study from the Agueda trial. Daily moderate-to-vigorous physical activity was measured with a movement sensor (GT3x+, Actigraph, Pensacola, US) worn on the no dominant wrist by the participants for 9 days and 12 hours. The first day and the remaining hours of the last day were excluded from the analyses. Participants wearing the device for at least 16 hours during four days (including at least one weekend day), out of the remaining eight complete days, were included in this analysis. T1-weighted images were acquired with a 3.0 T Siemens Magnetom Prisma Fit scanner. Gray matter volume was determined by voxel based morphometric analysis. The accelerometers raw data were processed using the GGIR package in R. General linear models were used to assess the association of moderate-to-vigorous physical activity with gray matter volume. All models were adjusted for sex, age, and years of education. The statistical threshold was calculated with AlphaSim and further Hayasaka adjustment was performed to account for the non-isotropic smoothness of structural images.
RESULTS: The results showed that higher daily moderate-to-vigorous physical activity was positively associated with a greater gray matter volume (p<0.001;) in in the right side of cerebellum posterior lobe (right cerebellum Creus II) (K=238; t= 4.76). No negative associations were found in any region of the brain.
CONCLUSION: A higher practice of daily moderate-to-vigorous physical activity could have benefits on brain structure, specifically on the cerebellar gray matter volume, but not on any other brain region. A greater gray matter volume supposes a healthier brain condition and one way to prevent cognitive decline in cognitively normal older adults. Future studies should investigate whether increasing the gray matter volume in the right cerebellum implies any benefit in the cognitive status in older adults.

**ASSOCIATION OF SCHOOL NEIGHBORHOOD-BUILT ENVIRONMENT WITH SCHOOL-AGED CHILDREN'S PHYSICAL ACTIVITY: A LARGE-SCALE CROSS-SECTIONAL STUDY OF FIFTH- TO TWELFTH-GRADE CHILDREN IN JAPAN**

OISHI, K.1,2, AOKI, T.3, MORI, T.1, IKEUE, K.1,4, YAMAGUCHI, H.1, HANANO, H.1, YAMAMOTO, Y.1, ITO, Y.1,5, ISHII, K.1

*1 DOSHISHA UNIVERSITY; 2 RESEARCH FELLOW OF JAPAN SOCIETY FOR THE PROMOTION OF SCIENCE; 3 MIYAGI GAKUIN WOMENS UNIVERSITY; 4 NATIONAL HOSPITAL ORGANIZATION KYOTO MEDICAL CENTER; 5 CHUBU UNIVERSITY*

INTRODUCTION: Physical activity in school-aged children is not only associated with various health indicators but also contributes to an active lifestyle and the prevention of chronic diseases in adulthood. In recent years, increasing numbers of studies have examined the built environment of neighborhoods as a potential factor related to physical activity. A neighborhood environment is essential for children because they have a limited range of activities and cannot make independent behavioral choices. However, previous studies have been biased in favor of a few countries, and evidence for children in Japan is limited. Thus, this study aimed to clarify the association of school neighborhood-built environments with school-aged children's physical activity.
METHODS: A total of 21,491 fifth- through twelfth-grade students from 76 schools covering all regions of Japan were included in the study. The International Physical Activity Questionnaire for Japanese Early Adolescents was used to investigate daily moderate-to-vigorous physical activity (MVPA). Using the geographic information system, the number of parks, sports facilities, public transportations, intersections, households, registered cars, and mixed land use within 500, 1000, 1500, and 2000 m in each school-centered network buffer were calculated. Multilevel linear regression analysis was used to examine the relationship between MVPA and built environment elements.
RESULTS: For elementary school boys, the number of parks and public transportations within 1500 m were significantly positively associated with MVPA. For elementary school girls, the number of parks within 500 to 1500 m was significantly positively associated with MVPA, while the number of sports facilities and the number of registered cars within 500 m were significantly negatively associated with MVPA. For junior high school boys, the number of parks within 500 m, the number of intersections within 500 to 2000 m, and the number of households within 500 and 2000 m were significantly positively associated with MVPA, while the number of public transportations within 500 and 1500 m, and the number of registered cars within 500 to 2000 m were significantly negatively associated with MVPA. For junior high school girls, the number of intersections within 500 to 2000 m was positively associated with MVPA, and the number of registered cars within 500 to 2000 m was significantly negatively associated with MVPA. Among high school boys, the number of households within 1000 m showed a significant negative relationship.
CONCLUSION: For elementary school students, having more usable exercise places in the school neighborhood was consistently associated with having more MVPA. For junior high school students, having good road connectivity and less reliance on the car in the school neighborhood were consistently associated with having more MVPA. For high school students, the association between the built environment of the school neighborhood and physical activity was not pronounced.

**SECULAR CHANGE IN SELECTED MOTOR PERFORMANCE PARAMETERS AND BMI IN SWISS PRIMARY SCHOOL CHILDREN FROM 2014-2021: THE SPORTCHECK+ STUDY**

NEBIKER, L., LICHTENSTEIN, E., HAUSER, C., LONA, G., ROTH, R., KELLER, M., HANSSEN, H., FAUDE, O.

*UNIVERSITY OF BASLE*

INTRODUCTION: Motor performance is known to be a meaningful marker for healthy child development [1] and the development of appropriate motor skills enhances the likelihood of lifelong physical activity [2]. Based on the mentioned associations, it has recently been suggested to apply regular and standardized monitoring of motor performance in childhood to identify individuals with diminished motor performance [3]. However, studies with population-based samples and standardized monitoring of motor performance in childhood including regular measuring points over several years are scarce.
METHODS: The aim of this study was to describe secular changes in motor performance (20-m sprint, balancing backwards, jumping sidewards, 20-m Shuttle Run Test (SRT)) and anthropometric data (BMI) in Swiss first graders from 2014 to 2021. The sample included eight birth cohorts with a total of 10'953 children. Multilevel mixed-effects models were used to estimate secular trends for boys vs. girls, lean vs. overweight as well as fit vs. unfit children.
RESULTS: In our sample, balance performance decreased (-1.1 steps per year, 95% CI [-1.16;-0.93]; 2.8%), whereas we found improvements for jumping (0.6 jumps per year, [0.47;0.68]; 1.3%) and BMI (-0.12 kg/m2 per year [-0.14;-0.10]; 0.7%). 20-m SRT performance increased by 0.6% per year in unfit children (0.1 [0.07;0.20]). Secular trend revealed enhanced jump performance development for boys when compared to girls, but also more pronounced decrease in 20-m SRT in fit girls compared to fit boys.
CONCLUSION: Secular changes differed in various motor performance parameters showing plateaus (20-m sprint and 20-m SRT), improvements (jumping sidewards, BMI) and deteriorations (balancing backwards). Identified increase in 20-m SRT performance over years in unfit children is encouraging as poor physical fitness levels during childhood are associated with negative health trajectories. However, it remains unclear whether the improvements in unfit children are already relevant from a public health perspective.

### A DELAYED EVENING MEAL ENHANCES SLEEP QUALITY IN YOUNG RUGBY PLAYERS

LEHMANN, L.

*UNIVERSITÉ DE TOULON*

INTRODUCTION: The aim of this study was to examine the effect of delayed evening mealtime on sleep quality in young athletes.
METHODS: Twelve young rugby players (age 15.8 ± 0.7 years) participated in a cross-over within-participant design. Adolescents spent 5 consecutive days in each of two conditions, separated by a two-week washout period: routine dinner (RD, 3.5 hours before bedtime) and late dinner (LD, 1.5 hours before bedtime). Dietary intakes and amount of physical activity were constant throughout the study. Sleep was assessed using polysomnography on the first and the last nights of each condition. Data were analyzed using Student paired t-test or Wilcoxon tests.
RESULTS: Sleep efficiency (SE) was of 4.8% higher in LD compared to RD ($p = 0.001$, $d = 1.24$). An increase in total sleep time by 24 min ($p = 0.001$, $d = 1.24$) was obtained during LD. Improvement in SE was mainly due to a lower wake after sleep onset (-25 min, $p = 0.014$, $d = -3.20$), a decrease in the number of micro-arousals (-25%, $p = 0.049$, $d = -0.64$) and awakenings of more than 90s (-30%, $p < 0.01$, $d = -0.97$) in LD compared to RD. There were no significant differences in sleep architecture except for a shorter slow-wave sleep (SWS; N3) latency (-6.9 min, $p = 0.02$, $d = -0.778$) obtained during LD compared to RD.
CONCLUSION: Evening dinner 1.5 hours before bedtime leads to better quality and less fragmented sleep compared to evening dinner 3.5 hours before bedtime in young athletes.

### FACTORS RELATED TO THE PERCEPTION OF BARRIERS TO PHYSICAL ACTIVITY PRACTICE IN ADOLESCENTS

CAMPOS, W., BACIL, E.A., COSTA, C.G., LÓPEZ-GIL, J.F., CAMARGO, E.M.

*UFPR*

INTRODUCTION: Different social contexts foster different types of behavior [1]. Receiving social support from parents and friends for physical activity has been shown to increase physical activity levels in adolescents [2]. Conversely, barriers to physical activity have been explored by several researchers, with the aim of discovering what prevents adolescents from engaging in physical activity [3]. The aim of this study was to verify whether adolescents who have active parents and receive social support to practice physical activity (from parents and friends) perceive lower barriers to physical activity practice.
METHODS: A cross-sectional study including a representative sample of 1984 adolescents (55.9% girls), aged 15-17 years, from a southern city of Brazil. The ASAFA scale (Scale of Social Support for Physical Activity) was used to determine the social support from parents and friends, and the questionnaire "Barriers for the practice of physical activity in adolescents" to investigate the barriers related to the physical activity engagement. The adolescents' physical activity level was assessed by the QAFA (Physical Activity Questionnaire for Adolescents) and the parents' physical activity level was evaluated by the IPAQ (International Physical Activity Questionnaire). For the statistical analyses, a conceptual model of structured equations, weighted least squares means and variance adjustment were applied (Software R versão 3.6.1).
RESULTS: Parental social support increased the number of barriers perceived by adolescents (10.9%), while social support from friends reduced the number of perceived barriers (10.0%). Boys perceived lower barriers in comparison with girls (119.7%). Physically active parents provided more social support to their adolescents (149.5%). The analyzes were significant for $p<0.05$. Having physically active parents was not significant in explaining adolescents perception of barriers. The results showed good quality of fit (CFI=0.939; TLI=0.903; RMSEA=0.077; SRMR=0.081).
CONCLUSION: Active parents provide more social support to their children and social support from parents has been shown to increase the number of barriers perceived by adolescents. However, receiving social support from friends for the practice of physical activity seems to reduce the number of barriers perceived by adolescents.

### CP-MH01 COVID-19: Effects on sports and physical functions

### THE IMPACT OF COVID-19 ON THE ORGANISATION OF INTERNATIONAL SPORT EVENTS

MATE, T., ANDRÁS, K.

*CORVINUS UNIVERSITY OF BUDAPEST*

INTRODUCTION: Safety has been a long-standing issue in the sport business trends, but since 2020, this area has taken on a new meaning, with health safety becoming the main issue. The health situation, which is still predominant today, has affected international sport events that attract large crowds and consumers who attend them in person.
METHODS: Investigate the impact of the health crisis of the last two years on international sport events, we used a qualitative research method, drawing on primary and secondary sources.
We analysed international sport events from a risk management perspective. By secondary sources we identified global economic impacts and risks associated with the organisation of international sport events.
We investigated sports event management solutions and risk management strategies over the past two years. As a primary source, we interviewed experts from the organisers of international sport events in Hungary. Our research question: what are the impacts of COVID-19 on the organisation of international sport events? This question is broken down into sub-questions: what are the risk management solutions? What trends can be identified in the impact of COVID-19 on international sport events?
RESULTS: Recent sport events highlighted the need for new risk management.
In our study, we distinguish four temporal phases in the way sporting events are organised, which can be linked by applying Leopkey and Parents (2021) seven risk mitigation strategies of (1) reduction, (2) avoidance, (3) redistribution, (4) dispersal, (5) prevention, (6) legal measures and (7) relationship management (Leopkey and Parent 2021).
Based on the experiences of the expert interviews in 2020 and 2021, three versions of implementation scenarios can be identified: 1) bubble system, 2) sport events with the participation of domestic fans and 3) sport events with the participation of international fans.

Technological developments, the focus on fan experiences, the need for a change of business model, the rise of over-the-top content are some of the sport business trends that have emerged or been reinforced by the impact of COVID-19 on the organisation of international sport events.
CONCLUSION: Strategies for organising international sport events before 2020 need to be rethought. The main aspect of organising a sport event is the safety of life, reducing and then stopping the spread of the epidemic, and thus protecting the human side: the health of athletes, participants and fans.
Despite the new health, safety and hygiene measures fully "safe" sport events cannot be guaranteed. Instead of "Covid-safe" sport events, we can talk about "Covid-reduced" sport events. Sport must adapt to changing environmental factors. In terms of sport business trends, 2022 is the year of adaptation and innovation.

**PHYSICAL ACTIVITY AND ITS INDIVIDUAL AND INTERPERSONAL CORRELATES AMONG YOUNG ADULTS DURING THE COVID-19 PANDEMIC**

MIEZIENE, B., EMELJANOVAS, A., KAWACHI, I.

*LITHUANIAN SPORTS UNIVERSITY*

Introduction
COCID-19 pandemic brought out many challenges for physical and mental health of populations around the globe. Health-related behavior in general and physical activity in particular was also affected. Meanwhile, lack of physical activity is correlated with many health outcomes. The purpose of this study was to assess the physical activity of adults aged 18-36 years old during the pandemic and determine the relationship between physical activity, body mass index, sociodemographic characteristics, psychological distress, nutrition habits, and social capital indicators as the protective factors.
Methods
One thousand two hundred fourteen participants filled the questionnaire. The physical activity was identified by IPAQ questionnaire, nutrition habits were measured by MEDAS scale, psychological distress was measured by Kessler 6 scale. Cognitive social capital was identified in the context of family, neighborhood, peers, and colleagues as indicators of social trust, support, coherence. Structural social capital was defined as the number of people within the participant's social network and the frequency of participation in social gatherings. Body mass index was calculated from height and weight, sociodemographic characteristics were also identified.
Results
On average young adults are physically active at a moderate-to-vigorous level of 4.3 hours a week, 47 percent lack adequate physical activity. Regression analysis revealed that higher social trust, number of friends, having fun with friends, higher adherence to a healthy diet is related to higher and sedentary behavior to lower moderate-to-vigorous physical activity. Among sociodemographic characteristics, male gender and lower education predict higher physical activity. Neither body mass index nor psychological distress was related to physical activity.
Discussion
Almost half of the young adults were inadequately physically active in the period of the COVID-19 pandemic. Wider social networks, social trust, and social participation serve as the factors encouraging physical activity among young adults. Physical activity and healthy nutrition are interrelated. Sedentary behavior and female gender are risk factors. Building social capital at university and work settings by encouraging team sports and sports competition is an option to increase both physical activity and social capital. Access to physical activity-friendly environments should be provided.

**EFFICACY OF COVID-19 SAFETY PROTOCOL AT THE 2021 WRESTLING EUROPEAN OLYMPIC GAMES QUALIFIER ORGANIZED IN BUDAPEST**

AMBRUS, M., LACZA, ZS., MOLNÁR, SZ., SHADGAN, B., KORÖSI, É., MENSCH, K.

*UNIVERSITY OF PHYSICAL EDUCATION*

INTRODUCTION: The pandemic Covid-19 imposes several difficulties to organize multi-day international sports events. This is - in part - due to the close physical contact among the athletes, known to promote the spread of virus, even in individual sports, such as wrestling. Thus, at the Wrestling Qualifier it was utmost important to introduce screening for the disease and exclude infected participants (and then isolate them). We have developed a screening protocol and aimed to test the efficacy during this competition.
METHODS: The event was attended by 281 competitors from 37 countries. The criteria to enter Hungary were a negative polymerase chain reaction (PCR) test, epidemiological and symptomatic negativity within 72 hours. We have also performed Antigen rapid tests (ART, chromatographic immunoassay) and retesting if necessary. Upon departure a negative PCR test or a certificate issued after the end of the quarantine period was required.
RESULTS: In total, 1,500 PCR tests and 1,250 rapid tests were performed. At arrival, there were 21 PCR positive (1.4%) individual, and they were quarantined. At the departure 6 PCR tests were positive (0.47%). One of the ARTs performed at the accreditation was positive.
CONCLUSION: We have developed a successful protocol to screen for Covid-19 and isolation of participants as indicated by the very low positivity for Covid-19 at departure. Thus such protocol can be used for organize multi-day international sports events.

**POST-COVID PERFORMANCE IN FRENCH SWIMMING CHAMPIONSHIPS**

MIGUENS, N.

*INSEP*

INTRODUCTION: Performance trends of French swimmers were assessed before and after the lockdown associated with the first anti-COVID-19 policies.
METHODS: Individual best performances were collected for all events at the French national championships from 2000 to 2020. Yearly proportions of swimmers who improved, stagnated, or regressed in performances were assessed compared to their previous year performances.
RESULTS: In 2020, the proportion of swimmers with performance regression has significantly increased (33% vs 17% in 2019). Women showed a higher proportion of performance regression (41%) than men (26%, $p < 0.0001$) in 2020. Only 39% of women and 53% of men

experienced progression in 2020 (vs 60.8 ± 3.7 % and 66.7 ± 5.2% respectively in the previous years). Between 2005 and 2020, only for the 2008-2009 championships, the coefficient of performmance regresion doesn't increase with age. Consequently, the 2010 championship highlight a coefficient of athletes with performance regression higher than previous year equivalent to the regression coefficient in 2020. Long-distance events showed higher regression (36.2 ± 0.5% for 400-800-1500m races) than short-distance ones (32.1 ± 3.2% for 50-100-200m events). Breaststroke events also showed higher regression (42.4%) than other styles (30.5 ± 2.1%). Younger swimmers more often improved their performance than older ones (61.9 ± 8.5% for swimmers under 18 vs 20.0 ± 10.8% for those over 25).
CONCLUSION: A high proportion of swimmers experienced performance regression during the 2020 French national championships. A higher impact was observed among female, long-distance and breastroke swimmers. Eight weeks of lockdown without training may have led to poorer swimming performances.

## IMPACT OF LOCKDOWN ON PHYSICAL ACTIVITY, BODY COMPOSITION, RESTING METABOLIC RATE AND MAXIMUM STRENGTH AND POWER IN PHYSICALLY ACTIVE FEMALES

PANAYIOTOU, G.1, LADAS, A.1, GOUNITSIOTI, A.1, BOGDANIS, G.C.2

*1. EUROPEAN UNIVERSITY OF CYPRUS, 2. NATIONAL AND KAPODISTRIAN UNIVERSITY OF ATHENS, GREECE*

INTRODUCTION: The restrictive measures imposed to control the spread of the COVID-19 virus have led to unprecedented conditions of confinement and isolation [1]. The closure of social, gym and sports facilities led to changes in daily habits and physical activity [2]. Short-term abstinence from organized training and possible changes in daily physical activity patterns are likely to affect body mass and composition, resting metabolic rate (RMR), and muscle strength and power. Thus, the present study examined the effect of a 12-week lockdown due to the pandemic on body mass, body composition, RMR as well as upper and lower body strength and power.
METHODS: Ten physically active women (age: 30.1 ± 5.8 yrs) with at least one year of resistance training experience, were examined before and after 12-weels of lockdown in Cyprus. Body mass and height were measured, and physical activity was evaluated using the IPAQ questionnaire. RMR was measured using a metabolic system. Maximum strength and power in ten selected resistance upper and lower-body exercises were also recorded.
RESULTS: The 12-week lockdown resulted in a 12.1% decrease in physical activity (from 5871.7 ± 2449.9 met·min-1·wk-1 to 5163.2 ± 3276.7 met·min-1·wk-1, $p<0.05$), a 7% increase in RMR (from 1918.2 ± 158.5 kcal·day-1 to 2058.9 ± 346.7 kcal·day-1, $p<0.05$), a 2% decrease in body mass (from 60.6 ± 9.8 kg to 59.1 ± 9.3 kg, $p<0.05$), accompanied by a 5% decrease in body fat (from 18.3 ± 4.5 % to 17.4 ± 3.7 %, $p<0.05$). Maximum strength was similar in 9 out of the 10 exercises. However, maximum power decreased by 10.1%-21% ($p<0.05$) in 4 out of the 10 selected exercises (leg extension, leg curl, low row and deadlift) and increased by 5% and 7.3% ($p<0.05$) in the shoulder press and squat respectively.
CONCLUSION: During the quarterly lockdown, alternative training solutions were sought by previously active females, which seem to have functioned as an effective training stimulus for improving or maintaining muscle power in some exercises. The increased RMR and possible dietary modifications, which were not recorded, may explain the small but significant body fat loss. Organized strength-power training at home may serve to maintain and even improve strength and power under similar circumstances in the future.

## EFFECT OF INJURY ABSENCE ON THE ACCELERATION-SPEED PROFILE AND THE DIFFERENCE BETWEEN COVID-19 AND TRAUMATIC OR OVERUSE INJURY.

ALONSO-CALLEJO, A.1, QUINTANA-MATOSES, C.1, FELIPE, J.L.2, GARCIA-UNANUE, J.1, HERNANDEZ-MARTIN, A.1

*1. IGOID RESEARCH GROUP, UNIVERSITY OF CASTILLA LA MANCHA; 2. FACULTY OF SPORTS SCIENCES UNIVERSIDAD EUROPEA*

INTRODUCTION: The acceleration-speed profile (ASP) is a new method for evaluating players with Global Postioning System (GPS) devices [1]. Maximal theoretical acceleration (A0) and maximal theoretical speed (S0) are the main variables collected from the ASP. After an injury, strength levels as other physical capacities show a significance decrease [2]. Therefore, the aim of this study was to compare A0 and S0 values pre-injury and post-injury and to analyze the differences between suffer from COVID-19 or another musculoskeletal injury.
METHODS: All injuries of a professional football team (2nd spanish division) were collected from the beginning of the present season until March by GPS WIMU PROTM 15Hz. It was considered as injury any complaint that unable a player to take part of a session [3]. Injuries were grouped into two: traumatic and overuse (T-O) (n=7) and COVID-19 (n=16). The variables of A-S profile A0 and S0 [1] were considered for the analysis. Pre-injury and post-injury data of those variables were analysed in different time frames of 7, 14 and 21 days in which included training sessions and matches. It was considered pre-injury the days before the injury occured. Post-injury collection started from the return to full participation. Shaphiro Wilk´s test was used to test the normality distribution. T-test for paired sample was developed for each time-frame of the variables and for each injury category (e.g. A0 7 days-preinjury and A0 7 days-post injury). The confidence level was established at 95%. Significance was set at $p<0.05$.
RESULTS: The T-O group, in the 7 days previous to the injury showed higher values than the same time post-injury (0.99 m/s2;-0.21 to -2.21 m/s2; d= 1.31). A0 values dicrease is also significance in T-O category for the 14 days timeframe (0.64 m/s2;-0.79 to 2.06 m/s2; d= 1.54). However, the COVID-19 group showed significance lower values in pre-injury block for A0 in the 7 days previous when compared to post-injury (-0.72 m/s2;-1.44 to -0.01 m/s2;d= 0.92). For S0, both groups showed lower in pre-injury 7 days block when compared to the same time post-injury (T-O: 1.17 m/s;-0.1 to 2.44 m/s; d=1.37) (COVID-19: 0.58 m/s;-0.18 to 1.33 m/s; d=0.98). Furthermore, the decrease of S0 remained until 28 days timeframe in both groups (T-O: 0.86 m/s;-0.1 to 1.83 m/s;d=1.04) (COVID-19: 0.58 m/s;-0.11 to 1.3 m/s; d=1.07).
CONCLUSION: T-O injury showed a decrease in A0 and S0 in post-injury. However, COVID-19 reduced only S0. It might be due to T-O had rehabilitation period in which activity is minimal, but COVID-19, despite being confinated, they could train at home with fitness equipment. Being A0 a variable related to horizontal force, its decrease could be atenuated by the endurance training at home. Nevertheless, COVID-19 group could not train properly speed demands because of the available space and it might justify lower values in S0 in both gropus after injury.

**EFFECT OF PROTEIN INTAKE ON BODY COMPONENTS AND PHYSICAL FUNCTION IN OLDER ADULTS IN A RURAL COMMUNITY OF SOUTH KOREA DURING THE COVID-19 PANDEMIC**

LI, X.1, KIM, H.2, KIM, D.1, ZHANG, Y.3, SEO, J.1, AHN, S.1, SONG, W.1,4

*1.DEP OF PHYSICAL EDU, INST OF SPORT SCIENCE, SEOUL NAT. UNI, SOUTH KOREA, 2.KWANGWOON UNI, SOUTH KOREA, 3.THE CHINESE UNI OF HONG KONG, SHENZHEN, CHINA, 4.INST ON AGING, SEOUL NAT. UNI, SOUTH KOREA*

INTRODUCTION: South Korean society is facing an unprecedentedly high and fast population aging in the rural community. The average age of farm owners exceeds 65 years old, and the sustainability of rural communities is also threatened. Thus, physical function or muscle strength is particularly important for this population. On the other hand, sarcopenia, as a new disease in older adults, which is defined by both loss of muscle mass and loss of muscle function or strength, is entering the public consciousness. Low physical activity, decreased protein synthesis, or increased protein degradation are all possible mechanisms of sarcopenia. Therefore, we aimed to investigate the effects of nutritional supplements (protein and vitamins) on sarcopenic components and physical function among the elderly living in rural communities in South Korea during the COVID-19 pandemic.
METHODS: This study was designed to analyze the effects of nutritional diets on skeletal muscle and physical function in older adults in rural communities. For eight weeks, participants aged more than or equal to 65 years old were randomly assigned to a protein intake group (n= 12) and a vitamin group (n= 12) and given 23 g/d of nutrition (protein: whey, soybean, BCAA; vitamins: B, C, D, E, and mixed minerals such as calcium, magnesium, and zinc). They returned twice as the COVID-19 situation worsened. It was delivered to each participant with the help of Sunchang Country officials and a courier, and at the same time, the instructions on how to take it and precautions were explained over the phone. All of the people who took part in the study had their height, weight, skeletal muscle mass, body mass index, and body fat percentage measured using bioelectrical impedance analysis (BIA). The physical function of the body was measured by instrument short physical performance battery (SPPB).
RESULTS: When compared to the baseline, there was a higher level (2.33 %) of SMM ($p<.01$) in the protein group ($p=.002$, 4.92 %). When compared to the baseline, the vitamin group had a significant increase in body fat percentage ($p=.001$, 15.35 %): it fell by 4.49 %. Grip strength and weight, SPPB, gait speed, chair stand test, and sensation of balance did not differ significantly between the two groups.
CONCLUSION: More protein intake helps improve body composition in older adults but has no effect on physical function. The findings revealed that protein consumption was effective in promoting older adults health in rural communities in South Korea during the COVID-19 pandemic. In the context where the health of the older adults in rural communities is deteriorating due to the decrease in physical activity due to COVID-19. Therefore, this study will provide an established basis for the future provision of personalized nutrition for older adults in rural communities.

**NEUROMUSCULAR FATIGUE AND RECOVERY IN PATIENTS AFTER SARS-COV2 INFECTION**

GATTI, M., COLOSIO, M., BROCCA, L., CADILE, F., CANEPARI, M., PELLEGRINO, M.A., POLLA, B., BOTTINELLI, R., PORCELLI, S.

*UNIVERSITÀ DEGLI STUDI DI PAVIA*

INTRODUCTION: COVID-19 is a respiratory disease caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV2) [1]. Although some patients present severe form of the disease, most infected people are asymptomatic or experience mild symptoms, not requiring hospitalization [2]. Emerging evidences suggest a substantial proportion of patients refers persistent muscle weakness and exercise intolerance after 4–7 months from infection: "Post-Acute Sequelae of COVID-19" (PASC) [3]. The aim of this study was to evaluate the cause of muscle weakness and fatigability in PASC patients.
METHODS: 18 patients previously infected by SARS-CoV2 were recruited after 4-8 months from negative COVID-19 test and divided into two groups according to their quality of life (QL; [4]): PASC (n=9, QL<85, 54±9ys) and CTRL (n=9, QL>85, 46±10ys). Patients visited the laboratory on 3 non-consecutive days. After familiarization session and clinical measurements, neuromuscular functions were assessed. We measured: i) rate of torque development (RTD) from single isometric maximum speed contractions of knee extensor (KE); ii) maximal voluntary isometric contractions (MVIC) torque of KE and iii) torque from on high-frequency electrically-evoked potentiated doublet (Db100pot) delivered on femoral nerve. MVIC and Db100pot were performed before (PRE), immediately after (POST) and 10 minutes (POST10) after 80 maximal velocity contractions (1 contraction every 3s) with 20% of the MVIC load. Finally, specific isometric force (P0/CSA) and the no-load shortening rate (V0) of chemically skinned single muscle fibres isolated from muscle biopsies samples of vastus lateralis were determined with the slack test technique [5].
RESULTS: RTD was lower in PASC compared to CTRL (428±139 vs 769±12Nms-1; $p=0.001$). At PRE, MVIC and Db100pot torque were lower in PASC than CTRL (41±18 vs 68±36Nm and 123±36 vs 196±60Nm, respectively; all $p<0.009$). At POST, MVIC and Db100pot torque decreased similarly from PRE in both PASC (-28±13% vs -18±17%; all $p<0.04$) and CTRL (-26±13% vs -15±7%; all $p<0.009$). At POST10, MVIC remained lower from PRE in PASC than CTRL (-18±6% vs-6±5% from PRE; $p=0.001$), while Db100pot was not different between PASC and CTRL (-7±6% vs -9±8% from PRE, respectively; $p>0.05$). P0/CSA and V0 were not different between PASC and CTRL.
CONCLUSION: Muscle weakness reported by PASC patients is accompanied by reduced maximal force-generating capacity and ability to generate force within a short time interval of the KE which seem not attributable to altered actin-myosin cross-bridge. Interestingly, PASC patients also showed a slower recovery of torque after a dynamic fatiguing task which we can speculate being independent from excitation-contraction coupling impairments.

**LIFESTYLE HABITS IN OVERWEIGHT AND OBESE ADULT POPULATION: THE ROLE OF PHYSICAL ACTIVITY, SLEEP AND DIET**

GALASSO, L.1, CASTELLI, L.1, DE AMICIS, R.2, MULÈ, A.1, BERTOLI, S.2,3, BATTEZZATI, A.2, ESPOSITO, F.1,4, ROVEDA, E.1,4, MONTARULI, A.1,4

*1,2.UNIVERSITY OF MILAN;3.IRCCS ISTITUTO AUXOLOGICO ITALIANO, OBESITY UNIT AND LABORATORY OF NUTRITION AND OBESITY RESEARCH;4.IRCCS ISTITUTO ORTOPEDICO GALEAZZI*

INTRODUCTION: Overweight and obesity compromise health, leading to significant long-term consequences, including the development of several chronic diseases such as diabetes, coronary heart disease, and osteoarthritis as well as increasing the risk of developing cancers [1].

Overweight, and obesity in particular, are rapidly growing public health problems affecting an increasing number of countries worldwide [2], so acting on lifestyle habits may be the best strategy [3]. The present study aims to assess the relationship between body mass index (BMI) and lifestyle habits, such as physical activity levels, chronotype, sleep and adherence to the Mediterranean diet (MD), in an overweight and obese adult population.
METHODS: We recruited 744 participants (516 females, 70%, 228 males, 30%; 49.4 +/-12.7 years) who spontaneously attended the International Centre for the Assessment of Nutritional Status (ICANS), University of Milan. Participants filled out the Godin Shephard Leisure-Time Physical Activity Questionnaire (GSL-TPAQ), the reduced version of the Morningness–Eveningness Questionnaire (rMEQ), the Pittsburgh Sleep Quality Index (PSQI) and the Mediterranean Diet Adherence Screener (MEDAS), to assess physical activity levels, chronotype, sleep and MD, respectively. Data were analyzed with SPSS version 27.
RESULTS: Based on the scores of the questionnaires administered, the participants were classified as active (n=487, 66%) and inactive (n=257, 34%), Morning-types (n=237, 32%), Neither-types (n=421, 57%) and Evening-types (n=86, 11%), good sleepers (n=406, 55%) and bad sleepers (n=338, 45%), adherent to MD (n=151, 20%) and not adherent to MD (n=593, 80%).
The correlation analysis on the entire sample showed that higher adherence to the MD (rs -0.13, p<.001), higher levels of physical activity (rs -0.12, p<.001), more hours spent in bed (rs -0.07, p<.05), and more slept hours (rs -0.11, p<.001) significantly reduce the BMI. Additionally, higher PSQI score, which is indicative of poor sleep quality, significantly increased BMI (rs 0.08, p<.01). No correlations were found between rMEQ score and BMI.
CONCLUSION: These findings show the importance of promoting strategies aimed at maintaining healthy active lifestyle in order to reduce the onset of overweight and obesity. Multidisciplinary interventions including physical activity, diet and sleep counseling could be effective in improving the overweight and/or obesity condition.

#### EFFECT OF 8 WEEKS OF INDIVIDUALIZED CONTRAST TRAINING ON PHYSICAL PERFORMANCE OF BASKETBALL PLAYER

BARRERA-DOMINGUEZ, F.J., SÁEZ DE VILLARREAL, E., ALMAGRO TORRES, B.J., MOLINA-LÓPEZ, J.
*FACULTY OF EDUCATION, PSYCHOLOGY AND SPORTS SCIENCES, UNIVERSITY OF HUELVA, AVDA. TRES DE MARZO, S/N, 21071 HUELVA, SPAIN*

INTRODUCTION: High intensity ballistic actions such as sprints, jumps and changes of direction are decisive in the sports performance in team sports, complex and dynamic such as basketball, so developing interventions that improve these physical qualities are of great interest to basketball coaches and physical trainers. Therefore, the aim of this study was to examine the effects of 4 and 8 weeks of contrast training based on individualized vertical force-velocity profile upon linear velocity, vertical and horizontal jumps, and change of direction in basketball players.
METHODS: Thirty senior basketball players participated in the study. The players were randomly divided into: control group (CON, n = 15; age, 22.7 ± 4.93 years; height, 1.84 ± 0.05 m; weight, 82.2 ± 6.00 kg), who performed their usual training schedule; intervention group (INT, n = 15; age, 22.9 ± 6.52 years; height, 1.88 ± 0.08 m; weight, 90.3 ± 23.0 kg), who underwent individualized intervention based on the protocol of Jiménez Reyes et al. (2019), in addition to continuing with basketball training. At baseline (T1), at week 4 (T2), and at week 8 (T3) of intervention, an evaluation was performed including different jumping tests, linear speed and changes of direction. Training effects were evaluated at 4 and 8 weeks of intervention by 2x3 repeated measures ANOVA.
RESULTS: The imbalance in the force-velocity profile was significantly improved after the intervention in the INT group ($p < 0.05$), which led to significant improvements after 4 weeks of intervention in vertical jumping actions ($p = 0.00$), both bilateral (7.29%, ES = 0.73) and unilateral (12.1%, ES = 0.67), but not in horizontal jumping. Such improvements were also observed for speed actions and changes of direction, showing greater changes in the angles of 45º (-8.43%, ES = 0.32, $p = 0.01$) and 180º (-6.58%, ES = 0.51, $p = 0.00$), although the latter were only observed at 8 weeks of intervention.
CONCLUSION: An optimized and individualized contrast training improved the physical performance after 8 weeks of intervention, being observed changes in vertical jumping and sprint since 4 weeks. Therefore, the authors would think that these variables obtained faster changes than the COD and that the improvements were specific with respect to the trained force vector, since the proposed intervention emphasized the vertical vector and the highest percentages of change were observed in this vector. Even so, we would recommend to strength and conditioning coaches to develop individualized training based on the strength demands of their athletes and to combine different intensities in order to optimize the force-velocity continuum.

#### EFFECTS OF VELOCITY LOSS THRESHOLDS DURING RESISTANCE TRAINING ON STRENGTH, MUSCLE HYPERTROPHY, AND SPRINT AND JUMP PERFORMANCE: A SYSTEMATIC REVIEW AND A META-ANALYSIS

MOCHIZUKI, Y.1, ZEMPO, H.2, SAITO, M.1, INOGUCHI, T.3, NAITO, T.1, HOMMA, H.1, ZEMPO-MIYAKI, A.4, KIKUCHI, N.1
*1> NIPPON SPORT SCIENCE UNIVERSITY, 2> TOKYO SEIEI COLLEGE, 3> MEIJI GAKUIN UNIVERSITY, 4> RYUTSU KEIZAI UNIVERSITY*

INTRODUCTION: Velocity based training has been reported as an effective resistance exercise method for manipulating intensity and volume during resistance exercise by several research groups (Hickmott et al. 2022). This study aimed to examine the effects of velocity loss (VL) thresholds during resistance training on muscle strength, muscle hypertrophy and sprint and jump performance using a meta-analysis.

METHODS: For this study, literature searches of the PubMed and SPORTDiscus databases were conducted from all time points until (December) 2021. Criteria for the study included (a) studies examining training effectiveness using velocity loss training methods, (b) outcome measures included a measure of strength, hypertrophy or sprint and jump performance, and (c) data necessary to calculate effect sizes (ESs) must be included or available. Combinations of the following keywords were used as search terms: velocity-based training, velocity based training, velocity loss, absolute velocity, load-velocity profile, load velocity profile, weight-training, weight training, resistance-training, resistance training, resistance-exercise, resistance exercise, strength-training, strength training, one-repetition maximum, one repetition maximum, strength, muscle strength, hypertrophy, muscle hypertrophy, muscle size, muscle thick-ness, muscle cross-sectional area. The average and variance of pre and post each measurement were extracted from the adopted studies. Cohen's d and their variance as ES of training response were calculated from average, variance and N for each of the 116 measurements in eight studies. VL was divided into three groups: low (VL0-10), medium (VL15-25), and high (VL30-50).
RESULTS: Result of meta-analysis of eight studies revealed in training responses (ESs) in VL thresholds as: muscle strength was 0.67 ($p<0.0001$), 0.69 ($p<0.0001$), and 0.72 ($p<0.0001$); muscle hypertrophy was 0.13 ($p=0.62$), 0.51 ($p=0.02$), and 0.42 ($p=0.04$); and sprint and jump performance was 0.48 ($p<0.0001$), 0.39 ($p=0.01$), and 0.15 ($p=0.18$), for VL0-10, VL15-25, and VL30-50, respectively.
CONCLUSION: Muscle strength was found to increase over a wide range of VL (VL0-50), muscle hypertrophy over a medium to high VL (VL15-50), and sprint and jump performance over a low to medium VL (VL0-25). Traditionally, low VL is known to improve muscle strength and high VL is known to improve muscle hypertrophy, but the present results suggest that a high VL may also improve muscle strength via muscle hypertrophy. Furthermore, the new finding of improving sprint and jump performance at the VL0-10 has an advantage of less exercise volume than medium to high VLs. Therefore, low VL is an effective tapering method.
Hickmott LM, Chilibeck PD, Shaw KA, Butcher SJ: The Effect of Load and Volume Autoregulation on Muscular Strength and Hypertrophy: A Systematic Review and Meta-Analysis. Sports Med Open 2022, 8(1):9.

**EFFECTS OF DIFFERENT VELOCITY LOSS THRESHOLDS IN FULL SQUAT WITH BLOOD FLOW RESTRICTION IMPLEMENTATION ON LEG STRENGTH AND JUMP PERFORMANCE**

SÁNCHEZ-VALDEPEÑAS, J.1,2, CORNEJO-DAZA, P.J.1,2, RODILES, L.1,3, PÁEZ-MALDONADO, J.1,3, CANO-CASTILLO, C.1, SÁNCHEZ-MORENO, M.1,3, SÁEZ DE VILLARREAL, E.1,2, PAREJA-BLANCO, F.1,2

*1,2- UNIVERSIDAD PABLO DE OLAVIDE, SEVILLE, SPAIN. 3-UNIVERSIDAD DE SEVILLA, SEVILLE, SPAIN.*

INTRODUCTION: Interest in resistance training with blood flow restriction (BFR-RT) has increased markedly due to higher evoked adaptations in muscle hypertrophy and strength gains (Lixandrao et al, 2018). On the other hand, velocity loss (VL) induced within the set during velocity-based resistance training (VBRT) programs is well known as a critical variable to determinate leg strength adaptations (Pareja-Blanco et al, 2020). However, the long-term effects of BFR-RT inducing different degrees of fatigue within the set have not been studied yet. Therefore, the aim of this study was to analyze the changes of two BFR-RT programs with different VL thresholds (20% vs 40%) in the full squat (SQ) exercise on leg strength gains and vertical jump performance.
METHODS: Twenty-five strength-trained men (n=25) carried out a longitudinal research design and were randomly assigned to two groups, BFR20 (n=12) and BFR40 (n=13). Subjects followed an eight-week (twice per week) VBRT program from 55 to 70% of 1RM using the SQ exercise. The VL was the independent variable (20% vs 40%). All subjects performed 3 sets per training session with 2 min rest between sets after a standardized warm-up without occlusion. Partial occlusion (50% arterial occlusion pressure) was maintained during the whole training session (excluding the warm-up). Subject carried out a battery of test (pre and post each protocol) in the following order to analyze the long-term effects: 1) countermovement jump (CMJ) and 2) incremental loading test in SQ. To compare the effects of each training intervention the following variables were analyzed: CMJ height; 1RM load; average mean propulsive velocity (MPV) attained against all absolute loads common at pre and post training (AV): average MPV attained against absolute loads that were moved faster or equal than 1 m/s at pre (AV ≥ 1) and average MPV attained against absolute loads that were moved slower than 1 m/s at pre (AV < 1).
RESULTS: A significant "protocol x time" interaction ($p = 0.013$) was reported for 1RM. Moreover, significant "time" effects were found for all variables ($p < 0.001$). Regarding intra-group differences, significant increases were reported by BFR20 and BFR40 ($p < 0.001$-$0.036$) in all variables too.
CONCLUSION: Despite both levels of fatigue induced improvements in all variables, a 20% VL threshold produced similar or even greater gains than 40% VL. For that, moderate level of induced fatigue within the set with BFR could be more beneficial than higher level to improve leg strength gains and vertical jump performance.

**RELIABILITY OF LEG PRESS POWER-FORCE-VELOCITY PROFILING OUTCOMES USING THE ISOMED 2000 DYNAMOMETER**

DIRNBERGER, J.1,2, WIESINGER, H.P.1, KRÖLL, J.1, FESSL, I.1,2

*<1> DEPARTMENT OF SPORT AND EXERCISE SCIENCE, UNIVERSITY OF SALZBURG; <2> OLYMPIC TRAINING CENTER SALZBURG*

INTRODUCTION: Vertical jump power-force-velocity profiling (P-F-v) is considered a time-efficient method to estimate the theoretical lower limbs maximum force (F0), velocity (v0), power (Pmax), and the slope of the force-velocity relationship (SFV). However, the latest research found limited reliability and advised caution – at least when testing athletes not highly familiar with vertical jumps.(1,2) Switching to the coordinatively less challenging leg press movement might be a solution. Actually, a recent study found acceptable reliability for leg extension P-F-v profiling outcomes in elite athletes from a wide variety of sports using a protocol for a pneumatic Keiser leg press device.(1) Here, we examined the reliability of P-F-v profiling outcomes for the first time using a protocol for an isokinetic leg press, specifically the IsoMed 2000 leg press device.
METHODS: Forty-five elite athletes (22 female) from various sports and all familiar with isokinetic testing participated in 3 identical sessions (T1–T3), separated by 7 days. In each session, subjects completed an isokinetic leg press (IsoMed 2000; D&R Ferstl GmbH) P-F-v profile consisting of maximum concentric leg extensions at 0.1, 0.3, 0.7 and 1.2 m/s (ROM at tension: ~80–170º). At each velocity, 4 trials were performed. Mean force and mean velocity throughout the whole ROM were calculated. The trial with the highest mean force of each velocity condition was used to create the P-F-v profile (F0, v0, Pmax, SFV). Reliability statistics were done between consecutive pairs of sessions (T1–T2, T2–T3): Two-tailed paired samples t-tests were applied for detection of systematic errors. Intraclass correlation coefficients (ICC(3,1)) and coefficients of variation (CV) were used to estimate relative and absolute reliability, respectively.(3)

RESULTS: No systematic errors were found over sessions. Values of ICC(3,1) ranged from .90 to .98 for T1–T2 and from .88 to .99 for T2–T3. Corresponding CV-values ranged from 2.6 to 5.8% for T1–T2 and from 1.9 to 5.4% for T2–T3.
CONCLUSION: Overall good to excellent relative and acceptable absolute reliability was found for P-F-v profiling outcomes using the IsoMed 2000 isokinetic leg press. These results are in line with the findings of Lindberg et al. using a pneumatic Keiser leg press. The better reliability of the pneumatic leg press compared to vertical jump profiling outcomes was partly attributed to a shorter extrapolation distance to the axis interceptions.(1) However, the extrapolation distance to the x-axis was considerably longer in the present study. Consequently, we attribute our results mainly to the better standardization and the lower coordinative demands of the leg press movement compared to vertical jumps, which leads to more reproducible force and velocity input data for the individual P-F-v profiles.

**EFFECT OF BENCH PRESS EXECUTION VELOCITY, LOAD, AND LOAD DISTRIBUTION ON PERCEIVED EXERTION AND NUMBER OF REPETITIONS PERFORMED**

MICHELI, L.1, SHOAEI, V.1, FRANCIA, P.1, GROSSI, T.1, BENELLI, P.1, FEDERICI, A.1, LUCERTINI, F.1, ZOFFOLI, L.1,2, FERRI MARINI, C.1

*1 DEPARTMENT OF BIOMOLECULAR SCIENCES – DIVISION OF EXERCISE AND HEALTH SCIENCES, UNIVERSITY OF URBINO CARLO BO, ITALY; 2 SCIENTIFIC RESEARCH & INNOVATION DEPARTMENT, TECHNOGYM S.P.A., ITALY*

INTRODUCTION: Barbell bench press exercise adaptations depend on how several of its parameters are tailored. Exercise intensity, which plays a pivotal role in resistance exercise adaptation, is generally prescribed as the load to be lifted for a specific number of repetitions. Traditionally, load is expressed as a percentage of one repetition maximum (i.e., the greatest resistance that can be lifted in a controlled manner with good posture) (1). However, execution velocity also affects exercise intensity (2). Moreover, no studies assessed the effect of load distribution (i.e., the distance between the disc stacks at the two sides of the barbell) on exercise intensity. The present study aimed to evaluate how different combinations of load, execution velocity, and load distribution on the barbell affect the number of repetitions to failure (REPfailure), and rating of perceived exertion (RPEfatigue) and number of repetitions (REPfatigue) at fatigue onset.
METHODS: Eleven males (age 23.3±1.8 years) performed bench press exercises to failure following the National Strength and Conditioning Association guidelines (3). Three loads (80% [1-RM80], 65% [1-RM65], and 50% [1-RM50] of one repetition maximum), execution velocities (90% [V90], 70% [V70], and 50% [V50] of maximal concentric velocity), and two distributions (narrow and wide) were randomly combined. Participants' perceived exertion was also recorded during the repetitions eccentric phases (4). Three separate three-way repeated-measure ANOVAs (α=0.05) were performed to assess the effect of load, velocity, and distribution on REPfailure, RPEfatigue, and REPfatigue normalized as a percentage of REPfailure.
RESULTS: REPfailure was affected by load ($p<0.001$), velocity ($p<0.001$), and distribution ($p=0.005$). The interactions between load and velocity ($p<0.001$) and load and distribution ($p=0.004$) showed a significant effect on REPfailure, whereas the interaction between velocity and distribution was not significant ($p=0.360$). More REPfailure were performed using lower loads (1-RM50=21.2±3.5; 1-RM65=12.1±1.8; 1-RM80=4.8±1.3), higher velocities (V90=14.2±8.0; V70=12.7±7.2; V50=11.0±5.9), and wider distribution (wide=13.2±7.5; narrow=12.2±6.8). RPEfatigue and REPfatigue were affected by load ($p<0.001$ and $p=0.007$, respectively) and velocity ($p<0.001$ and $p<0.001$, respectively), whereas they were not affected by distribution ($p=0.510$ and $p=0.571$, respectively) or the two-way interaction effects. Using higher loads yielded higher RPEfatigue but lower REPfatigue, while RPEfatigue and REPfatigue were higher when slower velocities were used.
CONCLUSION: The present study shows that, when prescribing resistance exercise intensity, not only exercise load but also execution velocity and load distribution should be considered.

**REGIONAL HYPERTROPHY: THE ROLE OF EXERCISE RESISTANCE PROFILE IN TRAINED WOMEN**

ZABALETA-KORTA, A.

*UPV/EHU*

INTRODUCTION: Inhomogeneous muscle growth, also known as regional hypertrophy, is influenced by several factors including exercise selection, time under tension, time spent in each phase of an exercise and performing only concentric/eccentric exercises. The aim of the present study was to analyse the role of exercises resistance profile in regional hypertrophy
METHODS: 39 healthy women participated in this study. All participants completed a 9-week resistance training program consisting of either 4 sets of 12 repetitions of inclined bicep curls (INC group) or preacher curls (PREA group) three times per week performing each set to muscle failure. Pre- and post-intervention Muscle thickness was measured using B-mode ultrasound imaging with a linear-array transducer. Scan acquisition sites were determined by measuring the 50%, 60% and 70% of the distance between the posterior crest of acromion and the olecranon. The center of the bicep brachii muscle was calculated as a line between the coracoid process and the anterocubital crest
RESULTS: No region of the INC group grew when comparing pre- to post-intervention ($p = 0.95$, ES = 0.019; $p = 0.520$, ES = -0.242 and $p = 0.536$, ES = -0.193 in the 50%, 60% and 70% region respectively). However, the 70% region of the PREA-group grew significantly ($p = 0.017$, ES = -0.623). We found no growth differences between regions when analysing per group ($p = 0.274$, ES = 0.014), Region ($p = 0.571$, ES = 0.013) or when anaysed per group * region ( $p = 0.367$, ES = 0.024).
CONCLUSION: This study shows that regional hypertrophy is affected by the resistance profile of an exercise. This means that different regions of a muscle will grow in response to exercises that place the highest difficulty in specific points of the range of motion. In particular, our results show that the distal region of the arm grows in response to exercises that place the highest amount of strain in the part of the range of motion in which the arm muscles are more elongated.

**CAN RATE OF FORCE DEVELOPMENT BE USED AS AN EFFECTIVE SCREENING TOOL FOR INJURIES IN HANDBALL?**

LEWIS, S., BAUMANN, T., MUND, D., ONGARO, A., FERREIRA, J., LEINEN, P., CROGNALE, D.

*UNIVERSITY OF SAARLAND & UNIVERSITY COLLEGE DUBLIN*

INTRODUCTION: Max Rate of Force Development (RFDmax) has been long looked at as a measure and predictor of athletic success in a variety of sports along with its role in the rehabilitation process. Its ability as an injury screening tool for lower limb injuries, however, has yet to be extensively examined. Olympic Handball has been recognized as having one of the highest injury rates of any Summer Olympic event. Dynamic in nature with sudden high velocity sprints, stops and, jumping moments, lower limb injuries of the ankle and knee are common occurrences. Recent injury reports stated that the average player was injured 2.8 times per season resulting in a month of missed training. Therefore, we examined an athlete's relative to bodyweight RFDmax from a countermovement jump (CMJ) and its ability to screen for lower limb injury in Handball athletes.
METHODS: In the preseason, within one month of their season beginning, 18 German youth Handball athletes (age range: 13-19 y.o., 9 female) volunteered to be a part of the study. After a warmup and trial jumps, participants completed 5 CMJs on a force plate to calculate their RFDmax. Players were then surveyed for the following 6 months collecting injury information.
RESULTS: The RFDmax cut-off value of the CMJ that was set at 125 N/s/kg is considered a suitable screening value for lower limb injures in this group of players. A Sensitivity value of 86% was recorded (6 athletes out of 7 with a score below cut-off value sustained an injury in the following 6 months), along with a Specificity of 67% (6 of the 9 athletes below the cut-off were injured).
CONCLUSION: RFDmax from a CMJ has strong evidence to assess those at risk for a lower limb injury in this group of athletes. Adding this test as a pre-season screening and subsequent corrective training for those below the 125 N/s/kg cut-off value could significantly impact the average amount of injuries per season per player and lower the total amount of training time lost. Further improvements of this screening could be explored by investigating if higher earlier RFD are more beneficial than later within a jump. In addition, specific cut-off values for sex, age group, and ability level should also be identified.

**ACUTE EFFECTS OF ECCENTRIC AND CONCENTRIC RESISTANCE EXERCISE ON THE NEUROMUSCULAR FUNCTION IN THE CONTRALATERAL ELBOW FLEXORS OF HEALTHY INDIVIDUALS**

VALDES, O., REHBEIN, C., NUÑEZ, O., SIRACUSA, J., CHALCHAT, E., GARCIA-VICENCIO, S., MARTIN, V., PEÑAILILLO, L.

*UNIVERSIDAD ANDRES BELLO*

INTRODUCTION: Cross-education effect refers to the neuromuscular adaptations transferred from the ipsilateral (or trained) to contralateral (or untrained) limb after strength training. The cross-education effect of eccentric resistance training has shown to decrease the detrimental effects on the morphological and neuromuscular function of skeletal muscles during immobilization more than concentric resistance training (1). Thus, it seems that contralateral training could be an interesting treatment during immobilization or desuse. However, the mechanisms of the acute neuromuscular adaptations (both central and peripheral) after one bout of eccentric and concentric exercise in the contralateral limb are unknown.
METHODS: Healthy young individuals were randomly allocated to ECC (n=10) or CONC (n=10) exercise conditions. Participants performed one bout of ECC or a CONC exercise (5 sets of 10 repetitions at 80% of their eccentric and concentric 1-repetition maximum, respectively), and a control condition without exercise (CTRL). NASA-TLX questionnaire was measured following ECC and CONC. Neuromuscular function (transcranial magnetic stimulation (TMS) and brachial plexus electrical stimulation) of the contralateral non-trained biceps brachii (BB) was evaluated during voluntary contractions and in relaxed muscle before and immediately after exercise. Voluntary activation level during maximal voluntary contractions (MVC), from peripheral nerve electrical (VA_PNS) and transcranial magnetic stimulations (VA_TMS) were also calculated. The amplitude of the potentiated twitch (Pt) and its contractiles properties, the evoked [M-waves, motor evoked potentials (MEPs) , cortical silent period (CSP)] and voluntary EMG activities were also recorded from the elbow flexors muscles before and after each experimental condition.
RESULTS: NASA-TLX after ECC showed greater cognitive demand than CONC. ECC induced a greater decrease in MVC strength than CONC in the contralateral limb, while CONC induced greater decrease in EMG of BB (RMS/M-wave) than ECC. VA_PNS showed an increase after ECC while it tended to decrease after CONC. Pt M-wave remained unchanged after ECC while increased after CONC. 10:100 Hz doublet ratio remained unchanged after both conditions. VA_TMS was similar between ECC and CONC, while MEPs (MEP/M-wave) at 25% and 50% MVC showed a greater increase after ECC compared to CONC. CSP at 25% and 50% MVC increased more after CONC compared to ECC.
CONCLUSION: These results show that a single bout of eccentric and concentric resistance exercise with similar relative intensity, but different absolute load and cognitive demand can modulate different peripheral and central neuromuscular changes in the contralateral untrained limb. Despite of a greater contralateral acute decrease of MCV after ECC than CONC, the tentative conclusion is that high load eccentric contractions are more effective to increase acutely the contralateral corticospinal excitability in comparison to concentric contractions.

**EFFECTS OF ECCENTRIC AND CONCENTRIC CYCLING TRAINING ON PLASMA MARKERS OF CARDIOMETABOLIC RISK, OXIDATIVE STRESS AND INFLAMMATION OF COPD PATIENTS**

VALERO-BRETÓN, M.1, VALLADARES-IDE, D.2, ÁLVAREZ, C.1, PEÑAILILLO, R.S.3, PEÑAILILLO, L.1

*1. UNIVERSIDAD ANDRES BELLO, 2. UNIVERSIDAD DE O´HIGGINS, 3. UNIVERSIDAD DE LOS ANDES*

INTRODUCTION: A common extra-pulmonary manifestation of chronic obstructive pulmonary disease (COPD) patients is the lower limb muscle dysfunction [1]. COPD patients typically show an increased systemic oxidative stress and inflammation, which can impact on skeletal muscle by increasing muscle proteolysis, worsening the muscle dysfunction [2]. The present study compared the effects of eccentric cycling (ECC) and conventional concentric cycling (CONC) training on plasma markers of cardiometabolic risk, oxidative stress and inflammation in patients with moderate COPD.

METHODS: Twenty patients with moderate COPD were randomly allocated to ECC (n=10) or CONC (n=10) group. They performed 12 weeks of ECC or CONC training. Before and after training peak oxygen consumption (V O2peak) and time-to-exhaustion (TTE) at 75% of maximal power output tests were assessed. Furthermore, plasma antioxidant (total antioxidant capacity; TAC, superoxide dismutase; SOD, catalase; CAT, glutathione peroxidase activity; GPx) and oxidative markers (thiobarbituric acid reactive substances; TBARS), insulin resistance (HOMA-IR), lipid profile (total cholesterol; TC, triglycerides; TAG, plasma high-density lipoprotein-cholesterol; HDL, low-density lipoprotein-cholesterol; LDL) and systemic inflammation (interleukin 6; IL-6, tumor necrosis factor α; TNF-α, interleukin 1 beta; IL-1β) markers were measured before and after training at rest, and before and following TTE.
RESULTS: VO2peak and TTE performance remained unchanged after ECC and CONC training. CONC induced a 137.9 ± 162.4% increase in TAC, while ECC decreased GPx 17.2± 20.8%) after training. CONC induced a -60.1 ± 205.3% lesser increase in TBARS following TTE (P=0.04). CONC induced a decrease in HOMA-IR (-30.8 ± 22.9%; P=0.0006) and a tendency to increase HDL (P=0.06).
CONCLUSION: These results suggest that CONC training induced an increase in antioxidant capacity at rest, and a lesser increase in oxidative stress markers following submaximal exercise. Furthermore, CONC reduced markers of cardiometabolic risk in moderate COPD patients. Thus, CONC seems to induced greater oxidative adaptations after training than ECC training.

**MYOSIN HEAVY CHAIN DETERMINATION IN HUMAN SKELETAL MUSCLE: VARIABILITY ASSESSMENT OF WITHIN-DAY REPEATED MUSCLE BIOPSIES**

MARTIN-RINCON, M.1, GALVAN-ALVAREZ, V.1, GALLEGO-SELLES, A.1, MARTINEZ-CANTON, M.1, SANTANA, A.2, CALBET, J.A.L.1

*1 DEPARTMENT OF PHYSICAL EDUCATION AND IUIBS, ULPGC, SPAIN; 2 CLINICAL GENETICS UNIT, COMPLEJO HOSPITALARIO-MATERNO INFANTIL, LPGC, SPAIN*

INTRODUCTION: In human skeletal muscle (SM) fibers, the three prominent myosin heavy chain isoforms are MHCI, MHCIIA and MHCIIX, whose proportions determine its contractile properties, histochemical type and rate of ATP utilization. MHC isoform separation by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) has been used extensively to study fiber type in humans, despite its inherent methodological challenges. Fiber type proportions present larger variability in humans than in smaller animals where, using histochemical techniques, variability has been found between repeated measurements from the same biopsy, as well as from one leg to the contralateral, and even the site and depth of the biopsied fibers from the same SM have an impact. However, no study has systematically investigated variability of fiber type composition using MHC-SDS-PAGE in the same SM, as well as in repeated biopsies from the same incision and compared it from one leg to the contralateral. Thus, the aim was to determine the variability of vastus lateralis intra- and inter-biopsy as well as between legs in human SM.
METHODS: SM biopsies from vastus lateralis were obtained (Bergstrom technique) from 65 volunteers, 52 males (age:22.7±2.9yo, weight:74±9kg, Fat%:18.3±5, VO2max:48.8±6.7 ml/kg/min) and 13 females (age:22.2±1.5yo, weight:59.2±11.6kg, Fat%:28.2±4.4; VO2max:39.9±3.5ml/kg/min). In 10 of the males, biopsies were taken from both legs at rest, and in two more occasions within 1h for a total of 6 biopsies per subject (3 from dominant, and 3 from non-dominant leg), from the same incision but varying needle inclination. MHC% was determined by SDS-PAGE. VO2max (IC) and body composition (DEXA) were assessed. Statistics: ANOVA, t-tests and CV (SD divided by mean, in %).
RESULTS: MHC% in the whole group was 42.1±14.8% for MHCI (range 16-71%), 45.1±11% (range 25-70%) for MHCIIA and 16.5±7.3% (range 5-40%) for MHCIIX. CV for duplicate measurements from the same biopsy (intra-biopsy) was 2.6 for MHCI, 2.0 for MHCIIA and 4.9% for MHCIIX. CV for the 3 biopsies from the same incision (inter-biopsy) was 14.9 for MHC-I, 16.2 for MHCIIA and 20.1% for MHCIIX. The proportion of MHCIIX was 3.3 (percentage units) lower in the dominant compared to the non-dominant leg (16.3% vs 13.3%; p=0.005) while MHC-I and IIX proportions were similar in both legs.
CONCLUSION: This study shows that MHC isoform proportions in repeated measurements from the same biopsy can be determined within the range of biological variability (6-8%) previously documented on fiber type assessment by histochemical techniques. Our data for biopsies from the same incision confirm those from histochemistry where variability inter-biopsy doubles intra-biopsy variability, achieving CVs up to 20%, confirming the importance of limb dominance randomization to avoid additional variation due to mechanical loading. Caution should be taken for interpretation of muscle fiber type data from repeated SM biopsies using histochemical and gel electrophoresis techniques.

**MYOFIBER HYPERTROPHY AND PROLIFERATIVE RESPONSES IN RAT SKELETAL MUSCLE INDUCED BY REPEATED COOLING STIMULATION**

TAKAGI, R., KANO, Y.

*RITSUMEIKAN UNIVERSITY, UNIVERSITY OF ELECTRO-COMMUNICATIONS*

INTRODUCTION: Cooling to a cellular environment of approximately 5 degrees Celsius increases intracellular calcium ion concentrations and causes contraction in rat skeletal muscle. This cooling-induced response is characterized by reversibility and a shift toward higher temperatures due to caffeine loading. The purpose of this study was to test the hypothesis that repeated stimulation of cooling-induced muscle contraction and caffeine loading leads to a hypertrophic response in myofibers.
METHODS: Male adult Wistar rats, including those fed orally with caffeine, were subjected to repeated loads of percutaneous icing under anesthesia to reduce the muscle temperature below about 5 degrees Celsius. The tibialis anterior muscle, which consists mainly of fast twitch muscle fibers, and the soleus muscle, which consists mainly of slow twitch muscle fibers, were sampled after 28 days of two-day cycle intervention.
RESULTS: Myofiber cross-sectional area, a marker of muscle hypertrophy, was increased (1.15±0.04 times) by cooling stimulation in tibialis anterior muscle. In the soleus muscle, no change was observed in the cross-sectional area, but the number of myofibers was significantly increased (1.21±0.07 times) by cooling in rats fed orally with caffeine. The calcium ion concentration response to cooling stimuli was elicited at a significantly higher temperature range in the soleus muscle than in the tibialis anterior muscle, and this difference was enhanced under caffeine-loaded conditions.
CONCLUSION: Changes in intracellular calcium ion homeostasis during muscle contraction, such as resistance training and electrical stimulation, have been reported to be the main factor leading to skeletal muscle plasticity. The present study confirms the hypertrophic and

proliferative responses of myofibers to chronically repeated cooling-induced increases in intracellular calcium ion concentrations. The increase in fiber number observed in soleus muscle may be related to myofiber splitting and satellite cell-induced proliferative responses observed in parallel with muscle hypertrophy. The findings of this study are noteworthy as a novel model that contributes to the maintenance of morphological and functional skeletal muscle through muscle hypertrophy and proliferation induced by the intracellular cooling environment.

**SKELETAL MUSCLE HSP70 EXPRESSION IS NOT ASSOCIATED WITH GLYCOGEN AVAILABILITY DURING RECOVERY IN ELITE ENDURANCE ATHLETES.**

GEJL, K., DALGAARD, L., HVID, L.G., ØRTENBLAD, N.

*UNIVERSITY OF SOUTHERN DENMARK*

INTRODUCTION: The 70-kDa heat shock protein (HSP70) is a ubiquitous molecular chaperone which is highly inducible by cellular stress such as exercise. HSP70 seems to be involved both in the acute cellular restoration following damaging exercise, and likely also in the long-term adaptations to training.
METHODS: To further understand the role of muscle glycogen content on the expression of HSP70, muscle glycogen was manipulated by consumption of either water (H2O) or a carbohydrate-enriched diet (CHO) during recovery from 4 hours of moderate-intensity glycogen-depleting cycling exercise in fourteen elite endurance athletes (VO2max: 66.2 ± 1.3 ml·kg-1·min-1). Muscle biopsies were obtained from m. vastus lateralis pre- and post-exercise, and after 4 and 24 hours of recovery, and analyzed for HSP70 mRNA expression, as well as HSP70 protein expression and muscle glycogen within the same skeletal muscle fibers using immunohistochemistry.
RESULTS: Exercise reduced muscle glycogen by 59 ± 10% ($P < 0.0001$). After 4hrs of recovery, glycogen approached resting levels in the CHO group (86% of pre, $P = 0.28$) but remained suppressed in the H2O group (41% of pre, $P < 0.001$) (group x time interaction: $P = 0.002$). The expression of HSP70 mRNA (+1.9 ± 0.9-fold, $P = 0.03$) and protein (+247 ± 99 % of pre, $P < 0.0001$) was substantially increased during exercise. During recovery, changes in the HSP70 mRNA and protein expressions followed the same pattern in the H2O and CHO group (group x time interactions: $P = 0.70$ and $P = 0.24$, respectively). After 4hrs of recovery, the HSP70 mRNA expression remained elevated in comparison to pre-exercise levels (H2O: 1.7 ± 0.8-fold, CHO: 1.4 ± 0.4-fold, $P = 0.004$). This was also the case with respect to the HSP70 protein expression which remained at post-levels at this time-point (H2O: 100 ± 23 % of post; CHO: 90 ± 16% of post, $P = 0.24$ in comparison to post). Importantly, the maintenance of the HSP70 protein expression in both groups was evident despite clear differences in muscle glycogen content and accordingly muscle glycogen content did not explain the variation in HSP70 expression at the 4-hour time-point ($r2=0.004$). After 24hrs of recovery, the HSP70 mRNA expression returned to pre-exercise levels (H2O: 0.96 ± 0.4-fold, CHO: 0.91 ± 0.4-fold, $P = 0.55$ in comparison to pre), which was also the case for the HSP70 protein expression (H2O: 136 ± 86% of pre; CHO: 108 ± 60% of pre, $P = 0.48$).
CONCLUSION: In conclusion, muscle HSP70 expression remained elevated during recovery from prolonged exercise in highly trained skeletal muscle, irrespective of glycogen availability.

**CHANGES IN SARCOLIPIN EXPRESSION DURING THE EARLY PHASE OF RESISTANCE TRAINING IN RAT SKELETAL MUSCLE**

OKUMURA, K., TAKEGAKI, J., SASE, K., FUKAO, N., FUJITA, S.

*RITSUMEIKAN UNIVERSITY*

INTRODUCTION: Sarcolipin (SLN) is an important protein in skeletal muscle metabolism and thermogenesis; increased SLN is considered to increase energy expenditure and prevent obesity (1). Previous studies have shown that the expression of SLN in skeletal muscle is increased by chronic resistance training and functional overload, but the changes in SLN expression during the early phase of resistance training remain unclear. Therefore, in the present study, we aimed to determine the changes in SLN expression and expressions of related factors in response to repeated resistance exercise bouts.
METHODS: Male Sprague Dawley rats (n=6 / group) were subjected to resistance exercise elicited by transcutaneous electrical stimulation. Under isoflurane anesthesia, the ankle joint was fixed at 90° and maximal isometric contraction of the gastrocnemius muscle was evoked (the condition of electrical stimulation was set to 100 Hz, 10-30 V). 10 bouts(B) of the exercise were performed on the right gastrocnemius muscle every 48 h. Each bout consisted of 5 sets of 3 s isometric muscle contraction and 7 s rest periods for 10 repetitions with 3 min rest between sets. Gastrocnemius muscle samples were taken 3 hours after the last bout. The left gastrocnemius muscle was served as an internal control. The expression levels of SLN, $Ca^{2+}$/calmodulin-dependent protein kinase II (CaMKII), and Calcineurin (CaN) were measured in each muscle using the western blot analysis.
RESULTS: SLN expression was significantly higher in the exercise leg at 5 B ($P<0.001$) and 10 B ($P<0.001$) compared to the non-exercise control leg. SLN was also significantly higher in the exercise leg at 5 B ($P<0.001$) and 10 B ($P<0.001$) than that in the exercise leg at 1 B. However, there was no significant difference in SLN between the exercise legs at 5 B and that at 10 B. Phosphorylated-CaMKII/Total-CaMKII showed no interaction and no main effect of exercise, although there was a significant positive main effect of time(bout). There was no interaction in CaN expression, but a significant positive main effect of exercise and time(bout) were observed.
CONCLUSION: The expression of SLN in gastrocnemius muscle increased in an exercise bout-dependent manner during the initial phase of the resistance exercise training, reached a plateau at 5B, and did not increase further. And the results indicated that the phosphorylation of CaMKII and the expression of CaN were elevated concomitant with the increase of SLN.

**MODELLING HIGH INTENSITY EXERCISE IN VITRO – THE EFFECT OF PH ON SKELETAL MUSCLE MITOCHONDRIAL BIOENERGETICS**

FRANGOS, S.M., HOLLOWAY, G.P.

*UNIVERSITY OF GUELPH*

INTRODUCTION: With increasing exercise intensity, fuel preference shifts from lipids to carbohydrates. Many factors have been proposed to contribute to this response, including a reduction in intramuscular pH, which has been shown to attenuate carnitine palmitoyltransferase-I (CPT-I) activity and limit lipid oxidation. However, it remains unknown if reductions in pH specifically attenuate lipid metabolism, or if aerobic metabolism is generally affected. Therefore, we aimed to model resting and high intensity exercise conditions in skeletal muscle (pH 7.2 vs 6.8) to examine how pH influences carbohydrate-, lipid-, ADP- and lactate-supported mitochondrial bioenergetics.
METHODS: Mitochondria were isolated from resting hindlimb skeletal muscles from wild type C57Bl/6N female mice. Mitochondrial respiration was performed (Oroboros) in buffers at pH 7.2 or 6.8. Substrates were titrated individually (lipids (palmitoyl-CoA (P-CoA), palmitoyl-

carnitine (PC)), l-carnitine (LC), carbohydrate-linked (pyruvate, succinate, glutamate), ADP and lactate), or in combination. Data was analyzed using a paired Student's t-test and expressed as mean±SEM.
RESULTS: Leak respiration and indices of coupling (ADP/O ratio, OXPHOS inhibition with oligomycin) were not influenced by pH. However, maximal complex I- and II-supported respiration was lower at pH 6.8, reducing respiratory control ratios. While PC-supported respiration was unaffected by pH, there was a trend for a reduction in submaximal P-CoA-supported respiration at pH 6.8 (p=0.10) suggesting the effect of pH is CPT-I specific. Further supporting this notion, submaximal respiration with LC was attenuated, and the ability of M-CoA to inhibit P-CoA-supported respiration was enhanced across a range of M-CoA concentrations (1-20 µM). This attenuating effect at pH 6.8 was not limited to lipids, as respiration with carbohydrate-linked substrates was also reduced (primarily at maximal ranges) by ~25-50%. ADP-supported respiration was pH independent, however, a strong trend (p=0.057) for a reduction in maximal respiration when ADP, succinate and pyruvate were titrated in combination was observed. Considering the mass-action dependence of the near-equilibrium lactate dehydrogenase (LDH) reaction on proton concentration, the role of pH in regulating lactate-supported respiration was also investigated. In the absence of LDH, lactate failed to drive respiration, however, in the presence of exogenous LDH, submaximal and maximal lactate-supported respiration was reduced at pH 6.8.
CONCLUSION: These data suggest that while a reduction in pH may contribute to attenuating CPT-I-dependent lipid metabolism with increasing exercise intensity, pH alone cannot explain fuel shifts considering pH also attenuated respiration with carbohydrate-linked substrates and lactate.

### FAT MASS PARAMETERS AND SERUM METABOLOMIC ADAPTATIONS FOLLOWING HIIT AND MICT IN OBESE OLDER ADULTS.

YOUSSEF, L., DURAND, S., APRAHAMIAN, F., LEFEVRE, D., BOURGIN, M., PEYRUSQUÉ, E., HAJJ-BOUTROS, G., MARCANGELI, V., CARVALHO, L., MAIURI, C., MORAIS, J., GAUDREAU, P., KROEMER, G.

*UNIVERSITE DE MONTREAL*

(co-authors: Gouspillou, G., Aubertin-Leheudre, M., Noirez, P.
INTRODUCTION: Nowadays, the health benefits of physical activity became widely recognized. Older adults are increasingly aware of the beneficial effects provided by aerobic training to maintain the health. The aim of this study is to evaluate the serum metabolomic adaptations correlated to fat mass parameters following High-Intensity Interval Training (HIIT) and Moderate-Intensity Continuous Training (MICT) in obese older adults.
METHODS: 71 obese sedentary elderly men and women completed 12-week HIIT training program or a 12-week MICT training program. Fat mass parameters and serum metabolomic profile (using 4 mass spectrometers) were assessed pre- and post-intervention.
RESULTS: Significant changes of different metabolites were identified following both training modalities. Following HIIT, we observed significant correlations ($p<0.01$) between aspartic acid change and several absolute fat parameters changes (android, gynoid and total fat mass) as well as relative fat mass parameters changes (gynoid and total fat mass). Following MICT, margaric acid change was significantly correlated ($p<0.01$) to the relative total fat mass change.
CONCLUSION: Aspartic acid and margaric acid could be possible useful biomarkers of HIIT and MICT adaptations respectively in geriatric and obese population when fat mass is considered. Further studies are needed to confirm these findings and to understand whether the mechanisms of these adaptations are specific to aerobic training or also influenced by age or obesity status.

### ASSOCIATION BETWEEN CKM RS8111989 POLYMORPHISM AND MUSCLE DAMAGE AFTER MAXIMAL ECCENTRIC EXERCISE

DEGUCHI, M.1, HOMMA, H.1, INOGUCHI, T.2, KOZUMA, A.1, SAITO, M.1, SAITO, A.1, NAITO, T.1, SHINOGI, M.1, TSUCHIYA, Y.2, KOZAKI, K.1, OCHI, E.3, OKAMOTO, T.1, NAKAZATO, K.1, KIKUCHI, N.1

*1 NIPPON SPORTS SCIENCE UNIVERSITY, TOKYO, JAPAN; 2 MEIJI GAKUIN UNIVERSITY YOKOHAMA, JAPAN; 3 HOSEI UNIVERSITY, TOKYO, JAPAN*

INTRODUCTION: Muscle damage due to maximal eccentric exercise can result in reduced muscle strength and range of motions (ROM), muscle soreness, and an increased blood creatine kinase (CK) level (1). However, individual differences in these muscle damage indicators, particularly remarkable in CK level, exist and may also be associated with genetic variants (2). Therefore, this present study investigated the association between the individual difference in muscle damage after eccentric exercise and polymorphism of CKM rs8111989, which encodes for skeletal muscle-derived CK.
METHODS: A total of 45 participants, including 29 men (age: 22.5 ± 2.2 years, height: 170.9 ± 6.0 cm, body mass: 67.6 ± 12.4 kg) and 16 women (age: 23.1 ± 1.6 years, height 160.5 ± 4.8 cm, body mass: 57.8 ± 6.5 kg), who had not participated in the daily strenuous exercise of biceps were enrolled in the study. Participants performed five sets of six maximal eccentric elbow flexion exercises. Maximum voluntary contraction (MVC), ROM, muscle soreness, and blood sampling were assessed immediately before and after, as well as 1, 2, 3, and 5 days after eccentric exercise. CKM rs8111989 polymorphism was genotyped using the Taqman approach.
RESULTS: Significant interaction of changes in MVC and CK among CKM genotype groups (AA vs. GA + GG, MVC: $p = 0.015$, CK: $p = 0.009$) were observed. Compared to AA homozygotes, G-allele carriers showed significant reduction in MVC between pre-exercise values (100%)and at 1 day (55.0% vs. 66.9%), 2 days (58.0% vs. 74.8%), and 5 days (64.8% vs. 80.4%) after exercise. Moreover, compared to AA homozygotes, G-allele carriers showed significant differences in CK levels between pre-exercise values and at 3 days (6813.7 U/L vs. 2155.7 U/L) and 5 days (9212.6 U/L vs. 2812.1 U/L) after exercise ($p < 0.05$). However, ROM and muscle soreness were not associated with CKM rs8111989 polymorphism.
CONCLUSION: Our study suggested that CKM rs8111989 polymorphism was associated with muscle dysfunction and CK after maximal eccentric exercise.

**ASSOCIATION OF THE GALNTL6 GENE RS558129 POLYMORPHISM WITH STRENGTH AND POWER OUTPUT PERFORMANCE IN ATHLETES**

KOZUMA, A.1, MIYAMOTO-MIKAMI, E.2, SAITO, M.1, HOMMA, H.1, DEGUCHI, M.1, SAITO, A.1, MATSUMOTO, S.1, MATSUMOTO, R.3, SUZUKI, K.2, MACHIDA, S.2, OKAMOTO, T.1, NAKAZATO, K.1, FUKU, N.2, KIKUCHI, N.1

*1 NIPPON SPORT SCIENCE UNIVERSITY; 2 JUNTENDO UNIVERSITY; 3 IKUEI UNIVERSITY*

INTRODUCTION: A rs558129 polymorphism of the N-acetylgalactosaminyltransferase-like 6 (GALNTL6) gene has been reportedly associated with sports performance. Previous studies have suggested that the GALNTL6 rs558129 polymorphism exhibits high-endurance performance in the C allele[1)] and high-power performance in the T allele[2)3)]. However, replication studies are required owing to the lack of studies. This study was aimed to determine the association of the rs558129 polymorphism of the GALNTL6 with power performance in an anaerobic test (Study 1) and isokinetic knee extension and flexion muscle strength tests (Study 2) in Japanese athletes.
METHODS: In Study 1, 112 athletes (67 men and 45 women) were participated. Subjects performed a 30s Wingate anaerobic test to assess the relative (per body mass) mean power and peak power. In Study 2, a total of 347 athletes, 213 men athletes as cohort 1 and 134 athletes (85 men and 49 women) as cohort 2, were participated. Subjects performed isokinetic knee extension and flexion muscle strength tests. For measurements, the angular velocity was set at 60 °/ s and the repetitions were conducted for three times in each participant. The value of the maximum strength was divided by the weight of each participant. Total DNA was extracted from saliva samples using an Oragene-DNA kit, and the rs558129 C/T polymorphism of the GALNTL6 was analyzed by using the TaqMan SNP Genotyping Assay. The 30s Wingate anaerobic test was analyzed via one-way ANOVA. Meta-analysis of strength in the two cohorts were conducted using the Review Manager.
RESULTS: Study 1 revealed that the relative peak power was significantly higher for the CT + TT genotype compared to the CC genotype (10.00 ± 1.93 W/kg vs. 10.88 ± 1.87 W/kg, respectively, p = 0.009). In addition, the CT + TT genotype had a significantly higher relative mean power than the CC genotype (7.58 ± 1.37 W/kg vs. 8.26 ± 1.50 W/kg, respectively, p = 0.012). The meta-analysis of Study 2 revealed that the relative isokinetic knee extension muscle strength was higher in the CT + TT genotype than in the CC genotype (p = 0.008). However, there were no significant differences in the relative isokinetic knee flexion muscle strength.
CONCLUSION: Our results suggested that GALNTL6 gene polymorphism is associated with strength and power output performance in Japanese athletes.

**GENETICS OF (INTER)NATIONAL COMPETING RUNNERS AND CYCLISTS - A SYSTEMATIC REVIEW WITH META-ANALYSIS**

KONOPKA, M.

*MAASTRICHT UNIVERSITY*

INTRODUCTION: Aim of this systematic review and meta-analysis was to identify the genetic variants of (inter)national competing runners and cyclists compared to controls.
METHODS: The Medline and Embase databases were searched until 15 November 2021. Eligible articles included genetic epidemiological studies published in English. Runners and cyclists competing at (inter)national level and sedentary controls were eligible for inclusion. Pooled odds ratios based on genotype frequency with corresponding 95% confidence intervals (95%CI) were calculated using random effects models. Heterogeneity was addressed by Q-statistics and I2. Sources of heterogeneity were examined by meta-regression and risk of bias was assessed with the Clark Baudouin scale.
RESULTS: This systematic review comprised of 43 studies including a total of 3815 athletes and 10630 controls in the pooled analysis. Of the 43 identified genetic variants, 13 were replicated in independent studies. Significant associations were found for five polymorphisms. Pooled odds ratio [95%CI] favoring athletes compared to controls was 1.51 [1.22-1.88] for ACE (rs1799752), 1.66 [1.26-2.19] for ACTN3 (rs1815739), 1.75 [1.34-2.29] for PPARGC1A (rs8192678), 2.23 [1.42-3.51] for AMPD1 (rs17602729), and 2.85 [1.27; 6.39] for HFE (rs1799945). Risk of bias was low in 25 (58%) and unclear in 18 (42%) articles. Heterogeneity of the pooled results was low (0-19.1%) except for HFE (71%), GNB3 (80.1%) and NOS3 (76%).
CONCLUSION: (Inter)national competing runners and cyclists have a higher probability to carry specific genetic variants compared to controls.

**MECHANICAL EXTERNAL WORK OF A FOOTBALL SEASON COMPUTED BY GPS**

PAVEI, G.1, OSGNACH, C.2, DI PRAMPERO, P.E.2,3

*1 UNIVERSITÀ DEGLI STUDI DI MILANO; 2 EXELIO SRL, UDINE; 3 UNIVERSITÀ DEGLI STUDI DI UDINE*

INTRODUCTION: The (positive) mechanical external work (Wext) is the work performed by the muscle-tendon unit to accelerate and lift the body center of mass (Peyré-Tartaruga et al. 2021). It has historically been investigated in steady locomotion, where it was able to explain most of the absolute metabolic cost and its variations (Peyré-Tartaruga et al. 2021). In recent years the mechanical approach has been applied also to unsteady locomotion (e.g. shuttle and sprint running) typical of team sports (Zamparo et al. 2019; Pavei et al. 2019) albeit still using optoelectronic systems, which is a standard for computation, but an unfeasible approach during team sports training or competitions.
METHODS: We used a GPS-tracking system to calculate the mechanical external work performed by various players during official football matches. According to Pavei et al. (2019), positive mechanical work was calculated as the sum of the work to accelerate forward, which can be derived by the velocity profile obtained by the GPS, the speed fluctuations and lift at each support. The players of a football club of the

Italian second division (Serie B) where monitored during the whole football season 2020-2021 (42 games) with a GPS-tracking system (gpexe pro2, sampling at 18.18 Hz). Only players that completed the whole match (90 minutes), goalkeeper excluded, were analysed.
RESULTS: A total of 203 tracks from 20 players were analysed. The positive mechanical work range over the whole 90 minutes was 7.9–15.7 KJ/kg with an average value of 10.8 KJ/kg (1.3 KJ/kg, SD). When expressed as mechanical power (in relation to the whole match time) 1.9 W/kg (0.2 W/kg, SD). The positive mechanical work was different among roles, with center back 9.7 KJ/kg (1.0 KJ/kg, SD), wide back 10.9 KJ/kg (0.7 KJ/kg, SD), midfielder 12.3 KJ/kg (0.9 KJ/kg, SD) and attacker 11.3 KJ/kg (0.7 KJ/kg, SD).
CONCLUSION: We showed for the first time the feasibility to calculate mechanical external work in a competition setting with a GPS-tracking system. The mechanical external work performed by the players reflects the muscle-tendon work that needs to be done in order to move the body. Hence, it accounts for accelerative and constant speed movements and could be a useful metric to monitor the work done by the (muscle-tendon unit of the) players, not just during the match but also during training. Although also the mechanical internal work has been shown to have an impact on the total mechanical work performed by the muscle-tendon unit in both shuttle and sprint running (Zamparo et al. 2019; Pavei et al. 2019), its computation is still challenging for the nowadays tracking systems, and only a fusion with video analysis or multiple magneto inertial measurement units could overcome those intrinsic limitations.

### HEART RHYTHM ASSESSMENT IN ELITE ENDURANCE ATHLETES: A NEW METHOD?

AUSLAND, Å., SANDBERG, E.L., JOSTVEIT, J., SEILER, S.

*UNIVERSITY OF AGDER*

INTRODUCTION: Cardiac arrhythmias (CA), especially atrial fibrillation (AF), are relatively common among elite endurance athletes. Conventional diagnostic tools for assessment of rhythm disorders suffer from limited availability, limited test duration time, and usability challenges, particularly during the demanding conditions of an elite athlete training many hours each day. In endurance athletes, there is a need for out-of-hospital monitoring and detection of arrhythmias under conditions that are relevant and potentially provocative. The Norwegian patch ECG247 Smart Heart Sensor has been developed to simplify the assessment of heart rhythm disorders. The current study aimed to evaluate the ECG247 Smart Heart Sensor function and practicalities in an elite athlete environment.
METHODS: A total of 13 professional cyclists at the UNO-X Pro Cycling Team were examined continuously with the ECG247 Smart Heart Sensor during a 14-day training camp in Spain, December 2021. All ECG data were automatically analysed by the ECG247 physicians at Sorlandet Hospital Arendal, Norway. Athletes completed a brief questionnaire registering their training (from on-bike monitoring units) and self-assessment of usability parameters after the test.
RESULTS: In 8 of 13 athletes (69% male, age 23+-4 years), two test periods were performed, resulting in a total of 21 long-term tests with continuous ECG monitoring. Average athlete ECG test duration was 144+-47 hours (89+-24hours/test). The athletes had an average of 15+-5 training hours during each test. The ECG quality from all tests was considered satisfactory for rhythm analysis – also during exercise. The reported usability of the ECG247 Smart Heart Sensor was high, and no athletes reported trouble sleeping or training with the sensor attached. The automatic arrhythmia algorithm reported of possible arrhythmia events in 13 (62%) tests; 9 atrial flutter and 4 supratventricular tachycardia. Retrospective thorough manual assessment by physicians revealed normal sinus rhythm in all tests.
CONCLUSION: The ECG247 Smart Heart Sensor allowed for high quality ECG monitoring during intensive exercise in athletes. The integrated arrhythmia analysing algorithm might be better adapted for this user group.

### ANALYZING MOTION CHARACTERISTICS AND METABOLIC POWER OF ELITE MALE HANDBALL PLAYERS

BASSEK, M., RAABE, R., MEMMERT, D., REIN, R.

*GERMAN SPORT UNIVERSITY COLOGNE*

INTRODUCTION: In complex team sports like handball, analysis of player load (PL) during competition is a challenging task. However, correctly assessing load and physiological requirements underlying successful game performance is critical for efficient training regimes, optimizing performance, and preventing injuries. Recent work analyzed PL using position data of official team handball matches using time on court and distances covered in different velocity zones (1). However, these measures give little insight intro PL because of players frequent accelerations and decelerations. In contrast, estimating Metabolic Power (MP; 2) allows to capture the energy expenditure over time, including the cost of accelerations and decelerations. The present study therefore analyzed PL in elite male handball players using distance covered and MP.
METHODS: Data from 290 male field players of 18 teams during 77 games of the 2019/20 German Men's Handball Bundesliga were analyzed. Position data was collected using a local positioning system at 20 Hz. For every player, total distance, and equivalent distance were calculated. Differences between distance covered and equivalent distance was analyzed with a 2 (distance vs. equivalent distance) by 3 (wings vs. backs vs. pivots) mixed-effects ANOVA. Statistical significance was set at $\alpha = 0.05$.
RESULTS: Statistical analysis for distance covered and equivalent distance revealed statistically significant group by distance interaction effects ($p < .01$). Post-hoc analysis showed a significant group effect between wings vs. backs ($p < .01$; $d = 0.92$), wings vs. pivots ($p < .01$; $d = .92$), but no group effect between backs vs. pivots. Repeated measure effects between distance and equivalent distance were significant for wings ($p < .01$; $d = 0.32$), backs ($p < .01$; $d = 0.25$), and pivots ($p < .01$; $d = 0.23$). Interaction effect for groups and (equivalent) distance were significant for wings vs. backs ($p < .01$; $d = 0.73$), wings vs. pivots ($p < .01$; $d = 0.86$), and backs vs. pivots ($p < .01$; $d = 0.22$), meaning that differences between distance and equivalent distance were greater for wings than for backs and pivots.
CONCLUSION: This is the first study that applied MP to handball. Our results indicate that distance covered underestimates player load of wings because their movement is characterized by frequent high intensity accelerations. Thus, standard approaches relying solely on distance covered are not sufficient to assess PL in handball. The MP concept seems to be a valuable approach to obtain more precise information about PL from position data in handball. Still, the effect of static efforts, e.g. from the pivot fighting for position, on internal PL remains unclear and warrants further investigation.

## DISCRIMINATIVE VALIDITY OF A LOWER EXTREMITY INERTIAL SENSOR SETUP TO QUANTIFY BIOMECHANICAL LOAD DURING A STANDARDIZED SOCCER TRAINING DRILL

BASTIAANSEN, B.J.C.1, VEGTER, R.J.K.1, LEMMINK, K.A.P.M.1, BRINK, M.S.1

*UNIVERSITY OF GRONINGEN, UNIVERSITY MEDICAL CENTER GRONINGEN, GRONINGEN*

INTRODUCTION: Training load quantification could support planning future training and thereby improve player performance. However, current monitoring systems do not monitor lower extremity biomechanical load and thus important information might be neglected. This explorative study assessed the discriminative validity of a new inertial sensor setup [1] to quantify lower extremity biomechanical load during a standardized soccer training drill.
METHODS: National (n = 11) and regional (n = 16) soccer players performed a standardized soccer training drill [2]. Participants wore inertial sensors at the lower extremities. Cumulative joint angular accelerations were used to quantify lower extremity biomechanical load indicators Hip and Knee Load. Additionally, Playerload, high intensity running distance (>15.00 km/h, HIRD), acceleration (>2.78 m/s2, HIAD) and deceleration distance (<2.78 m/s2, HIDD) were used to quantify training load [3]. Between group training load differences were compared using MANOVA tests with Cohen's D effect sizes.
RESULTS: National players had higher Knee Load (984 ± 122 vs. 900 ± 88, ES = 0.82, CI = -0.02 – 1.66, p=0.047), HIRD (83.2 m ± 12.9 vs. 66.4 ± 18.6 m, ES = 1.01, CI = 0.15 – 1.87, p=0.02), HIAD (9.1 m ± 1.3 vs. 6.0 ± 2.3 m, ES = 1.56, CI = 0.64 – 2.48, p<0.001), and HIDD (8.44 ± 2.8 m vs. 3.3 ± 2.6 m, ES = 1.93, CI = 0.95 – 2.9, p<0.001) compared to the regional players. No differences for Hip Load were observed (474 ± 86 vs. 450 ± 69, ES = 0.32, CI = -0.49 -1.13, p = 0.42).
CONCLUSION: Training load and Knee Load differences were observed, but discriminative validity of Hip Load could not be confirmed. Proximal-to-distal sequencing and limited number of passes during the training drill might explain the lack of difference in Hip Load. Future research should examine these differences further in formats with more passing opportunities such as small sided games [4].

## A 12-WEEK CONSUMER WEARABLE ACTIVITY TRACKER-BASED INTERVENTION REDUCES SEDENTARY BEHAVIOUR AND IMPROVES CARDIOMETABOLIC HEALTH IN FREE-LIVING SEDENTARY ADULTS: A RANDOMISED CONTROLLED TRIAL

FRANSSEN, W.M.A., NIESTE, I., VANDEREYT, F., SAVELBERG, H.H.C.M., EIJNDE, B.O.

*HASSELT UNIVERSITY*

INTRODUCTION: Reducing sedentary behaviour significantly improves cardiometabolic health and plays an important role in the prevention and management of CMDs. However, no specific effective strategies have been proposed to combat the negative effects of sedentary lifestyles. Therefore, we aim is to investigate the efficacy of a single component CWAT-only intervention and the added value of a multicomponent (CWATs + motivational interviewing) behaviour change intervention to reduce sedentary behaviour and increase physical activity within sedentary adults.
METHODS: In a three-armed randomised controlled trial, 59 (male/female: 21/38) sedentary adults were randomly allocated to a control group, a CWAT-only group or the CWAT+ group (CWAT + motivational interviewing) for 12 weeks. Physical activity (PA) and SB were assessed using the activPAL3™ accelerometer. In addition, anthropometrics, blood pressure, plasma lipids and insulin sensitivity using an oral glucose tolerance test were assessed at baseline and after the 12-week intervention period.
RESULTS: As compared with the control group, the CWAT+ group significantly reduced time spent in sedentary behaviour (-81 min/day CI[95%]: [-151, -12] min/day) and significantly increased step count (+3117 [827, 5406] steps/day), standing time (+62 [14, 110] min/day), light intensity PA (+28 [5, 50] min/day) and moderate-to-vigorous PA (+22 [4, 40] min/day). Body fat mass (-1.67 [-3.21, -0.14] kg), percentage body fat (-1.5 [-2.9, -0.1] %), triglyceride concentration (-0.31 [-0.62, -0.01] mmol/l), the 2h insulin concentration (-181 [-409, -46] pmol/l), QUICKI (-0.022 [-0.043, -0.008]) and tAUC (-6464 [-26837, -2735] mmol/l*min) were significantly reduced in the CWAT+ group, compared to the control group.
CONCLUSION: A 12-week multicomponent CWAT-based intervention (CWAT + motivational interviewing) reduces sedentary time, increases physical activity levels and improves various cardiometabolic health variables in sedentary adults, whereas self-monitoring on itself (CWAT-only group) has no beneficial effects on sedentary time.

## HEART RATE RESPONSES TO JUMPING LOAD DURING VOLLEYBALL WARM-UP AND COMPETITION

GIELEN, J., MEHUYS, E., BERCKMANS, D., MEEUSEN, R., AERTS, J.M.

*KU LEUVEN*

INTRODUCTION: Heart rate monitoring is a popular tool for quantifying internal load. In combination with monitoring external load on the athlete, the overall workload can be described in detail. In many sports and activities, there is still a challenge in determining the internal-external load relation. The activity during volleyball is characterized by explosive multidirectional movements, such as sprints, dives, and mostly jumps. The relationship between jumping load and HR is especially interesting because the accelerations are short, high intensity pulses, while the heart rate changes more gradually. This research investigates whether jumping acceleration is significantly correlated with heart rate during warm-up and competition gameplay.
METHODS: Eight male volleyball players participated in this study. They were monitored during 4 to 10 competition matches, resulting in 63 measurements. A Zephyr BioHarness 3.0 (Medtronic, Boulder, CO) was used to record 3D accelerometer data and heart rate at 1Hz. Furthermore, video recordings were used to select 40 volleyball spikes and 40 serves during the warm-up as well as the actual match to study individual jumping actions. This way, a total of 160 jumps were studied. Each event was selected based on the fact that it was performed in isolation from other actions within a time window of 30 seconds. Pearson correlation testing was performed between peak acceleration and peak heart rate of each jump.

RESULTS: The jumping actions performed during the warm-up showed a correlation coefficient (rho) of 0,49 (p > 0.001) and 0,62 (p > 0.001) for spiking and serving respectively. These results suggest that the variation in the heart rate during warm-up jumps can be (partially) explained by overall acceleration. Furthermore, the actions performed during competition resulted in a correlation coefficient (rho) of 0,12 (p = 0,45) and 0,21 (p = 0,20) for spiking and serving respectively. This indicates that in the case of actual gameplay, the correlation between internal and external load becomes insignificant although the events are still performed in isolation.
CONCLUSION: Our results are interesting to the ECSS community because they show how activity characterized by jumps can be related to the internal load of the volleyball athlete. The observed differences between warm-up and competition might be due to factors such as stress or fatigue. A more detailed of the workload throughout the match might provide better insights. Furthermore, given the highly variable nature of volleyball gameplay, other methods for quantifying this relationship might have to be considered. For instance, explicitly capturing second-by-second changes and dynamics with time-series analysis seems a suitable alternative.

**AIR QUALITY MONITORING DURING THE SCIENTIFIC TRAIL OF CLECY 2021**

MARTINET, Q., JOUFFROY, R., OSMONT, M., OLIVEIRA ALVES, A., MAUVIEUX, B., HINGRAND, C., DELAUNAY, P.L., COTE, F., BERTUCCI, W., JOLY, L., NOCENT, O., NOIREZ, P.

*UNIVERSITÉ DE REIMS CHAMPAGNE ARDENNE*

INTRODUCTION: The Scientific Trail of Clecy was an exploratory study on a trail of 156km and 6000m of elevation gain (D+), between 20 and 46 hours of running, divided into 6 identical laps of 26km each. Some publications have shown that the combined effect of air pollution and exercise could be associated with an increased potential risk on health problems and a reduced performance [1]. But these measures have never been done to our knowledge on ultra-trails.
During this ultra-distance race, we measured different pollutants in order to increase knowledge on the relationship between physical activity and air quality.
METHODS: Fifty-five subjects (43 men and 12 women between 25 and 70 years old, experienced in ultra-trail running events and with no contraindications to the practice of this sport) were included to participate in a trail race. 41 finished the race. To measure the air quality, we set up 2 sensors (Air Quality Transmitter AQT530, Vaisala, Finland) along the route at 1.70m height. These sensors measured gases (nitrogen dioxide (NO2), nitrogen monoxide (NO), carbon monoxide (CO), ozone (O3) as well as particulate matter (PM), fine particles with a diameter < 1µm (PM1), 2.5µm (PM2.5) and 10µm (PM10) and environmental parameters such as temperature (°C), humidity (%RH) and atmospheric pressure (hPa).
RESULTS: The World Health Organization (WHO) provides a recommended reference threshold over 24 hours of 15 µg.m-3, 45 µg.m-3 and 25 µg.m-3 for PM2.5, PM10 and NO2 respectively [2].
For the moment, there is no recommended reference threshold for PM1 because sensors that measure this type of particles are still rare. For all the gases, the concentrations were clearly lower than these thresholds with a maximum average concentration over a period of 24 hours less than 1 µg.m-3.
We obtained maximum average concentration over a period of 24 hours of 3.38 ± 0.33 µg.m-3 for PM1, 8.28 ± 1.48 µg.m-3 for PM2.5 and 12.20 ± 2.15 µg.m-3 for PM10.
The cumulative periods of time above the reference thresholds were 290 minutes and 60 minutes for PM2.5 and PM10 respectively throughout the race.
CONCLUSION: This study demonstrated the possibility to use a network of mobile and compact air quality sensors during a sporting event. Despite a very rural environment, we obtained peak PM values above the reference thresholds defined by the WHO but for a short period of time.
As a perspective we will cross our air quality data with the performance and physiological data of the runners collected during the event.

**MODELLING TEAM PERFORMANCE IN ELITE WOMEN'S BASKETBALL THROUGH PRINCIPAL COMPONENT ANALYSIS AND GENERALIZED MIXED MODEL**

XING, W.1, SHAOLIANG, Z.2, LORENZO, A.1, GOMEZ, M.1

*1UNIVERSIDAD POLITÉCNICA DE MADRID;2TSINGHUA UNIVERSITY*

INTRODUCTION: Multicollinearity and confounding bias were two difficulties that plagued researchers in interpreting key performance indicators and predicting basketball team success through performance regression analysis. Multicollinearity leads to high variance estimators of regression coefficients. Confounding bias, especially the team's performance style misleads the causal inference and the estimation of indicator effects. Therefore, the aim of this study was to remove the multicollinearity of the game-related data and identify the key performance indicators that really affect the match outcomes of elite women's basketball.
METHODS: 244 matches were collected from 2010 - 2020 world womens basketball top-level competitions. 1) use principal component analysis (PCA) for reducing the multicollinearity of team game-related statistics in and cluster team's performance styles based on principal components (PCs). 2)compare the impact of a teams own style with that of the opposing team on the match outcome and identify the relationships between PCs and match outcome by using a generalized linear model (GLM) as a baseline model and three generalized mixed linear models (GLMMs) consider different random factors (GLMM1, team's own style; GLMM2, opposing team's style; GLMM3 both teams own and opposing team's styles) as candidate models.
RESULTS: Seven PCs were selected from twenty original game-related variables and five team performance styles were identified according to PCs. The model comparison showed that the opposing teams style has a much greater impact on the outcome of the game than the team's own style. Two-point made, two-point made, and free throw rate had significant effects on the match outcome for all GLM and GLMM analyses while free throw percentage and steals had no significant effect. In terms of defensive rebounds and turnovers, the results of the GLM and GLMM analyses differed. For the GLM and the GLMM considering the teams own style, defensive rebounds had a significant effect on the match outcome, while turnovers had no significant effect. However, for the GLMMs considering the opponents style and both the teams own and opposing team's styles, the effects of defensive rebounds and turnovers on the match outcome were reversed.

CONCLUSION: PCA can effectively reduce the multicollinearity in regression models of team performance analysis in elite womens basketball. GLMM analysis is more powerful to identify the key PCs for teams' success than GLM. When considering the performance styles of the opposing team, turnovers may be a more important indicator than defensive rebounds for the match outcome. Incorporating (instead of ignoring) the styles of team performance on both team sides especially the opposing team's style in the model could improve our ability to describe how technical performance components relate to outcomes and allow sports scientists and coaches to get a better understanding of the success of women's basketball matches.

**RELIABILITY OF DXA FOR THE MEASUREMENT OF TOTAL AND REGIONAL BODY COMPOSITION IN ELITE SOCCER PLAYERS**

FANCHINI, M.1,2, RILLO, G.1, BRUNO, M.1, SHARP, C.1

*1. AS ROMA FOOTBALL CLUB, ROMA, ITALY, 2. UNIVERSITY OF VERONA, VERONA, ITALY*

INTRODUCTION: Dual-energy X-ray absorptiometry (DXA) is widely used for the assessment of total and regional body composition. Acquisition of the data can be done automatically with the in-built software however the software may under/overestimate regional parameters (i.e. legs). As such, the data may also be acquired by operator manual adjustment of the regions-of-interest (ROI) but the experience of the operator may influence the accuracy and reliability. In elite football monitoring leg muscle mass is relevant therefore operator adjustment may be required. The aim of this study was to examine the reliability of total and regional body composition when comparing automatic and manual ROI assessment performed by operators with different experience levels.
METHODS: Twenty-four elite soccer players (age 18 ± 1 yrs; height 179 ± 5 cm; body mass 72 ± 5 kg) from an Italian Serie-A team participated in a test-retest study. Tests were performed with Lunar iDXA (GE Healthcare Lunar, Madison, USA) and examined with in-built software (enCORE 17, GE Medical Systems Ultrasound & Primary Care Diagnostics, USA) on two different days. Total body fat mass (FM) and free fat mass (FFM) were examined as total body composition, and free fat mass of right and left legs (FFMR and FFML) were examined as regional body composition parameters. ROI were determined automatically (AROI) and by two operators with low and high experience (Low1 and High1). After two weeks, the operators were asked to do the analysis again (Low2 and High2) on the same images. Reliability was examined as Typical Error of Measurement (expressed as percentage, TEM) and Intraclass Correlation Coefficient (ICC).
RESULTS: The values were within the range 9.7-10.2 kg for FM, 58.8-59.5 kg for FFM, 10.3-12.8 kg for FFMR and 10.2-12.7 kg for FFML. The TEMs were within the range 2.0-2.4% for FM and 0.8-0.9% for FFM for all the assessment. The TEMs for FFMR were 1.4, 4.1, 1.2, 1.6, 1.3 % for AROI, Low1, High1, Low2 and High2 respectively. The TEMs for FFML were 2.0, 3.9, 1.1, 1.3, 1.1 % for AROI, Low1, High1, Low2 and High2 respectively. Low1 showed higher values of TEM for FFMR and FFML. The ICC were within the range 0.99-1.00 for FM, 0.82-0.98 for FFMR, 0.83-0.98 for FFML and 0.99 for FFM.
CONCLUSION: The reliability of total and regional body parameters found in the present group of elite soccer players was similar to the values reported in the literature (1, 2). No significant difference was found between reliability parameters in FM, FFM however the lowest reliability found in Low1 in FFMR and FFML suggested the low experience of the operator have influenced the DXA results in his first assessment. Even if operators are familiarized with ROI customization they need experience to provide reliable outcomes.

### CP-BM04 Upper extremity

**COMPARISON BETWEEN NORDIC WALKING AND LIGHT DUMBBELLS BASED EXERCISE ON UPPER BODY MUSCLE ACTIVITY**

PELLEGRINI, B., ZOPPIROLLI, C., MUOLLO, V., BORTOLAN, L., SCHENA, F.

*UNIVERSITÀ DEGLI STUDI DI VERONA*

INTRODUCTION: Tough While Nordic walking is generally recommended as an aerobic physical activity, it is often referred to as being suitable for exercising the upper body musculature. The aim of the present investigation was to compare the engagement of upper body muscles during Nordic Walking compared to common resistance training exercises performed with light weights typically proposed in circuit workouts for women.
METHODS: Eight women performed NW at 5.5 km/h without (NW) and with an additional 1kg wrist load (NWL). By using 1kg handheld dumbbells, they were also engaged in biceps curls, (BC), triceps kickback (TK), triceps extensions (TE), frontal rise (FR), and lateral raise (LR) strength training exercises. Muscle activity from Obliquus Externus Abdominis (OEA), Erector Spinae (ES), Anterior Deltoid (AD), Biceps Brachii (BB), Triceps Brachii (TB), Posterior Deltoid (PD) and Latissimus Dorsi (LD) was investigated by surface EMG. EMG amplitude during NW, NWL, and strength training exercises was normalized with respect to EMG amplitude during Maximal Voluntary Contractions (MVC) performed for each muscle, and compared over exercise conditions through one-way ANOVA for repeated measures.
RESULTS: During NW muscular activation for upper limb extensors were 31 ± 16% for TB, 22 ± 7% for PD, and 20 ± 9% for LB; for upper limb flexors were 8 ± 5% for AD and 13 ± 8% for BB; and were 12 ± 5% for ES and 20 ± 5% for EOA. A significant effect of exercise modality on activity level was found for all muscles. NWL condition was associated with a slightly higher activity with respect to NW only for BB.
NW and NWL allowed reaching higher muscles activity with respect to those elicited by most of the investigated dumbbell exercises for OEA, ES, and LD, whose activation is lower than 13%, 8% and 11% of MVC respectively. NW and NWL induced a muscular activation similar to those obtained with specific exercises, TRK and TRE for TB; TRE, TRK and LR for PD.
Only for upper limb flexors, the activation level during specific exercises with dumbbells was found to be superior to for NW or NWL. AD was indeed engaged more extensively during TE (51 ±21%), FR (39 ± 13%) and LR (43 ± 20%) exercise and BB was engaged at a superior level by BC exercise (32 ±10%) with respect to NW and NWL.
CONCLUSION: According to our results, NW can elicit muscle activation similar to exercise with light dumbbells exercise for upper limb extensors extensor and trunk stabilizers, but lower activation for upper limb flexors. The additional load applied to the wrists during NW seems not to be effective in eliciting a greater muscular engagement. Specific exercises should therefore be added to the NW activity when the workouts are aimed at exercising the flexors of the upper limbs. This investigation focused on the average level of muscular activation, NW has a further advantage to include a high number of repetitions than those typically performed in dumbbell-based exercises.

### EFFECTS OF REACHING MAXIMAL SPEED ON UPPER EXTREMITY AND TRUNK KINEMATICS DURING WHEELCHAIR PROPULSION

SEVERIN, A.C., TURKKI, V.M., DANIELSEN, J.

*NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY*

INTRODUCTION: Kinematic studies on manual wheelchair (MWC) propulsion commonly describe the upper extremity and trunk movements and the demands posed speed. It has been argued that because speed influences kinematics (e.g., range of motion, joint angles at start of the push phase etc.), different speeds should be considered in analyses of kinematics (1). Most kinematic studies on MWC propulsion are performed at speeds between 1.1 m/s and 1.7 m/s (2), but little research has examined the kinematic demands of propulsion at speeds approaching individuals' maximal speed. This study investigated differences in upper body kinematics at moderate and maximal speeds of wheelchair propulsion.
METHODS: Eighteen able-bodied individuals (8F, 10M, 33±11 yrs., 75.2±11.4 kg) performed an incremental MWC propulsion test on a treadmill, starting at 1.1 m/s (baseline) until they reached their maximal speed (1.9±0.4, range: 1.3-2.5 m/s) at 2.5° incline. An 8-camera Qualisys system tracked the trunk and upper extremities (120Hz). Kinematic data was analysed in Visual 3D (C-motion Inc., Germantown MD). The start of the push phase was identified, and cycles were time normalised. The Statistic Parametric Mapping (SPM) toolbox (3) for Matlab (MathWorks, Natick, MA) compared the excursions for the two speeds through a paired t-test, with the alpha-level set at 0.05. Tests were performed for 3 degrees of freedom (DOF) for the shoulder, 2 DOF for the elbow, and for trunk flexion/extension.
RESULTS: The analysis showed differences between speeds for all analysed joint excursions at some point through the movement ($p<0.05$) . Trunk range of motion showed the largest differences between the speeds (~20° at baseline, ~35° at maximal speed, SPM t-value: -8.10.05) mainly due to more trunk flexion during the push phase (0 – 25% of the cycle). The shoulders were also more abducted throughout the entire movement at maximal speed (SPM t-value: 0.60.05 for most of the cycle). The smallest difference was seen in shoulder internal/external rotation, where only the first 15% of the cycle were different (SPM t-value: -5.9 CONCLUSION: These data indicate that kinematics may differ between baseline and maximal speeds for novice wheelchair users. High-speed wheelchair propulsion seems to require increased involvement of the trunk which likely also affects the rest of the kinetic chain. This can have implications for day-to-day activities as well as sporting performance and should be considered when designing and interpreting studies on wheelchair propulsion kinematics and dynamics. These data also show that researchers should be cautious when selecting speeds for their research since some participants were close to their max speed already at the baseline speed.

### VALIDITY AND RELIABILITY OF SMARTPHONE APPLICATION FOR SELF-MEASURING OF ACTIVE SHOULDER RANGE OF MOTION IN A STANDING POSITION

SHIMIZU, H., SAITO, T., KOUNO, C., KAWABE, R., ONISHI, M., NAGAI-TANIMA, M., AOYAMA, T.

*KYOTO UNIVERSITY: KYOTO DAIGAKU*

INTRODUCTION: Shoulder range of motion (ROM) is one of the most important indicators for shoulder disease severity, function, and physical assessment. The universal goniometer (UG) was used as the gold standard method for ROM measurements. Recently, smartphone applications for ROM measurement have been attracting attention as an alternative method to UG. This study aimed to investigate the validity and reliability of active ROM measurements using a smartphone application goniometer that can be used by patients themselves in a standing position.
METHODS: The dominant shoulders of 19 healthy participants were included in this study. The two observers who are physical therapists used the UG, whereas the participants used a smartphone application goniometer to measure shoulder ROM. A recorder, a physical therapist independent of the observer and the participant, read and recorded the shoulder ROM measurements. The order of measurement movements and devices used was randomized.
RESULTS: The agreement between the smartphone application goniometer and the UG (the percentage of participants whose difference between the UG and application measurements was within ±20% of the mean of the goniometer and application measurements) ranged from 42% to 100%. The intraclass correlation coefficient (ICC 3,1) values for the agreement between the smartphone application goniometer and UG ranged from 0.72 to 0.97, showing significant and approximately perfect correlations.
CONCLUSION: High agreement with the UG showed excellent validity, indicating that the smartphone application goniometer used by participants in the standing position is an excellent method and instrument. The results suggest a simpler, more reliable, practical, and inexpensive method for measuring shoulder ROM required for the prevention of sports disorders and self-care.

### THE XCO ENDURANCE TEST : A NEW TEST TO ASSESS THE ENDURANCE OF ROTATOR CUFF MUSCLES

TOOTH, C., SCHWARTZ, C., GOFFLOT, A., CROISIER, J.L., FORTHOMME, B.

*UNIVERSITÉ DE LIÈGE*

INTRODUCTION: Shoulder injuries are common in overhead athletes. External rotators weakness has been often correlated with muscular or articular injuries at shoulder part. Muscle endurance can be defined as the ability of a muscle or a group of muscles to produce strength over a period of time. Since a lot of gestures are performed repetitively and with a high frequency in overhead sports, this quality seems to be interesting to assess in the screening of overhead athletes. Therefore, the objective of this study was to assess the reliability of a new functional test (the Xco Endurance Test) aimed to assess the endurance of rotator cuff muscles in overhead athletes.
METHODS: Thirthy-two healthy volunteers (mean aged 23.0±3.7 years, measuring 179.4±4.9 cms and weighting 75.9±11.5 kgs) were recruited. Eighteen of them practiced an overhead sport at least five hours a week. Fourteen of them did not practice any overhead sport. The Xco Endurance Test was performed on the dominant side, in a seated position, arm at 90° of abduction, with a 900g-Xco in the hand. The objective of the test was to repetitively perform an external rotational movement, with a range of motion of 90°, and return to initial position until exhaustion. The two sessions were organised, separated by seven days. The level of exhaustion during the test was quantified with the the Borg CR10 scale during the exercise. The intraclass correlation coefficient (ICC 2,1) as well as standard error of measurement and minimal detectable change were used to assess the realibility of the test.
RESULTS: The mean duration time of the test was about 222±94 seconds. The relative reliability was very high in all the population, with an ICC about 0.959 [0.917-0.980]. The standard error of measurement (SEM) was about 19.2 seconds, which can be considered as clinically acceptable while the minimal detectable change with 95% of confidence (MDC95) reached 53.3 seconds, which is quite high regarding to the duration of the test. The duration of the test was significantly more important ($p<0.001$) in the overhead in comparison to the non-overhead athletes (255±96 vs 181±76 seconds).

CONCLUSION: The Xco endurance test can be used to assess external rotators endurance in overhead and non-overhead athletes. The importance of the MDC95 can be explained by a learning effect for those who reached a better score or by an eventual global fatigue for those whose score was lower during the second session. Future studies will have to focus on specific populations to provide normative values for the test.

**KEY PERFORMANCE INDICATORS IN BOXING: A 3D MARKERLESS PROTOCOL BASED ON ACTION CAMERAS**

PAGNON, D., DOMALAIN, M., ROBERT, T., LAHKAR, B.K., MOUSSA, I., SAULIERE, G., GOYALLON, T., REVERET, L.

*LABORATOIRE JEAN KUNTZMANN, INSTITUT PPRIME, LBMC, INSEP, INRIA GRENOBLE*

INTRODUCTION: Marker-based kinematics is hardly compatible with sports movement analysis, especially because it hinders natural movement. Hence, deep-learning based markerless solutions are being developed, such as Pose2Sim [1]. Sports in competition may also be subject to setup constraints, preventing the use of heavy equipment and installation. The use of lightweight action cameras, with post-calibration and post-synchronization, can be pertinent in this context. This study aimed at investigating the accuracy of the Pose2Sim pipeline in such suboptimal conditions. We assessed the measures of key performance indicators in boxing, which involves swift and 3-dimensional full-body movements.
METHODS: One male elite boxer performed 6 repetitions of a boxing sequence composed of 3 punches (jab, high hook, low hook). His 3D motion was captured both with a marker-based protocol, and with a light-weight markerless one. The latter involved 8 GoPro cameras, which were post-calibrated based on the dimensions of the boxing ring, and post-synchronized based on time-lagged correlations of 2D keypoints speeds between paired cameras. The markerless kinematic analysis was then performed with Pose2Sim. Both protocols used the same OpenSim [2] model to optimize inverse kinematics. Displacement of lead foot, pelvis, lead fist, and velocity of lead fist were analyzed for the jab. Rotation of rear foot, pelvis, displacement of rear fist, and velocity of rear fist were analyzed for the hooks. Waveform similarity was assessed with the inter-protocol coefficient of multiple correlation [3]. Time and magnitude of peaks were also compared.
RESULTS: Results from the marker-based and markerless approaches demonstrated excellent waveform similarity (CMC>0.94), and times-to-peak exhibited intervals of under one frame (i.e., 17 ms). Magnitudes-at-peak were very close for displacements (below 6 cm), but not for fist velocity on jab (1.2m/s difference) nor for rotations on hooks (up to 20° difference, e.g. for pelvis rotation).
CONCLUSION: Despite the use of action cameras, and of suboptimal calibration and synchronization procedures, our lightweight markerless protocol gives satisfying results for the analysis of key performance indicators in boxing, especially for limb displacements. Nevertheless, results should be taken with caution for velocity and for rotation measurements. Such a light-weight markerless protocol could be useful in situations where more accurate marker-based approaches are not conceivable, such as sports competitions.

**USING PRINCIPAL COMPONENT ANALYSIS TO EXTRACT KINETIC FEATURES OF THE THROWING UPPER LIMB IN ULTIMATE COMPETITION FOREHAND THROWING MOTION: COMPARISON BY THROWING ABILITY EMPHASIZING DISC SPIN ANGULAR**

UENO, T.

*GRADUATE SCHOOL OF HOKUSHO UNIVERSITY*

INTRODUCTION: This study was designed to extract the dynamic characteristics of upper-limb motion by determining the angular velocity of disc spin in the action of a forehand throwing during ultimate competition.
METHODS: This study examined data obtained from 10 male players belonging to a university Ultimate game team (1.72±0.04 m height, 62.8±3.6 kg weight, 19.7±1.4 years of age). Each player made 20 forehand throws to constitute 200 total throws for our measurements. An optical 3D motion capture system was used to record the examinee actions. Using inverse dynamic analysis, we calculated the joint moments of the shoulder joint, elbow joint, and hand joint of the throwing arm during operation.
We grouped all the throwing trials, assessing motions by 10 subjects with 20 throws each, into three groups according to the angular velocity of disc spin immediately after DRL, as high, middle, and low groups. We used the angular velocity of the disc spin as our index for evaluation and applied the grouping above to ascertain the dynamic characteristic of these trials generating high angular velocity. Of the 200 data of trials, 13 data were discarded because of failure in data. The remaining 187 data were used for analyses. The angular velocities of the high group (number of samples n = 33) were greater than 60 rad/s. Those of middle group (n = 91) were 60 rad/s for less and greater than 45 rad/s. Those of the low group (n = 63) were 45 rad/s or less.
As a preliminary step of statistical testing, we conducted dimension reduction of data using principal component analysis.
RESULTS: Results the high group showed significantly greater inner rotation moment of the shoulder joint, pronation moment of the proximal radioulnar joint, ulnar flexion moment of the hand joint, and inner rotation moment of the distal radioulnar joint immediately before maximum external rotation (MER) of the shoulder joint compared with the other two groups ($p < .01$).
CONCLUSION: These moments exhibited peaks (extrema). These exertions of moment immediately before MER must have been preparation operations to store energy for quick twist return operation during MER and DRL, suggesting application of a stretch–shortening cycle to boost the disc spinning velocity.
The features in the high group were the following.
1) Strong development of the horizontal abduction moment of the shoulder joint immediately before DRL was inferred as a braking action of the adduction moment of shoulder joint.
2) Peaking of internal rotation moments of the shoulder joint was recognized, as were the pronation moment of the superior radioulnar joint, the flexion moment of the wrist joint, and the pronation moment of inferior radioulnar joint immediately before MER.

**CONTROL IN ACCURATE BASEBALL PITCHING EXPLORED FROM POSITIONAL RELATIONSHIP BETWEEN BALL AND FINGERS**

KUSAFUKA, A., NISHIKAWA, K., TSUKAMOTO, N., KUDO, K.

*THE UNIVERSITY OF TOKYO*

INTRODUCTION: Accurately controlling a ball to a target position repeatedly is one of the human specific motor skills. This can be observed as various sports-related skills, such as pitching, kicking, and batting. The final arrival position of the ball can be determined by its physical state at the release or impact, approximately. In baseball pitching, it is known to be necessary to reduce the variability of the ball's release angle especially to reduce the variability of pitch location. However, the body movements that should be performed to control release angles are still unexplained, although previous studies have suggested hand and finger movements are important. We focused on the

positional relationship between the ball and the fingers, which is the point of action the force on the ball that should be considered in terms of possible elements that humans can control, to clarify the characteristics of the body movements for the accurate pitching.
METHODS: Two high-speed cameras (960 fps) were used to capture the pitching motions of 14 skilled pitchers, and the 3D positions of the joints of wrist, index finger, middle finger, and the ball during each pitching of 30 fast balls were obtained using an automatic image recognition technique based on deep learning (DeepLabCut). Speed was defined as the magnitude of velocity vector at the ball release. The release angle was given by the elevation angle θ1 (−90◦ to 90◦) and the azimuth angle θ2 (−90◦ to 90◦) of velocity in polar coordinates.
RESULTS: The time series changes in fingertip positions of index finger and middle finger relative to the ball were compared among the pitchers, and it was found that the pitchers whose fingertips of middle fingers were in contact with the lower part of the ball about 20-30ms before the release showed less variability in release angle.
CONCLUSION: To clarify why correlations between the positional relationship and variability in release angle were found in such time periods, we calculated the time series change in the acceleration of the ball and compared it to these time periods. As a result, the middle finger positions are low when the vertical acceleration direction changes and the time periods are before the peaks of the vertical acceleration. It was thought that the lower middle finger positions before the peaks of the acceleration could have reduced the variability of the middle finger positions at the peaks of the acceleration where a large force occurred just before release, and consequently reduced the variability of the release angles. This suggests that pitchers with low variability in release angles employed movements that positioned their fingers robustly against spatial variability.

### VALIDITY AND RELIABILITY OF THE PERCEPTION NEURON SYSTEM TO QUANTIFY UPPER BODY KINEMATICS

WU, Y., SUN, L., HUANG, Y., LIU, F.
*BEIJING SPORT UNIVERSITY*

INTRODUCTION: As one of the most popular IMU-based motion capture system, the Perception Neuron system (PNS) has been widely applied within virtual reality interaction, film effects development and rehabilitation fields [1]. Its validity and reliability to quantify the lower body kinematics during functional movements have been proven [2], but those studies of the upper body are still lacking. Therefore, the aim of this study was to first evaluate the validity and reliability of the upper body kinematics provided by the PNS through comparison to a gold-standard optical system and then verify if the system accuracy depends on the task complexity and movement speed [3].
METHODS: Seven male adults (age: 23.28±1.25 years, height: 176.14±8.01cm, weight: 76±7.46 kg) participated in this study after signing informed consent forms. Upper body kinematics were collected simultaneously at 100 Hz by the PNS and a passive optical motion capture system (OptiTrack, Natural Point, USA) with ten high-speed cameras. Participants were required to perform both simple and complex tasks at fast and slow speeds, with the simple task defined as movements occurring in only one plane while the complex one in multiple planes. The simple task included 8 single DOF (degree of freedom) movements of the trunk (3), shoulder (3), and elbow (2). The complex task was to lift a 2.5 kg box over the shoulder [4]. To verify the reliability of the PNS, two sessions of testing were required, with the sensors being re-worn, reflective markers re-taped and recalibrated before each session.
RESULTS: Validity: High-level consistencies were observed for all joint kinematics in all planes across all simple tasks with the coefficient of multiple correlation (CMC) values of 0.86-0.99, the root mean square error (RMSE) of the two systems ranged from 3.6 to 11.3, and the mean neutral to peak range of motion differences (systematic bias) were all below 7.7. In the complex task, all plane joint kinematics had equally high consistency, with CMC values of 0.76-0.97, the RMSE was ranged from 2.1 to 12.3, and the systematic bias were all bellow 11.3. Reliability: All between-session intraclass correlation coefficient (ICC) of the angle from all motions were good to excellent for the PNS (ICC between 0.83 and 0.97) in simple and complex tasks, and these results were basically consistent with those from the optical system. Paired t-test revealed that the movement speed had no significant effect on these values ($p>0.05$) while the task complexity did ($p<0.05$) and the more complex task resulted in greater bias, but still acceptable (CMC>0.75) .
CONCLUSION: The PNS could accurately quantify upper body kinematics in different tasks regardless of the task complexity and movement speed. Our results suggest that the PNS is suitable for assessing upper body kinematics and could provide participants with accurate enough motion kinematics for further analysis.

### PHYSIOLOGICAL TREMOR AS A RESULT OF TIREDNESS RELATED TO MANUAL ACTIVITIES REQUIRING PRECISION

MAZUR-RÓZYCKA, J., LACH, P.
*CENTRAL INSTITUTE FOR LABOUR PROTECTION - NATIONAL RESEARCH INSTITUTE*

INTRODUCTION: Physiological tremor is defined as involuntary oscillations of individual parts of the body of healthy people resulting from the interaction of mechanical and nervous factors (Tomczak et al. 2014). Increased muscle tremor, limited motor skills and weakened eye-hand coordination may reduce the precision of activities. Physiological tremor can interfere with precise hand control in professional musicians and surgeons, as well as can impair motor performance in professional athletes. Tremor as a symptom accompanying fatigue can be treated as information about its intensity. The purpose of the study was to assessment of the impact of fatigue with manual activities requiring precision on the parameters of physiological tremor.
METHODS: 20 women and 20 men (25-35 years old) participated in the study. Fatigue was induced during a three-hour (180 minutes) two-handed upper limb coordination test. The test consisted of three stages. The first step lasted 30 minutes, the second 60 minutes (2 x 30 minutes continuously) and the third 90 minutes (3 x 30 minutes continuously). The accelerometric method using an acceleration measuring kit was applied to analyse tremor. Dominant and non-dominant hand physiological tremors were measured before exercise and after 30, 90, and 180 minutes of exercise.
RESULTS: The average waveforms of the spectral density function of the physiological tremor power were similar in shape to all subjects. They showed similar proportions of individual components and the correspondence of frequencies for which maxima occur. There were no statistical differences between dominant and non-dominant hand in the frequency range 1-5 Hz ($p=0.99$) and 8-14 Hz ($p=0.21$). The greatest increase in the amplitude of physiological tremor was observed after 30 minutes of the task duration for woman and after 180 min of exercise for men. For dominant hand in woman group there was a significant difference between subsequent measurements for 1-5 Hz ($p = 0.01$) as well as 8-14 Hz ($p = 0.03$).
CONCLUSION: Physiological tremor increased during performing manual activities. This phenomenon may influence psychomotor performance, deteriorating the ability to perform tasks requiring movement precision.

### CP-SH02 Talent identification and development

#### MORPHOLOGICAL AND PHYSIOLOGICAL PREDICTORS FOR SELECTION AT NATIONAL AND LEAGUE STATUS FOR YOUTH SOCCER PLAYERS

KALATA, M.1, WILLIAMS, C.A.2, VARJAN, M.1, BUJNOVSKY, D.1, ZAHALKA, F.1, MALY, T.1

*1 CHARLES UNIVERSITY 2 UNIVERSITY OF EXETER*

INTRODUCTION: Identifying talent with relevant physical predictors to establish players at the elite level has always been topical for soccer and sport science departments. But due to the large number of factors responsible for performance, there is still no consensus for the selection of key objective tests. However, the professionalisation of youth soccer has resulted in increased physical requirements of the players. Therefore, the aim of the study was to examine physical predictors to differentiate players who have reached the highest level (national team) of youth elite soccer compared to non-selected peers.
METHODS: Male youth players category U16 and U17 (n=32) from an elite academy were recruited (age, 15.74 ±0.58 y; stature, 177.3 ±5.9 cm; body mass, 64.9 ±6.7 kg). Isokinetic strength of knee extensors (KE) and flexors (KF) were measured (Cybex NORM®, Humac, USA). Vertical ground force reaction (VGR) and total impulse (TI) during countermovement jump were calculated (Kistler AG, Switzerland). Acceleration (0-5, 5-10, 10-20 m), change of direction (505R, 505L) and flying linear test (F10 and F20) by photocells were measured (Timer Browing system, Utah, USA). A treadmill v-VO2max was recorded (Cosmos, Germany). Body fat by bioimpedance was determined (Tanita Corp, Japan). Somatic maturity status was determined using peak height velocity (PHV). Predictors were classified into three blocks: speed (0-5 m, 5-10 m, 10-20 m, 505P, 505L, 10F, 20F, v-VO2max), strength (KE, KF, VGR, TI) and somatic (stature, body mass, % body fat, PHV). Binary logistic regression with stepwise forward likelihood method was utilised (entry and removal of model was set at $p < 0.05$). Based on the criteria of success in the national team, the players were classified into two groups: non-national team (NNT, n=17) or national team (NT, n=15). Pearson's correlation coefficient determined associations among variables.
RESULTS: Significantly higher values of acceleration 0-5 m and v-VO2max in NT compared to the NNT group were found (5.07 ±0.15 vs 4.85 ±0.16 m•s-2; 4.68 ±0.23 vs 4.50 ±0.20 m•s-1, $p<0.05$). Significantly lower times on 10F, 20F and 505L in NT compared to NNT group were found (1.17 ±0.04 vs 1.22 ±0.04 s; 2.34 ±0.06 vs 2.45 ±0.11 s; 2.26 ±0.07 vs 2.35 ±0.09 s, $p<0.05$). Significant high (r=0.7-0.9) correlations were found (0-5 m vs F20; 505R vs 505L; stature vs body mass, $p<0.001$). Significantly moderate (r=0.5-0.7) and negative correlation among blocks was found (VGR vs F20, $p<0.01$). Final model identified two significant variables (505L and 10F, $p<0.05$), which predicted correctly NT from 86.7% and NNT from 88.2% ($X2=21.62$, $R2=49.1$ %, $p<0.001$).
CONCLUSION: These findings indicate that speed abilities compared to strength and somatic characteristics favour success in youth soccer at a national level. Soccer coaches should continue to focus on important predictors of performance in the development of elite talent.

#### COMPARISON OF THE RELATIVE AGE EFFECT BETWEEN ELITE VERSUS SUB-ELITE LEVEL IN YOUTH FOOTBALL PLAYERS

BREUER, J., JAKOBS, J., STAUB, I., VOGT, T.

*GERMAN SPORT UNIVERSITY COLOGNE*

INTRODUCTION: The relative age effect (RAE) is a well-known phenomenon that has been observed in many sports. In this context, elite level football is amongst the fields of interest that have been studied frequently (Deprez et al., 2013). Thus, the level of competition is one of the factors affecting the RAE. Earlier studies showed that the RAE is more pronounced in higher competition levels, which is explained by an increase in selection pressure (Jackson & Comber, 2020). At the same time, elite academies have access to higher qualified coaches and extensive scientific resources regarding the selection of talents. For this reason, one would expect weaker RAE at elite level. To gain further sport specific insight, this study aims to compare the prevalence and magnitude of the RAE between elite and sub-elite level in youth football.
METHODS: A total number of 1.728 football players from age groups U10 to U19 representing a certified academy of a professional club of German Bundesliga (n=876) and a cohortof a sub-elite club of German 4th division (n=852), respectively, for subsequent seasons between 2015/16 – 2020/21 served as data pool. Birth dates were collected, differences between the observed and expected birthdate distributions were analysed using chi-square and Cramer's V was used to estimate the magnitude of effect sizes according to age groups.
RESULTS: The findings reveal birthday asymmetry in both elite and sub-elite cohorts, with a greater extent in elite level (e.g. 1st half year U10: 73.4% in elite versus 64.4% in sub-elite). While elite level players show a consistent significant RAE across all age groups (each $p<0.05$) with medium to large effect sizes, there is no RAE for age groups U10 to U15 in sub-elite level found (each $p>0.05$). However, there is a significant RAE in U17 ($p<0.05$) and U19 ($p<0.05$) with medium effect sizes in sub-elite level.
CONCLUSION: The findings confirm earlier results of consistent prevalence and magnitude of RAE in youth elite football players. The comparison shows that the effect is much more pronounced in elite level than in sub-elite level, supporting the line of argumentation that selection pressure has a strong impact on the magnitude of RAE. Further studies including additional factors (e.g. maturation, physical and psychological dimensions) are needed to gain more insights on this phenomenon.

Jackson, R. C., & Comber, G. (2020). Hill on a mountaintop: A longitudinal and cross-sectional analysis of the relative age effect in competitive youth football. Journal of Sports Sciences, 38(11-12), 1352-1358.

### ANALYSIS OF GROUP COHESION THROUGH VARIABLES RELATED TO EXPERT PERFORMANCE IN FOOTBALL

ASÍN-IZQUIERDO, I.1,2, GRAUPERA-SANZ, J.L.1

*1 UNIVERSIDAD DE ALCALÁ, MADRID, SPAIN; 2 PHYSICAL PERFORMANCE AND SPORTS RESEARCH CENTER, PABLO DE OLAVIDE UNIVERSITY, SEVILLE, SPAIN*

Introduction
Expert performance in sport is developed through deliberate practice in accordance with a social and relational system. The theoretical model developed by Carron and collaborators structures group cohesion via a dynamic process that settles the cohesion of a group towards the social and towards the task. Group cohesion can be essential in sports teams with a bidirectional relationship of complexity according to different variables related to expert performance.
Methods
The study included 876 football players, 219 women and 657 men, aged between 13 and 40 years (M = 18.96, SD = 4.54) and with a mean experience of 10.45 years competing. The instrument used was the Group Environment Questionnaire (GEQ), translated and validated into Spanish as the Cuestionario de Ambiente de Equipo (CAE). The data collection was achieved by an expert researcher in the sports facilities, in a group and prior to the training session. Participation was voluntary with informed and anonymous consent. The study was carried out in accordance with the Declaration of Helsinki. Data analysis was performed using the statistical package IBM SPSS v.26. The data normality and homogeneity of the variances of the groups were checked.
Results
Univariate Mancova tests (age as covariate) showed significant differences in Group Integration-Social ($p=0.034$; $\eta2=0.010$) by performance level with a very slight effect. The averages kept stable and there was only a decrease in the international performance. The univariate contrasts of the Manova proved significant differences between the sport category groups in Individual Attractions to the Group-Social ($p=0.025$; $\eta2=0.009$), with a very slight effect. The trend decreased a bit in scores from cadet to senior. The correlations of the GEQ with temporal variables related to expert performance showed coefficients lower than 0.10 with the four GEQ scales, except in Individual Attractions to the Group-Social, which had a negative and significant coefficient with Age (-0.13, $p<0.001$).
Discussion
In group cohesion, studies with soccer players of various performance levels (amateur, semi-professional and professional) were observed but differences between groups were not analyzed (similar results are seen in volleyball studies); however, regarding the category there are no previous references. There is controversy, in previous studies, about the correlations of temporal variables with group cohesion. In this study, a fairly stable trend towards the task and towards the social is observed (except for international level), both valued as the performance and category of the sports team increase. Group cohesion and its perception, especially towards the task, seem to establish a relationship, complex and controversial, with performance, deliberate practice and intervention in team sports, so it would be interesting to delve into the analysis of competitive performance and other variables.

### PHYSIOLOGICAL DEMANDS OF MEN ACADEMY RUGBY UNION PLAYERS AT NATIONAL LEVEL

DELFORGE, E., IMBERT, S., ZAMIA, S., DAUSSIN, F.

*UNIVERSITÉ DE LILLE*

INTRODUCTION: To make training effective, it is necessary to calibrate them according to the demands of the competition. While there is some data on senior elite and national level, there is little information about the physiological demands of a match in men academy rugby union players at national level. The aim of this study was to characterize the match activity of under 19 years old academy rugby union players in order to prescribe accurate trainings.
METHODS: Thirty-one male academy rugby players of the U19 national championship, (mean age: 16.8 ± 0.7 years, mean body mass: 81.4 ± 17.6 kg, mean height: 179.4 ± 7 cm) have been monitored during 11 competitive matches with GPS. Sixteen players were monitored per game with a least three players per position groups. The total distances, number of accelerations, peak velocity and the distance at high velocity (>21 km.h-1) were quantified. Position groups were defined as the forwards and the backs. The data obtained correspond to a specific position activity over an entire match. Forty-two sequences were included for forwards and thirty-nine for backs.
RESULTS: Backs travelled more distance over the game than forwards (5022±432 vs. 5480±565m, $p<0.05$). The number of acceleration (>2.5m. s-1) for the forwards and backs were 18 ± 9 vs. 26 ± 9 times ($p<0.05$), respectively. Higher high velocity running was achieved by the backs compared to forwards (26.3 ± 2.9 vs. 29.2±2.3 km.h-1, $p<0.05$). Backs covered greater distance at high velocity compared to forwards (140 ± 119 vs. 280 ± 114m, $p<0.05$, respectively).
CONCLUSION: These results suggest that the physical demands are specific to the positions and should be considered by coaches. It will be possible to create optimized position-specific training programs in U19 men rugby players at national level.

### INJURY AND HEALTH PROBLEMS IN GRASSROOTS YOUTH SOCCER PLAYERS: A STUDY OF PREVALENCE, SEVERITY AND ASSOCIATED DEMOGRAPHIC AND PSYCHOSOCIAL FACTORS

SERSLAND, A., JOHANSEN, B.T., ESPESETH, V.S., TØRRE, M., SOLSTAD, B.E.

*UNIVERSITY OF AGDER*

Introduction
Youth grassroots soccer is associated with a wide range of health benefits, but participation still poses a risk of injury and health problems. Yet, epidemiological evidence of injury and health problems prevalence and severity in the grassroots setting during a regular season is limited. Therefore, the purpose of the present study was twofold. First, the aim was to describe the prevalence, severity, and location of injuries and health problems in a large cohort of youth grassroots soccer players. Second, we wanted to investigate the relationship between prevalence of injury and health problems, and possible associated demographic (e.g., age, gender, number of training and match hours/week) as well as psychosocial factors (e.g., peer and coach autonomy support, social support).
Methods
Young soccer players (N = 588, Mage = 15.7 years; SD = 1.4) playing for teams (U14-U19) registered for the 2021 season in Agder county in Norway were recruited for this study. The Oslo Sports Trauma Research Centre (OSTRC) questionnaires on health and injury problems were used to record health problems and severity, while a modified practice history questionnaire was used to record training data. Classification and Regression Trees (CRT) were used for the data analyses. We analyzed the relationship between the independent variables and

four outcome variables (e.g., total health problems, total substantial health problems, injury problems, and substantial injury problems), resulting in four decision trees.
Results
The prevalence of all health problems was 76% (54% for only injuries), with 31% (23% for substantial injuries) experiencing substantial health problems. Girls reported higher prevalence (83%) of total health problems than boys (73%). Of anatomical areas, the knee displayed the highest prevalence (29%, 11% substantial) in this study. Girls reported more knee problems (37% vs 26%), while boys displayed more groin problems (18% vs 6%). The CRTs revealed low levels of peer autonomy support to be the main factor in three of the CRTs, with it being the only significant factor for both health and substantial health problems. For injuries, the group with low levels of peer autonomy support, along with higher amount of football activity and being a female player, showed the greatest prevalence of injuries. Regarding substantial injuries, players with more match time (> 3 hours a week) showed the greatest prevalence.
Conclusion
The results revealed the magnitude of health and injury problems in grassroots youth soccer, documenting a substantial impact of problems in this population. It also showed peer autonomy support to be the main associated factor for health and injury problems, with football activity, match time, and gender also being possible factors of importance. Researchers and practitioners are advised to take multiple factors into account when investigating or trying to prevent health and injury problems in young grassroots soccer players.

## A SURVEY EXAMINING ABOUT THE STATUS OF COMPLIANCE OF PITCH COUNT RECOMMENDATIONS AND JAPANESE LITTLE LEAGUE BASEBALL COACHES KNOWLEDGE OF IT, 9 YEARS COMPARISON

ONISHI, M.1, KOUNO, C.1, MATSUMURA, N.1, DOI, N.1, KAWABE, R.1, SHIMIZU, H.1, AOYAMA, T.1, NAGAI-TANIMA, M.1, TAHU, Y.2

*1 KYOTO UNIVERSITY, 2 KYOTO PREFECTURE SPORTS LITTLE LEAGUE BASEBALL ASSOCIATION*

INTRODUCTION: Pitch limit recommendations for preventing throwing injuries have been developed. The previous study was conducted 9 years ago and examined the level of knowledge and compliance with these recommendations among coaches of young baseball teams similar to this study. Over the years, the rules for baseball elbow prevention efforts and pitching restrictions have changed, and the current actual situation regarding baseball elbow disorders in youth baseball associated with it has not been adequately studied. This study was designed to compare the current situation and changes in coaches knowledge and compliance with 9 years ago.
METHODS: Coaches of youth baseball teams in Kyoto Prefecture responded to a questionnaire assessing their knowledge of and compliance to the recommendations. They also responded on the coachs age and coaching history. The ratio of coaches who had correct knowledge of the pitch count recommendations and who complied with these recommendations was calculated. Subsequently, the relationship between these ratios and coach age and years spent coaching baseball was analyzed using the unpaired t test.
RESULTS: In total, 213 baseball coaches participated in the study and 197 (80 teams) with no missing items were analyzed. 53.3% of coaches had correct knowledge of the recommendations. Among them, 43.8% (including non-respondents) complied with them. Those who did not comply with them (49.3±2.8 years old, 10.9±10.6 years) are significantly older($p=0.005$) and have longer($p=0.0068$) coaching experience than those who complied (43.2±6.1 years old, 5.5±3.9 years). The numbers in brackets indicate the coachs age in the former and coaching history in the latter.
CONCLUSION: The pitch limit recommendation for school-age baseball in Japan changed from "no more than 70 pitches per day and 300 pitches per week" to "no more than 50 pitches per day and 200 pitches per week" from the previous study (2013). Coaches knowledge of the recommendations increased compared to 39.8% in the prior study. The compliance with them had also increased compared to 28.3% in the prior study. In Kyoto Prefecture, the participants of this study, an initiative to prevent pitching injuries is being implemented by prefectural baseball federations. Once a year, physical findings and screening test of the elbow and shoulder joints are obligatory. As workshops are also held regularly for prevention, it is possible that coaches knowledge of the injury has developed as a result of their participation in these workshops, and that this may have changed the rate of knowledge and compliance with the recommendations. The older the coaches were and the longer they had been coaching, the lower level of the compliance with them. Older coaches may refer to their own past experiences to guide them and may fail to comply with the recommendations. In the future, it is considered necessary to have knowledge and comply with the recommendations regardless of age and years spent coaching baseball .

## RELATIONSHIP BETWEEN ANTHROPOMETRICS COMPOSITION, SPECIFIC FIELD TESTS AND THROWING BALL VELOCITY OF MALE TEAM HANDBALL PLAYERS: TECHNOLOGY FOR ASSESSMENTS TOOLS OF QATAR HANDBALL FIRST PROFESSIONAL L

ALNEAMA, A., HERMASSI, S., JABNOUN, M., CHELLY, M.S.

*ALARABI HANDBALL CLUB*

INTRODUCTION: Anthropometric parameters, physical motor test, and throwing ball velocity have been identified as fundamental in order to determine the success of the performance in handball helping in the optimal design of physical fitness programs 1,2. This study examined the relationships between the physical fitness, anthropometry, and throwing ball velocity of first-division male team handball players in Qatar sate.
METHODS: Thirty-two male team handball players (age: 25.5 ± 5.55 years; body mass: 92.9 ± 11.7 kg; height: 1.87 ± 0.07 m; BMI: 26.6 ± 3.72 kg/m2; body fat: 19.5 ± 4.56%) were recruited from the Qatar handball first professional league. The anthropometry and physical performance (yo-yo intermittent recovery test (Yo-Yo IR1), squat and countermovement jumps (SJ and CMJ), T-half test for change-of-direction (COD) ability, sprint tests (15 and 30 m) and handball jump throw velocity) were measured.
RESULTS: Only the body fat was significantly correlated with some performance parameter (jump throw: $p<.0.01$; $r=-0.746$). The t-half test ($p<.0.001$; $r=-0.668$) and Yo-Yo-IR 1 ($p<.0.001$; $r=-0.603$) followed. The position specific analysis revealed two relevant ($\eta p2 \geq 0.20$) differences for the parameters jump throw ($\eta p2=0.20$) and sprint 30 m ($\eta p2=0.20$). In both parameters, pivots showed the highest performance levels (jump throw: 33.5 ± 2.93 m/s; sprint 30 m: 4.03 ± 0.03 s). In contrast, goalkeepers (jump throw: 25.7 ± 4.97 m/s) and backs (sprint 30 m: 4.56 ± 0.39 s) demonstrated the lowest performance level. No relevant position specific differences were observed regarding CMJ ($\eta p2=0.09$) and SJ ($\eta p2=0.08$). In both tests, pivots showed the highest performance level, whereas backs were the players with the lowest level of jumping performance.
CONCLUSION: The above results could be useful for coaches and trainers, to develop position-specific training concepts as they are based on tests, which reflect the specific characteristics of individual playing categories. These findings could be added to the international literature and assist in recognizing the unique nature of training regimen needed to team handball practice and training prescription.
1Hermassi et al, Front Bioeng Biotechnol. Jun 21;7:149. (2019)

**THE CURRENT LANDSCAPE OF YOUTH MULTI-SPORT TRAINING: ATHLETE AND PARENT INSIGHT DATA**

ROBINSON, N.J., MCQUILLIAM, S.J., DONOVAN, T.F., LANGAN-EVANS, C., WHITEHEAD, A.

*LIVERPOOL JOHN MOORES UNIVERSITY*

INTRODUCTION: The intent to improve a youth athlete's ability is developed through structured focused training in the competencies within their sport. To date there is little evidence around how multi-discipline youth athletes organise their training load (TL) outlook in a multitude of sports.
METHODS: The aim of this study was to analyse the daily TL, distribution and wellness in aspiring 10- 15yr old pentathletes (n=31) over 152+-35 days. Athletes completed daily reports documenting sport mode, session duration, session rate of perceived exertion (sRPE) and wellness (sleep, stress, mood, fatigue, muscle soreness). Parental understanding of training periodisation was used to contextualise the athletes training patterns (n¼15) through semi-structured interviews
RESULTS: Weekly training duration was 5 h 59 min+-3 h 38 min. The swimming discipline dominates the overall time spent training (50.5%). Pentathlon specific TL was significantly higher in the 14–15 yrs (3000+-1207 AUT) in comparison to 10–11 yrs (1837+-874 AUT). Weekly micro TL fluctuations showed significant peaks on the weekend compared to Tuesday and Friday ($p<0.05$).Wellness scores were significantly worse on Monday to Wednesdays ($p<0.05$), compared to Fridays. Parent interviews suggest a multitude of coach input from solo disciplines over a typical week, with little inter-coach discussions.
CONCLUSION: In conclusion there is little structure on a micro or macro level in youth pentathletes training showing multiple-coach input with little coach crossover. Implications for the training/competition is based around convenience/holidays/availability of resources rather than overall individual development, which suggests the potential need for an early specialisation approach to support athletes within this style of multi-discipline sport.

### CP-PN07 Vitamins and hydration

**VDBP, FREE 25-(OH)D LEVELS AND MARKERS OF PSYCHOPHYSICAL STRESS IN PROFESSIONAL FOOTBALL PLAYERS**

ZAGRODNA, A., KSIAZEK, A., SLOWINSKA-LISOWSKA, M.

*UNIVERSITY OF HEALTH AND SPORT SCIENCES IN WROCŁAW*

INTRODUCTION: It has been proposed that serum free 25-hydroxyvitamin D (25-(OH)D) may better reflect vitamin D action than total 25-(OH)D based on the free hormone hypothesis. Vitamin D plays an active role in muscle inflammatory response, protein synthesis, and regulation of skeletal muscle function. Strenuous muscle contractions during exercise may induce mechanical muscle damage. Thus, monitoring of psychophysical stress markers in athletes may help to tailor training/competition and recovery regimes to optimize performance. Therefore, the aim of our study was to check the relationship between free 25-(OH)D levels and blood count, iron, ferritin, testosterone (T), cortisol (C), creatine kinase (CK), liver enzymes (ALT, AST) and high-sensitivity C-reactive protein (hs-CRP) in professional football players.
METHODS: Professional male football players (n=35, 26.8±4.8 yrs, body fat 17.6±3.2%) participated in the study. Total 25-(OH)D was assessed using LM-MS/MS. Free 25-(OH)D concentration was evaluated by calculation, using serum albumin and vitamin D binding protein (VDBP) levels. The following biochemical parameters using standard automated technique were assessed: blood count, iron, ferritin, T, C, CK, ALT, AST and hs-CRP. The T/C ratio was calculated by dividing the two hormone levels both expressed in nmol/l. Multiple regression was performed to analyse association between VDBP, free, bioavailable 25-(OH)D and biochemical, hormonal parameters. Statistically significant models were adjusted for age, body mass and body fat. A statistical level of $p< 0.05$ was accepted.
RESULTS: Our study showed decreased serum total 25-(OH)D levels (26.1±4.3 ng/ml) in 63% of the professional players. In studied football players, there was significant correlation between serum VDBP concentrations and cortisol levels ($p<0.001$). There was no correlation between total 25-(OH)D levels and studied variables. Serum free 25-(OH)D inversely associated with hs-CRP ($p<0.028$) and cortisol ($p<0.034$) concentrations. Serum bioavailable 25-(OH)D significantly correlated with hs-CRP ($p<0.017$) levels.
CONCLUSION: Based on the results of our study, we concluded that to check some of psychophysical stress parameters (hs-CRP, cortisol) in athletes measuring free, bioavailable 25-(OH)D may provide a better index of vitamin D status that total 25-(OH)D levels in such situations. Furthermore, seems justified to monitor the levels of vitamin D, cortisol and testosterone in professional football players could be decisive in the development of more specific supplementation and injury prevention strategies.

**VITAMIN D METABOLITES STATUS, BODY COMPOSITION AND PHYSICAL ACTIVITY IN HEALTHY MEN AND ATHLETES**

KSIAZEK, A., ZAGRODNA, A., SLOWINSKA-LISOWSKA, M.

*UNIVERSITY OF PHYSICAL EDUCATION IN WROCŁAW*

INTRODUCTION: The potential effects of vitamin D in athletes has received considerable attention in the literature. However, little is known about vitamin D metabolites and its association with body composition and physical activity level. Therefore, the primary purpose of our study was to assess circulating vitamin D metabolites concentration in healthy men and outdoor, indoor athletes by considering the behaviour of their physical activity. The second aim was to determine the relationship between metabolites of vitamin D and body fat, physical activity, training volume in studied groups.
METHODS: Sixty six participants (26 healthy men – control, 24 football players – outdoor, 16 judoists – indoor) took part in the study. Vitamin D metabolites (25-(OH)D3, 25-(OH)D2, 24,25-(OH)2D3, 3-epi-25-(OH)D3, 1,25-(OH)2D) were assessed using LM-MS/MS. Skinfold thickness was measured with a Harpenden skinfold calliper and percentage body fat was assessed using seven site method (triceps, chest, abdominal, suprailiac, midaxillary, subscapular, front thigh). Physical activity was evaluated using the International Physical Activity Questionnaire (IPAQ). Multiple regression was performed to analyse association between vitamin D metabolites levels and skinfold thickness, physical activity and training volume. Statistically significant models were adjusted for age, body mass and body fat. A statistical level of $p< 0.05$ was accepted.

RESULTS: Vitamin D metabolites did not differ between the studied groups. In the group of healthy men was a significant negative association between serum 25-(OH)D3 and biceps (p<0.033), abdominal (p<0.025), suprailiac (p<0.041) skinfold thickness. 24,25-(OH)2D3 levels inversely correlated with midaxillary (p<0.038), biceps (p<0.015), subscapular (p<0.032), abdominal (p<0.008), suprailiac (p<0.007) skinfold thickness, body fat (%) (p<0.018) in control. There was inverse association between serum 3-epi-25-(OH)D3 and abdominal (p<0.04), suprailiac (p<0.047) skinfold thickness in healthy men. In group of football players 25-(OH)D3 levels correlated with midaxillary (p<0.003), biceps (p<0.011) skinfold thickness. Serum 24,25-(OH)2D3 associated with biceps skinfold thickness (p<0.016) in outdoor athletess. In football players, there was association between 3-epi-25-(OH)D3 levels and midaxillary (p<0.014), biceps (p<0.025), subscapular (p<0.009) skinfold thickness. Serum 25-(OH)D2 correlated with physical activity level (p<0.025), training volume (p<0.027) in outdoor athletes. In group of judoists, serum 25-(OH)D2 was correlated with physical activity level (p<0.008).
CONCLUSION: Based on the result of our study, we concluded that 25-(OH)D3, 24,25-(OH)2D3, 3-epi-25-(OH)D3 circulating concentrations of these metabolites are linked with skinfold thickness and body fat. The different relationship between vitamin D metabolites and skinfold thickness in healthy men and outdoor athletes might be related with different lifestyle physical activity.

**THE EFFECT OF VITAMIN D ACTION IN SKELETAL MUSCLE ON BONE AND MUSCLE PERFORMANCES**

MORI, R., YAMANAKA, H., MASUYAMA, R.

*RITSUMEIKAN UNIVERSITY*

INTRODUCTION: Vitamin D endocrine systems are required for normal bone metabolism and calcium homeostasis, which even affects skeletal muscle performances by sustaining locomotive function. In the next step, the involvement of vitamin D actions on the crosstalk between systemic calcium metabolism and muscle function should be uncovered. Since ATP sustains skeletal muscle contraction that is triggered by the binding of calcium ion to the muscle protein, we investigated whether vitamin D action altered ATP metabolism in skeletal muscle.
METHODS: Firstly, vitamin D action in skeletal muscle was manipulated in mice by crossing skeletal muscle-specific cre (creatine kinase cre) mice with VDR flox mice, phenotype of the motor functions such as locomotor activity, muscle morphology, and bone histology were assessed. Furthermore, the effect of vitamin D on ATP metabolism in skeletal muscle cells were evaluated with cultured C2C12 cells. To analyze ATP metabolism in cultured cells, the protein levels of both Cx43, a promoter of ATP transport, and ENPP1, an eliminator of ATP, were evaluated by western blot analysis. Moreover, whether cellular ATP/ADP contents were responded to the blockade of ATP release, cultured C2C12 cells were treated with the Gap26 peptide, a specific antagonist to Cx43.
RESULTS: Compared to wild-type mice, lacking VDR activity in skeletal muscle decreased locomotor activity, whereas gross phenotype such as body weight was comparable between two strains. The composition of muscle fiber types and the muscle cross-sectional area were not affected by VDR activity. As bone phenotype, bone mineral density examined by micro CT analysis was decreased, and that was supported by the results of an increased in osteoclast activity in mice lacking VDR. As results of in vitro study, 1,25 (OH)2D3 stimulation increased ENPP1, but decreased Cx43 during myogenic differentiation. Also, the ratio of ATP/ADP at every 24-hour in cultured skeletal muscle was decreased by 1,25(OH)2D3 stimulation in a dose-dependent manner. In addition, inhibiting Cx43 by Gap26 peptide resulted in an increased intracellular ratio of ATP/ADP in C2C12.
CONCLUSION: The present study indicated that the local VDR action in skeletal muscle sustained motor functions in mice. The reduction of bone mass due to an accelerated bone resorption was involved in the phenotypes by lacking VDR activity in mice. Also, treatment of 1,25 (OH) 2D3 regulates the supply and the elimination of intracellular ATP was confirmed in vitro in this study. These results describe the physiological roles of 1,25 (OH) 2D3 action in entire locomotor organs. Further, 1,25 (OH) 2D3 treatment increased ENPP1 expression in C2C12 cells likely reduced the risk of ectopic calcification in muscle tissue instead of decreased in ATP/ADP ratio. In conclusion, the vitamin D action in skeletal muscle plays a role in maintaining motor function and bone mass, one of the mechanisms of this action involves the regulation of local ATP metabolism in skeletal muscle.

**HYDRATION AND FLUID REPLACEMENT KNOWLEDGE, ATTITUDES AND BEHAVIOURS OF GAELIC FOOTBALL PLAYERS**

NÍ CHÉILLEACHAIR, N., SKELLY, F., O CATHÁIN, C., O NEILL, C.

*TECHNOLOGICAL UNIVERSITY OF THE SHANNON: MIDLANDS MIDWEST*

INTRODUCTION: Euhydration is required for optimal health and sporting performance. Significant dehydration has been associated with impaired cognitive function and sporting performance and an increased perception of effort. Invasion team sports, such as Gaelic football, are characterised by intermittent high-intensity bouts of activity over a prolonged period and have been associated with potentially high sweat rates. Given the physically demanding nature of Gaelic football training and competition, adequate fluid intake is essential for optimal health and performance. Therefore the aim of this study was to investigate hydration and fluid replacement knowledge, attitudes and behaviours of Gaelic football players.
METHODS: One hundred and seventy-five Gaelic football players (m=85, f=90; mean age: 24±6.4 years; mean playing history: 15±5.8 years) playing at club (n=97), college (n=28) and elite (n=50) level were recruited. Participants completed a modified version of a previously validated survey [1]. The 59 question survey involved 4 sections including (1) background demographic information and (2) knowledge, (3) attitudes and (4) behaviour towards hydration and fluid replacement and was completed online. The maximum score obtainable in each of section 2, 3 and 4 was 17, with higher scores indicating positive hydration knowledge, attitudes and behaviours.
RESULTS: Players' mean hydration knowledge score was 12.9±1.7 (75.9%±9.7%). Almost 80% of players had a knowledge score of 12 (70%) or more. Only 4.5% (n=8) of players scored 100%. The mean attitude and behaviour scores were 12.2±2.2 (72%±12.8%) and 12.2±1.8 (71.9%±10.6) respectively. No significant differences were observed for knowledge, attitudes or behaviour between gender or playing level. Significant correlations were observed between knowledge, attitude and behaviour scores (p<0.05). Almost one-third (65.3%) of players did not know that consuming a sports drink is recommended when exercising for more than 60 minutes while almost one-half (47.2%) did not know that sports drinks are better than water at restoring muscle glycogen.
CONCLUSION: Although both male and female Gaelic football players had a good knowledge of general hydration further education is required around sports drinks and their use and role. Further education is also warranted on hydration guidelines and requirements and monitoring of hydration status.

### THE EFFECT OF COMBINED FOOD AND WATER INGESTION VERSUS WATER INGESTION ALONE ON HYDRATION STATUS AT REST

MIDWOOD, K.L., JAMES, L.J., MEARS, S.A.

*LOUGHBOROUGH UNIVERSITY*

INTRODUCTION: Maintaining and/or restoring a euhydrated hydration state is important for athletes in their preparation for, and recovery from exercise. Ingestion of beverages containing carbohydrates have shown to reduce urine production and promote prolonged fluid retention (1), but it is yet to be seen if there is an equivalent response when the carbohydrate is ingested as a solid food alongside water. Therefore, this study investigated the effect of combined water and food ingestion versus water alone on hydration status at rest.
METHODS: Twelve subjects (6 males, 6 females, 28 ± 5 y, body mass index (BMI) 26 ± 6 kg/m2), ingested either 1 L of water (WAT) or 1 L of water and an oat bar (WAT+F) over a 30 min period. The oat bar contained oats, sugar, olive oil and honey totalling 100 g carbohydrate and a minimal water content (~9 g). Urine output, serum osmolality and subjective feeling scales (0 = no symptoms, 10 = extreme symptoms) of hunger, thirst, stomach fullness and gastrointestinal (GI) comfort were measured at baseline, post-ingestion and at 1, 2 and 3 h post-ingestion. Two-way repeated measures ANOVA were used to analyse data containing two-factors (trial x time), and paired t-tests or Wilcoxon signed rank tests, as appropriate, were used to analyse data containing one factor. Data presented as mean ± SD.
RESULTS: Total urine output was not different between trials (WAT: 1135 ± 247 g, WAT+F: 1049 ± 216 g, P = 0.236). Greatest urine output was produced at 1 h before progressively decreasing at 2 and 3 h post-ingestion (P < 0.001). Serum osmolality was not different between trials (P = 0.118) and did not change over time (P = 0.459). WAT+F decreased sensations of hunger immediately post-ingestion (baseline: 5 ± 2, post-ingestion: 1 ± 1, P = 0.014) before returning to baseline values by 3 h. Hunger was lower in WAT+F vs WAT from post-ingestion onwards (P < 0.022). Stomach fullness scores post-ingestion increased from baseline in both trials but were greater in WAT+F (8 ± 2) compared to WAT (4 ± 2, P = 0.015). There were no time x trial interaction effects for thirst (P = 0.938) or GI comfort (P = 0.212).
CONCLUSION: The ingestion of food containing 100 g of carbohydrate alongside water did not improve fluid retention, and therefore improve hydration status at rest, compared to the ingestion of water alone. Further research is required to guide hydration practices for athletes when food is coingested. Specifically, this should explore the nutritional composition of the food, such as the addition of sodium, in aiding fluid retention.

### 24-HOUR FLUID BALANCE AND SWEAT LOSSES IN LACROSSE PLAYERS TRAINING TWICE-DAILY

MACRAE, H.Z., REYNOLDS, K., CABLE, T., BARUTCU, A., FUNNELL, M.P., HANSELL, E., MEARS, S.A., GOOSEY-TOLFREY, V.L., JAMES, L.J.

*LOUGHBOROUGH UNIVERSITY*

INTRODUCTION: Hydration status is important for lacrosse athletes as dehydration >2% body mass impairs intermittent exercise/skills performance. Athletes with training sessions in close proximity (e.g. training twice a day) must adequately rehydrate to avoid starting exercise dehydrated. Few studies have examined 24-h fluid balance in athletes training twice-daily and little is known about the fluid losses incurred during lacrosse training. Thus, this study measured 24-h fluid balance in lacrosse players training twice-daily.
METHODS: Twenty four-hour fluid balance and sweat loss was estimated in 22 university-level, British lacrosse players (8 males, 14 females; 21 ± 2 years). During testing (07:00-07:00) participants maintained their usual fluid and food intake, completed a weighed food diary and collected all urine produced. Participants completed two bouts of 1.5-h (males) or 2-h (females) of lacrosse practice (males: 12.6 ± 0.5°C, 70.0 ± 3.6% humidity; females: 21.1 ± 0.5°C, 55.6 ± 0.9% humidity) separated by 2-h rest. Participants provided a first-morning urine sample each day, as well as pre and post training sessions. Nude body mass was measured before and after training and corrected for food/drink consumed and urine/faeces produced during training to determine sweat losses. A sweat patch was applied to the right scapula and analysed for sweat sodium concentration. Data are presented as mean ± standard deviation.
RESULTS: Sweat rate was relatively low, but higher in males vs females (0.55 ± 0.38 L/h vs 0.31 ± 0.13 L/h; P=0.01). However, there was no difference in the volume drank during exercise (males: 382 ± 183 mL/h; females: 303 ± 216 mL/h; P=0.23). There was no difference in sweat sodium concentration (males: 45.5 ± 14.0 mmol/L; females: 37.3 ± 13.4 mmol/L; P=0.11). Dehydration at the end of each lacrosse practice was minimal, but greater in males vs females (0.40 ± 0.65% vs 0.01 ± 0.41%; P=0.02). Only one male athlete lost >2% body mass during training. Body mass at 24-h vs 0-h was lower for males (80.76 ± 7.96 vs 81.42 kg; P<0.01) but not different for females (0-h: 64.45 ± 11.60; 24-h: 64.55 ± 11.54; P=0.31). Waking urine specific gravity was not different between days for males or females (day 1: 1.0168 ± 0.0082; day 2: 1.0178 ± 0.0083; P=0.60).
CONCLUSION: The current hydration practices of the lacrosse players included in this study were generally appropriate. Only one male exceeded 2% dehydration at the end of practice with no females exceeding 1% dehydration indicating ad-libitum drinking was sufficient to maintain hydration status and that dehydration is unlikely to impair performance during training. Females maintained body mass over 24-h however this decreased in males, possibly indicating negative fluid balance. Waking urine specific gravity was >1.020 for 6 of 22 and 9 of 20 participants on days 1 and 2, respectively, indicating some players might be under-hydrated despite maintaining hydration status in training.

### REPLENISHING EXERCISE-DEPLETED CARBOHYDRATE STORES USING RECOVERY DRINKS DOES NOT AFFECT SHORT-TERM ENERGY BALANCE RESPONSES

PODESTÁ, I., BLANNIN, A.K., WALLIS, G.A.

*UNIVERSITY OF BIRMINGHAM*

INTRODUCTION: Exercise is a commonly used tool to favour weight management. However, compensatory responses have been shown to recover most of the energy expended during exercise. The mechanisms by which these compensations happen are not well established. Based on the glycogenostatic theory of energy intake control, reductions in the body´s glycogen stores could trigger increases in energy intake. Thus, carbohydrates replenishment after prolonged overnight-fasted exercising, where glycogen has been reduced, could help to reduce energy compensation. Therefore, the purpose of the present study was to compare the effects of post-exercise high-carbohydrate (HC) and high-fat (HF) recovery drinks on short-term energy balance components in normal-weight people.
METHODS: 12 physically active participants took part in this double-blinded randomised crossover study (10 men, 2 women; age 21 (±2.3) years; VO2peak 56 (±6.4) ml·kg·min-1; body fat 14.38 (±5.68) %. Each participant completed two experimental trials: an overnight-fasted 75-minute running bout with a controlled recovery period during which a recovery drink was provided and a 2.5-day free-living follow-up

period. After the exercise bout, participants consumed one of two isocaloric recovery drinks (HC: 92.2% carbohydrate, 7.3% protein, 0.5% fat; HF: 7 % carbohydrate, 5.3% protein, 87.7% fat; energy content: 1065 (±144) Kcal) designed to replace the energy expended during exercise. Also, they wore an Actiheart device to assess activity energy expenditure (AEE) during the recovery period and for the next 2.5 days. Participants were also provided with food (125% of their estimated energy needs) for the next 2.5 days and asked to eat "as much or as little as they want". A resting metabolic rate (RMR) assessment was performed in the morning on exercise visits. Cumulative energy intake was calculated based on the food energy provided less the food leftovers. Cumulative- AEE and total energy expenditure (TEE) were obtained after the input of the RMR on the Actiheart software.
RESULTS: The mean cumulative energy intake during the free-living follow-up period was 10,521 (± 2,007) in HC and 10,560 (±2,303) kcal in HF (p=0.915). Cumulative TEE was 7390 (±1,480) and 7058 (±1,174) kcal for HC and HF, respectively (p = 0.208). Cumulative AEE was 2345 (±340) Kcal and 2108 (±375) kcal for the HC and HF conditions, respectively (p = 0.098).
CONCLUSION: After exercising, HC or HF recovery drinks did not differentially impact upon short-term effect on energy balance components (cumulative energy intake, AEE and TEE). These results may indicate that a carbohydrate-based energy replacement would not attenuate an energy compensation and that glycogen stores are not strongly implicated in short-term energy balance regulation after exercise.

**SELF-REPORTED SEVERE GASTROINTESTINAL SYMPTOMS ARE NOT PREVALENT IN ELITE FEMALE SOCCER PLAYERS**

SELLORS, C.

*PEPSICO*

INTRODUCTION: Gastrointestinal (GI) symptoms during exercise are common in female athletes (Parnell et al, 2020). The prevalence and severity of symptoms varies between athletes, yet common symptoms can negatively impact performance and exercise completion. Pre- during- and post-exercise nutritional intake may be altered in an attempt to reduce GI symptoms and prevent performance detriments (Parnell et al, 2020). However, most research has been conducted in female endurance athletes, with limited data in team sport athletes. Therefore, the aim of this study was to identify the prevalence and severity of GI symptoms, and nutrition habits, in elite female soccer players.
METHODS: In this cross-sectional study, elite female soccer players (n= 106) from English, Spanish, and Italian leagues (n= 23, 73, 10 respectively) completed a GI symptom prevalence and nutrition habit questionnaire. Players rated the number and severity (1 (very mild) to 10 (extremely severe)) of GI symptoms experienced during soccer training and matches. Any symptom rated >4 was classified as severe. Questions on pre-exercise nutrition habits and food/drink avoidance were also included. Chi-square tests were used to determine relationships between nutrition habits and number of GI symptoms.
RESULTS: During training and matches, 20% and 13% of players experienced one GI symptom, and 8% and 12% of players reported experiencing two GI symptoms, respectively. Five players (5%) reported experiencing three or more symptoms during both training and matches. During training, flatulence (n=12), bloating (n=12), heartburn (n=11) and belching (n=11) were the most common symptoms. Eight players ranked the severity of the symptom as severe. During matches, bloating (n=15), flatulence (n=8), defecation (loose stool) (n=7), and stomach pain (n=6) were the most common symptoms. Ten players ranked the severity of the symptom as severe. A total of 28% and 35% of players reported regularly avoiding certain foods/drinks to prevent GI symptoms; this was most commonly high fat foods. Caffeine was frequently ingested prior to both training and matches but was not associated with the number or severity of GI symptoms experienced ($X2(8,n=110)=8.9$, $P=0.350$).
CONCLUSION: Most (70%) elite female soccer players do not experience GI symptoms during training and/or matches. The severity of GI symptoms experienced during training and matches was generally low but highly individual. The impact of mild GI symptoms on soccer specific performance warrants further investigation.

### CP-MH09 Ageing and exercise interventions

**EFFECTS OF A REAL-TIME VIDEOCONFERENCE-BASED EXERCISE PROGRAM ON THE MUSCULOSKELETAL PAIN OF ELDERCARE WORKERS: PRELIMINARY RESULTS OF A RANDOMIZED CONTROLLED TRIAL**

ESPIN, A.1, LATORRE EREZUMA, U.1, GARCÍA-GARCÍA, J.1, AIESTARAN, M.1, GALBARRIATU, I.2, GONZÁLEZ-TEMPLADO, V.3, RODRIGUEZ-LARRAD, A.1, IRAZUSTA, J.1

*1. UNIVERSITY OF THE BASQUE COUNTRY , 2. FUNDACIÓN ASPALDIKO, 3. CASER RESIDENCIAL BETHARRAM*

INTRODUCTION: The prevalence of musculoskeletal pain is high among eldercare workers. Exercise interventions have been shown to be able to reduce musculoskeletal pain in the workplace. However, exercise interventions in eldercare workers are scarce, and none of them have used the videoconference modality. Thus, the aim of this study is to assess the effects of a real-time videoconference-based exercise (RVE) program on the musculoskeletal pain of eldercare workers.
METHODS: A randomized controlled trial is being carried out (ClinicalTrials.gov code: NCT05050526). Inclusion criteria are the following: formal eldercare workers, aged 18 years or more, minimum 3 months of experience in the profession, employment contract until the date of study completion. Eldercare workers are randomly assigned in a 1:1 ratio to a control or experimental group. Participants in the control group do not receive any intervention, and participants in the experimental group take part in a 12-week supervised RVE program consisting of two weekly 45-minute sessions. Primary outcome measure is average pain intensity in the low back during the last 7 days, measured by an 11-point numerical rating scale. Secondary outcomes include validated questionnaires and tests to collect additional measures of musculoskeletal pain (average intensity, worst intensity, frequency and interference with work for pain in the low back, neck, shoulders and wrists/hands), psycho-affective state (happiness, anxiety, depression, burnout, sleep quality, health state), work-related variables (work ability, work performance, physical exertion at work, absenteeism), and physical fitness (muscle performance of lower limb, upper limb and trunk). Assessments are conducted at baseline, at 3 months (post-intervention) and 1 year (follow-up) from the beginning of the

intervention. Intervention effects are analyzed with a group by time ANCOVA including baseline measurements as covariate. The level of statistical significance is set at p <0.05.
RESULTS: 42 participants have completed the baseline and 3-month (post-intervention) assessments. A non-significant effect favoring the experimental group has been observed for the average intensity of pain in the low back (p=0.140). Significant effects favoring the experimental group have been observed for the interference with work of pain in the low back (p=0.003), average intensity, worst intensity, frequency and interference with work of pain in wrists/hands (p=0.028, p=0.035, p=0.045 and p=0.021, respectively), physical exertion at work (p=0.042) and muscle performance of the upper limb (p=0.027).
CONCLUSION: The RVE program seems to be able to improve several parameters of musculoskeletal pain in eldercare workers. Additionally, improvements in physical exertion and upper limb performance have been observed. However, it is necessary to increase the sample until reaching the required size to draw definitive conclusions.

### EFFECTIVENESS OF EXERCISE INTERVENTIONS TO IMPROVE LONG-TERM PATIENT-RELEVANT COGNITIVE AND NON-COGNITIVE OUTCOMES IN PATIENTS WITH MILD COGNITIVE IMPAIRMENT - PRELIMINARY RESULTS

DIECKELMANN, M.1, GONZÁLEZ-GONZÁLEZ, A.I.1,2, BANZER, W.3, BERGHOLD, A.4, JEITLER, K.5, PANTEL, J.1, SCHALL, A.1, TESKY-IBELI, V.1, SIEBENHOFER, K.1

*1INSTITUTE OF GENERAL PRACTICE, GOETHE UNIVERSITY, 60590 FRANKFURT / MAIN, GERMANY 2RED DE INVESTIGACIÓN EN SERVICIOS DE SALUD EN ENFERMEDADES CRÓNICAS , 28035 MADRID, SPAIN 3INSTITUTE FOR O*

INTRODUCTION: Patients with Mild Cognitive Impairment (MCI) have an elevated risk of developing dementia and burden of disease may be substantially reduced by delaying its onset. The aim of this project is to systematically review the literature to assess the effectiveness of exercise interventions according to patient relevant endpoints to improve long-term cognitive and non-cognitive outcomes in patients with MCI. Study registration: CRD42021287166
METHODS: MCI patients were involved in a workshop prior to study selection to define outcomes most relevant to them. Searches were performed in MEDLINE, Embase, CINAHL, SPORTDiscus, CCTR (Cochrane) and PsycInfo from 1995 to November 2021. Eligible were RCTs comparing 6-months+ exercise interventions with sham-exercise or active (but not physically active) controls. Studies were included if they reported any patient-relevant cognitive and non-cognitive long-term (12 months+) outcome in adults (50+ years) with MCI (all causes). Study selection, data extraction, risk of bias assessment was conducted in dual-review mode. Reporting quality of the exercise interventions was assessed using the Consensus on Exercise Reporting Template. Meta-analyses are planned if studies are homogeneous enough otherwise results will be presented narratively. Project data will be made available open access (10.5281/zenodo.5589277). Research findings will be translated into a patient-friendly video format for dissemination through Alzheimer Gesellschaft Hessen to reach patients and families concerned.
RESULTS: MCI patients rated non-cognitive, motivational and behavioural endpoints as well as psychosocial and physical functioning as most important outcomes to include in research. From 3986 studies identified, 13 studies were included at the time of abstract submission. Authors will have finished data extraction, synthetization and analysis by July 2022. Final results will be presented at the conference. The results will inform professionals in primary care about the effectiveness of exercise interventions and facilitate the translation from those research findings with a good reporting standard of exercise intervention details into evidence-based exercise recommendations for patients with MCI.
CONCLUSION: To enhance practical relevance of systematic reviews, we conducted an evidence synthesis that 1) gauged the extent of potential research waste caused by inadequate reporting of exercise intervention details and caused by reporting patient-irrelevant outcome parameters and 2) included both cognitive and non-cognitive outcomes to understand whether exercise effectively improved the health of MCI patients in the long run, as exercise regimens in real life are to be maintained and initiated by patients themselves. We made every effort to ensure that the results of this work are based on data that is both relevant to MCI patients and that general practitioners and their teams are able to apply in their practice routines to recommend exercise to those at risk of dementia.

### IMPLEMENTATION OF A MULTICOMPONENT INTERVENTION FOR THE PREVENTION AND REDUCTION OF PHYSICAL STRAIN IN ELDERLY CARE

OTTO, A.K., WOLLESEN, B.

*UNIVERSITY OF HAMBURG, TECHNICAL UNIVERSITY OF BERLIN*

INTRODUCTION: Health promotion is of particular relevance in the care of the elderly due to the increasing number of multimorbid residents, resulting in high physical and psychological strain associated with an increasing prevalence of back pain. Therefore, workplace health promotion programs for this target group are of utmost interest to secure the work capacity (van Hoof et al., 2018). The present study investigates the effects of ergonomics training (10 weeks) and back fitness training (12 weeks, BASE program; Wollesen et al., 2016) on ergonomic movement behavior, strength endurance of the lumbar extensors, low back pain, and functional impairment caused by back pain.
METHODS: The randomized controlled trial was conducted in two nursing homes and included n= 22 in the intervention and n= 20 nurses in the control group. The analysis combined physical tests with questionnaires (Progressive Isoinertial Lifiting Evaluation, PILE-Test; Biering-Sørensen-Test; Visual Analog Scale Pain, VAS; Oswestry Disability Index, ODI). Group differences were tested using Chi2-Tests, ANOVA, and Linear Mixed Models (SPSS 27).
RESULTS: The analysis showed significant differences between the intervention and control group in the lifted weight during the PILE-Test (95% CI, 1.378-7.810, p= .006) with fewer terminations due to dysfunctional posture (Chi2= 9.531, p= .002). In addition, the analysis revealed significant differences between both groups in back pain (95% CI, -1.987 - -0.034, p= .043). However, there were no differences in the functional impairment caused by back pain (ODI) and the test time regarding the Biering-Sørensen-Test.
CONCLUSION: The tailored multicomponent program (ergonomics plus strength training) improved intervention group nurses' lifting performance, illustrated by higher lifted weight and increased test aborts due to muscular fatigue. In addition, the analysis showed positive effects on back pain. The positive results are essential to derive specific recommendations for effective prevention in elderly care nurses. Furthermore, the results can be completed in future research with additional strategies for pain reduction, ratio prevention, and work situations.

**THE IMPACT OF MULTIMORBIDITY PATTERN ON PHYSICAL ACTIVITY AND PHYSICAL CAPACITY IN OLDER ADULTS PARTICIPATING IN A YEARLONG EXERCISE INTERVENTION**

SAVIKANGAS, T.1, SAVOLAINEN, T.2, TIRKKONEN, A.1, ALEN, M.3, HAUTALA, A.1, LAUKKANEN, J.A.4,5, RANTALAINEN, T.1, TÖRMÄKANGAS, T.1, SIPILÄ, S.1

*1 UNIVERSITY OF JYVÄSKYLÄ, 2 CITY OF HELSINKI, 3 OULU UNIVERSITY HOSPITAL, 4 UNIVERSITY OF EASTERN FINLAND, 5 CENTRAL FINLAND HEALTH CARE DISTRICT*

INTRODUCTION: Multimorbidity compromises physical activity (PA) and physical capacity (PC). Exercise may improve both, but the impact of multimorbidity pattern on these benefits is sparsely studied in older adults. The aim was to determine the impact of multimorbidity pattern on development of PA and PC during a yearlong exercise intervention, and on PA one-year post-intervention.
METHODS: Participants were 314 physically inactive community-dwelling older adults (60% women, 74.4±3.8 years) who did not have severe chronic conditions compromising exercise safety. Physician-diagnosed conditions were classified into 17 categories. Obesity was assessed with body mass index (BMI). Current PA was assessed with a one-item, 7-scale questionnaire at baseline (bl), 6 months (6m) and 12 months (12m), and after one-year follow-up (fu). PC measurements included five-time chair-stand time and six-minutes walking distance (6MWD) at bl, 6m, and 12m, and maximal isometric knee extension strength (KE) at bl and 12m. Intervention included supervised (twice weekly) and home-based progressive strength, balance, and walking exercises. Generalized estimating equation models were used to analyze the impact of multimorbidity pattern including chronic conditions as a predictor cluster and obesity on development of outcomes over time in men and women separately, adjusted for age.
RESULTS: Participants had on average two chronic conditions and BMI 27.9±4.7 kg/m2. Multimorbidity pattern had a small but significant impact on development of PA and all PC outcomes across all time-points in men (Chi-squared for multimorbidity-by-time interaction=28.90 to 358.87, df=18, p<0.001 to 0.050) and women (Chi-squared=26.92 to 111.40, df=16, p <0.001 to 0.042), except chair-stand at 6m in women (p=0.277). Time-point specific effect sizes ranged from <0.01 to 0.03.
Among men, diabetes associated with greater increase in PA at all time-points (condition-by-time interaction B=0.74 to 1.17, p=0.002 to 0.033). At 12m, chronic musculoskeletal disorders associated with less improvement in 6MWD (B=-23.42, p=0.043) and arthritis with less improvement in KE (B=-2.83, p=0.015). Among women, pulmonary disease associated with less increase in PA at all time-points (B=-0.60 to -0.86, p=0.003 to 0.005). At 12m, arthritis associated with less increase in PA (B=-0.49, p=0.018), but with greater improvement in chair-stand (B=-1.41, p=0.007). Hyperlipidemia associated with greater and cardiovascular disease with less improvement in KE (B=1.59, p=0.037 and B=-2.54, p=0.006, respectively).
CONCLUSION: Multimorbidity pattern had a significant yet very small impact on physical activity and physical capacity in a yearlong exercise intervention among community-dwelling older adults without contraindications for exercising. The impact of specific conditions varied by sex and outcome, but most conditions had no impact on the intervention effects. Multimorbid older adults may benefit from multicomponent exercise almost as much as healthier peers.

**HOW TO ENHANCE SPATIAL ORIENTATION IN NURSING HOME RESIDENTS: DEVELOPMENT AND FEASIBILITY OF A MULTICOMPONENT SPATIAL ORIENTATION TRAINING**

FRICKE, M.1, MORAWIETZ, C.2, MUEHLBAUER, T.2, JANSEN, C.P.3,4, SCHWENK, M.3,5, GRAMANN, K.1, WOLLESEN, B.1,6

*<1> TECHNICAL UNIVERSITY BERLIN, <2> UNIVERSITY OF DUISBURG-ESSEN, <3> HEIDELBERG UNIVERSITY, <4> ROBERT-BOSCH-KRANKENHAUS STUTTGART, <5> UNIVERSITY OF KONSTANZ, <6> UNIVERSITY OF HAMBURG*

INTRODUCTION: Spatial abilities, including orientation in and navigation through the environment, are known to deteriorate with age. While spatial orientation skills maintain relatively safe in familiar environments, they decrease notably in unfamiliar environments with increasing age (Colombo et al., 2017). Due to multimorbidity, some older persons need to be hospitalized in nursing homes and therefore experience an unfamiliar environment. Studies showed that their range of action is limited, leading to low physical activity and social interaction, and, as a consequence a lack of physical and cognitive stimulation (Schrempft et al., 2019).
METHODS: Since cognitive-motor training counteracting the decline of spatial orientation abilities has been rarely implemented for nursing home residents, a two-step process for the development of such training was conducted:
As a first step, a systematic literature search was conducted on spatial orientation interventions and exercises for healthy older adults. In the next step, six existing spatial orientation exercises were specifically adapted to the nursing home residents needs and integrated into an established group cognitive-motor training program. The training was monitored using systematic observations by an independent person, addressing the training modalities, comprehensibility of instructions, exercise performance, motivation, and the duration of performance of each orientation exercise. Additionally, pre-and-post measurements of mobility and life satisfaction were conducted.
RESULTS: N=40 nursing home residents (87.3 ± 7 years, 80 % female) participated in a total of 24 training sessions (twice per week, 45-60 minutes each) to promote spatial orientation. The feasibility analysis revealed that future interventions should consider that instructions of demanding spatial tasks should be accompanied by an example task, trainers should be encouraged to adjust task complexity and materials on an individual basis, acceptance of the training should be promoted among nursing staff, and surroundings with as little disturbance as possible should be selected for training. A positive trend was discerned for mobility and life satisfaction, comparing pre-and post-training data.
CONCLUSION: This trial resulted in an everyday-like, target group-specific training program for the promotion of spatial orientation abilities. To evaluate the training's effects a three-arm controlled-randomized trial is corrently conducted in 18 nursing homes. This study is expected to be completed by the end of 2022.

### TWO-WEEK REDUCED PHYSICAL ACTIVITY HAS LIMITED NEGATIVE EFFECTS ON FUNCTION AND HEALTH IN OLDER ADULTS

WALKER, S., SAHINAHO, U.M., VEKKI, S., SULONEN, M., SIPILÄ, S., PELTONEN, H., LAAKKONEN, E., LEHTI, M.

*UNIVERSITY OF JYVÄSKYLÄ*

INTRODUCTION: Punctuated declines in physical activity of older adults has been posited as a key factor accelerating the progression of sarcopenia [1], but direct assessment of this phenomenon in experimental settings is sparse with two studies out of three showing decreases in lean leg mass but no detriment in functional capacity after 2-week step-reduction (~1000 daily steps) [2]. The present study determined the effects of a 2-week step-reduction (simulating periodic low physical activity) then 4-week training period on functional capacity, body composition, and metabolic health in healthy, physically active older adults.
METHODS: Accelerometers tracked daily steps of 66 healthy older adults (72.6±2.7y) throughout the study. Participants were randomized into a step-reduction/gym training (intervention) group (n=32) or a control group (n=34); who continued living as usual. After the two-week period, intervention participants then underwent 4 weeks of gym-based training 4 times per week. Measurements were performed at baseline (PRE), after two weeks (MID), and after six weeks (POST) of the study. Functional capacity was assessed by maximal bilateral isometric leg extension force (MVC), 5 × sit-to-stand (STS), 10-step stair-climb, and normal and maximal 4m walking speed. In a fasted state, body composition was assessed by dual-energy X-ray absorptiometry and metabolic health by clinical blood biomarkers.
RESULTS: Significant Time(3)*Group(2) interactions were observed for step count ($F = 86.5$, $P < 0.001$), MVC ($F = 4.96$, $P = 0.009$) and HDL-C concentration ($F = 3.467$, $P = 0.041$). In the intervention group, steps decreased from PRE to MID (8287±2907 to 2261±718, $P < 0.001$) and rebounded at POST (6328±2214, $P < 0.001$), as did HDL-C (PRE to MID: 1.61±0.37 to 1.53±0.36 mmol/L, $P = 0.045$; MID to POST: 1.68±0.37mmol/L, $P = 0.002$). MVC did not change PRE to MID but increased from MID to POST (1925±591 to 2213±703N, $P = 0.001$). No other significant interaction was observed, although STS was close to being significant (Time*Group: $F = 3.031$, $P = 0.059$), with the intervention group improving MID to POST (8.3±1.2s to 7.9±1.1s, $P < 0.001$).
CONCLUSION: Two weeks of low daily steps (<2500) did not deteriorate total body composition nor performance of functional capacity measures, but MVC and STS were improved by gym-based training. Of the blood-based markers, HDL-C was most responsive to both physical inactivity and re-activity. Thus, it appears that short-term reduced physical activity (e.g. due to illness, inclement weather, quarantine) is not majorly detrimental to older adults' health status. Changes observed in HDL-C after step-reduction are reversible and maximal functional performance is improved through systematic, supervised training.

### PHYSICAL ACTIVITY CAN INFLUENCE FUNCTIONALITY, MUSCLE MASS AND QUADRICEPS STRENGTH IN COMMUNITY-LIVING OLDER PEOPLE WITH OSTEOARTHRITIS

BOTELHO, M.1, GUERREIRO, C.1,2, NETO, T.1, PAIS, S.2,1,3

*1 – ALGARVE BIOMEDICAL CENTER ALGARVE 2 – UNIVERSITY OF ALGARVE 3 - NOVA MEDICAL SCHOOL*

INTRODUCTION: Autonomy loss related to age is associated with joint function loss, mostly due to several pathologies that compromise their mobility and physical activity, such as osteoarthritis (OA). The aim of this study was to analyze the presence of OA in an elderly Portuguese population study and identify the influence of physical activity levels on functionality, muscle mass and quadriceps strength.
METHODS: A prospective, observational secondary analysis of data from the "Sarcopenia Screening Study in the Algarve Region" was performed. This study had the purpose of studying the effects of sarcopenia on fall risk, body composition, general health, and quality of life in older people and it was funded by the European Regional Development Fund (FEDER) through the PSL Project – Programme for a Long-lived Society (0551_PSL_6_E) - INTERREG V-A Cooperation Program, Spain-Portugal, (POCTEP), 2014-2020.
The quadriceps strength was calculated through the peak torque (PT) on a Humac Norm® dynamometer, the Lower Extremity Functional Scale (LEFS) was used to measure the functional level, the % of muscle mass was measured by bioimpedance, and Physical Activity Scale for Elderly (PASE) was used to measure the physical activity level (PAL).
RESULTS: Community-dwelling older adults (n = 217) were analyzed mean age 75.3±0.4 years (73.3% female; 26.7% male). In the studied sample pain comes as the most common health problem (73%) followed by osteoarthritis (60.4%) and hypertension (60%). Analyzing the subjects that met the NICE diagnose criteria for OA (n=131) with the 2 step-cluster classification multivariate technique, two large groups of OA patients (G1, n=73 and G2, n=58) strongly differentiated were created, hierarchically due to level of PAL and age.
Through a t-test we captured significant associations ($p \leq 0.05$) between the previous profile G1 (PAL=104.5±6.0) and G2 (PAL=169.4±8.2) with functionality (46.1±13.2; 53.6±14.2), % of muscle mass (22.9±3.7; 25.1±4.3) and quadriceps strength (51.8±20.6; 67.2±26.7). It was interesting to verify that both groups have moderate/severe pain most of the days and overweight, without significant differences.
CONCLUSION: Although both G1 and G2 subjects state to have the same level of pain and same body mass index, through the cluster analyses it was possible to verify that the G2 subjects are physically more active. Being physically active has a positive influence on functionality, % of muscle mass and quadriceps strength in elderly community living subjects. Our results show that although none of our subject were enrolled in any special exercise program for OA patients, general community exercise programs and active daily lifestyles have also a positive effect on physical health in OA elderly subject. It is essential to reinforce the importance of physical activity in maintaining functional capacity.

### IMPACT OF 14 DAYS OF HEAD-DOWN TILT BED REST, AND AN EXERCISE COUNTERMEASURE, ON MUSCLE PROTEOMICS IN OLDER ADULTS

LAGACÉ, J.C.1,2, ST-MARTIN, P.1,2, RUEL, M.1,2, MCPHEE, J.S.3, RIESCO, E., LAMBERT, K.4, DIONNE, I.J.1,2

*1 UNIVERSITÉ DE SHERBROOKE, CANADA. 2 RESEARCH CENTRE ON AGING, CANADA, 3 MANCHESTER METROPOLITAN UNIVERSITY, UNITED KINGDOM, 4 UNIVERSITÉ DE MONTPELLIER, FRANCE*

INTRODUCTION: The muscle is a highly plastic tissue and adapts quickly to contractile activity or lack thereof. Hence, long-term immobilization, as can be the case in the context of hospitalization, often leads to muscle atrophy and loss of function. Aging individuals are particularly at risk and the repercussion of long-term immobilization can alter one's autonomy. Previous studies have shown a complex proteasomal activity during early and late bed rest in young healthy male participants, but the impact of an exercise countermeasure on the

proteasomal activity of bedridden older adults has never been determined. The objective of this study was thus to verify how a head-down tilt bed rest (HDBR), with and without an exercise countermeasure, affected the proteasomal activity during the mid and late stages of bed rest. Furthermore, we wanted to determine how the changes in muscle strength correlated with changes in proteasomal activity.
METHODS: Healthy older adults (male: 9; female: 11) aged 55 to 65 years old underwent 14 days of 6˚ HDBR. Participants in the experimental group were engaged in an exercise countermeasure and participated in an hour of daily exercise comprising continuous aerobic, high-intensity interval aerobic and both upper and lower-body strength training. The control group remained inactive but received manual therapy from a trained physical therapist to limit discomfort. An isoenergetic diet, with a protein intake of 1.2g/kg/day was given to participants, and energy expenditure associated to exercise was accounted for. Muscle strength of the knee extensors was taken at baseline and after HDBR. Muscle biopsies were taken on the vastus lateralis at baseline, 8 days into and on the last day of HDBR. Muscle proteomic was analyzed through liquid chromatography and tandem mass spectrometry.
RESULTS: A total of 20 individuals (control: 9; Exercise: 11) completed the bed rest period. Fourteen days of HDBR resulted in a 13,7 ± 8,7% decline in knee extensor strength in the control group and a 9,8 ± 8,8% decline in the exercising group (p=0.348). Proteasomal activity has not yet been fully analyzed and the full data will be presented at the ECSS conference.
CONCLUSION: One hour of daily exercise does not seem to be sufficient to mediate the loss of muscle function induced by 14 days of HDBR. Proteasomal activity will inform how cellular processes are affected by exercise during the mid (day 8) and later (day 14) stages of bed rest. Better understanding these cellular processes in bedridden older adults will help tailor new interventions to limit the deleterious impact of long-term immobilization.

### CP-SH03 Cognition

#### THINK AND DO. MOTOR RATHER THAN COGNITIVE PERFORMANCE IS IMPAIRED IN DUAL-TASK SITUATIONS IN PRE-SCHOOL CHILDREN.

STÖCKEL, T., TIEDE, J.

*UNIVERSITY OF ROSTOCK*

The ability to perform two tasks at the same time, also known as dual-tasking, is crucial to cope with many tasks of our daily life. Most importantly, we have to take in and process a lot of information, and make decisions on the go (e.g. during walking, playing, and working). While growing evidence suggests that our dual-tasking ability is impaired in late adulthood, little is known of how young children perform in dual-tasking situations. The present study examined whether preschool children are able to deal with dual-task demands, and whether they would prioritize motor or cognitive demands during dual-task situations. Thirty-two preschool children (20 girls, mean age = 71.6 ± 4.0 months) were tested individually in their daycare facilities. All participants completed a manual dexterity task (Purdue Pegboard) under single and dual-task conditions. In dual-task conditions, children were confronted with either a working memory task (n-back) or an attention and inhibition task (AX-CPT task) that had to be performed concurrently to the motor task. Our data revealed that manual dexterity performance was negatively affected by both the n-back task (mean difference = 1.84; Cl: 0.92, 2.77; $p < 0.001$) and the AX-CPT task (mean difference = 1.52; Cl: 0.39, 2.63; $p = 0.002$). However, while also AX-CPT performance was reduced under dual- as compared to single-task conditions ($p < 0.001$), n-back task performance was not affected during dual-tasking ($p = 0.69$). These results suggest that preschool children are able to deal with dual-task demands with dual-task costs being between 7.6% and 9.4% for the motor task. As expected, motor performance was more affected by dual-task demands than cognitive performance, what may be explained with the nature of the tasks, the developmental stage of the children or the bottleneck theory. Considering the latter, the fact that both manual dexterity and working memory performance were reduced when being performed simultaneously provides further evidence that both are functionally linked at this age and draw on the same neuronal resources.

#### PROFICIENCY DIFFERENCES IN ANTICIPATION SKILLS REVEALED BY NEWLY DEVELOPED COGNITIVE-MOTOR TASK

NAKAMURA, O.1, KUDO, K.1, ONAGAWA, R.2, HIROSE, N.3

*<1>: THE UNIVERSITY OF TOKYO, <2> : WASEDA UNIVERSITY, <3> : WASEDA UNIVERSITY*

INTRODUCTION
In many sports, players gather information in a changing external environment and accurately anticipate their opponents' and teammates' following actions. Integrating time-varying information over time and reflecting it in anticipation is essential for superb performance. Here, the present study examined the differences in anticipation accuracy between expert and novice football players by focusing on the temporal changes in anticipation using a task to anticipate the course of a pass in football.
METHODS
Twelve students (males football players belonging to the first division of the Kanto University Football League in Japan) participated as the expert group. Twelve students (males with no specialized football experience) participated as the novice group. Nineteen videos were created using actual football game scenes. Each video duration was 10 s. The final scene in each video was stopped at the moment the player made a pass. After stopping a video, the participants were required to quickly anticipate the player to be passed and move their cursor using a pen-tablet toward the player within 2000 ms. Temporal changes in cursor position were obtained as the coordinates of a cursor projected on display. The distances between the cursor and the correct player to be passed were calculated at nine temporal segments (-2000, -1500, -1000, -500, 0, 500, 1000, 1500, and 2000 ms, where 0 ms indicates the timing when the video stopped). We compared the distances between the expert and novice players. A two-way ANOVA (2 [skill group] × 9 [time segment]) for the distances was performed. The correct response trial was defined as the distances within 50 pix at 2000 ms. A Pearsons correlation analysis was performed between the distance at 0 ms and the correct response rate among participants to examine the relationship between the early anticipations and the final responses.
RESULTS
The expert players moved closer to the correct ball receiver at 2000 ms ($p < .05$) compared to novice players. Moreover, the experts moved closer to the correct ball receiver at the start of the response period (0 ms) compared to the novice players ($p < .05$). There was a signifi-

cantly negative correlation between the distance at 0 ms and the correct response rate ($r = -0.50$, $p < .05$), indicating that the closer to the correct ball receiver at 0 ms, the higher the task accuracy.
DISCUSSION
The results indicate that expert soccer players complete their anticipations earlier than novice players. Moreover, the relationship between cursor position in the early task phase and the final anticipative accuracy suggested that narrowing down potential options earlier using information (such as game flow and players' placement) is essential for high anticipative accuracy within a limited time frame. Future studies are required to clarify the details of information gathering and movement preparation to achieve faster and more flexible anticipations.

### HOW OPEN- AND CLOSED SKILLS ATHLETES ADAPT DECISIONS TO AN UNCERTAIN ENVIRONMENT WITH AND WITHOUT A STRESSFUL CONDITION.

RUSSO, G.1, OTTOBONI, G.2, FARNÈ, M.3, CECILIANI, A.1, TESSARI, A.2

*UNIVERSITY OF BOLOGNA*

INTRODUCTION: Athletes must decide their actions under stressful situations. These abilities could also be transferred into a general domain (1, 2). Thus, the present research analyzed the decision-making processes of athletes in an uncertain environment and how they acted when exposed to stressful situations.
METHODS: Participants:
24 élite open-skills athletes (OSA; M age = 17.71 ± 1.02 y.o.), 13 élite closed-skill athletes (CSA; M age = 21.40 ± 3.55 y.o.) and 36 non-athletes ( (M age = 23.56 ± 1.57 y.o.) were recruited.
Instruments:
A reinforcement learning probabilistic task (3) with three levels of uncertainties (i.e., low, medium, and high) was employed. Participants had to score as many points as possible. The task was performed, in counterbalanced order across participants, two times: one in standard condition (SC) and one Under Pressure (UP). Heart rate was monitored. Several indexes, such as the Spatial Error (i.e., the ability to predict future events), the Gain (the ability to maximize the score), and the implicit decision confidence (through the bet on the decisions), were evaluated to examine the possible differences among the sport type (OSA vs CSA). The confounding factor of fluid intelligence was controlled (Raven-APM [4]) due to the possible relation between intelligence and decision-making.
Data analysis:
Linear mixed-effect regression for each index was performed. The independent variables were: sport type, condition, and level of uncertainty. Intelligence was set as a covariate variable. The subject was the random effect. Heart rate and mental effort analysed the effect of stressful condition.
RESULTS: Mental effort and heart rate analysis reported that they were higher in UP compared to SC. Spatial Error results revealed an effect of intelligence ($p < .001$) only when the uncertainty was low and in SC ($p < .05$). Even if the triple interaction level of uncertainty x sport type x condition was significant ( $p < .001$), sport type did not influence the ability of predicting events ($p > .05$). Gain results revealed triple interaction level of uncertainty x sport type x condition was significant ( $p < 0.01$). However, the post-hoc analysis highlighted an improvement of the score from SC to UP condition in the low uncertainty environment for the control group; while in medium uncertainty for OSA. Confidence analysis highlighted triple interaction level of uncertainty x sport type x condition was significant ($p < .001$). Post-hoc results showed that only OSA modulated the bet between the two conditions when the uncertainty was low and high ($p < .05$).
Conclusion
Sport type did not influence the performance of this perceptual-decision task. However, the perception of the risk changed in UP. Specifically, OSA seemed to behave conservatively when exposed to a stressful situation. Moreover, the results indicated that intelligence could help to predict events.

### EFFECT OF ATTENTIONAL FOCUS ON MENTAL EFFORT IN MOVEMENT EXECUTION: A META-ANALYSIS

LI, D.1, ZHANG, L.1, MEMMERT, D.2, ZHANG, Y.1

*1 BEIJING SPORT UNIVERSITY, 2 GERMAN SPORT UNIVERSITY COLOGNE*

INTRODUCTION: The majority of academics agree that mental effort is undesirable and that it originates from limitations in our subjective ability to exert control over task execution [1], but fortunately, external focus (EF; i.e., concentration on the intended movement effect) has been demonstrated to be more cost-efficient than internal focus (IF; i.e., concentration on the body movements) in mental efforts during movement execution [e.g., 2, 3, 4]. The present study aimed to synthesize previously available research investigating the intervention of EF vs. IF on mental effort during movement execution and to explore one perplexing issue about the effect (i.e., is the attentional focus effect in mental efforts the same between the experienced and novices?)
METHODS: This meta-analysis was performed based on the PRISMA guidelines [5]. Original research publications were searched in four electronic databases (APA PsycINFO, PubMed, SPORTDiscus, and Web of Science). Peer-reviewed research was considered eligible if it met all of the following criteria: (a) the participants were all healthy individuals, with an average age of more than 18 years; (b) an EF instruction was employed; (c) an EF was compared to an IF; (d) after the movement execution, the mental effort was measured immediately (e.g., ratings of perceived execution, mental demand, self-reported effort, and subjective rating of execution). The risk of bias in eligible studies was assessed using the Cochrane Risk of Bias Tool (RoB 2.0). A random-effects model was performed to pool Hedge's g with 95% confidence intervals. Subgroup analysis was performed to compare the attentional focus effect between different skill levels (the experienced vs. novices).
RESULTS: Overall, sixteen studies with 414 participants were found to meet the inclusion criteria. Results demonstrated an EF condition cost less mental efforts than an IF ($g = 0.210$, 95% CI [0.059, 0.361], $p = .006$) in the process of performance execution. The subgroup analysis suggested the cost advantage of EF in mental efforts might be weaker in novices ($g = 0.070$, 95%CI [-0.145, 0.284], $p = .524$) than that in the experienced ($g = 0.314$, 95%CI [0.126, 0.503], $p = .001$).
CONCLUSION: Although the reported attentional focus effect in managing and alleviating mental efforts is small, the result is significant in theory and practice, which reveals the instruction of external focus could be developed into reducing execution effort costs, making optimal use of the limited mental efforts, and promoting movement economy in motor control.

**VISUAL PERCEPTION IN ROCK CLIMBERS**

MARCEN-CINCA, N., SANCHEZ, X., OTIN, S., CIMARRAS, C., BATALLER, V.

*UNIVERSIDAD SAN JORGE*

As climbers ascend, their perspective change, as it does their perception of the holds they use to climb up the route; the visual system is persistently perceiving and processing information. The purpose of this study was to examine the visual perception in expert climbers through a psychophysical optical test in a cross-sectional study. Given the lack of research, we adopted a cross-sectional design whereby authors suggested that either (a) the climbers for whom the difference between their on-sight and red-point climbing levels was small (similar on-sight and red-point levels) would perform better at the psychophysical optic tests. That is, the visual hardware system would be further developed in climbers whose on-sight climbing skills are similar to red-point skills. Or, the opposite, that (b) the climbers for whom the difference between their on-sight and red-point climbing levels was large (better red-point climbing levels) would perform better at the psychophysical optic tests. That is, the visual hardware system would be further developed in climbers whose climbing skills are better. Twenty-eight male participants with an IRCRA best on-sight level between 18-27 and a best red-point level between 18-29 completed a series of psychophysical optic tests assessing their visual field, visual acuity, and contrast sensitivity. Climbers were divided into those whose rock climbing level gap between on-sight and red-pointed best leads was small (on-sight 20.17 +/- 1.80; red-point 20.50 +/-2.02) and those whose climbing level gap was large (on-sight 21.86 +/-3.23; red-point 24.21 +/-3.4). The group whose climbing level difference was large had more years of training experience (10.36 +/-6.18 years) and best red-pointed lead level (24.21 +/-3.4 IRCRA) than those whose climbing level difference was small (6.25 +/-2.63 years of training and 20.50 +/-2.02 IRCRA red-pointed level). Better visual perception outputs were produced by the group of climbers with a large difference between climbing levels in visual field tests; no differences were observed between the two groups for visual acuity and contrast sensitivity tests. Overall, findings indicate that best climbers performed better at the visual perception tasks testing their visual field. Regarding our visual field findings, we found an interesting difference between the performance of climbers at both tests (lower vs. upper). The group with a large difference between on-sight/red-point level showed superior upper visual field perception than those whose difference between climbing levels was small; thus, better climbers had a more-developed upper visual field than their counterparts. Such better perception from best climbers is discussed given (1) the greater time they spend coercing the visual system during practicing and (2) the specific complexity of the stimuli as they are confronted to harder routes where holds are less perceptible and the time to find best hold sequences is constrained.

**THE ROLE OF AGE IN THE EVALUATION OF HEAVINESS PERCEPTION**

ALBERGONI, A., BIGGIO, M., FAELLI, E., RUGGERI, P., AVANZINO, L., BOVE, M., BISIO, A.

*UNIVERSITÀ DI GENOVA*

Background
Physiological aging causes changes to motor and sensory systems that impact on the individual's functional independence. Muscle weakness is one of the mostly documented and it is at the origin of impairments in instrumental activities of daily living (IADL) (1), also because it determines proprioceptive dysfunctions (2), which likely alter the sense of effort and heaviness (3). Lifting an object is a common IADL, as well as observing an individual as he moves an object and passes it to us. In order to receive the object without getting hurt, the individual must be able to predict its weight and implement compensatory strategies. An altered sense of effort and heaviness might impair the ability to judge the weight of an object moved by another person. The purpose of this study is to clarify the role of age in the perception of object weight when looking at an individual performing an IADL.
Methods
Thirty-seven participants were enrolled and assigned to two groups according to their age, young adults (n=19, mean age = 24±5 years) and older adults (n=17, mean age: 74±7 years). The ability to perceive the heaviness was evaluated by means of a weight-discrimination task during which participants observed a couple of videos showing an actor lifting a box in a concentric and eccentric condition. The observer had to evaluate in which video the box was heavier. The video showed 7 different loads (0, 2.5, 5, 7.5, 10, 12.5, 15 kg). The 7.5kg-video was shown in every trial as the reference stimulus. A psychometric curve was built with participants' responses. The parameters of the curve were computed to describe the performance of the two groups. Young and older adults' performances were statistically compared by means of the Mann-Whitney test.
Results
In concentric condition, the upper asymptote, which gives information about the ability to discriminate the heavier loads, was significantly lower (p=0.026) in the older adults. In the eccentric condition, the lower asymptote, which gives information about the ability to discriminate the lighter loads, was significantly higher in the older adults (p=0.026) as well as the slope of the curve, which provides clues about the ability to discriminate both light and heavy loads) (p=0.014).
Conclusion
The present results showed that the perception of object heaviness in older adults compared with young subjects is altered. These findings suggest that age plays a key role in weight perception, affecting the ability to adequately assess loads.

### EXPLORING THE IMPACT OF DIVERSE STRESS FACTORS (MENTAL & PHYSICAL FATIGUE) ON LOWER COGNITIONS (ATTENTION, ANTICIPATION, AND VISUAL PERCEPTION) IN HEALTHY, ACTIVE, YOUNG ADULTS.

POHL, S.

*UNIVERSITY OF ROSTOCK*

Various studies have shown that physical and mental stress can have a detrimental effect on decision-making behavior and executive functions in athletes. However, existing findings are still ambiguous in how far stress negatively affects lower cognitions like attention and visual perception. Therefore, the aim of the present study was to explore the impact of different stress factors (mental and physical fatigue) on lower cognitions in healthy, active, young adults. 30 participants (21 men, nine women, Mage 22,8; SD = 2,35) completed three different fatigue conditions over a three-week period: no fatigue, mental fatigue (30-minute Stroop-Test) and physical fatigue (gradual individual stress test up to exhaustion on an ergometer). Cognition functions were assessed after completion of each fatigue protocol. Lower cognitions were tested using the Posner-Reaction-Task (attention), a Stop-Signal-Task (inhibition/anticipation), and a Pattern-Comparison-Task (visual perception). First, our data confirmed a significant reduction in perceived physical and mental performance in physical and mental fatigue conditions respectively. Performance in mental and physical fatigue conditions differed significantly from the no fatigue condition after stress was induced (VAS mental-performance: $F(2,58) = 19.86$, $p = <.001$, $\eta2 = .406$; BORG-Scale: $F(2, 58) = 66,95$, $p = <.001$, $\eta2 = .698$). A repeated-measures ANCOVA revealed a significant condition effect for inhibition/anticipation (SSRT integration) in the stop-signal task ($F(1.5, 50) = 3.66$, $p = .047$, $\eta2 = .128$), but no significant differences between conditions for attention ($F(2, 50) = 1.403$, $p = .255$, $\eta2 = .053$) and visual perception ($F(2,52) = .891$, $p = .416$, $\eta2 = .033$). The significant effect on inhibition/anticipation performance (i.e., lower performance following physical fatigue) and the absence of effects on other lower cognitions indicates that mental and physical fatigue have a lower impact on lower cognitions than what has previously been shown for higher-order cognitive functions like decision-making and executive functions.

### IS COGNITIVE PERFORMANCE RELATED TO THE SPEED OF UNPLANNED CUTTING MOVEMENTS IN HEALTHY MALES?

GIESCHE, F.1, PESKAR, M.2,3, MARUSIC, U.2,4

*1 INSTITUTE OF OCCUPATIONAL, SOCIAL AND ENVIRONMENTAL MEDICINE, UNIVERSITY OF FRANKFURT, GERMANY 2 INSTITUTE OF KINESIOLOGY RESEARCH, SCIENCE AND RESEARCH CENTRE KOPER, SLOVENIA*

INTRODUCTION: Evidence suggests that team sport athletes with low baseline cognitive scores are at higher risk of sustaining non-contact knee injuries during landing and cutting maneuvers that involve a time-constrained decision-making component (Wilke et al. 2020). While previous studies have focused primarily on biomechanical risk factors of unplanned landings (i.e., visual cue indicating landing side/cutting direction shown only during jump/run), it is largely unclear how cognitive performance relates to speed of task execution. This study investigated potential relationships between cognitive measures and reaction times (RTs) of unplanned cutting movements.
METHODS: Ten healthy males (age: 30±9 years; BMI: 26 Kg/m2) performed 64 drop-landings from a 60 cm box on a force plate immediately followed by an unplanned cut to one of four yellow light sensors positioned in semi-circular order (20° and 60° to both left- and right-hand sides from a participant's midline) and 150% of the participant's leg length. A blue light sensor placed in front of the box underneath the participant's non-dominant foot was deactivated by their take-off, which in turn triggered the yellow light stimulus (random order) during the fall. Upon landing, they needed to deactivate the yellow light stimulus rapidly by performing a subsequent cut directly in front of the corresponding sensor. The cut-landing needed to be performed with the right or left foot according to the sensors hemifield. Cutting RTs for each direction were measured as time between the deactivation of both stimuli. Peak vertical ground reaction forces (pVGRF) and contact times (latency to cut off from force plate) were recorded via force plate. All parameters were analysed for successful trials (cut-landing with correct foot and stabilising it >2 sec). PC (PsyToolkit) and pen-and-paper tests were used to assess selected cognitive measures, like simple and choice RT, short-term memory (Corsi), cognitive flexibility and working memory (Trail-Making-Test).
RESULTS: From 651 trials in total, 435 trials (67%) were successful. There was a significant relationship (Pearson`s $r=0.65$, $p=0.04$) between slower mean choice RT (413±51 ms) and longer contact times (503±59 ms). Cutting RTs (881±89 ms) and pVGRF (70±15 N/Kg) were not significantly correlated with any cognitive measure ($p>0.05$).
CONCLUSION: Slower cognitive choice RTs may prolong the initiation of complex motor reactions (e.g., cutting upon landing) under time-pressure, which may predispose athletes to injury during play. However, the potentially confounding influence of individual available response times during the fall (i.e., the time between yellow light sensor trigger and landing) is unclear, so the observed relationship must be interpreted with caution.

### WORLD CLASS AND INTERNATIONAL ELITE ATHLETES' AND COACHES' PERCEPTIONS OF MENTAL DEMANDS IN BEACH VOLLEYBALL

DELVIKEN, S.1, HOFSETH, E.1,2, RIISE, A.J.2, PETERS, D.M.3, HOIGAARD, R.1

*1 UNIVERSITY OF AGDER; 2 NORWEGIAN OLYMPIC SPORTS CENTRE; 3 UNIVERSITY OF WORCESTER, SCHOOL OF ALLIED HEALTH & COMMUNITY*

INTRODUCTION: In elite sport mental skills are essential for success. To develop optimal mental skills for an athlete it is essential to understand the mental demands that are critical in each sport (Taylor, 1995). Furthermore, it is essential to have knowledge about the individual athletes' exclusive needs and skills, and how they respond to the potentially unique mental demands and challenges they face in their sport. The aim of this study was to investigate how World Class and elite beach volleyball players and coaches perceive the mental demands in their sport, and how they prepare for and respond to these demands.
METHODS: Nine players (3 females and 6 males) and 4 coaches (1 female and 3 males) from the Norwegian national representative teams participated in individual semi-structured face-to-face interviews exploring perceived mental demands in Training, Competition and Relationships in high performance teams. The interviews were transcribed and coded using an inductive thematic analysis (Braun et al., 2016).
RESULTS: Three themes emerged in the Training context as 'presence', 'passion' and 'self-regulated learning' with presence then including subthemes of 'focus', 'resilience', & 'energy level', and self-regulated learning including subthemes of 'mastering', and 'knowledge development'. Five themes emerged in the Competition context as 'presence', 'fear & doubt', 'shared mental model', 'cope with pressure', and

'balance'. Two themes emerged in the Relationships in high performance teams context as 'intra-team cooperation' and 'inter-team cooperation', with intra-team cooperation including three subthemes of 'communication', 'trust & safety', and 'wellbeing & friendship'.
CONCLUSION: This study increases our understanding of the mental demands encountered by world class and elite beach volleyball players from the perspective of both the athletes and their coaches. Appreciation of the themes could enable coaches, and sport psychologists to optimize training sessions, competitions and relations using mental skill development strategies. Whilst the degree of the perceived mental demands could vary for each athlete, and notwithstanding the fact that individual adaptation is necessary for an athlete's best possible performance, psychological interventions that help athletes better understand and subsequently manage these unique mental demands could contribute to more optimal performance.

**DO ENERGY EXPENDITURE DIFFERENCES ACROSS WORK POSTURES INFLUENCE COGNITIVE PROCESSING SPEED? A COUNTER-BALANCED RANDOMISED CROSS OVER TRIAL**

RAJESHWARI, R., RAO, C.R., D'SILVA, R.M., CHANDRASEKARAN, B.

*MANIPAL COLLEGE OF HEALTH PROFESSIONS*

INTRODUCTION: Anecdotal evidence link occupational sedentary behaviour, low energy expenditure (EE) and cognitive dysfunction. Nevertheless, EE across different work postures including active workstations remains unclear and its influence on cognitive processing speed is yet to be established. We aimed to investigate differences in EE across various work postures and their influence on cognitive processing speed.
METHODS: In our counterbalanced randomised trial, sixteen desk-based employees performed simulated work tasks (typing, reading and cognitive tasks) in three different work positions (sitting, standing, walking) on three different days. EE was measured for three days consecutively for 30-minutes in each simulated position using indirect calorimetry. Processing speed was assessed through computer-based choice reaction times during each work posture. The outcome variables of interest (EE, reaction times and accuracy) were compared between work positions using repeated measures ANOVA and Pearson correlation.
RESULTS: Walking EE in walking was higher (5.57 ± 0.45 Kcal) than sitting (1.07 ± 0.12 Kcal) and standing (1.88 ± 0.42 Kcal). Total EE was significantly higher in walking than standing (35.17 ± 6.86 Kcal) and sitting postures (41.37 ± 8.46 Kcal). We did not find any significant differences in reaction times between different work postures except within standing work conditions (60.22 ±13.97 ms). Accuracy was found to be reduced in walking compared to sitting (0.76 ± 0.83%) and standing (0.43 ± 0.09%) but not reached significance.
DISCUSSION: Our study observed a significant increase in VO2 and METs in the walking group without a significant reduction in cognitive processing speed compared to prolonged sitting and prolonged standing groups during simulated work tasks. Excessive occupational sitting is found to be associated with low EE which leads to obesity and other metabolic risks such as hyperglycemia, hyperinsulinemia or hypertriglyceridemia. These metabolic derangements are found to have a negative influence on the brain glucose metabolism, hormonal balance (cortisol, BDNF) and brain vascular functions which in turn are speculated to influence cognitive performance and work productivity in workplace settings. Hence, replacing occupational sitting with standing or walking is speculated to be a successful strategy to combat the negative consequences on cognitive functions by increasing EE and reversing metabolic derangements during the typical working hours.
CONCLUSION: Though significant differences in EE were observed between work postures, walking or standing at work did not affect the cognitive processing speed.

**PREFRONTAL ACTIVITY OF SOCCER PLAYERS DURING GENERAL AND SPORT-SPECIFIC COGNITION IN MOTION**

SCHMADERER, L., REER, R., SCHUMACHER, N.

*UNIVERSITY OF HAMBURG*

Prefrontal activity of soccer players during general and sport-specific cognition in motion
Lena Schmaderer, Ruediger Reer & Nils Schumacher
University of Hamburg, Hamburg, Germany
Abstract
INTRODUCTION: To elucidate the underlying mechanisms of athletic expertise in cognitive tasks, studies examining the activity in the prefrontal cortex (PFC) could contribute (Tan et al., 2019). The importance of both general and sport-specific perceptual-cognitive abilities in team athletes has been demonstrated in several studies (Cole et al., 2017). However, these cognitive demands have not yet been studied in movement-intensive situations. The aim of this study was to analyze the prefrontal activity of soccer players during general and sport-specific cognitive tasks in motion.
METHODS: 37 semi-professional male soccer players (24.8 ± 4 yrs., age range 18 – 33 years) performed two cognitive tests requiring selective attention and decision-making in a general and a sport-specific task in motion (Witty SEM, Microgate, Italy). Meanwhile, the prefrontal activity was recorded using functional near-infrared spectroscopy (fNIRS) (NIRSport, NIRx Medical Technologies LLC, USA). Differences of prefrontal activation in general and sport-specific cognitive tasks were analyzed using a paired t-test.
RESULTS: Significant differences in prefrontal activity (oxyhemoglobin) between the general and the sport-specific cognitive task were found in thirteen out of twenty-one channels with increased activity during the general cognitive task (Ch.1: p=.04, Ch.2: p=.03, Ch.3: p<.01, Ch.4: p<.01, Ch.6: p=.04, Ch.8: p=.03, Ch.11: p=.04, Ch.12: p<.01, Ch.13: p<.01, Ch.15: p<.01, Ch.17: p<.01, Ch.20: p=.04, Ch.21: p=.05).
DISCUSSION: Our study indicates that the prefrontal cortex is more activated during the general cognitive task compared to the sport-specific cognitive task. This could be based on learned automatisms of experts in the field of sport-specific cognition in motion. These results seem in line with earlier research on novel and automated cognition (Sanchez-lopez et al., 2014) and the "repetition suppression theory" (Auksztulewicz & Friston, 2016) indicating lower prefrontal activity during familiar processes. However, further research is needed to clarify the prefrontal involvement on expertise in cognitive tasks in motion.

### CP-AP06 Monitoring in team sports

#### CHARACTERISTICS OF SPECIFIC INTENSE ACTIONS DURING TOP-LEVEL TEAM HANDBALL MATCHES

PANDURO, J., HOLMGAARD, E., RANDERS, M.B.
*UNIVERSITY OF SOUTHERN DENMARK*

INTRODUCTION: To best prepare players for team sport games such as elite team handball, it is paramount to understand the physical load and the position specific differences. The investigation of physical load in team sports have mainly been focusing on traditional tracking variables, such as distance in various speed zones and number of accelerations (Povoas et al., 2012; Manchado et al., 2021). To better understand the underlying mechanisms of specific intense actions, this study aims at describing the characteristics of various specific intense actions during top-level team handball games.
METHODS: Specific intense actions (sprints (>22 km/h), accelerations, decelerations, change of direction (CoD) and jumps) were extracted from 30 male top-level handball players (height: 193±5 cm, weight: 98±10 kg) during 6 handball matches. A total of 4300 specific intense actions – 418 sprints, 1669 accelerations, 1108 decelerations, 269 changes of directions, and 836 jumps were investigated. Participants were divided into three playing positions: pivot, back, and wing for investigating positional differences. Data were analyzed using a linear regression model. To adjust for multiple comparisons, Tukey's post hoc test was used. A significance level of 0.05 was chosen.
RESULTS: On all measured parameters, backs and pivots only differed in jumping height (0.21±0.18 m and 0.17±0.18 m respectively; $P<0.001$) and jumping distance (1.31±0.91 m and 1.26±0.92 m, respectively; $P<0.05$). During sprints, wings covered 14.7±5.0 m per sprint which was more ($P<0.001$) than both pivots (10.5±2.6 m) and backs (10.6±3.7 m). Pivots displayed lower magnitude of deceleration (1.4±0.6 m/s2) than both wings (2.1±0.8 m/s2; $P<0.001$) and backs (1.8±0.8 m/s2; $P<0.05$), and wings also showed greater magnitude of deceleration than backs ($P<0.05$). In contrast, no differences were observed between positions of magnitude of acceleration during CoD. During accelerations wings displayed longer duration (1.1±0.3 s) compared to both pivots (1.0±0.3 s; $P<0.001$) and backs (0.9±0.2 s; $P<0.001$). Additionally, pivots also displayed longer duration than backs ($P<0.001$). Maximum acceleration was higher in wings (2.9±0.5 m/s2) compared to pivots (2.6±0.4 m/s2; $P<0.001$) and backs (2.6±0.4 m/s2; $P<0.001$), but with no difference between pivots and backs.
CONCLUSION: Analysis of 4300 specific intense actions revealed great positional differences during top-level team handball matches, but with large variation of most parameters. Investigation of specific intense actions beyond traditional tracking variables reveal new insides to the demand of handball.

#### EFFECTS OF BIRTH QUARTER ON BODY WEIGHT, SLEEP QUALITY, FITNESS MEASURES AND NATIONAL AND REGIONAL RANKING POSITION: A PRESELECTION OF YOUTH ANDALUSIAN PADEL PLAYERS

MARÍN-GALINDO, A., PONCE-GONZÁLEZ, J.G.
*UNIVERSITY OF CÁDIZ, PUERTO REAL, SPAIN*

INTRODUCTION: Relative age effects (RAEs) appears affect physiological and physical aspects in a variety of sports, both at youth and adolescent level [1]. Children born early in the selection year are more likely to experience success and to sustain participation, which can influence the dropout of the other athletes. Despite that, little is known about the influence of RAEs on physical parameters in youth padel players. Hence, the aims of the study were to test: 1) whether the relative age effect (RAE) was prevalent in the pre-selection of young (10-18 years) Andalusian padel players, and 2) whether anthropometric, sleep quality, national and regional ranking and fitness measures vary according to birth date distribution in elite youth padel players.
METHODS: For the present study a pre-selection of youth padel players of the Andalusian Padel Federation (n = 69, 10-18 years old) were analysed. Body weight, sleep quality, national and regional ranking and fitness characteristics (Dominant-arm Hand Grip and Abalakov Jump) were measured. Chi-square tests were used to test the observed and expected birth distribution across the sample of players. A one-way analysis of variance ANOVA was used to compare all anthropometrical, sleep quality, performance and fitness variables across birth quarters for each age group.
RESULTS: Of the pre-selected players, 63,77% were born in the first half of the year, specifically 50%, 75%, 68,75% and 61,9% for the U12, U14, U16 and U18 categories, respectively. No significant differences were found in any of the anthropometric, sleep quality, skill level and fitness characteristics of the regional squad players born across different quarters.
CONCLUSION: Compared with early born, late born players did not seem to be different in anthropometric, sleep quality, national and regional ranking and fitness characteristics in youth elite padel players. Studies with a much larger sample are needed to obtain more conclusive results.
[1] António J. Figueiredo, Manuel J. Coelho-e-Silva, Sean P. Cumming & Robert M. Malina (2018): Relative age effect: Characteristics of youth soccer players by birth quarter and subsequent playing status, Journal of Sports Sciences, DOI: 10.1080/02640414.2018.1522703

#### PHYSICAL AND CARDIOVASCULAR DEMANDS PLACED ON COLLEGIATE DIVISION II WOMEN'S BASKETBALL PLAYERS – PRELIMINARY ANALYSIS FROM A SINGLE SEASON

MEHTA, H., FRIGO, J., SALAH, A., ANDERSEN, P., SAVLA, R., ANDERSEN, J.
*THE UNIVERSITY OF TAMPA*

INTRODUCTION: Monitoring the physical and cardiovascular demands that players are exposed to during games can help guide the training process and optimally prepare each player for game demands (1). The purpose of this investigation was to quantify the physical and cardiovascular game demands during a single season.

METHODS: Sixteen games during the 2021-2022 season were monitored using inertial movements units (Catapult S5, indoor mode, Catapult Sports Innovations) and integrated heart rate monitors (Polar). Four female division II (D2F) players (23+0.89 years) identified as guard or forward who met the criteria of participating in at least 10 live minutes per game were included in this preliminary analysis. Average game duration (DUR), average player load (PL), player load per minute (PL/min) and duration spent above 85% of the HRmax (% HI HRZ) were extracted from the data collected. Means and standard deviations along with 95% CI were calculated for each metric at the group and individual level.
RESULTS: The pooled results for the four players were 1) DUR of 29.9+7.33mins (CI: 28.09 to 31.75 min), 2) PL was 488.8±147.94 (CI:410 to 567), 3) PL/min was 8.03±1.61 (CI:7.17 to 8.89) and 4) %HI HRZ was 31.6+8.6 (CI: 27.04 to 36.21).The individual analysis for each included player identified the following: For Player 1, 1) DUR was 33.6+3.9 mins (CI: 31.62 to 35.76), 2) PL 685+430 (CI: 456.1 to 915.4), 3) PL/min 9.7+6.5 (CI: 6.25 to 13.19) and 4) %HI HRZ 50.5±10.5 (CI: 44.96 to 56.17). For Player 2, 1) DUR was 31.75+4.98 (CI: 29.1 to 34.4), 2) PL 411+101 (CI: 356.98 to 465.15), 3) PL/min 6.95+0.74 (CI: 6.17 to 7.73) and 4) %HI HRZ 50.9+3.34 (CI: 33 to 69). For Player 3, 1) DUR was 30+5.07 (CI: 28.11 to 33.52), 2) PL 404+138 (CI: 330.44 to 477.81), 3) PL/min 6.6+1.7 (CI: 5.73 to 7.56) and 4) %HI HRZ 9.06+0.9 (CI: 4 to 14). For Player 4, 1) DUR was 23.4+9.4 mins (CI: 18.41 to 28.46), 2) PL 454+166 (CI: 365.42 to 542.58), 3) PL/min 8.46+0.62 (CI: 8.13 to 8.8) and 4) %HI HRZ 12.12+9.56 (CI:7.03 to 17.22).
CONCLUSION: For the pooled results, these data indicate that D2F guards and forwards were exposed to an average DUR of 29.9 mins /game and %HI HRZ of 31.6%. The findings for DUR and %HI HRZ are consistent with recent data in NCAA Division I women's basketball (2). At the individual level, guards or forwards demonstrated variable responses on each metric which can be dependent on internal and contextual factors and requires more investigation. For practitioners, these data may be useful for optimizing training programs on a weekly basis for forwards/guards. While a recent study (2) suggested that to mimic in-game intensities, conditioning protocols can aim to engage players in >85% HRmax workloads, understanding in-game physical demands such as average PL and PL/min may be of importance as well and warrants further investigation.

**PHYSICAL DEMANDS OF FOOTBALL SPECIFIC DRILLS IN DIVISION II COLLEGIATE FEMALE FOOTBALL PLAYERS**

FRIGO, J., MEHTA, H., ANDERSEN, P., SALAH, A., SAVLA, R., ANDERSEN, J.

*THE UNIVERSITY OF TAMPA*

INTRODUCTION: GPS wearable technology allows practitioners to access data that may ensure the drills selected in training mimic the external and internal demands seen in matches1. The purpose of this study was to categorize common practice drills by comparison to match demands.
METHODS: Match and practice data for 11 NCAA Division II Women's Football players who played in 13 conference matches was collected using Catapult S5 GPS devices and integrated Heart Rate Monitors (Polar). Each player's average distance (D), duration (DUR, min), acceleration (ACC) and deceleration (DEC) efforts, high speed distance (HSD), and percent duration spent above 85% HRMax (%HI HRZ) was collected for each match and practice in season. Possession (P), shooting (SH), short-sided games [SSG] (classified as <6v6 and field dimensions smaller than half field), and big scrimmages [SCR] (≥7v7) drills were analyzed. All data were then expressed in relative terms as average percentage of match demand.
RESULTS: With respect to relative match demands for D, the largest average accumulation occurred in SCR (25%) followed by P (16%), SSG (14%), and SH (8%). For relative DUR, SCR (36%) demonstrated the largest average DUR followed by P (28%), SSG (26%), and SH (22%). Findings for relative ACC efforts were SCR (31%) followed by SSG (24%), P (16%), and SH (13%). Similar findings for relative DEC efforts were observed, SCR (32%), SSG (23%), P (7%), and SH (7%), respectively. The data indicated that, for relative HSD, SCR provided the largest relative HSD at 22%, followed by SSG (9%), and P and SH each providing 3%. The results for %HI HRZ indicated that relative to match %HI HRZ, SCR showed the highest value at 56% followed by SSG (51%), P (28%), and SH (18%).
CONCLUSION: Big scrimmages accumulated the highest amount of HSD as a percentage of game values as well as the highest percentage of ACC and DEC. SSG, while accumulating <10% of HSD relative to match HSD, provided moderately high amounts of ACC and DEC efforts. It is also notable that SSG provided the second largest relative %HI HRZ. These findings are consistent with previous work in elite football players showing that D, HSD, and ACC and DEC increase with pitch size2,3. Studies in professional football have also shown no difference in heart rate between short, medium and large area games 4. These findings shed light on the physical and metabolic internal demands of different football drills and may be useful for the practitioner when considering practice planning and return to play. To optimize training session drill structures, the physical and metabolic demands of matches must be understood to achieve the intended physiological and performance adaptations in training. Further investigation to improve the classification of drills into high, medium, and low intensity relative to match demands as well as drill manipulation on the observed metrics is needed.

**HUMAN MOVEMENT VARIABILITY IN SPIKE MOVEMENT WITH VOLLEYBALL CONSTRAINT IN DIFFERENT GAME POSITIONS OF FEMALE ELITE PLAYERS**

CATALA, J., FERNANDEZ-VALDES, B., MORAS, G.

*NATIONAL INSTITUTE OF PHYSICAL EDUCATION OF CATALONIA*

INTRODUCTION: In volleyball, the volleyball spike approach movement (SM) represents one of the more sophisticated attack actions and the spike after it, is the most important ability to win a game (1). The use of nonlinear tools like entropy can be a good alternative to explore the nature of human movement and its relationship with coordinative development (2), reflecting changes in movement variability (MV) during the movement execution and overt time. SM oscillations can be evaluated through entropy calculation techniques (3) that allow to identify variability from a spatiotemporal perspective. In general, change in movement complexity with practice find that, the complexity of the attractor dynamics (pattern of expected values of the movement) could be reduced as a function of practice (4), furthermore, athletes manage to reduce the variability of their sports movements (5), in volleyball game position puntas are the player who realizes more SM in practices and competition during a season (6)
The aim of this study was to identify the differences in human movement variability (MV) between game position in SM with and without ball constraint.
METHODS: One WIMU(Realtrack systems) were placed in a belt to forty eight female first division players in 4 different game positions: Punta(Mean ±SD: Age16,83±3,62; Height: 1,76±0,06; Weight: 65,95±7,15), Central (Mean ±SD: Age 18,42±3,40; Height: 1,82±0,03; Weight: 72,57±6,39), Colocadora (Mean ±SD: Age 17,00±3,51; Height: 1,77±0,02; Weight: 68,67±5,03), Libero (Mean ±SD: Age 19,80±3,37; Height:

1,71±0,04; Weight: 63,88±5,39) who performed SM in both conditions (with ball and without ball). The players performed an eight minutes standardized warm-up after which they realized four sets of six SM, two of them with ball and two of them without ball in random order, completing eight series performed in two sessions on different days. The human movement variability was analysed with entropy values in Sample Entropy (SampEn).
RESULTS: The SampEn response variable was analysed using a Mixed linear Model, where with or without ball is the main variable explanatory and, game position as a secondary variable explanatory. In SampEn without ball (Punta=0,153; Central=0,156; Colocadora=0,155; Libero=0,163) with ball (Punta=0,072; Central=0,079; Colocadora=0,074; Libero=0,081). Without ball there is no difference between positions, with ball position Punta is different to Central (p = 0,0117) and to libero (p = 0,0019).
CONCLUSION: At game position as a constraint, the MV decreases significantly between the position Punta and the rest of game positions, as in the conditions of the study, we could consider the Puntas probably are who realizes more SM in practices and competition (6), up to 40,000 during one season (7).

## USA BASEBALL SYSTEM: EXAMINING MICRO-LEVEL PRACTICES AGAINST A GLOBAL MODEL FOR INTEGRATED DEVELOPMENT OF MASS AND ELITE SPORT

SCHOEN, C., TATARYANTS, N., SMOLIANOV, P., BOUCHER, C., BLOOM, K., BAHNAN, N., CHEN, L., DION, S.

*SALEM STATE UNIVERSITY*

INTRODUCTION: This study was designed to help and improve international baseball performance as well as increase domestic sport participation in the United States. Over 200 sources of literature on sport delivery systems from 28 Australasian, North and South American, Western and Eastern European countries were analyzed to construct a globally applicable model of high performance skiing and snowboarding integrated with mass participation, comprised of the following seven elements across three levels:
Micro level (operations, processes, and methodologies for development of individual athletes):
1. Talent search and development,
2. Advanced athlete support.
Meso level (infrastructures, personnel, and services enabling sport programs):
3. Training centers,
4. Competition systems,
5. Intellectual services.
Macro level (socio-economic, cultural, legislative, and organizational):
6. Partnerships with supporting agencies,
7. Balanced and integrated funding and structures of mass and elite sport.
METHODS: The above model was used to design a questionnaire of 54 statements reflecting desired practices. 54 statements were validated by 12 international experts, including executives from sport governing bodies and academics who published on high performance and sport development. 2,000 baseball professionals' email addresses were collected from various sources, including web pages of national and regional skiing and snowboarding associations, college and university athletics as well as high school and club skiing and snowboarding teams. Completed online questionnaires were returned by 100 coaches from all key regions of the country for a response rate of 5%. Additionally, 6 regional administrators were interviewed to suggest possible sport system improvements.
RESULTS: Despite the significant resources available to US baseball, respondents were not satisfied with many current practices. More consistent Olympic performance and growth of national and international baseball participation have great unrealized potentials and can be achieved through further advancements of baseball programs domestically and globally. More than half of the open responses regarding talent search and development indicated the need for standardized USA Baseball coaching so that training and development of young athletes could lead to more opportunities for those less fortunate who cannot afford private coaching.
CONCLUSION: In conclusion, we have learned from the respondents that there needs to be more developmental programs available through public organizations. Grassroots programs need to be better structured and coaching needs to be equated with abilities rather than financial and political influence. To improve advanced athlete support, coaching and training methodologies should focus on less experienced baseball athletes to ensure all participants receive equally sufficient support, particularly via such grassroots programs as Babe Ruth Baseball, Cal Ripken Baseball, Dixie Youth Baseball and Dixie Boys Baseball.

## PHYSIOLOGICAL DEMANDS AND IMPACT OF A SIMULATED BEACH VOLLEYBALL TOURNAMENT ON ELITE MALE AND FEMALE ATHLETES

HARAT, I.

*WINGATE INSTITUTE*

INTRODUCTION: Beach Volleyball (BVB) is a high intensity sport that requires sprinting and jumping. A BVB tournament often involves several consecutive days of multiple games a day, separated by as few as 2 hours, in which case fatigue might impair performance.
METHODS: 12 national team adult BVB players (8 males: height 190.9±5.1 cm, weight 83.9±8.7 kg, %fat 8.7±0.6, age 22.5±5.3 years; 4 females: height 175.3±10.9 cm, weight 68.2±10.4 kg, %fat 18.3±2.2, age 19.5±1.9 years) were tested for blood lactate (La), countermovement vertical jump (CMJ; with shoes on hard floor, hands on hips) and 4m and 8m sprint (barefoot on sand) before and after 2 games separated by 2 hours to simulate a single day tournament. Total number of jumps and RPE (Borg 1-10) was also recorded. Teams were instructed to strategically attack the same opponent player throughout all matches to increase that player's physiological load.
A repeated measures ANOVA test was used to reveal differences in CMJ, 4m, 8m sprint times, and La between pre and post-match 1 and 2, between pre match 1 and pre match 2, and between pre-match1 and post-match 2.
RESULTS: There were no statistically significant differences in CMJ height or sprint speed between any of the time points sampled. No differences were found between males and females, between defenders and blockers, and between the 2 players in the same team.
La was higher post-match 2 compared to pre-match 1 (3.1 vs 1.2 ml/L, $p<0.001$, Cohen's d=1.2) and post-match 2 compared to pre-match 2 (3.1 vs 1.9, $p<0.05$. d=0.81).
RPE was higher post-match 2 compared to post-match 1 (6.9 vs 5.2, $p<0.005$, d=1.18).
Total number of jumps was significantly higher during the second match compared to the first match (63.7±18.06 vs 56.1±20.25, p=0.008, d=1.08).
CONCLUSION: Discussion: Although higher La and RPE values were recorded, both performance measures were not significantly affected by a simulated BVB tournament. CMJ is often used as a measure of neuromuscular fatigue (NMF). NMF may also be detected by more sensi-

tive tests, however, these performance indices were selected as they reflect the required actions performed in a VB match and may influence match success. Our results support results from previous studies in BVB.
Conclusions: We concluded that NMF was not apparent following 2 BVB matches, and performance was not significantly hindered. Future studies should investigate NMF and performance during a longer tournament (2-3 days) and ideally be performed during a real tournament and not a simulated one.

**REVIEW OF THE WORLD RUGBY 'TEST METHOD 01' FOR THE DETERMINATION OF THE CRITICAL FALL HEIGHT IN ARTIFICIAL TURF RUGBY SURFACES. A PILOT STUDY.**

COLINO, E., DOUGLAS, M., HARRISON, E., WEBB, C., DEL CORRAL, J., LÓPEZ-MOYA, E., GARCÍA-UNANUE, J.
*UNIVERSIDAD FRANCISCO DE VITORIA*

INTRODUCTION: Mechanical properties of the surface are significant to the performance and safety of the athlete in rugby union, a close-contact team sport in which players occasionally fall headfirst to the ground during various events of the game such as scrums and tackles. Consequently, one of the properties regulated on artificial turf rugby surfaces is the determination of the Critical Fall Height (CFH). This test evaluates the magnitude of the impact that a player would suffer on the head when falling to the ground from a certain height.
During the test, a 4.6kg-head-form falls freely to the ground recording the magnitude of the impact in HIC (Head Injury Criteria) units. The CFH is the height at which the HIC equals 1000.
According to the current test method, the CFH is calculated by performing drop tests from 4 different heights and obtaining the HIC for each of them, with 2 HIC values below 1000 and 2 above. The 4 height-HIC data pairs must also meet the following restrictions: (i) There is a maximum difference between highest and the lowest drop heights (1m); (ii) There is a minimum difference between consecutive drop heights (15cm); (iii) There should be no HIC value contained in a range around 1000 (975-1025). Once the 4 height-HIC data pairs are obtained, a linear regression model is used to calculate the CFH.
The objective of this study was to review the current method to check if it could be simplified or improved in any way. The method is considered improved if its repeatability increases, that is, if the percentage of outliers (%out) obtained during multiple tests decreases.
METHODS: A pilot study was performed on 7 artificial turf rugby fields. In each of them, one complete 3-drop procedure was performed initially to obtain a first estimate of the CFH (CFH0). Then, the procedure was repeated on each surface at 50mm intervals, from 600mm below to 600mm above CFH0. All possible combinations of 4 height-HIC data pairs with 2 HIC values below and above 1000 were obtained, with no other restriction applied at this stage. The %out obtained under these conditions was considered the reference value (%outref) to be improved with the application of restrictions (i) to (iii). Then, the %out obtained by restricting the aspects mentioned above (%outi, %outii, %outiii) was investigated. Finally, the %out obtained by applying the linear or quadratic fit (%outlin, %outcuad) was investigated.
RESULTS: Results are presented for each restriction: (i) %outi improves %outref. %outi is reduced as the total distance between drop heights decreases; (ii) %outii improves %outref. %outii is reduced as the distance between consecutive drop heights increases; (iii) %outiii worsens %outref. %outiii is reduced as the restricted area around 1000 decreases. Also, %outcuad improves %outlin.
The %out could be reduced from 1.08 (current method) to 0.15 by adapting test restrictions.
CONCLUSION: A thorough review of the current test method could improve its repeatability and decrease the % of atypical results.

### CP-PN08 Muscle function and damage

**EFFECTS OF INTERMITTENT EXERCISE ON THE POWER-DURATION RELATIONSHIP**

BLACK, M.I., LEWIS, J., WINN, B.J., KIRBY, B.S., VANHATALO, A., JONES, A.M.
*UNIVERSITY OF EXETER*

INTRODUCTION: Knowledge of the parameters of the hyperbolic power-duration relationship, the critical power (CP) and the curvature constant (W', which represents a fixed work capacity above CP), permits the prediction of both continuous and intermittent sprint exercise performance [1]. Recently, we have shown that during prolonged constant-work-rate, heavy-intensity exercise, there is a time-dependent reduction in both CP and W' [2]. However, the effect of prolonged intermittent sprint exercise, such as that which occurs in team sports like football, rugby and field hockey, on the parameters of the power-duration relationship, and the rate of W' recovery between high-intensity exercise bouts (W'REC), has yet to be examined. The primary purpose of this study was therefore to investigate the influence of high-intensity intermittent exercise on CP, W', and W'REC.
METHODS: Following ethical approval, thirteen (9 male, 4 female) team sport players completed a repeated all out sprint test without prior exercise (baseline), and immediately after a 40-min (40-IST), and an 80 min (80-IST) intermittent sprint test on a cycle ergometer. The repeated all-out sprint test consisted of a 3-min all-out test (3MT), for determination of CP and W', and a 2-min all-out test (2MT) that enabled the assessment of W'REC during the 90-s rest period separating the all-out tests. The IST was composed of a repeating 2-min block of exercise that included a 6-s all-out sprint, 100 s active recovery, and 20 s of rest to mimic the demands of team sports.
RESULTS: Work done during the 2nd half of the 80-IST (338 ± 60 kJ) was significantly lower than the mean for the first 40 min of the IST ($P<0.05$). For the 3MTs, total work done was significantly lower during the 40 3MT (50.1 ± 9.8 kJ) compared to the baseline 3MT (53.5 ± 10.2 kJ; $P<0.05$), and the 80 3MT (47.7 ± 10.4 kJ) was significantly lower than both the baseline 3MT ($P<0.001$) and the 40-3MT ($P<0.05$). There were no differences ($P>0.05$) in CP between the baseline 3MT (222 ± 52 W), 40-3MT (222 ± 57 W) and 80-3MT (213 ± 49 W). However, W' was significantly lower during the 40-3MT (10.1 ± 4.0 kJ; $P<0.01$) and 80-3MT (9.1 ± 3.5 kJ; $P<0.001$) compared to the baseline 3MT (13.5 ± 4.0 kJ). There was no difference in W'REC following the 40-IST (0.07 ± 0.02 kJ·s-1) and 80-IST (0.07 ± 0.02 kJ·s-1) compared to control (0.08 ± 0.02 kJ·s-1; all $P>0.05$).
CONCLUSION: Prolonged intermittent sprint exercise of at least 40 to 80 min in duration, such as that which occurs in team sports like football, rugby and field hockey, reduces W' without altering CP or W'REC. These findings provide new insight into the determinants of fatigue during prolonged intermittent sprint exercise.

### ADAPTATIONS TO CHRONIC RESISTANCE EXERCISE ON THE RATE OF STRENGTH INCREASES AND MUSCLE ARCHITECTURE IN MIDDLE AGED MEN

PHELAN, K., RANKIN, P., NULTY, C.

*INSTITUTE OF TECHNOLOGY CARLOW*

INTRODUCTION: Ageing has long been associated with reductions in strength and lean body mass, potentially due to cellular changes such as decreases in muscle fiber numbers and size, reduced response of satellite cells, changes in myofilament quality, as well as neural changes such as lower agonist activation and higher antagonist co-activation (1). Maintaining higher levels of muscle mass across the lifespan are associated with positive QOL outcomes. Resistance exercise (RE) has been consistently demonstrated to increase muscle size and strength in both younger (YA) and older adults (OA), yet ageing can attenuate the hypertrophic response of muscle groups to resistance training (2). There is still paucity in the data on the relative contribution of neural and morphological factors to gains associated with RE. Research tends to focus on extremes (YA vs OA) in order to view ageing effect yet excluding middle aged means rate of change with ageing is often overlooked. The aim is to assess the contribution of neural and architectural adaptations to strength gains
METHODS: N = 19 active, MAA (46.84±5.20 y) who were naïve to RE completed the study. At baseline, MT (muscle thickness) of and AOP (angle of pennation) of the m. vastus lateralis were assessed via ultrasonography. Maximal isometric voluntary contraction (MVC) and Rate of Force Development (RFD) were assessed using a Biodex System-3 isokinetic dynamometer (Biodex Corp., Shirley, NY, USA). A 10RM protocol during the barbell back squat was used to determine lower limb strength. Participants followed a 10-week progressive RE programme, two times per week. Participants returned 48-120 hours after the final exercise session of the intervention for reassessment of all measures
RESULTS: Paired Samples T-test revealed there was no sig. increase on both VL MT ($p = 0.983$) which remained at 24.2±2.3 mm (baseline = 24.2±3.2 mm), and VL AOP ($p = 0.166$) which increased to 17.1±1.9 mm from 16.4±2.9 at baseline, an increase of 4.3% over 10-weeks. Cohen'd illustrates a small effect size for VL MT ($d = 0.005$). Interestingly, Cohen's d shows a moderate effect size on VL AOP (0.33). 10RM significantly increased ($p < 0.0005$) by 33.63±10.26 Kg. Training had a large effect on 10RM ($d = 3.33$). A trend towards significance was observed in MVC ($p = 0.077$), with a moderate effect size ($d = 0.430$). RFD significantly increased ($p = 0.004$) with a large effect size ($d = 0.753$)
CONCLUSION: Similar to YA, progressive resistance training in MAA leads to an increase in strength. The findings of this research display that a 10-week resistance exercise program does not create significant changes in muscle architecture, however neural adaptations can be seen to improve MVC and RFD. It appears that the rate of increase in MVC is higher in YA displaying an increase 11.2%, whereas the current MA men increased by 5.2% over the same time period (3). RFD improves at a quicker rate in MA adults from the current findings. MA adults increased RFD by 20.5% whereas YA increased by 10.5%

### CIRCULATING MICRORNAS LEVELS AFTER EXERCISE-INDUCED MUSCLE DAMAGE AND THE REPEATED BOUT EFFECT

CHALCHAT, E., MARTIN, V., CHARLOT, K., BOURRILHON, C., BAUGÉ, S., BOURDON, S., GRUEL, A., LEPETIT, B., BANZET, S., GARCIA-VICENCIO, S., SIRACUSA, J.

*INSTITUT DE RECHERCHE BIOMÉDICALE DES ARMÉES*

INTRODUCTION: The neuromuscular system is able to quickly adapt to exercise-induced muscle damage (EIMD), such that it is less affected by subsequent damaging exercise, a phenomenon known as the repeated bout effect (RBE). Circulating muscle-specific microRNAs (myomiRs) may potentially predict the long-lasting maximal voluntary contraction (MVC) torque deficit (>24h), an indicator of EIMD. The aim of the present study was to investigate (1) how plasma myomiR levels are modified by the RBE and (2) whether plasma myomiRs are relevant to predict the long-lasting MVC torque deficit.
METHODS: Nineteen participants performed two identical bouts of loaded downhill walking separated by 2 weeks. MVC torque, creatine kinase (CK) activity, myoglobin (Mb) concentration and myomiR levels were measured before and up to 48 h after the exercises. Correlation and multiple regression analyses were performed to assess the ability of these markers to predict the largest MVC torque loss beyond 24 h post-exercise.
RESULTS: As MVC torque, CK activity and Mb concentration, some myomiR levels (hsa-miR-1-3p, hsa-miR-133a-3p) were less affected after the second bout of exercise compared to the first bout. CK, Mb and several myomiR levels (hsa-miR-1-3p, hsa-miR-133a-3p, hsa-miR-206) were correlated to the long-lasting MVC torque loss. The multiple regression showed that the best combination included some myomiRs, Mb and CK.
CONCLUSION: Some myomiR levels were less increased after the exercise 2 compare to the exercise 1, indicating the presence of the RBE. Measurement of myomiRs levels concomitantly to Mb concentration and CK activity could improve the prediction of long-lasting MVC torque deficit.

### INTRAMUSCULAR INJECTION OF MESENCHYMAL STEM CELLS ACCELERATES BOTH MUSCLE PROTEIN ANABOLIC RESPONSE AND CATABOLIC SYSTEMS AFTER ACUTE BOUTS OF RESISTANCE EXERCISE IN MICE

TAKEGAKI, J., KONO, Y., FUJITA, T., KONISHI, S., FUJITA, S.

*RITSUMEIKAN UNIVERSITY*

INTRODUCTION: Skeletal muscle mass is regulated by the net balance between muscle protein synthesis and breakdown. Resistance exercise is a strong intervention to accelerate muscle protein synthesis and induce skeletal muscle atrophy, and there are growing strategies to promote its effectiveness. Mesenchymal stem cells (MSCs) are multipotent cells and have been reported to have the capacity to secrete growth factors including insulin-like growth factor 1 which is known to stimulate muscle protein synthesis (1). Recently, we reported that intramuscular injection of MSCs enhances muscle protein synthesis (2). The present study aimed to investigate the effect of intramuscular injection of MSCs on muscle protein synthesis and breakdown-related factors after an acute bout of resistance exercise in mouse skeletal muscle.
METHODS: Male C57BL/6J mice were divided into placebo and MSCs groups (N = 6, respectively). All mice were intramuscularly injected with either MSCs (2.0 × 106 cells suspended in 20 µL PBS) labeled with green fluorescence protein or a vehicle-only placebo into right gastrocnemius muscle under isoflurane anesthesia. Two or seven days after the injection, all mice performed a single bout of resistance

exercise (consisting of 3s × 10 reps × 5 sets maximal isometric contractions elicited by transcutaneous electrical stimulation) on the right gastrocnemius muscle. Three hours after the exercise bout, muscle samples were collected. The left gastrocnemius muscle in each group was kept sedentary and served as the control. Muscle protein synthesis (MPS) was measured by the SUnSET method.
RESULTS: MPS was increased in the exercised muscles in both groups, while MPS in the MSCs group was significantly higher than that in the placebo group at 7 days after the injection ($P < 0.05$). The expressions of phosphorylated p70S6K (Thr389), rpS6 (Ser240/244), 4EBP1 (Thr37/46) were increased in the exercised muscles in both groups ($P < 0.05$), and the increase of rpS6 and 4EBP1 in MSCs group were significantly higher than those in the placebo group at 7 days after the injection ($P < 0.05$). On the contrary, protein ubiquitination was increased in the exercised muscles only in the MSCs group at both 2 and 7 days after the injection ($P < 0.05$).
CONCLUSION: The present results suggest that the intramuscular injection of MSCs activated not only MPS but also the protein catabolic system in mouse skeletal muscle.

**RESPONSE OF MUSCLE BIOMARKERS TO DETERMINE THE EXTENT OF MUSCLE DAMAGE AFTER A REPEATED MAXIMAL 40M SPRINTS**

MORENO, L., COSIO, P.L., LLORET, M., FUSTER, J., PADULLÉS, X., PADULLÉS, J.M., CARMONA, G., CADEFAU, J.A.
*INSTITUT NACIONAL DEDUCACIÓ FÍSICA DE CATALUNYA - UNIVERSITAT DE BARCELONA*

INTRODUCTION: Perform a high intensity exercise induced muscle damage, altering the muscle functions and performance, incrementing the risk of injuries. It has been demonstrated that repeated sprint exercise trigger muscle damage process (1) but it's unclear the magnitude of this damage. The changes on different serum markers can indicate the states of the cells and muscle fibre structures, which may determine the extent of the damage. While changes in CK may indicate membrane disruptions (2), changes in mitochondrial CK (sMtCK) concentration reflect muscle cell organelle disruption (3), and the changes in titin concentration may suggest muscle sarcomere structure damage (4).
METHODS: Amateur football player males (n=17, 23 ± 0.7 years, BMI 23.7 ± 0.4) and females (n=4, 24 ± 2 years, BMI 21.5 ± 1.2) performed 10 repeated maximal 40m sprints with a rest of 3 minutes between repetitions. Changes on force generating capacity (FGC), as an indirect markers of muscle damage, and serum levels of muscle enzymes (CK, sMtCK and titin) were measured at baseline and immediately after, at 24-, 48- and 72-hours post-exercise. Participants who did not recover at 72h baseline force values, were classified as responders (n=10) and those that recover baseline values as non-responders (n=10). One-way repeated measure ANOVA (time), Friedman and Wilcoxon test was used to identify changes from baseline on the different parameters analyzed. Data are presented as mean ± SEM and the level of significance was set at $p < 0.05$.
RESULTS: Repeated maximal sprints result in loss of strength of more than 20% on responders group at +48h and remained unrecovered +72h following exercise. Serum CK increased significantly from baseline (225,9 ± 20,1 ng·mL-1) until peak at +24h (516,8 ± 36,7 ng·mL-1) on responders and from baseline (121,9 ± 13,0 ng·mL-1) until peak at +24h (349,6 ± 25,2 ng·mL-1) on non-responders, indicating membrane disruption. sMtCK values also increased significantly from baseline (34,3 ± 7,0 ng·mL-1) until peak at +24h (91,6 ± 12,5 ng·mL-1) on responders and from baseline (24,3 ± 8,6 ng·mL-1) until peak at +24h (58,1 ± 9,3 ng·mL-1) on non-responders, reflecting cell organelle alterations. Both parameters remained unrecovered at +72h following exercise in both groups. Titin values didn't increase respect baseline, which leads us to assume that there was not damage on sarcomere structure.
CONCLUSION: A set of repeated maximal 40m sprint, performed by amateur footballers, is expected to produce moderate EIMD, with a membrane and organelle disruption, and a loss of muscle strength on responders, that is not recovered at 3 days after exercise.

**EFFECTS OF NOCICEPTIVE AND MECHANOSENSITIVE AFFERENTS SENSITISATION ON VASCULAR RESPONSIVENESS FOLLOWING EXERCISE-INDUCED MUSCLE DAMAGE**

ZAMBOLIN, F., GIURIATO, G., LAGINESTRA, F.G., FAVARETTO, T., OTTAVIANI, M.M., CALABRIA, E., DURO-OCANA, P., BAGLEY, L., FAISAL, A., PEÇANHA, T., MCPHEE, J., VENTURELLI, M.
*MANCHESTER METROPOLITAN UNIVERSITY, UNIVERSITY OF VERONA, UNIVERSITY OF UDINE, UNIVERSITÀ POLITECNICA DELLE MARCHE*

INTRODUCTION: Mechanoreflex hypersensitivity plays a significant role in cardiovascular diseases, where it may lead to dysregulated responses and decreased exercise capacity. More recently, studies have also suggested that it may be altered in pain-related diseases where nociceptive sensitisation and mechanical hyperalgesia is present. Indeed, the increased sympathetic activation due to the combination of mechano and nociceptive sensitivity may interfere with the peripheral haemodynamic, and being responsible of the aberrant cardiovascular response in these conditions. The present proof of concept study aimed to test the separated and combined effects of mechanoreflex activation and nociception through exercise-induced muscle damage (EIMD) on vascular responses to single passive leg movement (sPLM).
METHODS: Eight healthy young males undertook four experimental sessions, in which performed a sPLM manoeuvre on the dominant limb while in each specific session the contralateral was: a) in a resting condition (CTR), b) stretched (ST), c) resting after EIMD called delayed-onset-muscle-soreness (DOMS) condition, or d) stretched after EIMD (DOMS+ST). EIMD, used to induce DOMS in the following 24-48h, consisted of several maximal voluntary eccentric contractions of the non-dominant leg (~200-250). Femoral blood flow (FBF) was assessed using a doppler ultrasound while mean arterial pressure (MAP), heart rate (HR) and cardiac output (CO) were assessed non-invasively beat by beat via finger photoplethysmography. Leg vascular conductance (LVC) was calculated as FBF/MAP.
RESULTS: Resting FBF and LVC were decreased only in the DOMS+ST condition (Δ:-26ml/min and -50ml/mmHg/min respectively) and MAP, HR, CO, and SV were increased in ST and DOMS+ST compared with CTRL. Marked decreases of delta peaks and AUC for FBF (Δ: -146ml/min and -265ml respectively) and LVC (Δ: -8.66ml/mmHg/min and ±1.7ml/mmHg respectively) were found only DOMS+ST compared with CTRL. All, $p<.05$.

CONCLUSION: These results suggest that the combination of mechanoreflex and nociception reduces leg blood flow and increases central hemodynamic responses during sPLM. However, the effects of mechanoreflex activity or nociceptive sensitisation alone seem to not be sufficient to exert a significant reduction in peripheral haemodynamics.

## STRENUOUS EXERCISE RESPONSE OF SALIVARY HUMAN NEUTROPHIL PEPTIDES 1-3 (HNP1-3), SERUM HNP1-3 AND BLOOD NEUTROPHILS IN YOUNG MALE SUBJECTS

HANAOKA, Y., SHIMIZU, K., HIRAOKA, H., KIMURA, F., WATANABE, K., AKAMA, T.
*JAPAN INSTITUTE OF SPORT SCIENCES, JAPAN HIGH PERFORMANCE SPORT CENTER*

INTRODUCTION: In the field of athletics, the risk of upper respiratory tract infection (URTI) is one of the most important problems in athletes. Salivary human neutrophil peptides 1-3 (HNP1-3) have anti-virus activity, thereby preventing URTI. HNP1-3 are predominantly expressed in neutrophils. There is only one report about HNP1-3 in response to exercise. However, this response did not examine immediately after exercise. The aim of this study was to examine salivary HNP1-3 with serum HNP1-3 and neutrophils responses to strenuous exercise.
METHODS: Ten healthy young male subjects (23.4 ± 0.6 years) participated in this study. The subjects performed exercise experiment (exercise on a cycle ergometer at 75% VO2max for 60 min) and control experiment (non-exercise). Saliva and blood samples were collected pre exercise (7:30 A.M.), post exercise (8:30), post 1 h (9:30), post 2 h (10:30), and post 3 h (11:30), after the bout of exercise. HNP1-3 concentrations were measured by the enzyme-linked immunosorbent assay. Counts of neutrophils were obtained using an automated cell counter.
RESULTS: In the exercise experiment, salivary HNP-1-3 concentration didn' t significantly change after exercise. Otherwise, serum HNP1-3 concentration were significantly increased at post 2h and 3h after exercise compared with immediately after exercise ($p < 0.05$) and neutrophils count were significantly increased at post1h, post2h and post3h after exercise ($p < 0.05$). In the control experiment, serum HNP1-3 significantly decrease at 10:30 compared with 7:30. Otherwise, salivary HNP1-3 and neutrophils count didn't change.
CONCLUSION: In this study, salivary HNP1-3 didn' t significantly change after exercise, whereas serum HNP1-3 and neutrophils gradually increased after the exercise. Therefore, there might be the time lag between increased serum HNP1-3 and neutrophils responses to strenuous exercise.

## EFFECTS OF RESISTANCE EXERCISE-INDUCED HYPERURICEMIA ON POSTPRANDIAL GLUCOSE AND LIPID METABOLISM IN HEALTHY YOUNG MEN

TSAI, S.H., CHENG, H.C., HSIAO, P.Y., SHAO, Y.T., LIU, H.W.
*NATIONAL TAIWAN NORMAL UNIVERSITY*

INTRODUCTION: Hyperuricemia is a risk factor in the development of gout and is highly associated with cardiovascular diseases and type 2 diabetes. In vivo and vitro studies, elevated uric acid (UA) increases production of reactive oxygen species and causes endothelial dysfunction, which may impair insulin signaling pathway. On the other hand, UA is a major antioxidant in the human plasma. Increased UA levels after acute resistance exercise (RE) has been reported, but whether RE-induced hyperuricemia would impair postprandial glucose and lipid metabolism has yet to be thoroughly understood. Therefore, this study aimed to explore the effects of acute RE-induced hyperuricemia on postprandial glucose and lipid metabolism in healthy young men.
METHODS: Healthy young men (n = 11; age 23 ± 2 years, body mass index 22 ± 2 kg/m2) conducted a randomized crossover counterbalanced trial involving two different loads of RE (moderate (MOD): 4 sets × 8 repetition × 70% of 1 repetition maximum (1RM), LOW: 4 sets × 16 repetition × 35% of 1RM) and sedentary control (CON). Meal test was performed an hour after each trial. Blood samples were collected at the corresponding time points.
RESULTS: Uric acid levels were significantly increased in MOD and LOW from post 30 to meal 120 min ($p < 0.05$). In comparison with CON, higher total area under the curve (AUC) of uric acid was observed in both exercise trials (MOD: +33.0%, LOW: +25.3; $p < 0.05$). No differences were observed in postprandial AUC of glucose, postprandial AUC of insulin, postprandial insulin resistance and secretion index, postprandial AUC of triglycerides, and postprandial AUC of nitrate/nitrite (NOx) between the three trials ($p > 0.05$).
CONCLUSION: Acute RE-induced hyperuricemia seems not to impair postprandial glucose and lipid metabolism in healthy young men.

## CP-MH10 Physical fitness

### HEALTH RELATED QUALITY OF LIFE CHANGES IN A TRAINING PROGRAM BASED ON HIGH-INTENSITY TRAINING UNDER HYPOXIC CONDITIONS

CAMACHO-CARDENOSA, A.1,2, CAMACHO-CARDENOSA, M.3, OLIVARES, P.R.4,5, OLCINA, G.1, BRAZO-SAYAVERA, J.2

*1 UNIVERSITY OF EXTREMADURA, CÁCERES, SPAIN. 2 UNIVERSIDAD PABLO DE OLAVIDE, SEVILLE, SPAIN. 3 MAIMONIDES BIMEDICAL RESEARCH INSTITUTE OF CÓRDOBA, CÓRDOBA,SPAIN. 4 UNIVESITY OF HUELVA, HUELVA, SPAIN.*

INTRODUCTION: Mental disorders are an important source of disability that cause a decrease in HrQoL (Henares Montiel et al., 2020). It is estimated that in Spain and in the rest of European countries more than 25% of the population will suffer some mental health problem throughout their lives (Alonso et al., 2004). In this sense, regular physical activity has been reported how an effective tool to control emotions and even reduce the risk of mental disorders (Yan et al., 2020), inducing a potential direct and indirect effect on hippocampal thought brain derived neurotrophic factor (BDNF) production (Loprinzi & Frith, 2019; Rasmussen et al., 2009). However, higher BDNF concentrations have been reported after higher intensity of exercise (Chang et al., 2012; Jiménez-Maldonado et al., 2018). In addition to exercise, experiments in animals revealed that hypoxia conditioning may promote the expression of BDNF in the adult's hippocampus as well (Zhu et al., 2010). In this context, new strategies that sustain the benefits achieved in detraining periods are essential and the inclusion of hypoxic conditions during the HIIT program have been proposed like an effective strategy to achieve greater short-term and long-term health benefits (Camacho-Cardenosa et al., 2018). Therefore, the aim of this study was to determine the effect of 12-weeks of HIIT under hypoxic conditions following by 4-week detraining period on health-related quality of life and functional fitness of women adult health.
METHODS: Eighty-two participants were randomly assigned either to (1) experimental group (EG; n = 41), in which interval training under normobaric hypoxic conditions (17% of FiO2) was performed or to (2) the control group (CG; n = 41) in which interval training under normoxia was performed. Within one week before (pre), after (post) and four weeks after (det) the intervention health-related quality of life (through SF-36) and functional capacity: upper body strength (via "arm curl" test), lower body strength (via "chair stand" test), agility (via "8-foot- up and go" test) and aerobic capacity (via "6-minutes walking" test) and haemoglobin level were evaluated.
RESULTS: Compared to control group, after 12 weeks of training, the number of repetitions in the "Chair Stand tests" was significantly improved by 9.85% in EG vs 0.8% in the CG ($p = 0.033$). Compared with baseline, a significant improvement was observed on the number hand curls (+14.96%; $p < 0.001$), number of stands (+26.20%; $p = 0.011$), and agility (-4.94%; $p = 0.006$) in EG after 36 sessions of exercise. Additionally, when the exercise protocol was ceased, the distances walked during the 6-minutes's walk test was significantly extended of + 2.92% ($p = 0.05$), the number of hand curls remained increased by 16.03% ($p < 0.001$)
CONCLUSION: HIIT and normobaric hypoxia may be a promising strategy for improve the health-related quality of life in health women adults, with an additional benefit for maintaining the improvements even after training cessation.

### INTRACELLULAR BODY WATER AS A PREDICTOR OF ANAEROBIC PERFORMANCE IN CROSSFIT® ATHLETES

PONCE-GARCIA, T., ALVERO-CRUZ, J.R., GARCÍA-ROMERO, J.C., CARRASCO-FERNÁNDEZ, L., BENÍTEZ-PORRES, J.

*UNIVERSIDAD DE MÁLAGA*

INTRODUCTION: Body composition and its relationship to physical performance in athletes from different sports has been broadly studied. Hydration status and body fluids distribution has gained interest for showing association with certain health and performance variables. The purpose of the present study was to correlate intracellular (ICW) and anaerobic performance in CrossFit® (CF) athletes and develop multiple regression models.
METHODS: Thirty-four athletes (20 male; 14 female) volunteer to participate in this study (Age 32.55 ± 5.34 year; Height 171.29 ± 7.77 cm; Body Mass 73.88 ± 11.58 kg; BMI 25.13 ± 2.44). Intracellular (ICW) expressed in l were estimated by bioelectrical impedance analysis (Inbody 770, Cerritos, CA, USA). Anaerobic performance was tested by the Wingate test (WG), determining peak (WGPP), mean (WGXP) and minimal (WGMP) power values. Pearson correlation coefficient was used to define the association between variables and stepwise multiple regression analysis to determine their relationship.
RESULTS: ICW showed significant correlation with WGPP ($r = 0.90$, $p < 0.001$), WGXP ($r = 0.95$, $p < 0.001$) and WGMP ($r = 0.65$, $p < 0.001$). Two equations models, explained by intracellular water, were developed for peak and mean power: WGPP = -341.0015 + 37.7110 * ICW, R2-ajusted= 0.80, SEE= 3.2942 W, $p < 0.001$: WGXP = -277.5285 + 28.3841 * ICW, R2-ajusted= 0.89, SEE= 1.7095 W, $p < 0.001$.
CONCLUSION: Our results showed moderate to very-large correlation between ICW and anaerobic performance values. In summary, we can conclude that ICW is a strong predictor of anaerobic performance in CrossFit® athletes, explaining over 80% of power values.

### PHYSICAL FITNESS TESTS AND TRAINING INTERVENTIONS FOR JAPANESE ELITE PARA BADMINTON PLAYERS

KAMEDA, M., OISHI, M., ANDO, R., HAKAMADA, N.

*JAPAN INSTITUTE OF SPORT SCIENCES*

INTRODUCTION: Paralympic badminton has been adopted at the 2020 summer Paralympics in Tokyo. Paralympic badminton can be categorized into wheelchair athletes and standing athletes. So far there has never been researched on physical fitness tests and training interventions for Paralympic badminton athletes. The purpose of this study was to examine the effects of physical fitness tests and training interventions conducted on Paralympic badminton players.
METHODS: The participants were 14 Paralympic badminton players who can be divided into wheelchair athletes and standing athletes. This study measured for these athletes including body composition measurements, muscle strength tests, and aerobic capacity tests. Bodyweight, lean body mass (LBM), and body fat percentage were measured by the method of air displacement. Isokinetic strength of the extensor and flexor muscles at the knee joints were evaluated by dynamometry for standing athletes. On the other hand, upper muscle strength which includes push power and pull power were evaluated for wheelchair athletes. To measure the aerobic capacity, they performed on each multistage running test and bike ergometer test for standing athletes or hand ergometer test for wheelchair athletes, including 3-minutes stages separated by a 1-minute rest with speed or watt were increased every stage. All the tests were conducted 4

times from September 2020 to July 2021. The data that the initial day (pre) and the last day (post) were analyzed. 12 athletes of among them took part in training inventions.
RESULTS: The results showed that standing athletes' body composition measurements, muscle strength, and aerobic capacity for standing athletes were not significant compared pre and post. By contrast, body weight and body fat percentage were lower than in pre for wheelchair athletes. And upper muscle strength which includes push power and pull power were larger than in pre. On the other hand, aerobic capacity for wheelchair athletes were not significant compared pre and post.
CONCLUSION: This study has shown that wheelchair athletes improved data in body composition measurements and muscle strength tests, however, there was no significant difference pre and post for standing athletes. We can see the effects of the training interventions for particularly wheelchair athletes so that we discuss them in detail. Wheelchair athletes are required for not only badminton skills but also wheelchair skills and the power which are to move forward or backward. We conducted resistance training including push power and pull power focused on the upper body of wheelchair athletes. For this reason, Para badminton wheelchair athletes could improve upper body power. The main point of this study is that physical fitness tests and training interventions are effective for wheelchair athletes particularly.

### 3-M ROPE-CLIMBING TEST: A COMPARISON BETWEEN MALE AND FEMALE RESULTS

MAGRANER, J.M., BOTTA, W.C., BORIN, J.P.

*STATE UNIVERSITY OF CAMPINAS*

INTRODUCTION: Combat tasks (CT) expose soldiers to exhausting physical and physiological demands in war operations [1]. Specific training focused on simulated tasks (ST) can be considered the best way to increase physical readiness in combat [2] without exposing the troops to unnecessary risks. However, little is known about the differences in ST performance between men and women [3]. Thus, the purpose of the current study was to investigate possible sex differences in physical performance on a 3-m rope-climbing test (RCT).
METHODS: Two hundred cadets from the Brazilian Air Force (167 male) performed the selected test. The test began when the participant held the rope above the 1.6 m mark and started to climb. The test ended when the cadet put the two hands above the 4.6 m mark or when he gave up without completing the ST. All volunteers were already familiar with the test. Statistical analysis of group performance was compared using the chi-square test of independence. The significance level was set at $p<0.01$.
RESULTS: Significant differences were found between males and females. Male cadets had a significantly higher pass rate in the RCT ($X^2(2) = 39{,}403$; $p<0.01$). A total of 140 participants passed the test (132 men, 8 women; 94.3% and 5.7%, respectively), and 60 cadets did not complete the test (35 men, 25 women; 58.3% and 41.7%, respectively).
CONCLUSION: The physiological specificity of women may have contributed to a significantly lower performance in the RCT, which involved upper-body power. Therefore, it could be useful to take into account these differences in performance, considering that specific physical training could be developed for each gender to improve combat readiness levels.

### MEASURING FITNESS IN ARTISTIC GYMNASTS: THE UPDATED MEN'S ARTISTIC GYMNASTICS FITNESS TEST BATTERY (MAG-FTB)

KOLIMECHKOV, S., YANEV, I., KIUCHUKOV, I., STOIMENOV, E., PETROV, L., ALEXANDROVA, A., ZAYKOVA, D.

*STK SPORT*

INTRODUCTION: An objective assessment of specific physical fitness is an essential part of the training process of gymnasts. The Men's Artistic Gymnastics Fitness Test Battery (MAG-FTB) has been used for over 30 years as the main tool for testing specific fitness in Bulgarian male artistic gymnasts but it needed to be updated and improved due to modern developments in gymnastics. The aim of this study was to assess the need to update certain tests from the MAG-FTB and add components for monitoring and assessment of specific fitness.
METHODS: The study included 70 male gymnasts (mean age of 9.6 ± 2.5 years) who were members of the Bulgarian Gymnastics Federation. The participants completed the MAG-FTB, which included a total of 20 fitness tests with each age group undertaking between 8 and 10 tests. The modified shuttle run test on the 12m gymnastics floor was replaced with the original 20m shuttle run test (20m SRT) in order to assess gymnasts' maximal oxygen uptake (VO2max) for the gymnasts at the age of 13 and older. The test was administered by using BeepShuttle Junior software using Leger's equations to calculate VO2max. The MAG-FTB's points system for each test was modernized with percentile scores (for up-to-date application and comparison between ages), and the total test battery score was recalculated for each age group.
RESULTS: The total MAG-FTB scores showed that 4.3% of the male gymnasts were assessed as 'excellent', 18.6% as 'very good', 15.7% as 'good', 45.7% as 'fair', and 15.7% as 'poor' results. This wide variation of the results was due to the diverse nature of the gymnasts participating in the study, including both elite and intermediate level gymnasts. The relationship between total MAG-FTB scores and gymnasts' current competitive level was found to be moderately correlated ($r = 0.50$). The results from the 20m SRT showed a mean VO2max of 47.4 ± 4.0 ml/kg/min, which was close to published VO2max values for gymnasts (around 50 ml/kg/min) in different studies in the literature. The mean percentile score of VO2max was 63.5 ± 21.8. The 20m SRT provided more valuable information for the coaches in contrast to the replaced 12m shuttle run test which was previously used in the MAG-FTB. Moreover, testing gymnasts with specialized shuttle run software was well accepted, highly convenient, and comprehensive.
CONCLUSION: The MAG-FTB provides gymnastics coaches with a functional, field-based tool to measure and assess specific physical fitness for safe and effective participation in men's gymnastics. The updated battery considered the modern developments in gymnastics, and it can be easily incorporated into any artistic gymnastics program. Annual testing with the MAG-FTB can provide important information about individual training regimens, fitness deficits, and directions for training development.

**FIT FOR DUTY: THE IMPACT OF TACTICAL GEAR / LOAD CARRIAGE ON OCCUPATIONAL PERFORMANCE AND ITS RELATIONSHIP TO FITNESS ATTRIBUTES IN ELITE POLICE OFFICERS/OPERATORS**

MONTEIRO, L.1,2, OLIVEIRA, P.1, LANGFORD, E.L.3, ABEL, M.G.1,3

*1POLICE RESEARCH CENTER – ICPOL, LISBON, PORTUGAL; 2CIDEFES – RESEARCH CENTER - LUSÓFONA UNIVERSITY – LISBON, PORTUGAL; 3FIRST RESPONDER RESEARCH LABORATORY, UNIVERSITY OF KENTUCKY, LEXINGTON, KENTUCK*

INTRODUCTION: Several studies on physical fitness (PF) attributes and police performance [1-3] have reported that a steady set of attributes underlie the most frequent and critical tasks identified in police duties [3]. Given the need for officers to wear tactical gear, it is important to understand the effects this additional load can have on occupational performance [2-3]. O objective of this study was to evaluate the acute metabolic impact of wearing personal protective equipment (tactical gear) on the performance of elite police officers
METHODS: 42 police officers (Age = 39.4 ± 1.3 yrs., Height = 178 ± 0.01 cm, Body mass = 80.3 ± 1.3 kg, BMI = 26.2 ± 0.3 kg/m2, Fat mass = 15.4 ± 0.5%) performed a battery of physical fitness tests including: push-ups, shuttle test, handgrip strength (kg), throw medicine ball (3kg), countermovement jump (CMJ, cm), push-ups, T-test, standing broad jump, sit-up test, and flexibility. The participants performed the On-Duty Task (ODT) Police Physical Fitness Circuit twice. The ODT was composed of tasks: The first stage was supposed to mimic a foot pursuit, completing four laps with an obstacles sprint. The second part simulates the solving of the problem, where the participant should: (a) flip a 65-kg tire four times; (b) lift and carry a 25-kg bag for 10 m; (c) push a 65-kg sled for 10 m and pull it on his way back another 10 m; and (d) drag/carry a 48-kg dummy for 15 m. The total distance of the ODT-ST was 393 m, and the final time was recorded [3]. The first ODT trial was performed in physical training (PT) clothes, whereas the second trial was performed in tactical gear (TG). During the ODT, completion time, heart rate, blood lactate, and rating of perceived effort (RPE) were assessed. Paired sample t-tests were used to compare ODT outcomes between PT and TG conditions. Correlation and regression analyses were used to identify fitness correlates of ODT time and predictive factors of ODT time in the TG condition, respectively.
RESULTS: It was observed that Elite police have a good fitness level, and good body composition (10 to 20 % Fat mass, 82% of the sample) even in comparison with the international police panorama. The use of TG increased ODT time by 25% ($p < 0.01$), and RPE ($p<0.01$). There were strong negative correlations between almost all fitness variables and ODT time ($p<0.05$). The multiple linear regression analysis produced the following predictive equation: Performance in ODT with TG = 185.87 – (2969 * No. push-ups) + (15.777 * T-Test) - (1.732 * right handgrip strength) showing that the maximum number of repetitions of push-ups, agility test time, and the right-handgrip values explained 46.2% of the variance in ODT time
CONCLUSION: The use of tactical gear decreases Elite Police operators load carriage-based occupational performance, and this performance is related to a diverse set of fitness attributes.

**EFFECT OF THE TIME OF DAY OF EXERCISE TRAINING ON THE INCREASE IN STRENGTH AND ENDURANCE: A SYSTEMATIC REVIEW WITH META-ANALYSIS**

BRUGGISSER, F.1, KNAIER, R.2,3, ROTH, R.1, WANG, W.2, QIAN, J.2,3, SCHEER, F.A.J.L.2,3

*<1> UNIVERSITY OF BASEL, <2> HARVARD MEDICAL SCHOOL, <3> BRIGHAM AND WOMENS HOSPITAL*

INTRODUCTION: Diurnal variations in physiological body functions affect physical performance, with an apparent peak in the afternoon and evening [1]. However, it is unclear if training at particular times of day may result in larger improvements in physical performance. Thus, the aims of this systematic review were to investigate: 1) if in intervention studies the time of day of training influences the magnitude of the increase in performance, and 2) whether the improvement in performance is dependent on the time of day when the performance was assessed.
METHODS: EMBASE, PubMed, Cochrane Library, and SPORTDiscus databases were searched. Eligibility criteria of the studies were: (1) comparing exercise interventions between at least two different times of day, (2) examining structured exercise interventions with an intervention duration of a minimum of two weeks and at least two exercise sessions per week, (3) conducting strength and/or endurance interventions; and (4) applying a randomized parallel group or crossover design. A modified version of the “Cochrane risk of bias tool” was used to assess methodological quality of the studies. Due to the limited number of studies examining harmonizable outcomes, a meta-analysis was only conducted for jump height and maximum strength. In all studies part of the meta-analysis, all subjects performed morning and evening performance tests, both at baseline and post-intervention. The change in performance assessed in the morning and the change in performance assessed in the evening, from baseline to post-intervention was compared between morning and evening exercise interventions. Because effect sizes were reported for only some studies, Cohens d was calculated to estimate effect sizes. Here, positive Cohens d indicate larger performance improvements with evening exercise training and negative Cohens d indicate larger performance improvements with morning exercise training.
RESULTS: From 12,783 screened articles, 22 articles were included in the systematic review of which seven were also included in the meta-analyses. The overall effect sizes (95% confidence intervals) for the improvement in jump height tested in the morning was -1.11 (-2.18 to -0.03), suggesting that exercising in the morning might be beneficial to increase jump height achieved in the morning. In contrast, evening training seemed no to be beneficial for increasing jump height tested in the evening with 0.33 (-0.12 to 0.77). For maximum strength, the results were -0.14 (-0.60 to 0.32) and 0.34 (-0.03 to 0.71), for morning and evening tests, respectively.
CONCLUSION: There is little evidence that exercising at a specific time of day is more beneficial in increasing jump height or maximum strength as compared to another time of the day per se. However, the observation that morning exercise seems to improve morning performance and evening exercise improves evening performance to a higher extend, warrants further investigation.

**A SIX- MONTH TAILORED TELEPHONE AND EMAIL-BASED EXERCISE INTERVENTION INCREASED PHYSICAL FITNESS IN PHYSICALLY INACTIVE ADULT:A RANDOMIZED CONTROLLED TRIAL**

KJÆR, I.G.H., ANDERSSEN, S.A., TORSTVEIT, M.K.

*UNIVERSITY OF AGDER*

INTRODUCTION: Tailored mobile health physical activity (PA) interventions have proven effective in enhancing PA levels in adults (1), however the effect of such interventions on objectively measured physical fitness is scarce. The purpose of this parallel group randomized

controlled trial was to assess the effect of a six-month tailored telephone and email-based exercise intervention on cardiorespiratory fitness (CRF) and musculoskeletal- and neuromotor fitness (MSMF), in apparently healthy but physically inactive adults.
METHODS: A total of 111 physically inactive adults (40-55yr) from the Agder counties, Norway volunteered for the study. The participants were randomly assigned to an intervention group (IG;n=56) or a control group (CG;n=55), using random allocation numbering, stratified by gender. The IG received tailored exercise recommendations, every two months by email or mail (print) and supporting motivational follow-ups every fortnight, alternatively by email and telephone. The CG received no follow-up during the intervention period. Outcome measures were objective measures of physical fitness (CRF and MSMF), which were assessed at baseline and post-intervention (IG:n=39, CG:n=50). All personnel involved in the intervention and both assessments were blinded for group allocation. The data was analyzed by per-protocol using the Statistical Program for Social Sciences. Results are given in median and effect size. The significance level was 0.05.
RESULTS: The IG showed larger improvements compared to the CG in maximal oxygen consumption by VO2max, in ml/kg/min (ES:0.11, p=0.002) and in l/min (ES:0.12, p=0.002), muscular endurance of the back extensors (ES:0.21, p<0.001), flexibility of the hamstrings muscles (ES:0.12, p=0.006), and explosive power (ES:0.09, p=0.022), from pre- to posttest, when adjusting for baseline scores. When fully adjusted, the IG showed significantly larger improvements in VO2max in ml/kg/min (ES:0.17, p=0.002) and l/min (ES:0.13, p=0.008), compared to the CG.
CONCLUSION: A six-month tailored telephone and email-based exercise intervention had significant positive effects on several aspects of CRF and MSMF in physically inactive adults and may be a possible effective tool in promoting physical fitness in physically inactive adults.

### MULTIDISCIPLINARY PRACTICE PATTERNS CURRENTLY USED FOR ATHLETES WITH RELATIVE ENERGY DEFICIENCY IN SPORTS (RED-S)

PANTANO, K.

*CLEVELAND STATE UNIVERSITY*

INTRODUCTION: Relative Energy Deficiency in Sports (RED-S) is a condition that can develop when a person's exercise energy expenditure exceeds their energy intake. Prevention and intervention strategies for RED-S are necessary to avoid potential short and long-term consequences, such as stress fractures, osteopenia and osteoporosis. Sport health professionals are crucial for screening, treating and preventing RED-S and a multidisciplinary team approach is suggested. The purpose of this study was to examine if a multidisciplinary team approach is used for RED-S among coaches, athletic trainers, and physical therapists working with athletic populations in the U.S.
METHODS: Databases were obtained for currently practicing collegiate coaches, certified athletic trainers, and physical therapists in the U.S. A survey was developed, tested for content validity, and randomly emailed to potential participants using Qualtics. The questionnaire allowed participants to provide narrative descriptions for how they treat, prevent, and screen for RED-S and data were collapsed into themes. Participants used Likert Scales to rank the specific actions they practice when they come into contact with an athlete suspected to have RED-S.
RESULTS: Three hundred twenty-five participants (136 coaches, 85 athletic trainers 104 PTs) completed the survey. Athletic trainers and physical therapists were most likely to first discuss the condition with the athlete. Coaches were most likely to first discuss the athlete and condition with the athletic trainer. The most commonly practiced treatment strategies were nutritional education, multidisciplinary consultation, incorporating more resistance training in place of cardiovascular exercise, referral to a dietitian and sports psychologist (mental health specialist). The most common prevention strategies were employing multidisciplinary educational sessions about RED-S, pre-participation screening examinations, dietary counseling, and discussing RED-S individually with the athlete or with the athlete's physician and parents.
CONCLUSION: The survey respondents in this study indicated that they use similar multidisciplinary preventation and treatment approaches to RED-S, however the order of priority and use of referral sources may differ. Of interest in future studies is determining the specific treatment and prevention strategies dietitians and sports psychologists use for the treatment and prevention of RED-S.

### CP-BM05 Biomechanics and kinematics

### FOOTSTRIKE PATTERN INFLUENCE ON FOOT-ANKLE MUSCLE STRENGTH IN ENDURANCE RUNNERS.

ABRAN, G.

*UNIVERSITY OF LIEGE*

INTRODUCTION: Running with minimalist footwear appears to increase the strength of the ankle plantar flexors and the volume of the intrinsic foot muscles. However, authors also reported minimalist footwear induces a shift from rearfoot strike to non-rearfoot strike. Thereby, it remains unclear whether the strength gain in the foot-ankle muscle was induced by minimalist footwear or a forefoot striking pattern. The aim of this study was to assess the influence of footstrike pattern in foot-ankle muscle strength in endurance runners.
METHODS: Seventy-two volunteers filled out a questionnaire relative to their running level and training. The minimalist index of the two most frequently worn footwear during the previous six months was assessed. Maximal voluntary isometric contraction (MVIC) of six different foot-ankle muscles were assessed using a fix hand-held dynamometer. The footstrike pattern was determined with high-speed camera during a self-paced run on a treadmill. Each runner was categorized as either rearfoot or non-rearfoot strikers.
RESULTS: Data was collected amongst 36 runners with rearfoot strike and 36 with non-rearfoot strike. The results showed that non-rearfoot strikers had higher maximal voluntary isometric strength (MVIS) for ankle plantar flexors ($p = 0.015$), ankle dorsiflexors ($p = 0.01$), hallux flexors ($p = 0.04$) and toes flexors ($p = 0.0031$). No correlation was found between minimalist index and MVIS of foot-ankle muscles.
CONCLUSION: The footstrike pattern appears to have a larger influence on foot-ankle muscle strength than the type of footwear worn. However, an interventional study is needed to verify this observation.

**CORRELATION BETWEEN VARIABLES DEFINING THE FOOT-STRIKE PATTERN DURING RUNNING**

SKYPALA, J.1, HAMILL, J.1,2, JANDACKA, D.1

*1 UNIVERSITY OF OSTRAVA, 70200 OSTRAVA, CZECH REPUBLIC; 2 UNIVERSITY OF MASSACHUSETTS, AMHERST, MA 01003, USA*

INTRODUCTION: Currently, almost 11% of adults run regularly (1). Foot-strike pattern (FP) is one of the most heavily debated topics in the running population. There is a large volume of published studies focusing on the FP and running injuries; FP and running economy; FP in running preschool children etc. [2-4]. Foot-strike patterns are differentiated according to which part of the foot initially contacts the running surface first [5]. There are three types of FP - rearfoot, midfoot and forefoot. Various variables appear in the previous studies on the basis of how the authors define FP - vertical ground reaction force, foot-strike index, foot angle and ankle angle [3-5]. Foot-strike index is difficult to use on a treadmill because the movement of the belt can affect the accuracy of the center of pressure. Foot angle and ankle angle are kinematic measures that only indirectly indicate initial contact (IC). However, they are just useful in studies in which we do not have the ability of measuring ground reaction forces. If we want to compare the results of different studies that use different FP variables, we need to know if these variables are related. The aim of this study is to test whether different variables associated with FPs in the literature are correlated with each other (foot-strike index and foot angle).
METHODS: A total of 421 participants (166 females, 255 males) aged 30-50 years, from the database of the Healthy Aging in Industrial Environment-Program 4, were included in this study. Participants consisted of 327 recreational runners and 94 non-runners (mean age = 40.3±5.6 yrs, mass = 76.0±13.3 kg, height = 1.76±0.9 m and body fat = 28.2±6.2 %. All participants underwent kinematic and kinetic analysis of overground running at their self-selected speed (6). Foot-strike index and foot angle at sagittal plane at IC were determined (7). Spearman's rank correlation coefficient was used to determine the relationship between these variables.
RESULTS: The relationship between foot-strike index and foot angle at IC show a strong correlation (r=-0.81, r2=65.1%).
CONCLUSION: The main conclusion of the study is that there is a strong correlation between foot-strike index and foot angle which describes FP. Therefore, we could compare the results of different studies using different variables defining FP during running.

**NEUROMECHANICAL ADAPTATIONS OF FOOT FUNCTION TO CHANGES IN SURFACE DURING RUNNING**

BIRCH, J.V., KELLY, L.K., FARRIS, D.J.

*UNIVERSITY OF EXETER*

INTRODUCTION: We have shown previously that hopping humans exploit the adaptable mechanics of their feet to adapt to changes in surface. On an elastic surface, this resulted in participants selecting a posture at landing that allowed them to harness stored energy and reduce their active contribution to work. On a damped surface, participants activated their intrinsic foot muscles to contribute a substantial proportion of the additional positive mechanical work required to preserve motion. While hopping shares many mechanical characteristics with running, we have only been able to speculate if these observations are transferable. Here, we tested how running humans alter their foot function when interacting with a damped and an elastic surface and hypothesised that participants would harness energy stored in the elastic surface to reduce their intrinsic muscle activation and perform less work compared to when they ran across a damped surface.
METHODS: Nine participants ran across an adjustable platform in a damped and an elastic configuration. Three-dimensional kinematic and kinetic data were recorded in Qualisys alongside muscle activation from abductor hallucis (AH) and flexor digitorum brevis (FDB). Kinematic and kinetic data were processed in Visual3D (C-Motion) to calculate sagittal plane joint angles, moments and work performed at the midfoot using a multi-segment foot model. EMG data were processed in Matlab (Mathworks). Raw signals were band-pass filtered before root mean square (RMS) envelopes were computed and normalised for each participant to the peak amplitude recorded on a control surface.
RESULTS: Participants used similar ground contact times, landing posture and midfoot excursion on both surface configurations. The increase in energy returned from the platform in its elastic configuration meant that runners left the platform significantly faster than they did when it was in its damped configuration ($P = 0.04$), despite performing the same amount of work. Integrated EMG during contact revealed no change in activation of FDB ($P = 0.13$) or AH ($P = 0.22$) with surface.
CONCLUSION: Rather than reducing the work that they performed on the elastic surface, participants harnessed stored energy to increase their running speed. These results offer insight as to an energy-saving mechanism that may be exploited by the designers of footwear and other wearable devices to augment function.

**NEUROMECHANICAL ADAPTATIONS IN THE TRICEPS SURAE FOLLOWING CHRONIC EXPOSURE TO CYCLING AND TRIATHLON EXERCISE**

WALKER, J.1, BISSAS, A.2, HANLEY, B.1, WAINWRIGHT, B.1, CRONIN, N.J.3

*1. LEEDS BECKETT UNIVERSITY 2. UNIVERSITY OF GLOUCESTERSHIRE 3. UNIVERSITY OF JYVÄSKYLÄ*

INTRODUCTION: Chronic exposure to strenuous mechanical loading has been shown to alter muscle neuromechanical behaviour during locomotion (Bissas et al., 2020) and mechanical profiles such as joint moment-angle relationships (Herzog et al., 1991). These adaptations might be movement-specific, although there is a lack of empirical evidence showing whether changes to muscle-tendon mechanical profiles translate to improved neuromechanical performance during movement. Therefore, the purpose of the study was to compare muscle-tendon profiles in trained cyclists, triathletes, and untrained controls, and to quantify neuromechanical characteristics during steady state cycling.
METHODS: Twenty-nine participants (10 cyclists, nine triathletes and, 10 controls) cycled at four intensities (150, 200, 250, and 300 W). Measurements of pedal forces (Radlabor, Germany), joint kinematics (Qualisys, Sweden), muscle activity (Delsys, USA), and fascicle mechanical behaviour of the gastrocnemius medialis (Telemed, Lithuania) were measured during the final minute of each 5-min trial. In addition, muscle-tendon morphological and mechanical properties were measured in the form of B-mode ultrasound (Siemens, Germany) to

obtain muscle and tendon thickness, fascicle length, and pennation angle, as well as isometric/isokinetic dynamometry (Biodex, USA) to obtain passive ankle stiffness, moment-angle, and moment-velocity profiles.
RESULTS: Increases in pedal kinetics, ankle dorsiflexion angle, and normalised muscle activity were observed with an increase in exercise intensity (all $p < 0.001$). However, there were generally no differences in fascicle mechanical function (fascicle range, shortening velocity, pennation angle change), although some changes in muscle gearing were observed. There were also no differences between groups at any exercise intensity. There were typically no differences in isometric/isokinetic strength between groups. However, triathletes had a higher Achilles tendon thickness across multiple sites and a higher passive stiffness than the other groups ($p \leq 0.048$).
CONCLUSION: The triceps surae behave like a strut during cycling, transferring forces from proximal joints to the pedal. We showed that this behaviour is consistent across exercise intensities and between trained and untrained populations, concluding that the requirements and subsequent performance of the ankle plantarflexors at these intensities are unaffected by chronic exposure to loading. The tendon morphological and mechanical adaptations seen in triathletes appear to be specific to, or at least caused by, running but these do not lead to any neuromechanical differences during cycling.

### SMALL DIFFERENCES IN TURN CYCLE STRUCTURE ASSESSED THROUGH AN IMU COULD BE DECISIVE TO ENHANCE DESCENT PERFORMANCE OF ELITE ALPINE SKIERS IN DIFFERENT SLALOM COURSE SETTINGS

PÉREZ-CHIRINOS BUXADÉ, C., PADULLÉS RIU, J.M., GAVALDÀ CASTET, D., TRABUCCHI, M., FERNÁNDEZ-VALDÉS, B., TUYÀ VIÑAS, S., MORAS FELIU, G.

*NATIONAL INSTITUTE OF PHYSYICAL EDUCATION OF CATALONIA*

INTRODUCTION: Competitive alpine skiing is a sport that occurs between 40 and 150 km/h. At that speed, there are many details that could go unnoticed by coaches, especially when the differences between skiers are fractions of a second. Small differences in turn cycle structure translates into better performance on the turn. However, the influence on performance along a ski run (linked curves) has not been investigated yet. The aim of this study was to assess the influence of turn cycle structure on the performance of elite alpine skiers using an inertial measurement unit (IMU) in different slalom (SL) course settings.
METHODS: An IMU device was attached to the lower back of skiers. Four 10-gate SL courses were set: a flat-turned (FT), a steep-turned (ST), a flat-straighter (FS) and a steep-straighter (SS). Five elite alpine skiers (21.2 ± 3.3 years, 180.2 ± 5.6 cm, 72.8 ± 6.6) completed several runs at maximum speed for each SL course. A total of 77 runs were obtained. The skiers' performance was evaluated with the total time of each run calculated through a validated Magnet-Based Timing System (M-BTS). For each run, the acceleration signal on the Y-axis (lateral axis) was used to identified two main phases within the ski turn: Initiation (INI) and steering (STE) phases. By fusing the accelerometer information with the M-BTS, that provides the position of the gates on the magnetometer signal, it was possible to divide the STE phase by the turn's gate position leading to the steering phases into (STEIN) and out (STEOUT ) of the turn. For each run, the times corresponding to the same phase were added together, so the total time was decomposed into three partial times: INI time, time of STEIN and time of STEOUT. The two steering times were added together to obtain STEIN+OUT time. Statistical analyses were performed to assess the influence of turn cycle structure (partial times) on the total descent time. Pearson's linear correlation coefficient was used to calculate correlation. A Linear Mixed Model (LMM) was implemented for each partial time, where the skier corresponded to the random factor, the total time variable was the response variable and the partial time variable was the explanatory variable.
RESULTS: Fast total times correlate with a longer INI time in FT, a shorter STEOUT time in the FT and FS and a shorter STEIN+OUT time in the FT and SS courses. The LMM used for the analysis revealed that in the FT-course for each second increase in the INI time, the total time is reduced by 0.45 s, and for every one-second increase in the STEOUT and STEIN+OUT times, the total time increases by 0.48 s and 0.31 s, respectively.
CONCLUSION: Regardless of the SL set up, similar characteristics were observed in turn cycle structure for the fastest runs. To enhance descent performance, the skier should lengthen the INI time and shorten the STEOUT and STEIN+OUT time. Future studies could use an IMU to detect turn phases and analyze them using the other built-in sensors.

### THE EFFECT OF EXPERIMENTAL MUSCLE PAIN ON SELF-PACED CYCLING EXERCISE PERFORMANCE

NORBURY, R., SMITH, S., MAUGER, A.

*ST MARYS UNIVERSITY TWICKENHAM*

INTRODUCTION: Elevated muscle pain has previously been shown to reduce time to task failure exercise performance (1,2). However, the effect of increased muscle pain on self-paced exercise performance is currently unknown. Therefore, the purpose of this study was to experimentally induce muscle pain and investigate cycling time-trial performance.
METHODS: Eight healthy participants completed three experimental visits after a familiarisation session. After baseline measures of maximal voluntary force, voluntary activation, potentiated twitch force, corticospinal excitability and corticospinal inhibition, participants either received no injection (CTRL), a bilateral isotonic saline injection (1 mL, 0.9% NaCl; ISO) or a bilateral hypertonic saline injection (5.85% NaCl) into the vastus lateralis to cause quadriceps muscle pain (HYP). Participants then completed a 5-minute cycling time-trial whilst recording pain intensity on a visual analogue scale (VAS) and performed measures of neuromuscular fatigue and corticospinal excitability and inhibition 30 s post-exercise.
RESULTS: Time-trial performance in HYP (3.12 ± 0.38 km) was not different from CTRL (3.21 ± 0.24 km) or ISO (3.20 ± 0.26 km; $P = 0.171$). Pain intensity was similar between CTRL (average VAS = 45/100) and ISO (average VAS = 46/100; all $P > 0.05$) but was greater in HYP (average VAS = 63/100) compared to CTRL and ISO from 30 s to 150 s (all $P < 0.05$). There was a significant correlation between the mean pain intensity within minute 1 in HYP and the change in mean power between HYP and ISO ($r = 0.717$; $P = 0.045$). There was no change in the decline in maximum voluntary force (-27%; $P = 0.413$), and potentiated doublet amplitude (-29%; $P = 0.560$) across conditions whereas voluntary activation remained unchanged from baseline ($P = 0.071$). No differences in corticospinal excitability or inhibition were seen over time or between conditions (all $P > 0.05$).
CONCLUSION: Elevated muscle pain within the vastus lateralis may only impair short duration, self-paced cycling performance when the pain intensity from the hypertonic saline and exercise-induced pain reaches 'very strong'. Increased pain did not result in any neurophysio-

logical changes to exercise. Therefore, pain appears to have divergent neurophysiological and performance effects on open versus closed loop exercise.

**KINETIC ENERGY OF THE TRUNK, A KEY PARAMETER TO EXPLAIN PERFORMANCE IN SPRINT RUNNING ACCELERATION?**

SLAWINSKI, J.1,2, HOUEL, N.3, MILLOT, B.1, MAHLIG, A.1,4, DINU, D.1

*1 FRENCH NATIONAL INSTITUTE OF SPORT; 2 UNIVERSITY OF PARIS NANTERRE; 3 UNIVERSITY OF REIMS, CHAMPAGNE ARDENNES; 4 UNIVERSITÉ DE SHERBROOKE*

INTRODUCTION: Sprint performance is determined by the ability of the sprinter to generate high velocity (V0), high power (Pmax) and forces (F0) at the centre of mass (CoM) (1). To improve these parameters, it has been showed that kinetic energy (KE) of the trunk and the leg plays a central role during the starting phase and first step (2). However, the contribution of the trunk to the rest of the acceleration phase remains unknown. This study aimed to measure the contribution of each body segment to the production of total body kinetic energy during a 40-m sprint.
METHODS: Nine recreational sprinters performed two 40-m sprints wearing a MVN Biomech suit (Xsens). Kinematic data recorded were used to calculate total body KE, and the KE of each segment from the velocity of the CoM of the segments. The KE of each segment was then expressed as a percentage of the total body KE. We divided the sprint into 3 phases according to the methodology of Samozino et al. (3) to compute the force-velocity relationship: 1-start to maximal power (Pmax), 2-Pmax to maximal velocity (Vmax), and 3-Vmax to the end of the 40m.
RESULTS: Total body KE increased from the start to the end of the 40-m sprint (from 331.3 ± 68.4 J in phase 1 to 2378.8 ± 233.0 J in phase 3 $p \leq 0.001$). The contribution of the head-trunk increased (from 39.5 ± 2.4% to 46.3 ± 1.1% $p \leq 0.05$). Contribution of the upper and lower limbs decreased over the 3 phases (respectively from 15.7 ± 2.5% to 10.6 ± 0.6% and from 44.8 ± 2.1% to 43.1 ± 1.5%; $p \leq 0.05$).
CONCLUSION: This study revealed the important contribution of the trunk to forward propulsion throughout the entire acceleration phase. When typical continuous KE of lower limb and head-trunk limb is plotted expressed as a percentage of the total energy, the KE of he lower limb and the trunk limb are in opposite phase, and suggested that trunk and legs make an opening and a closing movement during the sprint. This closing-opening movement is particularly important with a great amplitude during the first steps of the sprint. This suggested that this "closing-opening" movement is a mechanism allowing to produce a great KE energy variation and to produce higher Pmax during the phase 1.

**EFFECTS OF WEARING NIKE DRAGONFLY TRACK SPIKES ON 3000M RACE PERFORMANCE AND STRIDE LENGTH: A PILOT STUDY.**

JIMÉNEZ-ORMEÑO, E.1, SORIANO, M.1,2, SALINERO-MARTÍN, J.J.3

*CAMILO JOSÉ CELA UNIVERSITY*

INTRODUCTION: Recently, several records have been broken in different athletic championships. The success has been partially attributed to including carbon or plastic fiber plates and other advanced materials in racing shoes (1). There is evidence that the novel racing shoes designed with carbon/plastic fiber plate have improved running economy (2,3) and performance (1,4) during long distance road races. However, research regarding track spikes is scarce. Therefore, this pilot study aimed to compare the effect of wearing Nike Dragonfly versus conventional track spikes on a 3000-m race performance in trained runners.
METHODS: Eight male trained middle- and long-distance runners, volunteered to participate in this experimental and ecological investigation (age: 31.88 ± 10.05 yrs; body mass: 64.88 ± 7.95 kg; height: 1.77 ± 0.04 m; running experience: 11.50 ± 5.98 yrs). In a randomized and counterbalanced design, all participants were tested in two simulated 3000-m competitions, separated by one week, using Nike Dragonfly (ND) versus their conventional track spikes (CS). The ND track spikes were provided to the participants for familiarization 2 weeks before starting the experiment.
During the testing days, participants performed a 40-min standardized warm-up, and then, they performed a simulated 3000-m competition on a conventional track wearing either the ND or CS. In addition, six marks were placed from 5 m to the finish line, separated by 1-m between them. A camera was placed 10-m apart to film this section at 240 frames/second for a posterior step analysis with Kinovea v.0.9.5 to measure the stride length (centimeters) and total time of the race (seconds). Paired t-tests were performed to compare the mean stride length and total time of the race between the ND and CS. Statistical significance was set at $p<0.05$.
RESULTS: There were significant differences for the total time ($p=0.012$) and stride length ($p=0.006$) between the ND and CS conditions during 3000-m competition. Performance was improved with the ND (548.14 ± 26.59 s) compared to CS (565.46 ± 33.24 s). In addition, the ND condition increased stride length in both right (ND = 161.75 ± 9.71 cm; CS = 160.34 ± 8.46 cm; $p=0.02$) and left leg (ND = 162.25 ± 8.78 cm; CS = 159.63 ± 9.05 cm; $p=0.001$).
CONCLUSION: According to the results of this pilot study, the ND, whose design includes a plastic fiber plate in the midsole, improve 3000-m performance and increase stride length compared to conventional track spikes. Similar to the racing road shoes, these new track spikes could be responsible, almost in part, for actual general improvement in the middle- and long-distance races in track.

### THE FOOTSTEPS OF A NEIGHBORING RUNNER AFFECT THE STEP FREQUENCY OF THE MAIN RUNNER

FURUKAWA, H.1, KUDO, K.1, SAITO, A.2

*1 THE UNIVERSITY OF TOKYO, TOKYO, JAPAN; 2 KYUSHU UNIVERSITY, FUKUOKA, JAPAN.*

INTRODUCTION: We sometimes coordinate our movements with those of others unconsciously. Such an interpersonal synchronization can occur in daily situations as well as in athletic situations. While it has been reported that interpersonal synchrony may occur during running competitions, it has not been clarified what kind of information is exchanged between runners to produce interpersonal synchrony during running. In this study, we investigated the possibility that auditory information (footsteps) is involved as a factor in the occurrence of interpersonal synchronization between long distance runners. In particular, we hypothesized that the tempo of neighboring runner (NR)s footsteps would entrain the step frequency (SF) of the main runner (SF would be closer to the tempo of the footsteps), and we aimed to clarify the effect of footsteps of a NR on the SF of the main runner.
METHODS: Ten healthy male trained distance runners participated in this experiment, in which the main runner (participant) and NR (examiner) ran with the same running speed on two adjacent treadmills separated by a thin wall. The participants were not told the true purpose of the experiment, but were told that the experiment was to measure their heart rate (HR) while running side by side. NR performed three trials of changing the footstep tempo by 5 bpm (beat per minute) faster (+5bpmFS), 5 bpm slower (-5bpmFS), or no footsteps (NF). Participants' SF were measured while running. In addition, HR and rate of perceived exertion (RPE) were measured as indices of physiological and psychological load that indirectly indicate effects on performance.
RESULTS: One-way ANOVA was performed for each measurement. While there was no main effect of running condition on neither the SF, nor the HE, nor the RPE, a significant main effect was found on the SD of SF ($p<.05$). As a result of multiple comparison, the +5bpmFS had an increase in the SD of SF compared to that of NF ($p<.01$).
CONCLUSION: Despite the faster or slower footstep tempo of a NR, there was no difference in the SF of the main runner relative to the NF. Thus, it was unclear whether the footsteps of NR produced entrainment of the running SF. However, the SD of SF increased under conditions of faster footstep tempo, suggesting that the footsteps of a NR may exert some disturbance on the SF of the main runner. The results of this study suggest that auditory information can influence the SF of long distance runners and that the footsteps of NR to them act as one of the interpersonal factors that affect performance.

### NORMALIZATION TO FAT-FREE MASS STRENGTHENS THE RELATIONSHIP BETWEEN HEMOGLOBIN MASS AND AEROBIC FITNESS AND REDUCES SEX-BASED DIFFERENCES IN INDIVIDUALS MATCHED FOR FITNESS

KONTRO, H., BERTAGNOLLI, C., AJAYI, O.O., MACINNIS, M.J.

*UNIVERSITY OF CALGARY*

INTRODUCTION: As body mass (BM) and body composition impact the interpretation of maximal oxygen uptake (VO2max) as a marker of fitness, particularly across sexes, VO2max must be appropriately normalized to accurately represent fitness status, and the same is likely true for hematological data. Females are typically reported to have lower absolute hemoglobin mass (Hbmass), blood volume (BV), plasma volume (PV), and red blood cell volume (RBCV) compared to males. Despite known differences in body composition between sexes, the convention is to normalize VO2max and hematological data to BM—rather than fat-free mass (FFM)—which may not be sufficient to investigate sex-based differences.
METHODS: Hematological data and ramp incremental cycle ergometer test data from 38 (21 male; 17 female) healthy young (mean [SD]; 29 [6] years) volunteers of heterogenous training status were analyzed. Hbmass and intravascular volumes (BV, RBCV, PV) were determined by the CO-rebreathing technique. Body composition was measured using dual-energy x-ray absorptiometry. Sex differences were analyzed by comparing relative values derived using two normalization methods between males and females (i.e., BM and FFM). Linear regressions were performed between absolute and relative (normalized to BM and FFM) values.
RESULTS: Males and females were matched for FFM-normalized VO2max (females 62 [12] and males 64 [12] mL/kg FFM/min; $p=0.68$). Absolute Hbmass, BV, RBCV, and PV were significantly higher in males than females (mean differences 36%, 23%, 35%, and 15%, respectively, all $p < 0.05$). [Hb] and hematocrit were higher in males (16.1 [1.1] g/dL and 48.6 [3.6] %) compared to females (14.1 [1.1] g/dL and 43.0 [2.2] %) ($p<0.001$ for both). Hbmass (13.5 [2.6] vs. 10.4 [1.4] g/kg) and BV (91 [16] vs. 80 [11] mL/kg) were significantly higher in males than females when normalized to BM ($p<0.001$ and $p=0.026$), but Hbmass (15.1 [1.6] vs. 14.2 [1.4] g/kg) and BV (103 [11] vs. 110 [11] mL/kg) were not significantly different between sexes when normalized to FFM ($p=0.054$ and $p=0.065$, respectively). PV was similar for males (51 [9] mL/kg) and females (49 [7] mL/kg) when normalized to BM ($p=0.54$), but higher in females (67 [7] mL/kg) than males (57 [7] mL/kg) when normalized to FFM ($p<0.001$). Absolute Hbmass showed a significant correlation with absolute VO2max ($r=0.82$, $p<0.001$). Normalization of both variables to BM resulted in a weaker, non-significant correlation ($r=0.19$, $p=0.26$), whereas normalization to FFM restored a significant correlation ($r=0.63$, $p<0.001$).
CONCLUSION: Differences between sexes were greatly reduced when data were normalized to FFM, suggesting that the difference in body composition contributes substantially to sex-based differences. Furthermore, Hbmass explained ~40% of the variation in fitness when Hbmass and VO2max were normalized to FFM but only ~4% when normalized to BM. Normalization to FFM seems to be the better strategy for investigating sex-based differences.

### ZUMBA DANCE ENHANCES FUNCTIONAL PERFORMANCES IN MIDDLE-AGED WOMEN

BEN WAER, F.

*UNIVERSITY OF SFAX HIGHER INSTITUTE OF SPORTS AND PHYSICAL EDUCATION OF SFAX: UN*

INTRODUCTION: Due to aging and menopause, functional problems and disability are burdens for middle-aged women. There is a need to identify strategies that target middle-aged women to have a global impact on such issues, which is potentially important to delay functional problems later in life. Strategies to promote physical activity at this stage of life can potentially prevent the risk of falls and enhance their

quality of life (King, 2012). Zumba has become one of the most popular high-impact physical activities. Scientific data in healthy women showed that Zumba has various positive effects on functional performances in terms of body composition, postural balance, aerobic fitness and physical fitness, as well as on psychological well-being (A. A. Delextrat et al., 2016). While the good feasibility in terms of adherence, and the reduction of sports barriers related to Zumba training, to the best of our knowledge, no data about this training modality effects on functional performances in middle-aged women was available. Therefore, the objective was to examine the effect of 12 weeks of a Zumba training program on functional performances in middle-aged women.
METHODS: 38 healthy inactive women aged between 50 and 60 were randomly allocated to a control group and a Zumba group. Functional performances were measured in two test sessions before and after the intervention period, using 10m Walk test for walking speed, Timed Up and Go test for functional mobility and 30-Second Chair Stand test for lower body strength.
RESULTS: The Zumba training programs showed a significant functional performances improvement ($p<.05$) in terms of mobility, gait speed and lower body strength while, as expected, the control group showed no significant changes in the post-intervention session compared to the pre-intervention session.
CONCLUSION: Our major results showed that Zumba training improved functional performances in terms of mobility, gait speed and lower body strength in our middle-aged women. In accordance, previous studies reported that this training modality improved functional performances (i.e. static and dynamic balance and lower body strength performances in young women (Donath et al., 2014) and even in patients with Parkinson's disease (A. Delextrat et al., 2016). These improvements could be due to the nature of the exercises involved in our Zumba training program. These exercises are based on turning, twisting, stepping and jumping elements that may lead to a higher muscle activity (Donath et al., 2014). In conclusion, 12-week Zumba training was sufficient to improve functional performances in terms of mobility, gait speed and lower body strength in middle-aged women. Thus, it could be recommended as an effective way to promote health in middle-aged women

**ARE PHYSICAL CHARACTERISTICS DIFFERENT BETWEEN WOMENS INTERNATIONAL XV AND SEVEN RUGBY?**

DAUSSIN, F.N.1, DELFORGE, E.1,2, BOISSIÈRE, J.1, JONCHEREY, H.3, VINCENT, J.1, IMBERT, S.1,2

*1 UNIV. LILLE, UNIV. ARTOIS, UNIV. LITTORAL CÔTE D'OPALE, ULR 7369 – UREPSSS, F-59000 LILLE, FRANCE. 2 LIGUE DES HAUTS-DE-FRANCE DE RUGBY, VILLENEUVE D'ASCQ, FRANCE 3 LABORATOIRE SPORT, EXPERTISE, PER*

INTRODUCTION: Seven rugby and rugby union are team sports characterized by their specific physical requirements. Even if the practice is rugby, it will be useful to identify specific physical profile in order to guide athletes towards a position that will allow them to best use their qualities. Description of performance levels in international womens rugby is very recent and comparison of physical profile between rugby union position and rugby seven has not been done. This study aims to describe anthropometric and physical characteristics of French woman international rugby union and rugby seven players and to determine if there are specific profiles to each position.
METHODS: Anthropometric and physical performances of French rugby union and seven women players were monitored at least two times per years by the French Rugby Federation. Positions, height, weight, body fat, maximal aerobic speed, 10m time, counter movement jump test, maximal bench press and rowing repetition performances between 2009 and 2020 were analyzed using a principal component analysis over 2009 to 2020. A total sample of five hundred and ninety-seven female French international rugby players was used and only the best performance per year of each player were analyzed.
RESULTS: Three clusters were detected by the database PCA analysis. In the first cluster, forwards were the most represented (84,9%, $p<0.01$) and were characterized by a higher weight, body fat, height and 10m time and a lower aerobic fitness ($p<0.01$). The backwards are the most represented in the second cluster (92,9% ,$p<0.01$) and were characterized by a higher aerobic fitness and lower 10m time, body fat, height and weight ($p<0.05$). The third cluster was composed by the seven rugby players (97,8%, $p<0.05$) and were characterized they have higher aerobic fitness and age, and a lower 10m time, weight and body fat ($p<0.05$).
CONCLUSION: The use of the variables in the study therefore partly explains the specificities of the position and of rugby practice. The PCA can be a decision support tool for the choice of an orientation towards rugby union or sevens rugby as well as for the position.

**MUSCLE QUALITY AND ITS ASSOCIATION WITH DISEASE-RELATED OUTCOMES IN WOMEN WITH SYSTEMIC LUPUS ERYTHEMATOSUS**

HERNÁNDEZ-MARTÍNEZ, A., MARTÍNEZ-ROSALES, E., SOLA-RODRÍGUEZ, S., GAVILÁN-CARRERA, B., VARGAS-HITOS, J.A., SORIANO-MALDONADO, A.

*UNIVERSITY OF ALMERÍA*

INTRODUCTION: Systemic lupus erythematosus (SLE) is an autoimmune multisystemic disease that may involve irreversible damage in any systems and organs which limits the activities of daily living and the quality of life. Patients with SLE are specially at risk for developing sarcopenia due to pro-inflammatory state and the decreases in muscle mass by inactivity and pain. Muscle quality is recognized as a prognostic factor of functional inability and mortality in obese people and elderly population. Detecting risk factors of functional inability based on muscle quality in SLE population is of clinical interest. The aim of the present study was to assess muscle quality and its association with the disease-related outcomes in women with SLE.
METHODS: This cross-sectional study included 75 women with SLE. Specific muscle power was created by the division of sit to stand power [W] (based on the 30-s chair stand test) and muscle mass [kg]. Specific muscle strength was created by handgrip strength [kg] divided by muscle mass [kg]. Muscle quality index was categorized following the criteria provided by Barbat-Artigas. Due to the lack of cut-off values for this population, tertiles were computed for each of the variables (specific strength and specific power, respectively) that creates the muscle quality index. The disease activity (SLEDAI), systemic damage index (SDI), and disease duration were assessed. Correlation analysis and linear regression models considering age and corticosteroid intake were used to assess the association between muscle quality-related parameters and disease-related outcomes.
RESULTS: Our results showed that 40% of women with SLE presented poor muscle quality index, 12% low and 48% normal. Pearson's correlation coefficients showed significant associations of specific muscle power with SDI ($r=-0.30$) and disease duration ($r=-0.45$). There was no association of specific muscle strength with disease-related outcome.
In the regression model, specific muscle power was significantly associated with disease duration ($\beta=-0.251$, $p=0.041$). Specific muscle strength was not significantly associated with any disease outcome in any analysis.
CONCLUSION: 40% of women with SLE presented a poor muscle quality index. Specific muscle power is significantly associated with degree of tissue damage and disease duration independently of age. Future research should assess the relationship of circulating biomarkers

related to muscle quality as inflammatory biomarkers are usually altered in women with SLE (i.e., C-reactive protein or inter- leukin-6). Furthermore, cut-off values appropriate for women with SLE are also needed due to the peculiarities of the disease.

### ULTRASOUND IMAGING BASED METHODS TO ASSESS BIOLOGICAL MATURITY DURING ADOLESCENCE AND POSSIBLE APPLICATION IN YOUTH SPORT: A SCOPING REVIEW

RÜEGER, E., HUTMACHER, N., EICHELBERGER, P., HINTERMANN, M., BORN, D.P., JAVET, M., ROMANN, M.

*SWISS FEDERAL INSTITUTE OF SPORT MAGGLINGEN*

INTRODUCTION: Bone age (BA) is an indicator that estimates the biological maturity (BM) of an individual. Particularly during adolescence, individuals show heterogeneous growth rates. Evidence suggests that differences in BM should be considered in talent identification (TID) and development (TD). Various assessment methods using X-ray of the left hand and wrist are considered the gold standard for estimating BM. The use of ultrasound (US) may be advantageous in various fields of application, however validity and reliability of US imaging procedures are under debate. Therefore, the aims of this scoping review are 1) to summarize the different methods for estimating BM by US imaging in adolescents, 2) to get an overview of the level of validity and reliability of the methods and 3) to discuss the practicability of these assessments in the field of youth sport.
METHODS: The first search was conducted using the keywords “ultrasonography”, “bone age” and “youth” in two electronic databases (PubMed, Mendeley). Articles published up until the 31st December 2021 were included. The inclusion criteria stipulated that participants fell within the age range of 8 to 23 years and were free of bone disease and/or fracture. In order to sort and furthermore analyze the extracted material, a data charting form was developed. An additional classification was developed based on the comparative techniques (device) and assessment methods (e.g. staging system, atlas) used, as well as the examined body regions. The articles were divided into two groups depending on whether the US assessment was compared to another validated assessment (validity group) or whether the US assessment itself was tested for its reliability (reliability group).
RESULTS: The VG included 15 studies, 7 of which also measured inter and/or intrarater reliability, while 15 studies were included in the RG. The research areas were pediatrics (43.3%), forensic medicine (40%), orthodontics (10%) and sports (6.7%). 8 body regions were investigated. Hand and wrist were most commonly investigated during both the comparative and the US assessments. The US assessment method was normally based on the estimation of a bone maturity stage than a decimal bone age (78.6 % in the VG, 100% in the RG). In both groups, 80% of the US assessments were evaluated as acceptable and 20% as not acceptable. In the VG, either the agreement was too low compared to the gold standard, or the staging system could not be transferred to US. In this same group however, inter and intrarater tests were all reliable. In the RG, either the staging system was not precise enough, or there was no significant difference between estimated stages and growth velocity.
CONCLUSION: None of the ultrasound assessments investigated can be referred to as the gold standard yet, as further validation studies are required. Despite low costs, portability and absence of ionization, the extension to non-expert examinators must be tested to facilitate the application for TID and TD in the field.

### EFFECTS OF A PHYSICAL ACTIVITY INTERVENTION FOR OSTEOPOROSIS PREVENTION ON BONE BIOMARKERS

SANCHEZ-TRIGO, H., SÁNCHEZ-OLIVER, A.J., SAÑUDO, B.

*UNIVERSITY OF SEVILLE*

INTRODUCTION: Physical exercise is considered an effective means to stimulate bone osteogenesis in premenopausal women. The use of bone mineral density (BMD) measurements using dual-energy X-ray absorptiometry (DEXA) to monitor exercise response is limited, since BMD changes need several months to be detectable. Besides, conducting DEXA scans frequently can be costly, and radiation exposure can add up. An earlier and inexpensive evaluation of the bone metabolic response to physical exercise would be useful. Bone turnover markers (BTMs) have been validated against the gold standard bone histomorphometry and become widely used to assess bone response to treatment because of their low cost and easy accessibility. The International Osteoporosis Foundation (IOF) and European Calcified Tissue Society (ECTS) Working Group recommended the use of C-terminal telopeptide of type I collagen (CTX) and N-propeptide of type I collagen (P1NP) as the reference markers for bone resorption and bone formation, respectively, for the fracture risk prediction and monitoring of osteoporosis treatment.
The aim of the current study was to assess the effect of a non-supervised physical activity intervention on BTMs, specifically P1NP and CTX.
METHODS: A randomized controlled trial was conducted over the course of twelve weeks. Forty-two sedentary premenopausal women (41 ± 5 years; 66 ± 18 Kg; 165 ± 7 cm) were randomly assigned to an experimental group (EG; N=24) and a control group (CG; N=18). The EG was instructed to complete 60 jumps per day, and at least 10000 steps per day at a minimum pace of 150 steps/min. The CG continued with their usual everyday activities. Compliance with the intervention was monitored using a wearable accelerometer. P1NP and CTX were measured pre and post intervention. Between-groups differences were assessed by analysis of covariance (ANCOVA) with baseline values as covariate.
RESULTS: Statistically significant between-group differences in favor of intervention were found for P1NP (F=5.578; p=0.023; Partial eta squared= 0.125) and CTX (F=4.373; p=0.023; Partial eta squared= 0.101).
CONCLUSION: The physical activity program carried out in this randomized controlled trial resulted in a significant reduction in P1NP and CTX. Since a decrease in P1PN and CTX is associated with an increase of BMD and a lower fracture risk, these BTMs could be employed as an early indicator of exercise efficacy and could therefore be useful in monitoring interventions to prevent osteoporosis.

**COMPARISON OF EFFECT OF KINECT-BASED MIXED REALITY AND UNSUPERVISED FIREFIGHTER FITNESS PROGRAM ON HEALTH-RELATED PHYSICAL FITNESS IN YOUNG ADULTS**

AHN, S.1, SUNG, Y.1, BAE, J.2, LIM, B.1, LI, X.1, KIM, D.1, SONG, W.1,3

*1 INSTITUTE OF SPORTS SCIENCE 2 INSTITUTE OF SPORTS & ARTS CONVERGENCE 3 INSTITUTE ON AGING*

INTRODUCTION: The development of informative communication technologies and virtual, augmented, and mixed reality (VR/AR/MR) techniques play an increasingly important role in health [1]. One of those devices is a Kinect-based mixed reality device (KMR) which can detect 25 joints of the users by Kinect and create a mixed reality environment by interacting with the users while producing exercises with feedbacks [2]. This seems to be beneficial to Korean Firefighters (KFFs) who have relatively low levels of fitness. But they have limitations in attending exercise by their occupational characteristics [3, 4, 5]. These problems can induce low performance, high risk of injuries [6]. So, we aim to evaluate the effect of a moderate level of fitness program for KFFs (KFFP-m) and to compare the effect between KMR and unsupervised individual training for 8wks.
METHODS: A total of 36 males were recruited. The screening was held on the same day as the pre-test. Seven were dropped and 27 males were randomly assigned into 3 groups, KMR group (KG; n=9), unsupervised individual group (UG; n=9), or a control group (CG; n=9). For the pre/post-test, skeletal muscle mass, body fat %, maximal oxygen consumption ($VO_2$max), grip strength, 2-min push-up, knee 60º of peak torque, and 180º of total work by the knee were measured. After the pre-test, KG and UG conducted KFFP-m for 3days/wk for 8wks. CG received health recommendation handbooks. All groups received calls every 2wks and were randomly asked to send a diet list for 3days per 4wks. A time (pre vs. post) x group (KG vs. UG vs. CG) factorial ANOVA with repeated measures was performed to determine differences between treatments. Significant main effects were followed up by Bonferroni post hoc test ($p<.05$).
RESULTS: All participants were normally distributed, and there was no significant difference in the baseline and nutrition intakes between groups. Body fat % was significantly increased, skeletal muscle mass significantly decreased in CG, and there was no significant difference between groups. $VO_2$max, 2-min push-up, and 180º of knee extension were significantly increased in both KG and UG. Sixty-degree knee flexion was significantly enhanced in UG and 180º of knee flexion in KG. $VO_2$max (KG>CG, UG>CG), 60º of knee extension (KG>CG), flexion (KG>UG, KG>CG), 180º of knee extension (KG>CG), and flexion (KG>CG) showed a significant difference between groups.
CONCLUSION: The novel finding of this study was that KG showed significantly greater results in 60º of knee flexion compared to UG and $VO_2$max, 60º of knee extension, 180º of knee extension, and flexion significantly enhanced in KG compared to CG. However, UG showed significant enhancement in $VO_2$max only compared to CG. In conclusion, KFFP-m was effective in health-related fitness in both ways, and KMR was more efficient in providing exercises than unsupervised individual training.

**THE ENERGY REQUIREMENTS OF PARALYMPIC CHAMPIONS.**

WEIJER, V.C.R., JONVIK, K.L., VAN DAM, C.H.J., PLASQUI, G., RAASTAD, T., VAN LOON, L.J.C., VAN DIJK, J.W.

*HAN UNIVERSITY OF APPLIED SCIENCES*

INTRODUCTION: To optimize nutritional counseling for Paralympic athletes, advanced insight into their energy demands is required. In the current study we conducted a comprehensive assessment of energy expenditure along with energy intake (EI) and body composition in a large group of Paralympic athletes, including many Paralympic champions.
METHODS: In this ongoing cross-sectional study, 39 Dutch and Norwegian Paralympic athletes with various disabilities, competing in Para cycling (PC; n=9; M/F 6/3), wheelchair tennis (WCT; n=10; M/F 5/5), wheelchair basketball (WCB; n=13; M/F 0/13) and cross-country skiing (XCS; n=7; M/F 4/3) participated. Total daily energy expenditure (TDEE) was assessed by the golden standard doubly labeled water method over a 14-day period, resting metabolic rate (RMR) by ventilated hood indirect calorimetry, EI by three unannounced 24h-dietary recalls, body composition by dual energy x-ray absorptiometry and exercise training duration by a training log. The physical activity level (PAL) was calculated as TDEE/RMR and the physical activity energy expenditure (PAEE) as TDEE - RMR - the thermic effect of food (0.1EI). Energy availability (EA) was calculated as (EI- PAEE)/fat free mass (FFM). Data are reported as means±SD. Differences between sports were conducted by one-way ANOVA with Bonferroni correction and correlations by a Pearson correlation test.
RESULTS: The mean RMR of 1482±257 kcal/day correlated well with FFM (48.8±9.3 kg; $r=0.76$; $p<0.001$). The mean TDEE was 2948±740 kcal/day, with PC (3691±826 kcal/day), and WCT (3082±381 kcal/day) showing substantially higher TDEE compared with WCB (2301±347 kcal/day; $p<0.05$), whereas TDEE in XCS (2903±541 kcal/day) was not significantly different compared with other sports. The mean PAL values of PC (2.15±0.4) and XCS (2.17±0.19) were significantly higher compared to WCB (1.71±0.18; $p<0.05$), but not compared with WCT (2.03±0.29; $p=0.08$). Furthermore, the PAL values (1.98±0.33) correlated well with exercise training duration (1.83±0.64 h/day; $r=0.51$; $p=0.006$). When considering athletes' EI (2397±961 kcal/day), 67% of the athletes were classified as low EA according to the threshold of 30 kcal/kg FFM, although this high prevalence might have been inflated by underreporting of EI.
CONCLUSION: Paralympic athletes experience high daily energy demands, with many athletes exceeding a PAL value of 2.0. Much of the variation in energy expenditure between sports and individuals can be explained by differences in fat free mass and exercise training load. The substantial energy demands of Paralympic athletes underline the need to prevent low energy availability in this population.

**PREDICTING NONCONTACT LOWER LIMB INJURY USING LUMBAR MORPHOLOGY IN PROFESSIONAL AUSTRALIAN FOOTBALL AND RUGBY LEAGUE PLAYERS**

DUHIG, S., HAJEK, M., WILLIAMS, M., BOURNE, M., ROBERTS, L., MORRIS, N., SHIELD, A., MINGIN, C., HEADRICK, J.

*GRIFFITH UNIVERSITY*

INTRODUCTION: Non-contact lower limb injuries are common within the Australian Football League (AFL) and National Rugby League (NRL). Smaller (<8.5 cm2) lumbar multifidus at the fifth vertebra (LM L5) and larger (>8.2 cm2) quadratus lumborum (QL) cross-sectional area (CSA) have been associated with increased non-contact lower limb injury risk in AFL players. These associations have not been ex-

plored in an NRL cohort. This study will attempt to replicate previous research findings by confirming that muscle morphology is associated with non-contact lower limb injury.
METHODS: AFL (n = 87) and NRL (n = 151) players underwent LM L2-L5 and QL CSA ultrasound measures during preseason. Each club's medical staff reported all non-contact lower limb injuries sustained in the subsequent regular season. LM and QL CSA, age, body mass index and non-contact lower limb injuries were analysed using multivariable logistic regression.
RESULTS: Seventy-two players sustained a non-contact lower limb injury in the 2020 regular season (AFL = 21, NRL = 51). The multivariable logistic regression (OR: 1.36, 95%CI: 1.02-1.85, p = 0.038) identified AFL players with larger QL CSA at increased risk of sustaining a non-contact lower limb injury during the regular season but no relationship was found for LM CSA and non-contact lower limb injuries in the AFL (OR: 1.01, 95%CI: 0.36-2.78, p = 0.591) or NRL (OR: 0.63, 95%CI: 0.29-1.33, p = 0.149).
CONCLUSION: AFL players who sustained regular season non-contact lower limb injuries had larger QL CSAs in pre-season tests. no significant associations between either LM L5 CSA or LM L5 to QL ratio and regular season non-contact lower limb injuries were found.

## DOSE-RESPONSE RELATIONSHIP AND EFFECT MODIFICATION IN NON-SPECIFIC LOW BACK PAIN: SECONDARY INDIVIDUAL PATIENT DATA RE-ANALYSIS ON 1,483 STABILISATION EXERCISE PARTICIPANTS

NIEDERER, D.

*GOETHE-UNIVERSITY FRANKFURT/MAIN*

INTRODUCTION: Exercise therapy for low back pain results in low to moderate group effects and displays large inter-individual heterogeneity. This heterogeneity may be explained by a dose-response relationship and further effect modifiers. In the present study, we derived a dose-response relationship under consideration of further effect modifiers in stabilisation exercises on low back pain.
METHODS: In this planned project-wide secondary analysis within the MiSpEx Network, 1,483 participants with low back pain (57% females, mean age 40.9 years (standard deviation 14 years)) performed stabilisation exercises with either an additional behavioural module or an add-on stretching task or an attendant perturbative motor task (3 weeks supervised, 9 weeks self-administered). Patients reported pain intensity, disability and disability days at baseline, 3 weeks, 12 weeks and 6 months post-randomisation. All exercise characteristics and potential effect modifiers (sociodemographic factors, anxiety, depression, perceived social support and pain medication) were prospectively monitored. Linear mixed models for all pain and disability outcomes with each exercise intervention type (random), dose (duration (random) and frequency (fixed)) and covariate (effect modifiers (fixed)) were calculated.
RESULTS: Longer durations of the intervention led to larger symptom reductions. Higher exercise frequencies were associated with a decrease in pain intensity: to train once more per week led to a mean decrease of 0.93 points in pain intensity (estimate = -0.93 [95 % confidence interval = -1.54 to -0.32]). Disability days were also impacted (-0.07 [-0.14 to 0.00]), disability was not (-0.09 [-0.67 to 0.48]). The type of exercise had an impact on the symptoms; the stabilisation and perturbation exercise was superior to the other exercises. The dose-response relationships were found to be robust when the additional effect modifiers were considered. The odds for a clinically important treatment effect in pain intensity decreased at 3 weeks (frequencies above 2.5 times per week led to an odds ratio = 0.71 [0.618 to 0.813]) and increased at 12 weeks (1.13 [1.006 to 1.270], > 1.5*week-1) with higher mean exercise frequencies.
CONCLUSION: Using longer intervention durations, adding perturbation components to stabilisation exercise and utilising higher frequencies (up to a certain point) led to more beneficial responses for symptom reduction in patients with low back pain. Developing strategies to maintain an exercise frequency of at least two times per week, including the self-administered intervention periods, may be relevant in exercise therapies to treat low back pain. A stabilisation exercise frequency of three to five times per week with a duration of 20 to 30 minutes was found to be the most effective. Certain patients with an endurance-related response to pain may have to reduce their training frequency, whereas others must be engaged fully.

## EVALUATION OF THREE BACK-SUPPORT EXOSKELETONS DURING A REPETITIVE LIFTING TASK: INFLUENCE OF DESIGN ON CARDIORESPIRATORY PARAMETERS

SCHWARTZ, M.1,2, DESBROSSES, K.2, THEUREL, J.2, MORNIEUX, G.1,3

*1 UNIVERSITÉ DE LORRAINE, DEVAH, NANCY, FRANCE ; 2 WORKING LIFE DEPARTMENT, INRS, VANDOEUVRE-LÈS-NANCY, FRANCE ; 3 UNIVERSITÉ DE LORRAINE, FACULTY OF SPORT SCIENCES, NANCY, FRANCE.*

INTRODUCTION: Low back pain remains an important issue for workers in many companies. New technologies, such as back-support exoskeletons, have been designed to prevent these musculoskeletal disorders (1). These systems provide force assistance in order to reduce the physical workload of the task performed by workers. Previous studies have shown that back-support exoskeletons could reduce lumbar muscles activity, more or less pronounced depending in particular on the exoskeleton design. Despite the possible benefits on local muscle stress, the effects in terms of overall physical workload have been little studied (2). Thereby, the objective of this laboratory study was to assess the cardiorespiratory consequences associated with the use of different back-support exoskeletons, with special attention to their design.
METHODS: 14 women and 13 men performed a 5-min repetitive manual lifting task, with a 10-kg load, involving a full flexion/extension of the trunk in the sagittal plane. Four exoskeleton conditions were studied: with a passive exoskeleton (PASSIVE), with two active exoskeletons (ACTIVE_1 and ACTIVE _2), as well as without exoskeleton (FREE). Metabolic and cardiac costs induced by the task were analyzed using a general linear model with exoskeletons and sex as main effects ($p<0.05$).
RESULTS: The use of each exoskeleton (PASSIVE, ACTIVE_1 and ACTIVE _2) significantly reduced the metabolic cost as compared to FREE. In addition, ACTIVE_1 showed a significant larger decrease (-28%) than PASSIVE (-7%) and ACTIVE_2 (-13%). Compared to FREE, the cardiac cost was only reduced for ACTIVE_1 (-24%). The metabolic cost did not significantly differ between men (11.6 ± 2.7 ml.min-1.kg-1) and women (10.6 ± 2.0 ml.min-1.kg-1), while women presented a significantly higher cardiac cost (61.7 ± 10.6 bpm) than men (49 ± 12.7 bpm). No interaction effect between exoskeleton and sex has been reported.
CONCLUSION: Occupational back-support exoskeletons appear to reduce the overall physical workload associated to a repetitive manual lifting task. The different exoskeleton designs, such as the technology used (passive vs. active) or the level of anthropomorphism (related to the number of joints of the device), could explain the different effect levels among the exoskeletons. The lack of interaction between exoskeleton and sex leads to the conclusion that these assistive devices provide benefits on the overall physical workload for both men and women.

**MARKED IMPROVEMENT OF MULTIFIDUS MUSCLE QUALITY AFTER A REHABILITATION PROGRAMME BASED ON HEAVY LOADED ISOLATED LUMBAR EXTENSION RESISTANCE EXERCISE (ILEX) IN PATIENTS WITH SPECIFIC SPINAL DISORDERS**

GOLONKA, W.1, BRAUN, H.3, RASCHKA, C.2, SPANG, C.1

*1 ORTHOPAEDIC SPINE CENTRE DR ALFEN WUERZBURG, 2 UNIVERSITY OF WUERZBURG, 3 RADIOLOGY CENTRE HOECHBERG*

INTRODUCTION: A loss of lean muscle mass and local fat infiltration in the paraspinal extensor muscle (intrinsic part/ m. multifidus) are common observations in patients with chronic related spinal disorders and in age related degeneration (Hodges & Danneels, 2019, Dahlqvist et al., 2017). Despite of promising clinical results of ILEX-based exercise intervention, there is little information on the morphological effects of this specific treatment (Steele et al., 2015, Golonka et al., 2021).
METHODS: This pilot case series represents five male patients (mean age 51,8, range 36-70) with disc herniations/protrusions, spondylarthritis and radiculopathies who underwent an ILEX-based exercise intervention consisting of 25 exercise sessions (ES) with 18 ES 2x/week and seven additional ES 1x/week. Range of Motion (ROM) was limited in order to protect passive structures. Before and after the treatment MRI was taken and analysed muscle cross sectional area (CSA, in cm2), lean muscle mass (LM, in cm2) and fat fraction (FF, in %) of m. multifidi for both sides (r/l) in three lumbar spinal segments L3, L4 and L5.
RESULTS: MRIpost showed an increase in CSA and LM and a reduction of FF compared to MRIpre for all patients at all examined segments. The following results represent mean values for both sides for all patients in L3-L5: (CSApre/CSApost/ΔCSA) in L3 (7.4/8.2/+9.5%); in L4 (10.5/11.2/+7.1%); in L5 (11.2/12/+6.7%); (LMpre/LMpost/ΔLM) in L3 (6.1/6.9/+13.1%); in L4 (8.1/9/+12.2%); in L5 (8.7/10/+14.4%); (FFpre/FFpost/ΔFF) in L3 (17.8/15.3/-14%); L4 (22.2/18.5/-16.7%); in L5 (22/16.1/-26.7%).
CONCLUSION: Heavy loaded ILEX leads to a marked improvement in the morphology of m. multifidus and is therefore a suitable treatment option for patients with specific spinal disorders. Furthermore, it can be potentially used for delaying age-related muscle atrophy and for maintaining spinal health. To the best of our knowledge, this is one of the first studies comparing quality of m. multifidus pre and post exercise intervention through MRI measurements. Further studies with more probands are being designed at the moment.

**PEAK HEAD ACCELERATIONS IN ELITE RUGBY UNION PLAYERS DURING MATCH-PLAY COLLISIONS: A PRELIMINARY STUDY COMPARING MALES AND FEMALES USING INSTRUMENTED MOUTHGUARDS**

IZRI, E., BROWN, M.R., JONES, C., KILDUFF, L.P., WALDRON, M.

*SWANSEA UNIVERSITY*

INTRODUCTION: The collision-dominant nature of rugby union exposes players to head acceleration events (HAEs), which are a potential risk factor for the development of brain injuries, such as concussion. Instrumented mouthguards enable direct measurement of the magnitude of these HAEs during training and competition. The differences in physical demands of the game, and physical characteristics of males and females, suggests that they might experience different magnitudes of head accelerations owing to a collision; however, this has not been investigated among elite rugby players. The aims of this preliminary study were to compare the magnitude of peak linear and angular head accelerations i) experienced by male vs. female players and ii) during head vs. body impacts.
METHODS: Using the PROTECHT instrumented mouthguard system (Sports & Wellbeing Analytics, UK), a total of 822 HAEs were recorded across 100 male (27 ± 4 years, 103 ± 14 kg, 1.86 ± 0.10 m, 659 HAEs) and 37 female (26 ± 4 years, 73 ± 22 kg, 1.68 ± 0.107 m, 163 HAEs) rugby union players from match collisions during the English Premiership, United Rugby Championship and Premier 15s 2021/2022 and 2022/2023 seasons. All HAEs were video-identified and classified into direct head or body impacts according to the anatomical location of initial impact on the player being monitored. Linear and angular acceleration signals were filtered using a zero-phase lag 4th order Butterworth filter, with a low-pass cut-off frequency of 160 Hz. Linear acceleration signals were transformed to the head centre of mass. Peak linear (PLA) and angular acceleration (PAA) values were defined as the resultant signal maxima. Data were log-transformed and grand-mean centred prior to performing multi-level linear models, comparing the magnitude of PLA and PAA, with player as a random factor and sex (male/female) and impact location (head/body) as fixed factors. Significance was set at $P < 0.05$ and significant fixed effects were followed up with Bonferroni post-hoc tests.
RESULTS: There were no differences in PLA nor PAA ($P > 0.05$) between males (24.0 ± 16.8 g, 1703 ± 1948 rad/s^2, n = 659 [80%]) and females (PLA; 22.2 ± 14.7 g, PAA; 1719 ± 1365 rad/s^2, n = 163 [20%]). Both PLA and PAA were significantly greater ($P < 0.001$) in HAEs resulting from impacts imparted to the head (PLA; 33.7 ± 23.6 g, PAA; 2304 ± 2384 rad/s^2, n = 141 [20%]) vs. body (PLA; 20.9 ± 12.0 g, PAA; 1494 ± 1358 rad/s^2, n = 581 [80%]). There were no interaction effects to indicate differences between male and females at the two anatomical locations.
CONCLUSION: This preliminary analysis, comparing males and females, demonstrated no differences in the peak linear and angular head acceleration magnitudes during match HAEs, despite the physical differences typically observed between sexes. The higher magnitudes during direct head impacts compared to body impacts warrants further investigation into the contextual factors surrounding a direct head impact to better understand the potential causes.

**THE IMPACT OF SPINE MOBILIZATION EXERCISES ON MOBILITY AND PAIN IN THE CERVICAL SPINE IN OFFICE WORKERS**

LACH, P., MAZUR-ROZYCKA, J.

*CENTRAL INSTITUTE FOR LABOUR PROTECTION - NATIONAL RESEARCH INSTITUTE*

INTRODUCTION: Musculoskeletal disorders (MSDs) are a common health problem for office workers who suffer from back pain in particular. Occupational health promotion programs that include exercise can help reduce sickness absenteeism by reaching large target groups

and being easily accessible. The aim of the study was to test the effect of a home-based exercise program to reduce back pain and increase work comfort among office workers.
METHODS: 133 office workers were qualified for the exercise program (women, n=98, 25-62 years old and men, n =35, 26-63 years). The inclusion criterion was the presence of mild pain in the cervical spine, with varying frequency, for more than 3 months, good general health and no contraindications to exercise. The subjects performed a set of exercises for 8 weeks (minimum 3 times a week). The exercise program focused on relaxing, mobilizing and gently strengthening the body parts most exposed to overload in office work. Before and after the start of the exercise program, the range of cervical movement between the designated anatomical points (flexion, extension, lateral flexion, rotation) was measured and a questionnaire survey was carried out (own survey).
RESULTS: After the 8-week exercise program, participants reported subjective improvement in fitness, reduced pain levels, increased body awareness and physical activity. The analysis of the results of the range of motion of the cervical spine showed no statistically significant differences. Employees report lack of time and household responsibilities as the main reasons for not taking up physical activity in their free time. However, they show great interest in educational programs organized in the workplace.
CONCLUSION: Health promotion programs can contribute to increasing knowledge about the importance of physical activity in the fight against ailments related to the type of work performed. Preventive programs based on physical activity, organized regularly in the workplace, can be an excellent element in the prevention of diseases of the musculoskeletal disorders.

### BIOMECHANICAL EFFECTS OF USING PASSIVE AND ROBOTIC BACK-SUPPORT EXOSKELETONS DURING A LIFTING TASK

MORNIEUX, G.1, SCHWARTZ, M.1, THEUREL, J.2, DESBROSSES, K.2

*1UNIVERSITÉ DE LORRAINE ; 2WORKING LIFE DEPARTMENT, INRS*

INTRODUCTION: Previous studies have shown that both passive and active back-support exoskeletons could be an effective countermeasure to prevent low back pain by reducing the stress on the lower back muscles (1). However, the possible interaction effect between exoskeleton and sex on lower back muscle activity (2,3) and lumbar kinematics (4) remains unclear. The purpose of this study was to evaluate the effects of back-support exoskeletons and sex on these biomechanical parameters.
METHODS: Fifteen men (25±5 years, 1.80±0.04 m, 75.5±7.9 kg) and fourteen women (24±6 years, 1.66±0.06 m, 63.6±13.3 kg) performed a standardized manual lifting task in the sagittal plane with the stoop technique. They handled a 15kg-box at an imposed rhythm of 15 cycles.min-1. Three exoskeleton conditions were tested: without assistance (FREE), with a passive exoskeleton (P-EXO; BackX, SuitX, USA; 4.5 kg; set at the highest assistance possible), and with an active exoskeleton (A-EXO; Cray X, German Bionic, Germany; 11 kg; set at 72N.m assistance). The level of muscle activity (percentage of a maximal voluntary contraction) was calculated from electromyographic recordings of erector spinae (ES) and rectus abdominis (RA) muscles. Back curvature was evaluated thanks to inertial measurement units in order to provide lumbar and thoracic range of motion during trunk flexion (LF and TF, respectively). An analyse of variance was conducted to determine the influence of exoskeletons (repeated measures) and sex on the different variables ($p<0.05$).
RESULTS: There was a main exoskeleton effect on ES muscles activity ($p<0.001$). Mean ES activity with A-EXO (76.3±20.8%) was significantly lower ($p<0.001$) than both P-EXO (90.0±23.3%) and during FREE (93.3±23.9%). However, no sex nor interaction effect was found on ES muscles activity. Mean RA muscles activity (3.5±3.7%) was kept at the same very low level whatever the exoskeletons or the sex conditions, and no interaction effect was reported.
Mean LF and TF range of motion values (24.7±19.3° and 42.2±34.6°, respectively) were not significantly influenced by exoskeletons or sex and no interaction effect has been observed.
CONCLUSION: Occupational back-support exoskeletons reduce trunk extensors activity during a lifting task, while keeping at the same level the neuromuscular activity of the trunk flexors. This reduction was however only significant for the active Cray X exoskeleton. It is worth noticing that this benefit was true for both men and women. Moreover, the use of these exoskeleton designs did not affect spine kinematics. Together with the reduction of back muscle activity, this might speak in favour of reduced low back disorders with the use of the Cray X exoskeleton.

### EFFECTS OF ELECTROMYOSTIMULATION ON PERFORMANCE PARAMETERS IN TRAINED ATHLETES: A SYSTEMATIC REVIEW AND NETWORK META-ANALYSIS

MICKE, F., HELD, S., LINDENTHAL, J., DONATH, L.

*GERMAN SPORT UNIVERSITY COLOGNE*

INTRODUCTION: Exercise training with electromyostimulation (EMS) evolved to an increasingly popular complementary training approach to improve muscular strength and muscle mass in various populations [1,2]. As trained athletes are confronted with limited margin of performance gains, such training approaches might provide further adaptive potential. However, available evidence on training recommendations for trained athletes in terms of application and stimulation are still lacking. Therefore, this systematic review with a network meta-analysis assessed the occurrence and magnitude of EMS training effects on performance and its surrogates in trained athletes using direct and indirect comparison computing a meta-analytical network.
METHODS: The research was conducted using the electronic online databases PubMed, Web of Science, Cochrane and SPORTDiscus for studies with the following inclusion criteria: (a) controlled trials, (b) EMS trials with at least one exercise and/or control group, (c) strength and/or jump and/or sprint and/or aerobic capacity parameter as outcome (d) sportive/trained subjects. Standardized mean differences (SMD) with 95% confidence interval (CI) and random effects models were calculated. Interventions were ranked using the P-score and relative pairwise effects were presented via the SMD and 95% CI. Study quality was rated using the PEDro scale.
RESULTS: Thirty-six studies with 1.092 participants were selected and 4 distinct networks (strength, jump, sprint, aerobic capacity) were built. The highest effects for pairwise comparisons against the reference control “active control” were found for the combination of resistance training with superimposed EMS and additional jump training (outcome strength: 4.43 SMD [2.15; 6.70 CI]; outcome jump: 3.14 SMD [1.80;4.49 CI]), jump training with superimposed whole-body electromyostimulation (WB-EMS) (outcome sprint: 1.65 SMD [0.67; 2.63 CI] and high intensity bodyweight resistance training with superimposed WB-EMS (outcome aerobic capacity: 0.83 SMD [-0.49; 2.16 CI]. Other variations of EMS applications or training combinations resulted in merely trivial to moderate, occasionally even negative effects.

CONCLUSION: Our findings indicate that the choice and the combination of EMS training with other training methods has notable impact on the magnitude of the effects and should therefore be carefully considered in trained athletes. Superimposed EMS with relatively low volume, high intensity and outcome-specific movement pattern appeared to most promising and beneficial EMS training approach in trained athletes.

**IMMERSIVE VIRTUAL REALITY MAY CHANGE SENSORY WEIGHTING DURING UPRIGHT STANDING**

BARBANCHON, C.
*UNIVERSITÉ LIBRE DE BRUXELLES*

INTRODUCTION: Immersive virtual reality (VR) has emerged over the last decade as a promising clinical and scientific tool [1]. For example, VR allows to design specific visual stimuli that can be used to challenge postural control [2], and thereby to induce specific adaptations within the postural control system. The aim of this study was to assess whether repetitive VR induced changes in postural control in healthy young adults.
METHODS: Fifty-nine participants [mean (SD); 31(13) yrs] stood upright during 6 bouts of 90-s within a VR environment simulating forward and backward displacements (VR practice). Before and after VR practice, the path length of the center of pressure (CoP-path) was recorded for 60-s while participants stood upright on a force platform, with eyes open (EO) and closed (EC). In addition, participants performed two 60-s VR trials during which a forward (one trial) or backward (one trial) displacement was simulated for 15-s. During these trials, the CoP-path and mean CoP position (CoPmean) were measured by 15-s epochs (0-15s: no simulated displacement; 15-30s: simulated displacement; 30-45s and 45-60s: no simulated displacement). A control group (n=8) performed the same experiment without the VR practice.
RESULTS: Although the CoP-path with EO did not change after VR practice ($p=0.87$), the CoP-path with EC and the EO/EC ratio decreased significantly (mean (SD); -3.14(15.5)% and -3.18(16.9)%, respectively; $p<0.05$]. During VR trials, the CoP-path decreased for the 15-29s and 30-45s epoch for forward [median(interquartile); 15-29s: -22(48)mm; 30-45s: -5(38)mm, $p<0.05$] and backward simulated displacement [15-29s: -36(43)mm; 30-45s: -11(32)mm, $p<0.05$]. No statistical change was observed for the control group.
CONCLUSION: In agreement with a previous study, the results indicate that one VR session decreased postural response to simulated displacement [1]. Furthermore, the decrease in CoP-path during EC trials and the decrease in the EC/EO ratio suggest a sensory re-weighting, likely increasing the contribution of proprioceptive information to control posture [3]. Overall, this study indicates that VR can be a relevant tool to improve postural control.

**THE FENDURA PROJECT: DOES MENSTRUAL CYCLE PHASE INFLUENCE RECOVERY MEASURES IN ENDURANCE ATHLETES? A PILOT STUDY.**

DE MARTIN TOPRANIN, V., SANDBAKK, Ø., NOORDHOF, D.A.
*NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY*

INTRODUCTION: Recovery is crucial for inducing training adaptation and minimizes the likelihood of non-functional overreaching and injuries (1). The hormonal fluctuations during the menstrual cycle (MC) are likely to exert an effect on women's exercise physiology, as well as on perceived feelings, and could therefore result in variations in commonly used markers of recovery. However, the influence of the MC on subjective recovery measures, subjective sleep quality and resting heart rate (HR) in highly trained athletes has not been investigated. The purpose of the present study was to investigate how MC phases influence resting HR, subjective sleep quality, as well as physical and mental readiness to train among endurance athletes.
METHODS: This study was part of the Female Endurance Athlete (FENDURA) project led by the UiT The Arctic University of Norway (Tromsø).Fifteen naturally menstruating, highly trained (14±4 hours/week) endurance athletes (24±7 years old) recorded daily data representative of recovery, training sessions as well as MC-related side effects for 2±1 MCs. Resting HR was assessed using night-recording watches or a standardized procedure upon awakening; subjective self-report measures of sleep quality, physical and mental readiness to train were assessed with a visual analogue scale (1-10). Four MC phases were determined using the calendar-based counting method and the urinary ovulation prediction test and identified based on the current methodological guidelines for studies in sport and exercise science with women as participants (2): early follicular phase (EFP), late follicular phase (LFP), ovulatory phase (OP) and mid-luteal phase (MLP). Data were analyzed using mixed-effects modelling, with MC phase, MC-related perceived side effects and ovulatory/anovulatory cycles (for resting HR only) as fixed effects, recovery variables as outcome, and participant cluster as random effect.
RESULTS: Resting HR was significantly higher in ovulatory compared to anovulatory cycles ($p=0.020$), without a significant change between MC phases. MC phase had a significant influence on the subjective recovery measures: subjective sleep quality was decreased in the OP ($p=0.006$) and MLP ($p=0.006$), physical and mental readiness to train were lower in the MLP ($p=0.030$; $p<0.001$) compared to the EFP. Increased MC-related perceived side effects were associated with a reduced mental readiness to train ($p=0.024$).
CONCLUSION: We found decreased subjective recovery in the MLP which suggests that there could be a diminished recovery capacity in this MC phase. However, the reduced mental readiness to train associated with higher MC-related perceived side effects implies a higher perception of MC symptoms in the MLP. Altogether, these findings indicate that the MC should be accounted for when monitoring recovery, as MC phase, including MC-related side effects, and menstrual disturbances can influence recovery.

### VIGOROUS - NOT MODERATE - PHYSICAL ACTIVITY IS ASSOCIATED TO REDUCED CARDIAC ADIPOSE TISSUE IN WOMEN WITH OBESITY

FERNANDEZ DEL VALLE, M., THAPA, S., BHARATH, S.S., DAVIS, P., GIVAN, A.H., SMITH, B., PEREZ-RIVERA, J.A., KLINGEN-SMITH, J.D.

*UNIVERSIDAD DE OVIEDO*

INTRODUCTION: Obesity is a known risk factor for cardiovascular disease, diabetes, and hypertension, and other diseases, and it is characterized by excess adipose tissue. Under normal conditions, fat accumulates in deposits adjacent to the myocardium and within the pericardium. The cardiac adipose tissue (CAT) protects the heart under normal physiological conditions by secreting numerous molecules; nevertheless, increased excess CAT has been identified as a risk factor for cardiovascular disease and other medical complications1. Observational research on whole-body adiposity has uncovered a negative link between physical activity (PA), fat mass and fat dispersion. The same way poor levels of physical fitness (PFit) have consistently been linked to an increased risk of mortality and cardiovascular disease. However, the relationship between PA, PFit and CAT volumes is unknown. Therefore, the goal of this study was to analyze the associations between CAT, PA, and PFit in a group of obese, but otherwise healthy, women.
METHODS: A total of 26 women with obesity (age: 23.41± 5.78 years-old) participated in this cross-sectional study. Physical activity was measured using accelerometry (Actigraph GT3X), cardiorespiratory fitness was measured breath by breath using the Bruce protocol, muscular strength was evaluated through a one maximum repetition test, and body composition was determined using dual-energy X-ray absorptiometry and anthropometric measurements. The CAT was quantified using magnetic resonance imaging (3.0T MRI). Associations were examined by Pearson's and Spearman correlation analyses.
RESULTS: Analysis showed negative associations of CAT with vigorous physical activity (VPA) levels ($r_S$ = - 0.41, p = 0.037), and positive associations with waist circumference ($r_S$ = - 0.58, p = 0.002) and visceral adipose tissue ($r_S$ = - 0.60, p = 0.001). All PA levels showed positive associations with and upper-body lean mass [Low Physical Activity (LPA): $r_S$ = 0.52, p = 0.007; Moderate Physical Activity (MPA): $r_S$ = 0.53, p = 0.005; VPA: $r_S$ = 0.40, p = 0.044]. Negative associations between PA levels, and %BF and lower body fat mass (FMlegs) were also described (%BF: LPA$r_S$ = - 0.65, p < 0.001; MPA$r_S$ = - 0.62, p = 0.001; VPA$r_S$ = - 0.41, p = 0.037; FMlegs: LPA$r_S$ = - 0.49, p = 0.011; MPA$r_S$ = - 0.42, p = 0.034; VPA$r_S$ = - 0.43, p = 0.027).
CONCLUSION: All types of PA showed a positive influence on whole-body and lower body fat in women with obesity, whereas only VPA had a significant impact on CAT volume. Previous studies utilizing exercise as a tool to reduce CAT showed that only those with sufficient intensity and frequency were capable of inducing CAT loss2. Therefore, VPA could be key for the prevention of gains and reduction of cardiac fat deposits. Nevertheless, more research is required to support our findings, and to uncover the most optimal forms of vigorous exercise that would aid in CAT reduction and prevent gains long term.

### THE EFFECT OF ORAL CONTRACEPTIVE USE ON THE PRO- AND ANTI-INFLAMMATORY CYTOKINE BALANCE AFTER ACUTE STRENGTH EXERCISE

NOTBOHM, H.L., UMLAUFF, L., SCHUMANN, M.

*GERMAN SPORT UNIVERSITY*

INTRODUCTION: Previous research has shown that a controlled release of cytokines is essential for morphological muscle adaptations in response to strength training. An acute release of pro-inflammatory cytokines to initiate muscle repair is followed by anti-inflammatory cytokines to avoid an excessive inflammation[1]. However, hormonal fluctuations in women, either due to the menstrual cycle or contraceptive use, may impact inflammatory processes[2]. Especially oestrogen is discussed to attenuate pro-inflammatory responses[3]. Therefore, we aimed to compare changes in key-players of pro- (IL-1β) and anti-inflammatory (IL-1ra) cytokines after acute strength exercise between naturally menstruating women and women using oral contraceptives.
METHODS: Twentyone women (age: 23±3 yrs, weekly strength training: 4.4±1.7 h) were separated into two groups: 1) a naturally menstruating group without hormone use (MC, n=13) and 2) a contraceptive group (OC, n=8) regularly using a monophasic combined pill (>9 months). Testing consisted of a one repetition maximum test (1RM) and a strength training session in the deep squat (4x10 repetitions at 70% 1RM). Venous blood sampling for the assessment of IL-1β and IL-1ra and explosive strength testing to assess mean propulsive velocity (MPV) were performed before (t0), directly after (t1) and 24 h after (t2) strength exercise. All testing was performed in the follicular phase (MC) or the pill free interval (OC).
RESULTS: MPV showed no effect for time ($F_{[2,38]}$=2.77, p=.076, $\eta^2$=.127) or interaction ($F_{[2,38]}$=1.54, p=.227, $\eta^2$=.075). For IL-1ra an effect for time was found in the OC group only ($F_{[2,14]}$=5.25, p=.02, $\eta^2$=.429), with concentrations increasing from t0 to t1 (+51.1±59.4%, p=.197) and decreasing from t1 to t2 (-38.6±17.4%, p=.013). There was no interaction effect ($F_{[2,38]}$=1.30, p=.283, $\eta^2$=.064). For IL-1β no effect for time ($F_{[2,38]}$=.03, p=.975, $\eta^2$=.001) or interaction ($F_{[2,38]}$=.06, p=.944, $\eta^2$=.003) was found. Additionally, an association between the changes in MPV and IL-1β was found from t0 to t1 across both groups (r=-.447, p=.048).
CONCLUSION: While the strength exercise did not statistically cause reductions in strength performance, larger losses in MPV were associated with greater increases in the pro-inflammatory cytokine IL-1β. Furthermore, compared to the follicular phase, the pill-free interval of oral contraceptives seems to produce a greater response to strength exercise in the anti-inflammatory cytokine IL-1ra. This could potentially impact the pro-inflammatory effects of IL-1, such as stem cell activation and muscle regeneration[4]. However, the effect on the overall pro-/anti-inflammatory cytokine balance remains to be determined and further cytokines should be investigated.

**URINARY STEROID VARIATIONS IN ACTIVE WOMEN USING AN ORAL CONTRACEPTIVE PILL**

MOREILLON, B.1, SALAMIN, O.1,2, KRUMM, B.1, IANNELLA, L.3, DE LA TORRE, X.3, FAISS, R.1, BOTRE, F.1,3

*1RESEARCH AND EXPERTISE IN ANTIDOPING SCIENCES , UNIL, LAUSANNE, SWITZERLAND; 2SWISS LABORATORY FOR DOPING ANALYSES, CHUV, LAUSANNE, SWITZERLAND; 3LABORATORIO ANTIDOPING FMSI, ROME, ITALY*

INTRODUCTION: The Athlete Biological Passport (ABP) longitudinally monitors steroidal variations that could be indicative of doping. This study investigated the potential influence of the oral contraceptive pill (OCP) cycle on the steroidal biomarkers of the ABP in physically active women taking OCPs.
METHODS: Urine and serum samples were collected weekly from 15 physically active women taking OCPs during two consecutive cycles. Urinary steroid values (testosterone (T), androsterone (A), etiocholanolone (Etio), 5a-androstane-3a, 17b-diol (5aAdiol), 5b-androstane-3a,17b-diol (5bAdiol) and epitestosterone (E)) were determined by gas chromatography coupled to tandem mass spectrometry (GC-MS/MS) according to the World Anti-Doping Agency (WADA) guidelines and entered into the Anti-Doping Administration and Management System (ADAMS) computing longitudinal profiles.
RESULTS: The values of the T/E ratio could not be determined in 61% of the samples (n=73) since the urinary concentrations of T and/or E were below the limits of quantification (LOQ, 1 ng/ml). Consequently, only the A/Etio and 5aAdiol/5bAdiol ratios were considered for statistical analyses. The longitudinal monitoring of the steroidal passport in ADAMS did not elicit any atypical passport finding (ATPF) at a 99.9% specificity level. In contrast, when data was pooled in function of weeks following the bleeding (W1, W2, W3 and W4) A, Etio and 5bAdiol yielded significant differences (W1=1083 vs. W2=1584 ng/mL [p<0.05]; W2=2183 vs. W3=1531 ng/mL [p<0.05]; W1=78.1 vs. W2 53.0 ng/mL [p<0.05]; respectively). A significant increase in A/Etio was observed at W3 (0.96 +/- 0.39; p<0.05) and W4 (0.93 +/- 0.30; p<0.05) compared to the preceding 2 weeks (W1, 0.79 +/- 0.34; W2, 0.79 +/- 0.30). In serum, values for progesterone (1.1 +/- 0.4 nmol/L) and estrogen (53.8 +/- 39.4 pmol/L) were in accordance with previously published ranges in woman using OCPs. Spikes occurred during the placebo phase of the OCP cycle (i.e. W1) with LH higher (3.2 +/- 2.2 IU/L) compared to W3 (1.8 +/- 2.7; p<0.001), and W4 (0.9 +/- 1.4; p<0.001). FSH was also higher in W1 (6.4 +/- 3.1 IU/L) compared to W2 [4.1 +/- 2.7; p<0.001], W3 [2.1 +/- 2.4; p<0.001] and W4 [1.2 +/- 1.8; p<0.001]).
CONCLUSION: Urinary steroidal hormones varied in active women using OCPs with significant differences between successive weeks after bleeding. However, the analyses of variations using individual ABP profiles reflect that actual variations were limited within the narrow individual limits of the longitudinal model. Our results therefore support the relevance of the Bayesian approach of the ABP that focuses on individual variations rather than population means. As expected T/E ratios could not be determined (i.e. with T and/or E undetectable) in a majority of the women considering the low androgenic hormonal levels. The latter is however supportive of the steroidal ABP module aimed at detecting abnormal increases due to exogenous steroids intake.

**ASSOCIATION OF MATERNAL PHYSICAL FITNESS, GESTATIONAL WEIGHT GAIN AND PRE-PREGNANCY AND POSTPARTUM BODY MASS INDEX WITH THE DESCENDANT'S BODY COMPOSITION AT 4 YEARS OLD: THE GESTAFITOS PROJECT**

SÁNCHEZ-PARENTE, S.1, FLOR-ALEMANY, M.2,3, BAENA-GARCÍA, L.4, CASTRO-PIÑERO, J.1,5, APARICIO, V.A.2,3

*1 GALENO RESEARCH GROUP, UNIVERSITY OF CADIZ; 2 UNIVERSITY OF GRANADA; 3 UNIVERSITY OF GRANADA; 4 UNIVERSITY OF GRANADA; 3 BIOMEDICAL RESEARCH AND INNOVATION INSTITUTE OF CADIZ .*

INTRODUCTION: Physical fitness (PF) and body composition are considered important markers of health throughout the life course. Regarding pregnancy, both outcomes could influence early programming and have an influence on the body composition of the descendants. The purpose of this study was to investigate the association between maternal PF at the 16th gestational week (g.w.), pre-pregnancy body mass index (BMI), gestational weight gain and postpartum BMI with the body composition of the offspring at 4 years old.
METHODS: Sixty-seven pregnant women (33.2±4.1 years) and their descendants were included for the present analyses. Cardiorespiratory fitness, muscular strength, flexibility and overall PF was measured at the 16th g.w. Pre-pregnancy body mass index, differences in body weight from the 16th g.w. until the 34th g.w. and BMI 6 weeks-postpartum were registered. Body weight, height, lean mass and fat mass percentage of the offspring were measured at 4 years of age.
RESULTS: After adjusting for potential confounders, a greater maternal flexibility at the 16th g.w. was associated with lower body fat in the children (β=-0.272, p=0.027). A higher pre-pregnancy BMI and a higher postpartum BMI were associated with greater body fat in the children (β=0.263, p=0.048 and β=0.276, p=0.031, respectively). No other statistical differences were observed (all p>0.05).
CONCLUSION: Higher flexibility during pregnancy and BMI before pregnancy and at the postpartum period were associated with lower body fat in the offspring at 4 years of age. Further studies are needed to explore the potential mechanism behind the association found between maternal flexibility and lower body fat in the descendants.

**THE EFFECTS OF MENSTRUAL CYCLE PHASE ON ELITE ATHLETE PERFORMANCE: A LONGITUDINAL AND PROSPECTIVE STUDY**

ALICE, M.

*INSEP*

INTRODUCTION: In elite athletes, training individualization is widely recommended to optimize competitive performance. Previous studies have evidenced the impact of hormonal fluctuations on different performance parameters among female athletes, but the parameters themselves, the magnitude and the direction of the effects are inconclusive. While consideration of menstrual cycle phases as a parameter in training individualization strategies is necessary, systematic evidence identifying such impacts in elite athletes should be evaluated. Additional longitudinal and prospective studies to systematically monitor on-field performance parameters are urgently required to enable recommendations and training individualization in female elite athletes.
METHODS: The EMPOWER project proposed a longitudinal and prospective study coupled with robust statistical methods to establish and validate causal links, quantify impacts, and make reliable recommendations that can guide evidence-based future training individualizations. The follow-up started with 12 rowers and para-rowers, 16 cyclists, 1 fencer, 6 artistic gymnasts, 23 football players, 5 biathletes, 5 skiers and 4 cross-country skiers. During the follow-up, athletes were asked to fill in a short questionnaire every morning notably with information related to sleep, mood, training performance and feelings. On a regular basis, in each phase of the cycle, athletes had to take a saliva sample to accurately quantify five hormones (testosterone, estrogen and progesterone) as well as a sport-specific performance test for rowers and skiers. Every day their trainings were monitored using different connected devices (watches, power meters…) or questionnaires to quantify the training load of athletes.

RESULTS: Before starting the protocol, we assess the necessity of such a monitoring on athlete and their need to an individualized training. First results revealed that each athlete reacts differently to issues related to their gender, and high-level athlete reacts differently from less-trained athletes. In particular, the symptoms related to menstrual cycles are different from those who practice less sport. Athletes are very sensitive to these issues, and this may explain the high level of compliance with the questionnaire (more than 85% of assiduity depending on the sport). Among the population of athletes monitored, we observed divergent hormonal profile. Each female athlete is different from another and does not respond similarly to training throughout the menstrual cycle. There is a variety of athlete responses to physical tests.
CONCLUSION: As highlighted in the divergent literature, responses to menstrual issues regarding performance is widely heterogeneous from one athlete to another. These findings emphasize the need for researchers and support staff to undertake menstrual cycle profiling and monitoring and continue to develop awareness, openness, knowledge and understanding of menstrual cycle.

**ASSESSMENT OF ABDOMINAL MUSCLE THICKNESS IN POSTPARTUM WOMEN WITH AND WITHOUT EXERCISE DURING PREGNANCY**

KAWABE, R.1, KAJIWARA, Y.2, INOUE-HIRAKAWA, T.3, MATSUMOTO, D.2, IGUCHI, S.4, MORINO, S.5, ONISHI, M.1, KOUNO, C.1, SHIMIZU, H.1, NAGAI-TANIMA, M.1, AOYAMA, T.1

*1 KYOTO UNIVERSITY 2 KIO UNIVERSITY 3 NAGOYA UNIVERSITY 4 OITA UNIVERSITY, 5 OSAKA METROPOLITAN UNIVERSITY*

INTRODUCTION: Pregnancy and childbirth can affect abdominal muscles morphologically and functionally. Previous studies have reported morphological changes and dysfunction in the abdominal muscles of postpartum women, with concerns that they may be a risk factor for persistent postpartum back pain. Such problems for postpartum women may pose difficulty in returning to daily life and sporting activities. Approaches to maintaining the condition of abdominal muscles during pregnancy for comfortable postnatal activity are necessary, and exercise can play an important role. Therefore, we focused on postpartum abdominal muscle thickness as a morphological indicator of the muscles. Thus, this study aimed to compare the thickness of abdominal muscles postpartum with and without exercise during pregnancy.
METHODS: This study enrolled 34 women within 6 months of postpartum. The thickness of the abdominal muscles was measured in the rectus abdominis, external oblique, internal oblique, and transversus abdominis muscle (TrA) using ultrasound imaging. Participants were classified into two groups: one group performing exercise during pregnancy (EX group) and another without exercise during pregnancy (no-EX group). The abdominal muscle thickness in both groups was compared using an unpaired two-tailed t-test or the Mann-Whitney U test. The statistical significance was set at $p<0.05$.
RESULTS: The EX and no-EX groups comprised 9 and 25 women, respectively. The TrA muscle thickness was significantly thicker ($p=0.014$) in the EX group (2.9 ± 0.7 mm) than that in the no-EX group (2.2 ± 0.6 mm). No significant differences were observed in the thickness of the remaining three abdominal muscles.
CONCLUSION: This study showed differences in the postpartum TrA muscle thickness with and without exercise during pregnancy. TrA has been reported to be an important muscle for spinal and pelvic stability. In addition, most biomechanical studies indicate that TrA is the most important abdominal muscle involved in back pain. The results of this study suggested that exercise during pregnancy might help maintain postpartum abdominal muscle thickness. Although further research is needed, exercise during pregnancy might lead to more comfortable postnatal daily physical and sports activities, which could contribute to improved quality of life in postpartum women.

**EVALUATION OF A CO-DESIGNED ADAPTED PHYSICAL ACTIVITY INTERVENTION FOR PREGNANT WOMEN: PRELIMINARY RESULTS FROM THE WELL-DONE!STUDY**

MARINI, S.1, MASINI, A.2, MESSINA, R.3, CARAVITA, I.3, ZANNONER, A.2, SCOGNAMIGLIO, F.2, COA, A.A.2, RESCIGNO, I.2, SICARI, G.2, CASTAGNA, G.2, LECCESE, V.3, BERTINI, V.3, PARMA, D.3, DALLOLIO, L.2

*ALMA MATER STUDIORUM UNIVERSITY OF BOLOGNA*

INTRODUCTION: Nowadays, the importance of practicing physical activity (PA) during pregnancy is widely known and recommended thanks also to several guidelines. Nonetheless, fewer than 15% of pregnant women reach these recommendations. Given the above, the implementation of adapted physical activity (APA) intervention emerges among the possible strategies that allow pregnant women to perform the right dose of PA. Childbirth preparation classes (CPCs), offered by the national healthcare system, can represent an ideal setting for the promotion of PA during pregnancy and the implementation of APA programs. The aim of this study was to co-design an intervention of APA tailored for pregnant women to be included in the CPCs and to evaluate the feasibility and efficacy in terms of PA levels and physical performance.
METHODS: Pregnant women have been recruited at the University Hospital of Bologna (Italy) and assigned to two different groups: the experimental group (EG) and the control group (CG). EG attended 1hour/week session of APA during the usual CPCs for a 6 weeks period. While the CG received a one hour lesson regarding PA recommendation during pregnancy. Physical activity levels were assessed through the Pregnancy Physical Activity Questionnaire (PPAQ) at baseline (T0) and follow-up (T1). Variations in physical performance were assessed by Sit-to-Stand test and 6-Minute Walking Test. Data analysis was conducted using STATA software.
RESULTS: A sample of 50 pregnant women aged between 29-46 (mean age=35.44 ± 3.99) were involved in the study. The total activity score (-0.72 ± 34.30 MET-h/wk in the experimental versus -10.18 ± 40.72 MET-h/wk in the control) showed that PA levels decreased in both groups. Sedentary activity score was more reduced in the EG compared to the CG, without statistically significant differences (-10.20 ± 24.12 MET-h/wk in the EG versus -4.59 ± 24.99 MET-h/wk in the CG). Light and moderate activity scores increased in the EG, while were slightly reduced in the CG. As far as concerned physical performance, the EG showed a greater increase both in the number of repetitions and in the total distance, without statistically significant differences in comparison to the CG.
CONCLUSION: Preliminary results suggest that, albeit without being statistically significant, we observed a positive trend in the EG. Specifically, this group showed a reduced sedentary time, an improved moderate activity and physical performance. It is notably that sedentary activity also decreased in the control group, although to a lesser extent than in the EG. This data underlines that even a purely informative intervention, such as the one the control group was subjected to, can be effective in sensitizing women to reduce their sedentary lifestyle.

**EFFECTS OF A TRAINING INTERVENTION TAILORED TO THE MENSTRUAL CYCLE ON ENDURANCE PERFORMANCE AND RECOVERY AND STRESS BALANCE IN FEMALE RECREATIONAL RUNNERS – A RANDOMIZED-CONTROLLED PILOT STUDY**

KUBICA, C., BERNHARD, J., SCHWENDIMANN, N., LEHMANN, A., WIDMER, M., NIGG, C.R.

*INSTITUTE OF SPORT SCIENCE, UNIVERSITY OF BERN*

INTRODUCTION: Polarized training is well known to stimulate training effects and improve performance in recreational runners [1]. On the other hand, the menstrual cycle (MC) may affect performance in eumenorrheic women [2,3]. Adaptions of a traditional training program on the MC phases may impact training response in female runners. Therefore, this study aimed to assess the effect of the adaption of the polarized training adapted to the MC phases on performance development and recovery-stress balance.
METHODS: Sixteen eumenorrheic, moderately-trained female runners (age: 24±2.8 years; height: 169±8cm; weight: 62±8 kg; maximal oxygen uptake: 43±5 mL/min/kg) took part in an 8-week running training intervention consisting of three weekly training sessions. The participants were randomly assigned to a control and an intervention group. The control group followed a training program based on polarized training [1] consisting of two 4-week mesocycles. The mesocycles included three weeks of progressive training load and one week with a reduced load. The intervention group followed the same training content, but the single training sessions were adapted to their MC with a higher training load within the follicular phase, medium training load within the luteal phase, and regeneration during the menstrual phase. A baseline and post-assessment were used to analyze anthropometrics (weight, height, waist circumference, body composition), cardiovascular (blood pressure, heart rate variability), and performance changes (CMJ (OptoGait, MicroGait, Italy), ventilatory thresholds, VO2peak (running graded exercise test; treadmill: Quasar, h/p/cosmos, Germany; respiratory gas analyzer: MetaMax 3B, Cortex, Germany). The heart rate training stress score (hrTSS) and subjective Intensity (BORG-RPE) were collected to determine training loads for each training session. Further, the short version of the Recovery-Stress-Questionnaire was used at the baseline assessment, after four weeks of training, at the end of the training period.
RESULTS: Data is currently collected and analyzed. The following parameters will be compared between the intervention and control group and presented at the conference: Anthropometrics, cardiovascular and performance parameters, and information about subjective and objective training loads.
CONCLUSION: The novel findings of this pilot study could enhance our knowledge about the influence of adapting polarized training programs to the MC phases in female recreational runners, and could provide knowledge for further studies.

**CAN LIFELONG PARTICIPATION IN TEAM SPORTS MAINTAIN MECHANICAL MUSCLE FUNCTION IN WOMEN?**

FRISTRUP, B., HAGMAN, M., THORSTEINSSON, H., KRUSTRUP, P., AAGAARD, P.

*UNIVERSITY OF SOUTHERN DENMARK*

INTRODUCTION: Age-related impairments in mechanical muscle function are typically manifested as decreases in maximal muscle strength, power and rate of force development (RFD). Participation in team sports such as football and team handball has previously proven effective in maintaining or even improving muscle strength and functionality. The aim of this cross-sectional study was to compare elderly lifelong trained team sport players with age-matched untrained controls, young team sport players and young untrained controls.
METHODS: A total of 129 women were recruited for the study and divided into four groups as follows: elderly trained (ET) (n=35), aged 63.9±0.7 yrs (mean±SD), with regular participation in team handball training for 43.3±2.0 yrs; elderly controls (EC) (n=35), aged 66.1±0.6 yrs, with no regular participation in exercise for 14.7±3.2 yrs; young trained (YT) (n=29), aged 22.5±0.6 yrs, with regular participation in elite football training for 14.9±0.6 yrs; young controls (YC) (n=30), aged 24.9±0.4 yrs, with no regular participation in exercise for 4.8±0.9 yrs prior to this study. Following standardized warm-up, maximal voluntary isometric contraction (MVIC) strength along with early (0-50 ms) and late (0-200 ms) phase RFD of the knee extensor and knee flexor was measured in the dominant leg. In addition, handgrip strength of the dominant hand and performance in a 30-s sit-to-stand (STS) test was measured.
RESULTS: Despite a 41-yr difference in average age, there was no difference in knee extensor MVIC strength between ET (165.5±29.2 Nm) and YC (184.6±39.1 Nm) ($p=0.14$). Early and late phase RFD for the knee extensor were not different ($p>0.05$) between ET and YC (562.2±428.6 and 563.1±225.4 Nm/s) or between ET (371.0±342.4 and 424.6±226.1 Nm/s) and EC (283.3±276.4 and 339.8±177.4 Nm/s). Knee flexor MVIC strength did not differ ($p=0.06$) between ET (71.5±16.4 Nm) and YC (83.2±17.5 Nm). There were no difference in early phase RFD of the knee flexor between ET (160.0±138.8 Nm/s) and YC (227.6±148.0 Nm/s) ($p=0.16$) or between ET and EC (129.0±92.5 Nm/s) ($p=0.75$). Late phase RFD for the knee flexor showed no difference between ET (178.1±93.5 Nm/s) and EC (143.4±61.5 Nm/s) ($p=0.31$). The handgrip strength was not different between ET (32.2±6.4 kg) and YC (30.4±6.1 kg) ($p=0.53$) or between ET and YT (35.4±4.9 kg) ($p=0.10$), but results showed a significant difference between ET and EC (26.6±5.1 kg) ($p<0.00$). In the sit-to-stand test, there was no difference between ET (22.5±4.7 STS) and YC (24.0±5.4 STS) ($p=0.60$). For all other comparisons, ET was superior ($p<0.05$) compared to EC, and YT was superior ($p<0.05$) compared to all three groups.
CONCLUSION: This study indicates that lifelong participation in team sports is effective in reducing the age-dependent impairment in mechanical muscle function (MVIC and handgrip strength) and functionality (STS), as elderly lifelong trained women showed comparable values to young untrained controls despite an 41-yr age-difference.

**LONGITUDINAL COMPOSITIONAL ANALYSIS OF 24-HOURS ACTIVITY BEHAVIORS COMPOSITION DURING PREGNANCY: A NOVEL APPROACH FROM THE PREGNACTIVE PROJECT.**

OVIEDO-CARO, M.

*UNIVERSITY PABLO DE OLAVIDE*

INTRODUCTION: During the course of pregnancy it has been described a reduction of physical activity levels (Barone Gibbs et al., 2021). Despite the different potential effects of moderate-to-vigorous physical activity (Davenport et al., 2018) or sedentary behavior (Fazzi et al., 2017)) on health, it is essential to know what activity behavior is selected by pregnant women when reducing the time spent in physical activity. This study aimed to properly analyze the longitudinal changes in the components of the 24-h day by using the compositional data analysis approach (Chastin et al., 2015).
METHODS: Eighty one pregnant women were longitudinally evaluated from midpregnancy to later pregnancy. The 24-h activity behaviors: sedentary time, sleep, light intensity physical activity, and moderate to vigorous intensity physical activity were objectively assessed by multi-sensor monitors. Statistical analysis included the Hotelling T2 test which was used to test if the perturbation between mid-pregnancy

and later pregnancy compositions indicated a significant change, and the compositional regression test which was developed for test the explanatory factors of the perturbation coordinates.
RESULTS: The Hottelling T2 test indicated that the compositional change between the mid-pregnancy and later pregnancy was statistically significant (F-stat= 6.4, p = 0.001). The relative contributions of light intensity and moderate-to-vigorous intensity physical activity, and sleep to the 24-h activity behavior composition decreased over time while increased sedentary time (≈3.1%). Compositional regressions developed for the perturbation coordinates indicated that MVPA increases when occupational status was maintained along pregnancy and when pregnant woman has higher educational level.
CONCLUSION: These findings reinforce the need to promote an active lifestyle during pregnancy to, at least, maintain physical activity levels and limit sedentary time along the course the pregnancy. The fact that higher educational level predisposes to increase physical activity levels suggest the importance of guarantee the access of pregnant women to the knowledge about the benefits and limited risk of physical activity during pregnancy .

### IS-PN08 Muscle structure and function in health, ageing, and pathological scenarios: new advances of an old tale

#### SARCOMEROGENESIS AND MUSCLE PLASTICITY: THE "OLD STORY

FRANCHI, M.

*UNIVERSITY OF PADOVA*

Muscles undergo continuous turnover and adaptation in response to daily functional requirements. This represents a fundamental capacity for our survival, as, across different species, muscles have considerably evolved to make motion possible and to remarkably perform a variety of tasks. The modulations of sarcomere length and addition are thought to be two of the main mechanisms by which muscle plasticity is displayed in living organisms. The current and main accepted hypothesis is that muscle adaptations to loading and unloading are predominantly mediated by the addition or subtraction of muscle fundamental units, the sarcomeres, either placed in-parallel or in-series. For these reasons, sarcomerogenesis has been studied since the 1960s to clarify the mechanisms responsible for muscle plasticity. Interestingly, serial sarcomerogenesis phenomenon has been studied mostly in animal models, within different species, and across different muscles with distinct architecture and biomechanical functions, using different conditions and intervention durations. It follows that the literature presents contradictory findings regarding muscle adaptations to loading and disuse, and this can limit the current practice of orthopaedic decision making, of rehabilitation strategies, or simply our understanding of optimal exercise prescription, as sarcomere adaptations strongly influence muscle contractility and force generation. The present lecture aims to provide a critical discussion on sarcomerogenesis literature up to now, discussing the main accepted results and current limitations. Starting from Goldspink's work of the 70's and 80's, the main objective will be to present novel insights into muscle plasticity which have been recently introduced by the acquisition in vivo of images of human sarcomeres by microendoscopy technique1,2. The lecture will then present very recently published data on sarcomerogenesis in humans investigated by three-dimensional ultrasound and microendoscopy after 3 weeks of an eccentric exercise protocol3, discussing the possible strategies of muscle remodeling to specific mechanical stimuli. Not only the topic is of broad interest for sport scientists, kinesiologists, biomechanics professionals and researchers, physiologists, but it will also lay the ground for the other two talks, which will cover the relation between structure and function in health, ageing, and pathological settings.

#### LONGITUDINAL MUSCLE REMODELLING ON MECHANICAL FUNCTION

POWER, G.

*COLLEGE OF BIOLOGICAL SCIENCES, UNIVERSITY OF GULEPH*

Our group is interested in the effects of chronic changes to muscle fascicle length on mechanical function. Here we use two models to explore this relationship: aging which results in a loss of sarcomeres in series, and downhill running which results in an increase of sarcomeres in series.

Aging muscles undergo structural remodelling, whereby fascicle lengths become shorter in old as compared with young. Thus, the fascicles and sarcomeres of muscles in older adults may experience greater relative length changes for a given displacement, resulting in increased passive tension as compared with young. In a young (≈9 months ≈20 human years) and old cohort (~32 months; ≈75-80 human years) of rats we compared the medial gastrocnemius to determine differences in fascicle length, serial sarcomere numbers and sarcomere length, and record passive tension from short to long muscle lengths. The MG was surgically isolated, and passive force was recorded. The animals were sacrificed and the hind limb was fixed in formalin at the muscle length corresponding to optimal force. The muscles were then dissected into 4 lengthwise sections medial and lateral of the centre and sarcomere length measurements were obtained. From these experiments we showed the age-associated reduction in muscle fascicle length is primarily owing to fewer sarcomeres arranged in series, without a significant difference in sarcomere length. Additionally, passive force was greater in muscles from the old rats as compared with young at long muscle lengths. It was expected that shorter fascicles and fewer serial sarcomeres in muscles from old experienced greater relative length changes for a given displacement however this was not the case.

Increased serial sarcomere number (SSN) has been observed in rats via downhill running training, however, little is known about the influence on dynamic contractile function. Therefore, we employed 4 weeks of downhill running training in rats, then assessed soleus SSN and work loop performance in vitro to characterize dynamic performance. Thirty-one Sprague-Dawley rats were assigned to control (n=18) or training (n=13). Following sacrifice, the soleus was dissected and tied to a force transducer and length controller, then the optimal muscle length (LO) was determined. Muscles then performed work loops (active shortening followed by passive lengthening) about LO at various cycle frequencies. Next, muscles were fixed in formalin at LO for 1 week, then digested in nitric acid. Fascicle lengths and sarcomere lengths were measured and used to calculate SSN. From these experiments we show training-induced longitudinal muscle growth can improve dynamic performance.

Taken together it seems that longitudinal muscle remodeling whether it be a loss or gain of serial sarcomeres can alter passive and dynamic mechanical function.

The talk is of interest of movement scientists, as it covers fundamental knowledge of how muscles adapt to maintain optimal function.

### MULTI-SCALE MEASURES OF MUSCLE ARCHITECTURE IN THE BICEPS BRACHII: LOSS OF SERIAL SARCOMERES ACCOMPANIES CHRONIC HEMIPARETIC STROKE

MURRAY, W.

*NORTHWESTERN UNIVERSITY*

INTRODUCTION: Human muscle structure and function is plastic. However, few studies quantify muscle structural adaptation in vivo as needed to compute optimal fascicle length and physiological cross-sectional area (PCSA). By integrating 3 imaging methods (second harmonic generation endoscopy, extended field-of-view ultrasound, MRI), my lab quantified structure at the sarcomere, fascicle, and whole muscle scales in living humans [1]. We establish confidence in the ability to quantify these data and demonstrate that current approaches can detect structural adaptation in human muscle.
METHODS: Optimal fascicle length and PCSA were calculated from sarcomere lengths, fascicle lengths, and muscle volume measured in biceps brachii of both arms of 11 subjects (7 with chronic hemiparetic stroke; 2 female/5 male, 60 ± 9 yrs, Fugl-Meyer 26±9, 13±10 yrs post-stroke; 4 age-range matched participants without stroke; 2 female/2 male, 62±6 yrs). All length data were collected in the same posture, under passive conditions. We used sarcomere images from these participants and two additional unimpaired participants (1 female 28 yrs/1 male 29 yrs) to quantify experimental uncertainty associated with these novel data. Our methods are described in the literature [1, 2].
Results: Interlimb difference in volume for the stroke participants (med: 42.67 cm3, IQR: 23.54 cm3) was significantly larger than for those without stroke (med: 0.48 cm3, IQR: 7.65 cm3), indicating substantial loss of muscle (32.7%) in the paretic limb. Biceps fascicle lengths were shorter in the paretic limb; interlimb differences in stroke were significantly larger than without stroke. Interlimb differences in sarcomere length were comparable between groups. When computed from the fascicle and sarcomere length data, optimal fascicle length for the paretic biceps (i.e., the number of sarcomeres in series) was 20.0% shorter than the contralateral, nonparetic limb. When computed from muscle volume and optimal fascicle length, PCSA (a correlate of maximum isometric force) was significantly smaller in the paretic biceps. Normalized interlimb differences in PCSA (15.6%) were smaller than volume. The magnitude of the uncertainty for in vivo sarcomere length was ~0.25µm. When propagated, this uncertainty yields uncertainty in optimal fascicle length and PCSA of ~7–8%.
Conclusions: A loss in muscle volume (area×length) is often considered synonymous with a loss of PCSA. Our data show that loss of muscle volume can involve loss of sarcomeres in series, which has different functional implications. The uncertainty in sarcomere length and its propagation through calculation of the most functionally meaningful muscle architecture parameters, suggests measuring sarcomere length and studying muscle adaptation in vivo is practical and of interest for movement scientists, orthopaedic researchers and clinicians.

## Invited symposia

### IS-BM03 Wearable accelerometry-based technology to assess functional activities in older populations: from the laboratory to the free-living environment

#### A BODY-FIXED SENSOR-BASED ANALYSIS OF STAIR CLIMBING CAPACITY IN LABORATORY SETTINGS

VAN ROIE, E.

*KU LEUVEN*

Reduced lower-limb muscle power has been proposed as an important predictor of age-related deterioration in functional capacity. Clinically feasible measurements of lower-limb power are crucial to enable frequent assessments and to detect early changes, so that exercise interventions can be initiated in time. This session demonstrates the use of sensor-based trunk kinematics to estimate the vertical power produced during stair ascent in older adults. Different stair models (3 step – 6 step – 12 step) will be compared. Reliability of the measurement, the relationship with leg-extensor power and the age-related changes will be discussed.

#### THIGH-WORN ACCELEROMETRY TO DETECT AND QUANTIFY FREE-LIVING SIT-TO-STAND TRANSITIONS

LÖPPÖNEN, A.

*UNIVERSITY OF JYVÄSKYLÄ*

Sit-to-stand (STS) transitions are one of the most common activities of daily life and good STS performance is an important factor in maintaining functional independence. Usually, STS assessments is based on laboratory measurements, such as the five-times STS test. However, laboratory measured capacity should not be equated to functioning in free-living environment when measuring older adults without mobility limitations. This session demonstrates the use of thigh-worn accelerometers to detect and quantify sit-to-stand (STS) transitions in free living environment. The relationship between sit-to-stand performance in free-living environment and laboratory-based lower-extremity capacity will be examined.

#### CAPACITY IN THE LAB VERSUS DAILY LIFE PERFORMANCE: THE STRENGTH OF ASSESSING BOTH

RANTALAINEN, T.

*UNIVERSITY OF JYVÄSKYLÄ*

There is a clear distinction between a person's ability to perform a skill in the laboratory ("capacity") and his/her ability to perform that same skill in a natural environment ("daily performance"). This is particularly the case in individuals without mobility limitations. Individuals with a high strength reserve, i.e. much higher than the minimum strength required for a certain functional task, do not need to use their full capacity in free-living environments. However, this does not mean that free-living data cannot give important insights in the functioning of an individual. In this session, Dr. Rantalainen will discuss how to analyze free-living data by zooming in on 'best' performance in daily

life (“capability”). In addition, he will discuss how to use the complementary information of laboratory and free-living data to identify individuals at risk for functional decline.

## Invited symposia

### IS-MH07 Exercise as medicine in obesity-related breast cancer prevention and survivorship: From muscle to adipose tissue

#### EXERCISE AS MEDICINE IN BREAST CANCER PREVENTION. THE ROLE OF MYOKINES IN THE MUSCLE-ADIPOSE TISSUE-IMMUNE SYSTEM COMMUNICATION NETWORK

PÉREZ LÓPEZ, A.

*UNIVERSITY OF ALCALÁ*

During menopause, adipose tissue became the primary source of estrogens and androgens, altering glucose and lipid metabolism and increasing visceral fat mass accumulation. When these metabolic changes are accompanied by physical inactivity, the risk of obesity and the development of comorbidities, such as breast cancer, increased due to an augmented inflammatory state caused by adipocytes and immune cells release of pro-inflammatory cytokines (e.g., IL-6, IL-13 or IL-15) into the circulation to promote damaged tissue reparation and toxic agent neutralization. However, the chronic presence in the circulation of these pro-inflammatory cytokines contributes to an inflammatory spiral that damages several tissues’ metabolism and elevates the risk of non-communicable diseases. Exercise training can restore some of the metabolic disturbances experimented during menopause by regulating sex hormones production and promoting anti-inflammatory effects. Nevertheless, the mechanisms by which exercise facilitates muscle-adipose tissue-immune system crosstalk communication resulting in fat mass and breast cancer risk reduction are not entirely understood.
Myokines are among the main candidates to enable muscle-adipose tissue crosstalk communication. The acute release of some of these myokines (e.g., IL-6, IL-13, IL-15, IL-15Rα and FGF21) stimulates fatty acid oxidation in skeletal muscle and liver, lipolysis in skeletal muscle, a reduction in lipid accumulation in adipose tissue and improve glucose uptake and oxidation in skeletal muscle, liver and adipose tissue. These effects allow establishing a muscle-adipose tissue-immune system by which exercise can attenuate inflammatory state, restore sex hormones production and reduce fat mass accumulation.
Therefore, this presentation will aim to discuss the role of myokines in muscle-adipose tissue-immune system communication network, particularly in postmenopausal women with obesity at high risk of breast cancer.
RELEVANCE
Breast cancer is one of the most commonly diagnosed cancers in women worldwide. Obesity and physical inactivity are associated with postmenopausal breast cancer risk since inflammation and fat mass increase. Therefore, lifestyle interventions are required in women to facilitate the metabolic changes experimented during menopause to prevent or at least minimize breast cancer occurrence. We have used exercise as medicine to improve health outcomes and markers of breast cancer risk in postmenopausal women focused on elucidating the role of myokines and sex hormones in the muscle-adipose tissue-immune system communication network.
TARGET AUDIENCE
This presentation could be relevant to medical, nutrition and exercise practitioners interested in non-pharmacological strategies to prevent breast cancer or other chronic non-communicable diseases in postmenopausal women, from the basic science behind the inter-tissue communication to the practical application of exercise intervention.

#### EXERCISE AS MEDICINE DURING BREAST CANCER TREATMENT: HIGH INTENSITY INTERVAL TRAINING (HITT) AS A TIME-EFFICIENT APPROACH

GONZALO-ENCABO, P.1,2, KYUWAN, L.3, CHRISTOPHER, C.1,2, NORMANN, A.1,4, YUNKER, A.1,5, NORRIS, M.1, WANG, E.6, DIELI-CONWRIGHT, C.1,2

*1.DANA FARBER CANCER INSTITUTE, MA.: 2.HARVARD MEDICAL SCHOOL, MA.; 3.CITY OF HOPE, CA.; 4.BOSTON UNIVERSITY, MA.; 5. HARVARD T.H. CHAN SCHOOL OF PUBLIC HEALTH, MA.; 6.KAISER PERMANENTE ORANGE COUNTY*

While breast cancer is the most diagnosed cancer in women worldwide, cancer treatments have permitted an average 5-year survival rate for women with non-metastatic invasive breast cancer of 90%. Treatment strategies may include surgery, radiotherapy, and systemic therapy (e.g., endocrine therapy or chemotherapy). However, breast cancer and its treatments have multiple detrimental side effects, including physical, physiological, and psychosocial deficits. For example, for women diagnosed with early and advanced-stage breast cancer, the most commonly used treatment is anthracycline-based chemotherapy, which is associated with cardiotoxicity, and thus increases the risk of cardiovascular diseases. Other common side effects include weight gain, cancer-related fatigue, osteoporosis, muscle weakness, sarcopenia, declines in physical function, impaired quality of life, depression and anxiety, treatment-related cognitive impairments, and weight gain. Given the burden of pharmacological treatments experienced by cancer patients, it is important to explore non-pharmacological strategies that could counteract treatment side effects. In this regard, exercise is a low-cost, non-pharmacological strategy to promote clinical and health outcomes during breast cancer treatments. Particularly, high-intensity interval training (HIIT) is a time-efficient exercise type that combines exercise bursts with recovery periods. HIIT has shown beneficial effects in other clinical populations, whereas clinical oncology exercise research using HIIT remains largely unexplored. The purpose of this presentation will be to discuss the impact of breast cancer treatments on health-related outcomes such as cardiovascular and cognitive health, and the use of exercise (particularly HIIT) to improve health outcomes in breast cancer patients undergoing chemotherapy from previous and ongoing exercise oncology clinical trials.
RELEVANCE
Given the burden of breast cancer worldwide, it is important to understand how exercise can improve clinical and health outcomes during breast cancer treatment, with the ultimate goal of reducing comorbidities and mortality. In this regard, we have used exercise as medicine in our laboratory to improve health outcomes during breast cancer treatments, particularly prescribing a supervised and periodized HIIT intervention considering cancer-related side effects.
TARGET AUDIENCE

The content of this presentation is relevant to clinicians and for the sports science community, particularly for those who work with clinical populations living with chronic diseases. Transferring research into practice, our main goal with this presentation is that clinicians, researchers and trainers understand that exercise is medicine during breast cancer treatment.

### EXERCISE AS MEDICINE AMONG BREAST CANCER SURVIVORS: THE TRANSLATION OF SPORTS SCIENCE INTO CHRONIC DISEASE TO IMPROVE HEALTH OUTCOMES

DIELI-CONWRIGHT, C.

*DANA-FARBER CANCER INSTITUTE*

Individuals diagnosed with cancer experience a milieu of adverse treatment-related side effects that persist for many years negatively altering the risk of comorbid diseases and quality of life. Specifically, metabolic dysregulation (MetD), defined here as metabolic syndrome (MSY), insulin resistance (IR), and visceral adiposity (VA), and sarcopenia are long-term complications of curative treatment for many cancers including breast, prostate, and testicular. MetD in breast cancer survivors (BCS) is a serious concern during cancer survivorship that if treated may improve survivorship and further prevent cancer recurrence. MetD, due to heightened adipose and systemic inflammation, and increased cell proliferation, may influence one's risk for cancer recurrence and mortality. BCS represent a distinctive group who endure many treatment-associated alterations in lifestyle habits including weight gain, skeletal muscle loss, reduced physical activity levels, and worsening metabolic profiles leading to MetD. Exercise may be an effective intervention for attenuating MetD and sarcopenia, thereby reducing risk for additional associated chronic diseases. Since lifestyle factors such as exercise and dietary intake affect the risk of developing MetD, it is important, possibly preferable, to target lifestyle factors to prevent/manage MetD in BCS, particularly due to the fact that cancer survivors have undergone the physiologic burden of other cancer-related pharmacologic treatments with varying side effects. The purpose of this presentation will be to discuss the impact of MetD and sarcopenia on cancer-related outcomes and the utilization of exercise to target said health measures in BCS from previous and ongoing exercise oncology clinical trials.
RELEVANCE
Cancer affects millions of patients and caregivers worldwide that results in declining health outcomes at an earlier age and progress more rapidly when compared to age-matched adults and children without cancer. Thus the application of exercise to improve various health outcomes has the ability to improve survivorship and quality of life. Importantly, our research laboratory uses an exercise as medicine approach to deliver exercise in a highly prescriptive manner thus increasing the potential efficacy of the interventions we employ. Said interventions utilize basic principles of exercise and sports science yet with rigorous considerations based on cancer-related treatment side effects.
TARGET AUDIENCE
Based on the clinical implications of this presentation, this content is relevant to medical and exercise practitioners, particularly those who encounter individuals with chronic diseases. In addition, our research utilizes exercise prescription principles, such as the principle of overload, thus our exercise interventions are pertinent to clinicians and fitness professionals alike.

## Invited symposia

### IS-AP08 Overcoming challenges of COVID-19 for sport and exercise scientists: harnessing remote technology to measure sport and exercise outcomes

### MOVING SPORT SCIENCE FROM THE LABORATORY TO HOME: VIRTUAL ENVIRONMENTS AND SPORT PERFORMANCE

EDWARDS, A.

*CANTERBURY CHRIST CHURCH UNIVERSITY*

With COVID-19 restrictions placed on sport and exercise scientists to continue testing in laboratories and maintain a social distance, conducting testing in the laboratory is problematic. As an alternative, sport and exercise scientists can adopt virtual training environments to examine and manipulate sport performance from a remote setting. Virtual environments refer to a computer reality that aims to induce a sense of being mentally and physically present in another place, and in the last five years, prevalence of use has increased exponentially. A range of virtual environment software is available to athletes where they can interact with the environment to stimulate "real world" training and competition. This technology is highly useful for athletes wanting to compete and train at a time when social restrictions may prevent these from taking place. In fact, such technology has made it possible to augment and improve the performance of athletes, which is an invaluable tool that can be accessed from home.
An inherent advantage with virtual environment is that researchers can conduct a study from home without the need to supervise participants. One popular virtual environment software, with over 2.5 million users in over 190 countries, is Zwift, whereby cyclists ride their bikes on a stationary trainer that provides measures of power, speed, cadence, and heart rate. This software could be used as an alternative for sport and exercise scientists being in the laboratory and provides opportunities to examine and manipulate various forms of outcome measures related to, for example, physiology, biomechanics, and psychology.
In this session, the speaker will provide an overview of virtual environment software that sport and exercise scientists can use to obtain valuable outcome measures. This will be followed by empirical data related to the reproducibility of performance using virtual environment software (i.e., Zwift) and the outcomes of a nutritional intervention using the software. Implications about the advantages and disadvantages will be discussed, alongside how sport and exercise scientists can maximise their use of remote technology to help them continue their scientific endeavours.

### THE ROLE OF AVATARS TO HELP IMPROVE SPORT PERFORMANCE AND EXAMINE COMPETITIVE BEHAVIOUR

HETTINGA, F.

*NORTHUMBRIA UNIVERSITY*

Social distance restrictions have reduced the occurrence of sporting competitive events worldwide and impeded sport scientists examining in-person competition and training. Competition between athletes is central to sport, which has shown to influence performance via a

myriad of factors related to behavioural, psychological, and physiological mechanisms. Athletes need to determine how and when to invest their limited energy resources to optimise their pace and self-regulate their pace depending on the physiological and biomechanical capacity and environmental factors, such as the presence and behaviour of another athlete. Excellence in many sports involves mastering of tactical competitive elements, and athlete motivation for training and competition is hugely influenced by other exercisers and/or competitors.
Remote technology can be used to help identify the interaction of competition on an athlete's performance or offer competitive training scenario's and motivation without F2F contact. One method is via the use of avatars, which can be a graphical representation of an athlete's own performance or that of another athlete. A body of research has shown that avatars can influence emotional and psychological responses, which in turn influences that athlete's performance. This research has shown that avatars can influence self-regulatory processes, which affects beliefs, motivations and perceptions of energy and fatigue.
In this session, the use of remote technology to replicate competitive sport environments will be discussed and how they can help understand more about the myriad of factors that impact competitive sport performance.

**EXERGAMING AS A TOOL TO PROMOTE PHYSICAL ACTIVITY AT HOME**

LAMOTH, C.

*UNIVERSITY OF GRONINGE*

Physical inactivity is associated with cardiovascular disease, type II diabetes and obesity, which in turn can increase the risk of premature mortality. In the context of COVID-19, maintaining and increasing physical activity is challenging with gyms and fitness centres being closed, and exercise events, such as parkrun, being cancelled. Similarly, while evidence suggests people have more time to be physical activity due to working from home, the impact of social restriction measures has negatively affected mental health outcomes, such as stress and depression, which can further negatively affect physical activity levels. In short, the restrictions associated with COVID-19 has significantly affected people's physical activity behaviour.
In the past two decades, a growing body of evidence has examined the use of interactive gaming (i.e., exergaming) to help increase physical activity and thus improve a person's health and wellbeing. Exergaming offers an immersive experience that simulates an active gaming experience to function as a form of physical activity by using videogames and devices to convert a person's body movements into an avatars movements on their TV screen. Exergames are relatively easy to use, with instructions being available to help guide the user through the game without the need of supervision. As such, exergames offer an easy, remote, and engaging platform in which to examine and measure physical activity outcomes remotely.
In the present session, the use of exergaming to benefit physical activity outcomes will be discussed. Algorithms for adaptive games and feedback to the user at different time scales to enhance exercise outcomes will be discussed as well as an overview of the evidence that exergaming can increase physical activity. This in turn will be followed by a critique of how unsupervised exergaming can be used to improve physical activity that is feasible and practical.

## Oral presentations

### OP-PN32 Energy expenditure and metabolism

**LOWER BASAL METABOLISM IS ASSOCIATED WITH ELEVATED CIRCULATING LEVEL OF INTERLEUKIN-6 IN TYPE 2 DIABETES MELLITUS: THE APETEX/EDUGUTION STUDY**

CASALS, C., CORRAL-PÉREZ, J., REBOLLO-RAMOS, M., MARÍN-GALINDO, A., MONTES-DE-OCA-GARCÍA, A., RAMÍREZ-JIMÉNEZ, M., OPAZO-DÍAZ, E., CALDERON-DOMINGUEZ, M., PONCE-GONZÁLEZ, J.G.

*UNIVERSITY OF CADIZ*

INTRODUCTION: The elevated circulating level of interleukin-6 (IL6) has been identified as an independent predictor of type 2 diabetes mellitus (T2DM). Thus, IL6 is considered to be involved in the development insulin resistance and β-cell dysfunction as a pro-inflammatory marker. Nevertheless, IL6 is a multifunctional cytokine and an increasing number of evidence have suggested that it has an anti-inflammatory role and could improve glucose metabolism. Therefore, the aim of this study was to analyse the relationship between IL6 and relevant health parameters, including glycosylated haemoglobin (A1c), body composition, basal metabolism, fat oxidation capacity and cardiorespiratory fitness in patients with obesity and T2DM.
METHODS: This pilot study of the APETEX/EDUGUTION project included a first batch of 15 patients (6 females) with a body mass index over 30 kg/m2 and diagnosis of T2DM. All participants were non-smokers and non-insulin-dependent patients. Blood samples were collected from the antecubital vein to measure IL6 and A1c. Body composition was estimated by bioimpedance. Basal metabolism was registered through indirect calorimetry with the subject lying in supine position during 30 min; then, FatMax (the intensity of maximal fat oxidation capacity) was calculated with an incremental test consisted in 3-min steps of 15W at 60-80 rpm on a cyclo-ergometer until RER reached 1, followed by a 1-min incremental test until exhaustion to estimate VO2max. Also, body composition was estimated by using bioimpedance. All measurements were performed in the morning and in fasting conditions (8-10 h). Additionally, 7 days before measurements, diet was registered by the weighting method.
RESULTS: Linear regression models with the stepwise method showed that the elevated levels of IL6 were associated with lower basal metabolism in T2DM (β=-0.61, R2=0.37, p=0.015); the rest of variables were excluded. Moreover, by including A1c as dependent variable, it was showed an association with basal metabolism and FatMax (R2=0.55, p=0.009).
CONCLUSION: Lower basal metabolism is associated with elevated IL6 circulating levels in patients with obesity and T2DM. As basal metabolism is the largest component (60–75%) of daily energy expenditure for most individuals, its relevance with body mass management is highlighted. Also, as it was expected, a poorer diabetes control, estimated with A1c%, leads to a worse FatMax that can be considered a relevant marker of metabolic flexibility. It was presented without a significant effect of the VO2max, although it must take into account that this population (obese patients with T2DM) has a lower cardiorespiratory fitness compared with healthy subjects. A higher sample will be studied in this project which consists in a randomized clinical trial with exercise interventions and nutritional counselling, leading to a

better understanding of IL6 signalling mechanisms and its relation with T2DM. GRANTS: PID2019-110063RA-I00, PID2020-120034RA-I00, and LI19/21IN-CO09.

### ACUTE EFFECT OF CONCENTRIC AND ECCENTRIC CYCLING EXERCISE ON SUBSTRATE OXIDATION AMONG OBESE MALE

CHE MAT ARIFFIN, N.H.1, AHMAD YUSOF, H.1, NOSAKA, K.2, CHE MUHAMED, A.M.1

*1ADVANCED MEDICAL AND DENTAL INSTITUTE, UNIVERSITI SAINS MALAYSIA, PENANG, MALAYSIA. 2CENTRE FOR EXERCISE AND SPORTS SCIENCE RESEARCH, EDITH COWAN UNIVERSITY, WESTERN AUSTRALIA, AUSTRALIA.*

INTRODUCTION: Greater fat utilisation has been previously shown during eccentric compared to concentric cycling at the same workload among healthy men (Penailillo et al. 2014). Among obese individuals, there are evidence of an impaired lipid oxidation during exercise as the result of reduced mitochondrial content (Kim et al. 2000), lower oxidative-enzyme capacity (Simoneau et al. 1999) as well as reduced insulin concentration (Thyfault et al. 2004). Based on this evidence, this study aims to explore the acute effect eccentric cycling exercise among obese male.
METHODS: Eleven overweight men (35 ± 3 years; 35.8 ± 3.7 %Body Fat) performed a concentric (CON) and two eccentric (ECC1, ECC2) intermittent cycling exercise bouts for 45 min. The intensity of exercise for CON and ECC1 and was set at 60% of CON maximal power output (POmax), while the intensity for ECC2 was set at 120% CON POmax. Prior to exercise testing, each participant was provided with three familiarisation sessions.
During exercise, Fat and carbohydrate utilisation during exercise were estimated from the RER measured by the metabolic cart (ParvoMedics, Sandy, USA). Substrate oxidation was estimated using the stoichiometric equations assuming a non-protein respiratory quotient (Jeukendrup and Wallis, 2005). In each trial, participants provided venous blood samples at the start and the completion of the exercise. Blood samples were analyzed for triacylglycerols (TG), total cholesterol (TC), low-density lipoprotein (LDL), and high-density lipoprotein (HDL).
RESULTS: There was no significant difference in fat utilization during exercise between CON to both ECC1 and ECC2 trials (139.8kJ ± 150.7 vs. 152.3kJ ± 57.3 and 254.3kJ ± 118.6, respectively; P>0.05). There was a significantly higher CHO utilization during the CON exercise when compared with both ECC1 and ECC2, respectively (1690.8kJ ± 473.5 vs. 476.9kJ ± 161.95 and 729.2kJ ± 118.6, respectively; P<0.05). There was no significant (P>0.05) difference in the percent change in TG, TC, LDL and HDL from the start to the end within the CON and ECC1, and ECC2.
CONCLUSION: This study observed that a single bout of eccentric cycling did not show a favorable fat utilization as compared to concentric cycling among obese men. Reduced mitochondrial content and lower oxidative-enzyme capacity have been previously shown to limit lipid oxidation during exercise among obese individuals (Arad et al. 2020).

### COMPARISON OF METABOLIC PARAMETERS AND, PERIPHERAL AND CENTRAL OXYGENATION, BETWEEN HEALTHY AND TYPE 2 DIABETIC WOMEN.

ÁVILA, L., PONCE-GONZÁLEZ, J.G., MONTESDEOCA, A., CORRAL-PÉREZ, J., OPAZO, E., MARÍN-GALINDO, A., RAMIREZ-JIMENEZ, M., ORELLANA PECINO, I., REBOLLO-RAMOS, M.

*UNIVERSITY OF CÁDIZ*

(co-authors)González Mariscal, A., Pérez-Bey, A., Casals, C., Velázquez-Díaz, D.
INTRODUCTION: Cardiorespiratory fitness (CRF) and fat oxidation (FO) are lower in sedentary women with diabetes compared to their healthy counterparts (1), however, the differences in other metabolic parameters, as resting FO, is unclear. A previous study suggests that peripheral oxygenation may be impaired in the lower extremities in T2D (2), although, few studies have analysed the differences of peripheral and central between healthy women and women with T2D. The aim of this study was to analyse the differences of CRF, FO and peripheral and central oxygenation between healthy and women with T2D.
METHODS: 17 women (33.8±14.9 years; 6 with T2D) were included in this study. Resting FO were registered through indirect calorimetry. Then, an incremental exercise protocol on a cycle ergometer with two phases was performed. The first phase aimed to determine maximal FO and consisted of 3-min steps of 15/30W (depending on the weight of the individual) maintaining a pedalling cadence of 60-80 rpm. This phase was stopped when RER≥1. The second phase to detect the VO2max. Near Infrared Spectroscopy (NIRS) at rest and during the incremental test was used. One NIRS sensor was placed on the non-dominant frontoparietal area for estimation of central oxygenation, while another sensor for estimation of peripheral oxygenation was placed on the vastus lateralis. Student t-test was applied to analyse the differences between groups.
RESULTS: CRF was higher in healthy women compared to diabetics (p<0.001). Women with T2D showed higher resting FO than healthy women (p=<0.002), however, these significant differences were not observed with maximal FO. Regarding resting peripheral oxygenation, there were significant differences between healthy and women with T2D, being higher in healthy individuals (P=0.002), however, women with T2D showed higher peripheral oxygenation at light, submaximal and maximal exercise intensity than healthy women (all p<0.005). There were no significant differences regarding central oxygenation.
CONCLUSION: Women with T2D showed a higher FO at rest compared to healthy women. Moreover, women with T2D achieved higher peripheral oxygenation level during light, submaximal and maximal exercise intensity than healthy women, although, healthy women showed a higher peripheral oxygenation at rest. These findings suggest that women with T2D had higher peripheral oxygenation than healthy women during exercise.

**INVESTIGATING THE ROLE OF TESTOSTERONE IN SKELETAL MUSCLE ADAPTATION IN PRE-MENOPAUSAL FEMALES**

ALEXANDER, S., AISBETT, B., WADLEY, G.D., LAMON, S.

*DEAKIN UNIVERSITY*

INTRODUCTION: Testosterone is the major male sex hormone and promotes virilising traits. Testosterone is also present in females, albeit at concentrations 10-fold lower than in males. Testosterone positively regulates skeletal muscle mass and function in males via binding to its receptor, the androgen receptor, and increasing muscle protein synthesis. However, evidence is emerging that, when at physiological levels, total testosterone may not be related to muscle mass nor strength in pre-menopausal females. This study aims to establish whether testosterone concentrations are predictive of the muscular adaptations that occur in response to 12 weeks of resistance training in pre-menopausal females.
METHODS: Twenty non-resistance trained, pre-menopausal females (age 23.4 years ± 4.6) underwent 12 weeks of resistance training designed to maximally increase muscle size and strength. Thigh muscle cross sectional area, measured via peripheral quantitative computed tomography, and muscle strength, measured via leg press 1RM, were assessed before and after the training program. Sex hormone levels were assessed via ELISA. Muscle biopsies were collected before and after the training program. The muscle transcriptome was sequenced using RNASeq and the protein levels of the total and phosphorylated forms of the androgen receptor as well as common markers of muscle protein synthesis and degradation were analysed via western blot.
RESULTS: The average testosterone concentration of participants at baseline was 1.99 ± 0.53 nmol/L and did not fluctuate with training. Lower limb strength and thigh muscle cross sectional area increased by 28.5 and 7.3%, respectively. Total testosterone was not significantly correlated to muscle strength or size at baseline, or with the changes that occurred with training. Similarly, testosterone levels were not related to androgen receptor protein content or the relative expression of total or phosphorylated markers of protein synthesis.
CONCLUSION: Twelve weeks of resistance training increased muscle size and strength in pre-menopausal females. Total testosterone levels were however not related to increases in muscle size or function, nor to downstream markers of protein synthesis. This suggests that total testosterone plays a minor role in the regulation of muscle growth and function in pre-menopausal females.

**VALIDATION OF THE APPLE WATCH AND FITBIT FOR ASSESSING ENERGY EXPENDITURE DURING WHEELCHAIR PROPULSION IN ABLE-BODIED PARTICIPANTS AND WHEELCHAIR USERS**

LYNG DANIELSSON, M.

*NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY*

INTRODUCTION: Wheelchair users (WU) have a higher risk of obesity compared to able bodied (AB) individuals, mainly due to a lower daily energy expenditure (EE) . Closely monitoring EE and physical activity can serve as a tool for matching daily EE with energy intake, and thereby prevent or counteract obesity. The Apple watch is currently the only commercially available, wrist-worn watch with specific setup and EE estimation algorithms for wheelchair users. However, the accuracy of EE estimations from the Apple watch compared to other commercially available watches without a wheelchair-specific setup has not yet been established. Therefore, the purpose of this study was to investigate if the Apple watch and Fitbit accurately estimate EE during wheelchair propulsion.
METHODS: Data of 20 AB participants are currently included (age: 33 ± 11 years, height: 176 ± 10 cm, body mass: 75 ± 11 kg), while data from 20 manual WCU are still being collected. Criterion data for EE was measured with an ergospirometer (Vyntus CPX) during three 4-min stages of treadmill wheelchair propulsion at a 2.5% incline (women:2,3,4, men:3,4,5 km/h). Simultaneously, participants wore the Apple watch (set to wheelchair propulsion at walking pace) and Fitbit (set to treadmill running) on the non-dominant wrist. Placement of the devices (i.e., closeness to the wrist) was counterbalanced. Bland-Altman plots with mean differences (MD) between the average EE (kJ/min) recorded by the criterion device compared to either the Apple watch or Fitbit including lower and upper limits of agreement (LoA) were used to establish absolute agreement. Intraclass correlation coefficients (ICCA,1) were used to establish relative agreement.
RESULTS: The Apple watch underestimated EE with larger LoAs at higher intensities, with MDs [lower, upper LoAs] of: Stage 1 (-3.5 [-8.7,1.6]), stage 2 (-6.3 [-12.7,0.1]) and stage 3 (-10.1 [-1.4, -18.7]).The Fitbit overestimated EE for all three stages: Stage 1 (11.7 [3.5, 19.8]), stage 2 (12.5 [3.8, 21.1]) and stage 3 (12.9 [1.9,23.8]). Furthermore, ICCs were low to moderate during all stages for the Apple watch (0.47,0.27, 0.19) and the Fitbit (0.26, 0.5, 0.72).
CONCLUSION: Based on current preliminary findings, our result suggested that both the Apple watch and Fitbit were not accurate enough for estimating EE during wheelchair propulsion in AB people. Additional data on WCU still needs to be investigated before any definite conclusions can be drawn for the EE estimation of Apple watch and Fitbit.

### OP-AP14 Monitoring in soccer

**POSITIONAL DIFFERENCES IN ABSOLUTE VS. RELATIVE TRAINING LOADS IN ELITE ACADEMY SOCCER PLAYERS.**

DOUCHET, T., PAIZIS, C., BABAULT, N.

*UNIVERSITÉ DE BOURGOGNE – UFR STAPS*

INTRODUCTION: The quantification of relative training loads (RTL) is useful to assess how much players are exposed to competitive demands during training [1,2]. However, this alternative method to absolute training loads (ATL) quantification has only been scarcely used. Most studies have mainly expressed the RTL without considering the position of the players. This study therefore aimed to evaluate ATL and RTL and compare positions over the full in-season in an elite soccer academy.
METHODS: Twenty-four elite academy soccer players were categorized in five positions (CD: central defender; FB: full back; CM: central midfielder; WM: wide midfielder; FW: forward) and monitored using global positioning system (GPS). Only the weeks that fulfilled the following criteria were considered: (i) the team played only one match during the week, (ii) with a minimum of 6 days between the matches, (iii) players should complete all training sessions of the considered week, and (iv) should play the whole match. Firstly, ATL were calculated using day-by-day (according to their distance from match day [MD]) mean values from the considered weeks. Then, RTL were calculated using ATL expressed as a fraction of mean values of all the competitive matches of the considered weeks. GPS-derived data included

total (TD), moderate (MSD; [15-20[ km·h-1), high (HSD; [20-25] km·h-1), and sprint distance (SPRa; > 25 km·h-1), the total number of accelerations (ACC; > 3 m·s-2) and decelerations (DEC; < -3 m·s-2). One-way ANOVA were performed to evaluate differences between positions, followed-up by Bonferroni post-hoc procedures. Cohen's d effect size were calculated. Significance was set at p<0.05.
RESULTS: Absolute TD was greater for WM than CD (p=0.003; d=1.268) on MD-3, while relative TD did not demonstrate significant difference. Absolute MSD did not highlight difference across positions, while relative MSD showed that CD performed greater distances than CM, WM, and FW over the entire microcycle (p=0.045; d=1.248). Additionally, FB also performed a greater relative MSD than WM, on MD-4, MD-3, and MD-2 (p=0.001; d=1.107). On MD-4 and MD-3, WM demonstrated greater absolute ACC and DEC values than CD (ACC: p=0.047; d=1.057; and DEC: p=0.007; d=1.149) and CM (ACC: p=0.039; d=1.167; and DEC: p=0.011; d=1.423), while relative ACC and DEC did not differentiate positions.
CONCLUSION: Our results therefore highlight the need to quantify RTL over ATL. Quantifying RTL adds context to training loads by taking into account the competitive demands, and result in markedly different conclusions.

## WITHIN PLAYER MONITORING OF WELLNESS, SLEEP AND READINESS TO PLAY AND THE EFFECT OF TRAINING LOAD IN ELITE FOOTBALL

SPENCER, M., WIIG, H., ANDERSEN, T.E., INGEBRIGTSEN, J., LUTEBERGET, L.S.

*UNIVERSITY OF AGDER*

INTRODUCTION: Frequent matches and training sessions in elite football result in high training loads and constrained time for recovery. Careful planning of training loads, using valid and reliable tools, may assist to reduce injury risk and increase physical performance [1]. Monitoring individual training load, perception of wellness and sleep may be useful tools for tracking training load and the response to training and matches, and therefore improve training preparations. An important question is therefore how training load is related to wellness, sleep and readiness to play. Therefore, the aim of this study was to assess how wellness, sleep, readiness to play vary in the days pre- and post-match over two consecutive seasons within one elite football team.
METHODS: Thirty-one players (age 25.5±5.1 yr) from an elite Norwegian football team participated in the study over two consecutive seasons. Sixteen players participated in both seasons, while the remainder participated in either season. Each player reported daily their individual session rating of perceived exertion training load (sRPE-TL), wellness questionnaire [2], hours of sleep and readiness to play via a mobile-app. The data was pooled into days (-3 to +3 relative to match day [MD]) and analyzed using a linear mixed effects model, adjusting for training load, training load x day interaction, season trend and random effects for player and week.
RESULTS: Large day-to-day differences of sRPE-TL (ES: 1.1-2.5; p<0.01), hours of sleep (ES: 0.5-1.1; p<0.01), readiness to play (ES: 0.7-2.4; p<0.01) and wellness (ES: 0.3-1.5; p<0.01-0.03), with the exception of MD-1, were observed in the periods of MD-3 to MD+3 days relative to the matches in season 1. In season 2, these equivalent day-to-day differences were very similar for sRPE-TL (ES: 0.7-2.5; p<0.01), hours of sleep (ES: 0.4-1.1; p<0.01-0.02), readiness to play (ES: 0.7-2.7; p<0.01-0.05) and wellness (ES: 0.4-1.6; p<0.01), with the exception of MD-1.
CONCLUSION: The study shows that sRPE-TL, wellness, hours of sleep and readiness to play are sensitive to day-to-day differences in the days before and after the match, and are consistent over two seasons in this cohort. Hence, these variables are practical to include in a player monitoring regime. Furthermore, training load had an effect on wellness and readiness to play the day after the match, but not on the other days, highlighting the impact of the match.

## ANALYSIS OF THE PHYSICAL DEMANDS AND LOAD REQUIRED IN TRAINING AND MATCHES IN YOUNG U10 AND U12 SOCCER PLAYERS

HERNÁNDEZ-MARTÍN, A.1, SÁNCHEZ-SÁNCHEZ, J.2, GALLARDO, L.1, ALONSO-CALLEJO, A.1, HERNANDO-BARRIO, E.1

*1-UNIVERSITY OF CASTILLA-LA MANCHA. DEPARTMENT OF PHYSICAL ACTIVITY AND SPORT SCIENCES. IGOID RESEARCH GROUP. 2-UNIVERSITY EUROPEA OF MADRID, SCHOOL OF SPORT SCIENCES.*

INTRODUCTION: The Global Positioning System (GPS) is widely used in professional football and in the adult population, providing external load data that allows coaches to analyze physical demands according to the different playing positions in matches and to program training loads (1-2). However, there is a paucity of knowledge of the external load in training and matches for young players. Therefore, the aim of the present study was to analyze the performance variables and physical demands of U10 and U12 football players according to playing position, pre-match, and match training (MD-4, MD-2 and MD).
METHODS: Twenty-one U10 (age= 10.2 years) and U12 (age= 12.3 years) amateur players were analysed using the GPS WIMU PROTM 15Hz, with a total of 504 observations in a period of 3 months of 8-a-side football training and matches. The variables of total distance, distance in high intensity and sprint, maximum speed, time interval between accelerations, maximum speed acceleration, maximum acceleration, acceleration distance and number of high-intensity accelerations were analysed in absolute and relative values with respect to competitive match play.
RESULTS: The most notable differences in the U10s showed that midfielders in matches covered higher distance and higher intensity acceleration than in training (p<0.05; ES: 0.72 to 1.57) and at a with respect to defenders and forwards (p<0.05; ES: 1.05 to 2.00). In the U12s the midfielders in matches covered a higher distance and at a higher intensity than in training (p<0.05; ES: 1.05 to 2.39). The relative results compared to to match day in the U10 category, showed midfielders had a significantly lower percentage of total distance than defenders and forwards (p<0.05; ES: 0.76 to 0.83).
CONCLUSION: The present study indicates that the physical demands of young footballers in training and competition are influenced by the playing position and the age category. The playing position influences the physical performance in such a way that the U10 and U12 midfielders cover longer distances and perform a higher number of high-intensity actions in training and matches than the defenders and forwards. With regard to the importance of the category, the U12 players present fewer differences in physical demands between positions and trainings and matches due to their greater experience and age. The physical demands of the players in training are higher than in matches due to the rules of the game itself because the training is longer than a match and based on a learning and development approach, contrary to the loads of training in adult players, which are based on reaching the match day in the best shape.

**ACUTE FUELLING AND REFUELLING PRACTICES OF MALE ACADEMY SOCCER PLAYERS: IMPLICATIONS FOR PHYSICAL DEVELOPMENT AND PERFORMANCE**

STABLES, R.G., HANNON, M.P., COSTELLO, N.B., CLOSE, G.L., MORTON, J.P.

*LIVERPOOL JOHN MOORES UNIVERSITY*

INTRODUCTION: The energy expenditure of male adolescent soccer players [1] from the English Premier League (EPL) is comparable to (or greater) than adult players [2]. Given the requirement to promote growth and maturation in this population, there is a necessity for players to consume sufficient energy and macronutrient intake (EI) in the hours before and after training. "Under-fuelling" at this time is likely to reduce training performance and may increase the risk of injury to bone and tendinous structures. Accordingly, the aim of this study was to quantify the EI of male adolescent soccer players in the four hours pre- and post-training.
METHODS: During a 3-day data collection period, youth soccer players from an EPL academy (n = 48; U12, U13, U14, U15/16, U18, U23, all n = 8) self-reported their EI in the four hours pre- and post-training via the remote food photography method. Pitch-based loading was quantified using GPS technology during three (U12, U13, U14) and four (U15/16, U18 and U23) training sessions over the assessment period.
RESULTS: Total distance was greatest in the U15/16 (6162 ± 1165 m) squad, more than the U18 (5099 ± 1160 m) and U23 (4878 ± 1171 m) squads (both P<0.05). Distance covered by the U12 squad (6057 ± 1494 m) was greater than the U23 squad (P<0.05). No differences were found between the U13 (5931 ± 646 m) and U14 (5715 ± 1978 m) squads compared to all other squads. EI was consumed in closer proximity to the start of training in the U15/16 squad (- 40 ± 28 mins) compared to the U12 (- 91 ± 77 mins), U13 (- 99 ± 63 mins), U14 (- 104 ± 56 mins), U18 (- 114 ± 71 mins) and U23 (- 99 ± 52 mins) squads (P<0.05). There was no difference between the timing of EI between groups post training, (U12: + 56 ± 39 mins; U13: + 50 ± 34 mins; U14: + 39 ± 27 mins; U15/16: + 53 ± 25; U18: ± 54 ± 91 mins; U23: + 70 ± 84 mins). CHO intake pre-training was greater in U12 (1.4 ± 0.9 g.kg-1; all P<0.05) and U13 (1.5 ± 1.0 g.kg-1; all P<0.05) squads compared to U14 (0.8 ± 0.5 g.kg-1), U15/16 (1.0 ± 1.1g.kg-1) and U23 (0.7 ± 0.4 g.kg-1) squads. CHO intake in the U18 group (1.2 ± 0.1 g.kg-1) was not different from any other squad. Post-training relative CHO intake was greater in the U12 (1.5 ± 0.9 g.kg-1; all P<0.05) and U13 (1.6 ± 0.8 g.kg-1; all P<0.05) compared to U14 (0.8 ± 0.4 g.kg-1) and U23 (0.9 ± 0.4 g.kg-1) squads. CHO intake in the U14 squad was less than U15/16 (1.3 ± 0.6 g.kg-1) and U18 (1.6 ± 0.6 g.kg-1) squads (all P<0.05). CHO intake was lower in the U23 (0.9 ± 0.4 g.kg-1) compared with the U18 squad (P<0.05).
CONCLUSION: When compared with current recommendations to promote high CHO availability before and after exercise, data demonstrate that the present cohort of players under-consume CHO. Given the requirement to promote physical development alongside training intensity in an adolescent population, careful consideration should be given to the "acute" fuelling and re-fuelling practices for elite youth soccer players.

**VISUAL SCAN PATTERNS OF FOOTBALL ASSISTANT REFEREES WHEN JUDGING OFFSIDE.**

ALBALADEJO-GARCÍA, C., LUIS, V., GOTARDI, G.C., MORENAS, J., MORENO, F.J.

*UNIVERSIDAD MIGUEL HERNÁNDEZ*

INTRODUCTION: Decision-making in sports is mediated by perceptual-cognitive mechanisms. Visual scan patterns have been studied in multiple contexts to analyze observers perceptual abilities. However, the structure of these patterns has not been extensively studied in athletes. This work aimed to analyze the visual search strategies and decision-making processes of a group of football assistant referees.
METHODS: Ten national-level (9.0 ± 4.3 years of experience) and ten regional-level (8.6 ± 5.3 years of experience) football assistant referees (AR) were recruited for the study. Participants watched twelve task-specific video clips where the relative position of the attackers had to be perceived (i.e. onside/offside position) while wearing eye-tracker glasses. Four areas of interest (AOI) were established: attacker with the ball, attacker receiving the ball, defenders, and intermediate space. A visual fixation was defined if the gaze remained at the same AOI for a minimum time of 100 ms. Differences between groups were analyzed for dependent variables: response accuracy, stationary gaze entropy (SGE), and gaze transition entropy (GTE). Finally, the Kendall agreement coefficient (W) was calculated for one trial to analyze if participants tend to visit AOI in the same order.
RESULTS: No statistical difference was found between national- and regional-level ARs in response accuracy (58.5 ± 15.3% vs 60.9 ± 9.0%, p=0.673), SGE (92.3 ± 6.3% vs 92.8 ± 6.1%, p=0.859), and GTE (64.3 ± 16.4% vs 62.5 ± 19.0%, p=0.824). Concordance coefficient showed absence of agreement in national-level AR (W = 0.04; p>0.05). However, concordance coefficient showed agreement in the order of fixation locations in regional-level participants (W = 0.59; p<0.05).
CONCLUSION: AR in both groups showed a high gaze dispersion and transition rate between AOI, which highlights the relevance of the available stimuli when refereeing offside situations. However, regional-level AR presented a more predictable ordering when visiting AOI. On the other hand, national-level AR showed no systematic ordering when visiting AOI. These results suggest that each participant within the national-level AR group has developed a particular strategy when exploring the environment during offside judgments. However, these differences did not have an impact on the response accuracy, as both groups showed similar values. Further research should explore the timing of visual fixations that occurs between AOIs and the importance of the last fixation, also known as quiet eye.

## OP-PN33 Thermoregulation II

### SEASONAL HEAT ACCLIMATISATION IN HEALTHY ADULTS: A SYSTEMATIC REVIEW

BROWN, H.1, TOPHAM, T.1, CLARK, B.1, SMALLCOMBE, J.2, FLOURIS, A.3, IOANNOU, L.3, TELFORD, R.1, JAY, O.2, PÉRIARD, J.1

*RESEARCH INSTITUTE FOR SPORT AND EXERCISE (UCRISE), UNIVERSITY OF CANBERRA. THERMAL ERGONOMICS LABORATORY, UNIVERSITY OF SYDNEY. FAME LABORATORY, UNIVERSITY OF THESSALY*

INTRODUCTION: Physiological heat adaptations can be induced following various protocols that use either artificially controlled or naturally occurring environments. During the summer months in seasonal climates, adequate exposure to outdoor environmental heat stress should lead to transient seasonal heat acclimatisation.
Objectives: To assess the available literature and characterise seasonal heat acclimatisation during the summer months and identify key factors that influence the magnitude of adaptation.
METHODS: Eligibility criteria: English language, full-text articles that assessed seasonal heat acclimatisation on the same sample of healthy adults a minimum of three months apart.
Data sources: Studies were identified using first- and second-order search terms in the databases MEDLINE, SPORTDiscus, CINAHL Plus with Full Text, Scopus, and Cochrane, with the last search taking place on 15th July 2021.
Risk of bias: Studies were independently assessed by two authors for the risk of bias using a modified version of the McMaster critical review form.
Data extraction: Data for the following outcome variables were extracted: participant age, sex, body mass, height, body fat percentage, maximal oxygen uptake, time spent exercising outdoors (i.e. intensity, duration, environmental conditions), heat response test (i.e. protocol, the time between tests), core temperature, skin temperature, heart rate, whole-body sweat loss, whole-body and local sweat rate, sweat sodium concentration, skin blood flow and plasma volume changes.
RESULTS: Twenty-nine studies were included in this systematic review, including 561 participants across eight countries with a mean summer daytime wet-bulb globe temperature (WBGT) of 24.9°C (range: 19.5 to 29.8°C). Two studies reported a reduction in resting core temperature (0.16°C, $P<0.05$), 11 reported an increased sweat rate (range: 0.03 to 0.53 L/h, $P<0.05$), two observed a reduced heart rate during a heat response test (range: 3 to 8 beats/min, $P<0.05$), and six noted a reduced sweat sodium concentration (range: -22 to -59%, $P<0.05$) following summer. The adaptations were associated with a mean summer WBGT of 25.2°C (range: 19.6 to 28.7°C).
CONCLUSION: Limitations: The available studies primarily focussed on healthy male adults and demonstrated large differences in the reporting of factors that influence the development of seasonal heat acclimatisation, namely, exposure time and duration, exercise task and environmental conditions).
Conclusions: Seasonal heat acclimatisation is induced across various climates in healthy adults. The magnitude of adaptation is dependent on a combination of environmental and physical activity characteristics. Providing environmental conditions are conducive to adaptation, the duration and intensity of outdoor physical activity, along with the timing of exposures, can influence seasonal heat acclimatisation. Future research should ensure the documentation of these factors to allow for a better charactersation of seasonal heat acclimatisation.

### HEAT ACCLIMATION/ACCLIMATIZATION AND ASSOCIATED NUTRITION PRACTICES: A SURVEY TO DETERMINE PRACTITIONER AND ELITE ATHLETE KNOWLEDGE AND USE (SHOULD WE BE CONCERNED?).

TAYLOR, L.1,2, GALÁN-LÓPEZ, N.1,3, HILL, T.1, JAMES, L.1, CHRISMAS, B.4, RACINAIS, S.5, STELLINGWERFF, T.6, LEAL, D.7, HAUSEN, M.8, CHAMARI, K.5, FULLAGAR, H.2, ESH, C.5,1, ALABDULWAHED, S.1

*1LOUGHBOROUGH UNI, 2UNI OF TECHNOLOGY SYDNEY, 3COVENTRY UNI, 4QATAR UNI, 5ASPETAR, 6CANADIAN SPORT INSTITUTE-PACIFIC, 7UNI OF MAIA, 8OLYMPIC LABORATORY - BRAZIL OLYMPIC COMMITTEE.*

INTRODUCTION: Heat acclimation/acclimatization (HA) is the principal and most effective intervention to protect athletes from heat-mediated performance decrements and provide some protection against heat illnesses when exercise is performed in thermally challenging environments. That said, relatively little is known regarding how centuries worth of data in these regards, penetrates the knowledge and practice of elite athletes and practitioners. With the ever-increasing globalization of sport on a consistently warming planet, elite sport, including mega events, are increasingly held in such thermally challenging environments (e.g., Tokyo 2020ne). Thus, practitioners and their athletes alongside policy makers have a responsibility to prepare their athletes appropriately and educate their members, respectively. Additionally, the events themselves require diligent infrastructural and logistical preparation to deliver evidence-informed performance-facing support and potentially life-saving medical services. Therefore, the purpose was to survey elite athletes and practitioners to identify: (i) knowledge and application of heat acclimation/acclimatization (HA) interventions; (ii) barriers to HA application; and (iii) nutritional practices supporting HA.
METHODS: Practitioners (99) and elite athletes (55) completed an online survey. Pearson's Chi-square [ES; Phi] and logistic regression determined relationships. Differences between ROLE (athletes vs. practitioners) and CLIMATE (hot vs. temperate) were determined by Mann Whitney-U tests [effect size (ES; r)].
RESULTS: Practitioners were more likely to report measuring athletes' core temperature (Tc) [training: practitioners 40% (athletes 15%); $p=0.001$, Odds Ratio (OR) = 4.0, 95% Confidence Interval (CI) 2 to 9%; competition: practitioners 25% (athletes 9%); $p=0.020$, OR=3.4, 95% CI 1 to 10%]. Practitioners [55% (15% athletes)] were more likely to perceive rectal as the gold standard Tc measurement-site ($p=0.013$, phi=0.49, medium ES). Temperate [57% (22% hot)] CLIMATE dwellers ranked active heat acclimatization effectiveness higher ($p<0.001$, r=0.30, medium ES). Practitioners commonly identified athlete's preference (48%), accessibility and cost (both 47%) as barriers to HA. Increasing carbohydrate (CHO) intake when training in the heat was more likely recommended by practitioners (49%) than adopted by athletes (26%; $p=0.006$, 95% CI 0.1 to 1%). Practitioners [56% (28% athletes)] were more likely to plan athletes' daily fluid strategies, adopting a pre-planned approach ($p=0.001$, 95% CI 0.1 to 1%).
CONCLUSION: Practitioners and to a greater extent athlete's lacked self-reported key HA knowledge (e.g. Tc assessment/monitoring methods) yet demonstrated comparatively more appropriate nutritional practices (e.g. hydration). Concerningly, reported data included biologi-

cally implausible values and assertions, emphasizing the need for palatable educational resources from policy makers and/or stakeholders for their members.

**IMPACT OF ACUTE AND PROLONGED COOLING ON SKELETAL MUSCLE FORCE IN YOUNG MALES**

CHAILLOU, T.1, TREIGYTE, V.2, EIMANTAS, N.2, VENCKUNAS, T.2, BRAZAITIS, M.2

*1 SCHOOL OF HEALTH SCIENCES, ÖREBRO UNIVERSITY, ÖREBRO, SWEDEN; 2 LITHUANIAN SPORTS UNIVERSITY, KAUNAS, LITHUANIA*

INTRODUCTION: In athletes, exposure to cold during winter sports may impair physical performance. Severe muscle cooling appears to reduce maximal force and induces a shift towards a slower contractile profile. However, whether moderate muscle cooling and the duration of cooling affect muscle contractile profile (assessed from electrically evoked torque at low and high frequencies) and maximal voluntary force (isometric and isokinetic contractions) remains to be clarified. Therefore, the aim of this study was to investigate the impact of acute and prolonged cooling on electrically evoked torque and maximal voluntary contraction torque in young males.
METHODS: Twelve active males (27.2 ± 6.6 years old) were recruited for this study, consisting of 2 phases: acute and prolonged exposures. During each phase, participants were randomly exposed to cold water immersion (CWI, 10°C, up to the iliac crest) or passive resting (PR). Exposure to CWI was either continuous during 45min (acute CWI, A-CWI) or intermittent during a period of 300min [prolonged CWI (P-CWI) including immersions between baseline to 45min, 165 to 180min, and 255 to 270min]. Muscle (Tmu, average across 1, 2 and 3cm depth) and rectal (Trec) temperatures were assessed using thermo-sensors. Transcutaneous electrical stimulation of the quadriceps muscle was performed to determine torques at low (20 Hz: P20) and high (100 Hz: P100) frequencies, and P20/P100 ratio was calculated. Maximal voluntary isometric torque of the knee extensors (MVIC), as well as peak isokinetic torques (90°/s) of knee extensors (KE-IsoC) and flexors (KF-isoC) were determined. Neuromuscular tests were performed at baseline (BL) and 60min after BL during acute exposure, and at BL, 60, 90, 150 and 300min after BL during prolonged exposure.
RESULTS: Trec did not change after A-CWI while it was reduced (0.8 ± 0.4°C, $p<0.001$) after P-CWI compared to BL. Tmu decreased during A-CWI and P-CWI compared to BL (6.1 ± 2.2°C and 4.6 ± 1.1°C, respectively, $p<0.001$), with larger reduction of Tmu after A-CWI than P-CWI ($p<0.05$). P20 was not affected by the conditions. P100 was lower after 60min in A-CWI and P-CWI compared to PR ($p<0.05$). After the last bath (60min in A-CWI and 300min in P-CWI), P100 was nearly significantly higher in A-CWI than P-CWI ($p=0.05$). P20/P100 was higher after 60min in A-CWI and P-CWI compared to PR ($p<0.001$), but this ratio was lower in P-CWI than A-CWI after the last bath ($p<0.05$). MVIC torque remained unchanged during A-CWI and P-CWI, while KE-IsoC and KF-IsoC torques were similarly reduced after A-CWI and P-CWI compared to PR ($p<0.05$).
CONCLUSION: Moderate muscle cooling preferentially impairs maximal force production of dynamic contractions, but not isometric contractions, regardless of exposure duration. A shift towards a slower contractile profile (i.e., increased P20/P100) is more evident after A-CWI than P-CWI, which may be partially explained by a larger reduction of Tmu rather than the exposure duration or reduced Trec.

**FACTORS CONTRIBUTING TO THE CHANGE IN THERMONEUTRAL MAXIMAL OXYGEN CONSUMPTION AFTER FIXED-INTENSITY HEAT ACCLIMATION OF VARYING INTENSITY, VOLUME AND THERMAL LOAD**

WALDRON, M.1,2, PEEL, J.1, JOHN, K.1, HEFFERNAN, S.M.1, JEFFRIES, O.3

*1 - SWANSEA UNIVERSITY, UK; 2 - UNIVERSITY OF SUNSHINE COAST, AUSTRALIA; 3 - NEWCASTLE UNIVERSITY, UK*

INTRODUCTION: Performing heat acclimation has been reported to improve exercise capacity and maximal oxygen consumption (VO2max) when measured in a thermoneutral environment. However, there are various ways to administer exercise training and heat acclimation programmes, including the number of days, ambient temperature or humidity and exercise intensity; however, there is limited guidance on which combination of factors maximises the training response. Likewise, it is unclear whether participants' responses to the programme explains their adaptation capacity. The aim of this study was to evaluate factors explaining variance in thermoneutral VO2max adaptation to training in a hot environment, with consideration of training programme parameters, individual biophysical variables and responses to training.
METHODS: Seventy-one participants from a range of training backgrounds, consented to perform fixed-intensity training (range: 45% - 55% VO2max) in a controlled thermal chamber (range: 30°C - 38°C; 20% - 60% relative humidity) on consecutive days (range: 5 days -15 days) for between 50-min and-90 min. The range of conditions provided variation in training and thermal stimuli. The participants were evaluated for their thermoneutral VO2max in the preceding 72-h and re-assessed between 24-h and 96-h after. The change in resting plasma volume was assessed across the training period. Participants' sweat rate, heart rate, core temperature, perceived exertion and thermal comfort were measured throughout all sessions, and the percentage change in these responses across the programme was also determined as an indication of adaptation. Partial least squares regression was used to explain variance in the percentage change in VO2max across the programme using 24 latent variables. The number of components that minimised the root mean squared error of prediction (RMSEP) and explained the greatest variance (R2) in VO2max change, based on cross-validation analysis was used in the final PLSR model. The contribution of each latent variable to the overall model was calculated by applying the Jack-knife function.
RESULTS: Sixty-three percent of the participants increased VO2max more than the typical error of the test with a mean improvement of 2.6 +/- 7.9%. The final model contained five components, explaining 75% of the variance in VO2max change. The variables significantly contributing to the overall model were: average core temperature (beta = 2.05, P = 0.022), relative change in perceived exertion (beta = 1.06, P = 0.044) and the number of days post-testing (beta = 2.84, P = 0.017).
CONCLUSION: Within the range of programme parameters evaluated, training at a fixed-intensity in artificial heat increases (63% of the time) thermoneutral VO2max, with the average core temperature, the reduction in perceived exertion across the programme and the number of days between the final training day and post-testing providing the greatest contributions.

**THE EFFECTS OF WEARING A CHANGE ROBE GARMENT AFTER COLD WATER IMMERSION ON PHYSIOLOGICAL AND PERCEPTUAL RESPONSES**

READ, D.

*MANCHESTER METROPOLITAN UNIVERSITY*

INTRODUCTION: Open water swimming often takes place in cold water, with this exposure potentially leading to a phenomenon known as post-immersion afterdrop, where there is a continued drop in core body temperature during the rewarming phase. Recommendations for rewarming include consuming a hot drink, relocating to a warmer environment and changing into appropriate clothing. A Dryrobe® is a commercially available clothing garment primarily designed for individuals rewarming after cold water immersion, although scientific

studies have yet to test this product. The aim of the study was to investigate the effects of wearing a change robe garment after cold water immersion on physiological and perceptual responses.
METHODS: Unhabituated healthy male participants (n=15) were recruited (only data from participants who have completed all conditions n=6 is presented in this abstract). A randomised repeated-measures design was used, with participants assigned to wearing a Dryrobe®, towel, or foil space blanket. Core body temperature was measured using an ingestible telemetric pill and skin temperature using wireless iButtons. Thermal sensation (1-7 Likert) and comfort (1-4 Likert) were measured using standardised ASHRAE scales. Baseline data (10-min) was recorded before participants were immersed in cold water (14oC) for 30-min. Once participants exited the water they were then provided with either a Dryrobe®, a towel, or a foil space blanket. To simulate the conditions following open water swimming participants were then positioned in front of fans to replicate wind speed (10 mph) for 15-min. All data was collected in standardised environmental conditions (12oC, 35% RH).
RESULTS: Core body temperature had the smallest afterdrop between 0 and 15-min post immersion in the Dryrobe® condition (37.04 (0.43) vs. 36.97 (0.46)oC; -0.07 (0.19)oC) compared to the towel (-0.17 (0.27)oC) and foil space blanket (-0.11 (0.21)oC). Skin temperature increased the greatest between 0 and 15-min post immersion in the Dryrobe® condition (15.5 (0.6) vs. 18.7 (1.2)oC; 3.2 (1.0)oC) compared to the towel (1.1 (1.3)oC) and foil space blanket (2.5 (1.2)oC). After 15-min positioned in front of the fans post immersion, participants rated their thermal sensation score higher in the Dryrobe® (3.3 (0.8) AU) compared to the towel (1.5 (0.5 AU) and foil space blanket (1.5 (0.8) AU). Thermal comfort was also rated higher in the Dryrobe® (3.5 (0.5) AU) compared to the towel (1.8 (0.8 AU) and foil space blanket (2.2 (0.8) AU).
CONCLUSION: In these data, the Dryrobe® condition had the smallest afterdrop in core body temperature and the largest increase in skin temperature following cold water immersion compared to a towel and a foil space blanket. Thermal sensation and thermal comfort were also rated higher in the Dryrobe® condition. From this initial data, it appears that it would be advantageous to wear a change robe garment such as the Dryrobe® following cold water immersion, although further data is required to substantiate this.

### OP-BM06 Biomechanics and sprinting

#### SPRINT ACCELERATION FORCE-VELOCITY PROFILE DERIVED FROM GPS DATA: A MULTI-DEVICE COMPARISON STUDY

FORNASIER-SANTOS, C.1, ARNOULD, A.1, GUILHEM, G.1, SAMOZINO, P.2, SLAWINSKI, J.1, MORIN, J.B.2

*1 LABORATORY SPORT EXPERTISE AND PERFORMANCE, INSEP, PARIS, FRANCE; 2 LIBM, SAINT-ETIENNE, FRANCE*

INTRODUCTION: Global Positioning System (GPS) is a useful device to analyse high-intensity training and competition demands in many sports (Cummins et al., 2013), and may be used to derive macroscopic sprint mechanical components based on velocity data over time and Newtonian laws of motion. Indeed, a simple field method has recently been validated to compute ground reaction force and running velocity outputs during sprint acceleration from kinematic data (Samozino et al., 2016; Morin et al., 2019). The aim of the present study was to determine the accuracy and reliability of GPS to compute the force-velocity sprint profile on a 40-m linear sprint, in comparison to other field devices that had been previously used to perform this analysis.
METHODS: Eighteen participants performed 3 sprints on a 40-m outdoor track, with a 3-point start. A laser (Muscle Lab; 1000 Hz), 1080 Sprint (1080 motion; 333 Hz), Radar (Stalker Pro II; 48 Hz), timing gates (Witty Microgate; 0, 5, 10, 15, 20, 30, 40 m) and a GPS unit (Catapult Vector S7; 10 Hz) were used to record running velocity during each sprint. Force-velocity profiles for the 2 best trials were computed for the 5 devices from the method proposed by Samozino et al. Maximal velocity (Vmax), Tau, theoretical maximal velocity (V0) and horizontal component of the ground reaction force (F0) were calculated. For velocity recording devices, data retained for analysis ranged between 0.5 m.s-1 and the last velocity point of the Vmax plateau. Mean, standard error and absolute bias were computed on the main variables to compare data between the different devices and more especially between GPS and the 1080 Sprint, considered as a 'silver standard'. Coefficients of variation (CV) were calculated for each variable between the 2 best trials to assess reliability.
RESULTS: Vmax was close between 1080 Sprint (8.02±1.20 m.s-1), Laser (8.00±1.15), Radar (8.00±1.15), timing gates (8.04±1.15) and GPS (8.01±1.18). However, Tau showed larger differences between 1080 Sprint (1.22±0.12 s), Laser (1.18±0.12), Radar (1.24±0.12), timing gates (1.25±0.11) and GPS (1.29±0.16). While GPS Vmax remained close to 1080 Sprint with a standard error of -0.006±0.085 m.s-1 (CI: -0.210 ; 0.188) and an absolute bias of 0.98± 0.78%, GPS Tau was higher compared to 1080 Sprint with 0.067±0.128 s (CI: -0.184 ; 0.319) and 9.55±7.50%, respectively. The following inter-trial CVs were obtained across the five devices for Vmax and Tau, respectively: 1080 Sprint (15.0%; 9.4%), Laser (14.3%; 9.8%), Radar (14.4%; 9.4%), timing gates (14.3%; 8.9%) and GPS (14.7%; 12.2%).
CONCLUSION: Given the inter-device and inter-trial differences observed, the GPS system tested here can be considered a relevant system to compute force-velocity sprint profile using Samozino et al.'s validated approach. However, data interpretations should be context- and device-dependant. These results suggest several practical applications such as regular analysis of the sprint mechanical profile in prevention or injury management.

#### CONCURRENT VALIDITY OF AN INERTIAL MEASUREMENT SYSTEM TO DETERMINE SPRINTING CENTER OF MASS VELOCITY AND FORCE-VELOCITY-POWER PROFILES IN WELL TRAINED SPRINTERS

MILLOT, B.

*FRENCH INSTITUTE OF SPORT - FRENCH ATHLETICS FEDERATION*

INTRODUCTION: The use of inertial measurement systems (IMS) to perform on-field kinematic analysis of sports activities has gained interest over the past decade. IMS have shown good concurrent validity for whole body 3D kinematic analysis in comparison to optoelectronic systems (OS) for different activities and high-velocity sport disciplines [1, 2, 3]. A recent comparison of the force-velocity-power profiles (FVP) mechanical variables computed from the center of mass (COM) velocity-time curve using an IMS and the athlete's velocity measured with a radar [4] found good agreement between both systems for the theoretical maximal force, the theoretical maximal velocity and the associated maximal power output. However, radars measure the velocity of all moving objects within their scope, not specifically the COM velocity. Therefore, the comparison of the COM velocity between IMS and force platforms (FP) has not yet been done.

METHODS: Nineteen (15 male and 4 female) sprinters (mean ± SD: age = 23.9 ± 3.7 years; body mass = 73.9 ± 7.4 kg; height = 178.8 ± 7.0 cm) performed 5 straight-line sprints (10, 15, 20, 30 & 40 m) during which COM velocity was measured with both an IMS (MVN Biomech Link device, Xsens Technologies BV, Enschede, The Netherlands) sampling at 240 Hz and 6 FP connected in-series (1.2 x 0.6 m, KI 9067; Kistler, Wintherthu, Switzerland) sampling at 1 000 Hz and embedded within the track. Averaged step-by-step and maximal COM velocity for each sprint, as well as the FVP relationships and the associated mechanical variables already presented by Samozino et al. [5] over a reconstructed 40-m sprint were computed with both systems and compared using Pearson's correlations coefficient as well as bias and limits of agreements.
RESULTS: Mean IMS step-by-step velocities were very highly to almost perfectly correlated with those calculated from FP data ($0.897 < r < 0.983$; $p < 0.001$), and mean bias was low (between -4.87 to -0.61% for the different intervals). Correlations for FVP mechanical variables between the IMS and FPs ranged from moderate to almost perfect ($0.609 < r < 0.989$; $0.01 < p < 0.001$) with mean bias comprised between -5.43 to 0.97% for all FVP variables.
CONCLUSION: The present findings showed good to excellent concurrent validity between data from an IMS and FPs for the computation of the COM velocity-time curves and the FVP mechanical variables computed from the reconstructed 40-m sprint. Together with studies that demonstrated the validity of IMS data for the computation of 3D kinematics in various high-velocity movements, these results show that IMSs can be used to compute on-field 3D joints' and segments' kinematics as well as COM velocity-time curves and FVP either indoors or outdoors.

**RELATIONSHIPS BETWEEN STARTING BLOCK PERFORMANCE AND DYNAMIC STRENGTH INDEX IN ELITE SPRINTERS**

CAVACA, M.L.1,2, ABRANTES, J.M.2, VALAMATOS, M.J.1,2

*1.BETTERY LIFELAB, BETTERY S.A., ; 2.FACULTY OF HUMAN KINETICS – LISBON UNIVERSITY*

INTRODUCTION: In short sprinting events like 100m race, performance at the starting block (SB) phase has a critical importance to the final outcome. Among different variables mentioned as critical of SB performance, normalized average horizontal power (NAHP) was identified as the most appropriate measure of performance [1]. This indicates that the athletes ability to produce horizontal power (HP) in a short period of time is a decisive factor in this phase of race. Thus, it is of great interest for strength and conditioning coaches who work with sprinters to understand the associations between athletes SB and their lower limbs strength and power qualities.
We aim to understand the relationship between SB performance of elite male sprinters and their lower-body dynamic strength index (DSI).
METHODS: Eleven male elite sprinters, (age 23.5 ± 2.9 years; height 1.82 ± 0.04m; body mass 76.8 ± 5.9kg; 100m PB, 10.56 ± 0.27s), performed 3 maximal 10m sprints start on an indoor track, from instrumented SB (Kistler Instruments AG. Winterthur. Switzerland), sampling at 1000 Hz. Block performance was quantified trough NAHP as described by Bezodis et al. [1], where the HP was averaged over the duration of the block phase and normalized to sprinters' body mass and leg length. The best NAHP obtained over 3 trials were used for analysis. To determine DSI, all sprinters performed 3 trials of isometric mid-thigh pulls (IMTP) (isometric task) and countermovement jumps (CMJ) (dynamic task) on a homemade force platform (Shear Beam Load Cells - Flintec BK2) and connected to an A/D converter (MP100 – Biopac Systems Inc. 16 bits) with a sampling rate of 1000 Hz. Best trails were used for analysis. Vertical ground reaction peak force (PF) attained during CMJ was divided by the PF attained in the IMTP to obtain the DSI, as described by Comfort et al [2]. Pearson's correlation coefficients (r) were used to test the relationship between dependent variables. A statistical significance was set at $\alpha = 0.05$.
RESULTS: NAHP was correlated with the block velocity ($r = 0.60$; $P = 0.03$). Furthermore, a very large significant correlation was identified between the NAHP and DSI ($r = 0.85$). A very large significant correlation was also observed between NAHP and CMJ force ($r = 0.86$). No significant associations were observed between NAHP and IMTP force ($r = -0.26$; $P = 0.220$).
CONCLUSION: The main conclusion was that NAHP has strong associations with muscle power indicators, measured through CMJ and DSI. These results indicated that DSI and CMJ can be used as indicators of SB performance, in elite male sprinters. These results also highlighted the importance of high-power capacities for a successful sprint start. Thus, the sprinters' strength and power qualities regularly monitored through DSI are very important and determinant to individualize strength-training programs and optimize training stimulus for overall performance improvement.

**EFFICIENCY AND KINEMATIC ANALYSIS OF INITIAL STEP PATTERNS FOR MULTIDIRECTIONAL ACCELERATION IN TEAM AND RACQUET SPORTS**

VUONG, J., VOß, P., FERRAUTI, A.

*RUHR UNIVERSITY BOCHUM*

INTRODUCTION: The ability for quick multidirectional accelerations over short distances is crucial for athletic performance in team and racquet sports (Northeast et al., 2019; Taylor et al., 2017). So far, there is only few research dedicated to the different initial step patterns usually applied by players. Therefore, the present study investigated the kinematic characteristics and efficiency of the step patterns, Jab Step (JS), Pivot Step (PS), Gravity Step (GS) and Counter Step (CS).
METHODS: Twenty-two male competitive team and racquet sport athletes (age: 22.1 ± 2.7 years; height: 185.9 ± 7.3 cm; body mass: 84.1 ± 9.9 kg) completed maximum lateral accelerations (90° to the start position) utilizing four different initial step patterns (JS, PS, GS, CS). The step patterns were trained in a familiarization session until reaching a performance plateau (2.5% deviation of three successive sprints, relative to the fastest attempt). On one experimental day for each of the four step patterns, three 5m sprints into both directions (left & right) in response to a visual stimulus were completed. Sprint times (5 m) and the translation of the center of mass (CoM) as well as joint angles of the hip, knee and ankle joints from movement initiation were obtained using three-dimensional motion analysis (Vicon). The sequence of the four step patterns was matched in a counterbalanced order. Resting time was 30s between sprints followed by a 3 min rest after three trials.
RESULTS: The 5 m sprint times of the CS were significantly faster compared to GS and PS for both directions ($p<0.01$). A detailed distance-time analysis revealed that for shorter distances (<100 cm) only the JS was faster than the GS ($p<0.01$) while no advantage for CS compared

to any other step pattern remained. Regarding the sequence in which the maximum angular velocities in the hip, knee, and ankle were reached during push off, there was a proximal-to-distal sequence for JS and CS, while the hip reached its maximum angular velocity before the knee for GS and PS.
CONCLUSION: The results reveal that the JS and the CS are superior for accelerations towards the lateral. Specifically, they indicate that the JS is more suitable for covering very short distances and the CS is superior for covering further distances. In addition, the distal-to-proximal sequence of the maximum angular velocities during push-off in the GS and the PS might indicate a lower kinematic efficiency.

## THE EFFECT OF HIP EXTENSION VELOCITY ON THE ASSOCIATION BETWEEN HIP EXTENSION TORQUE AND SPRINT HORIZONTAL FORCE IN ELITE ATHLETES

HEGYI, A.1, FORNASIER-SANTOS, C.2, HOLLVILLE, E.3, GIROUX, C.3, LEBOEUF, F.4, LACOURPAILLE, L.1, NORDEZ, A.1, RABITA, G.3, SLAWINSKI, J.3, MORIN, J.B.5, DOREL, S.1, HUG, F.2, GUILHEM, G.3

*1.UNIVERSITY OF NANTES, 2.UNIVERSITY COTE-DAZUR, 3.INSEP, 4.CHU NANTES, 5.UNIVERSITY OF SAINT-ETIENNE*

INTRODUCTION: Hip extensors have a major contribution to sprint running propulsion in the early stance phase when glutes and hamstrings shorten at high velocities (1). Considering the difficulties to perform isokinetic testing of this muscle group, hip extensors are typically tested in isometric conditions, which may not reflect the role of hip extensors in sprinting. The aim of this study was to 1) develop a protocol for testing hip extensors in isometric and concentric conditions, and 2) examine the association between hip extension torque measured at different velocities and sprint horizontal force in elite athletes.
METHODS: A total of 82 elite athletes from sprint-based sports (track and field, rugby 7) participated in this two-part study. In Part 1, 13 sprinters/hurdlers performed maximal isometric (50 deg hip flexion) and concentric hip extensions on a dynamometer at four velocities (60, 120, 180, and 350 deg/s) with their dominant leg, in supine position. Contractions were performed with knee flexed to 30 deg (externally fixed), as well as without fixing the knee but asking the athletes to keep it at ~90 deg flexed position. Torque and dynamometer position, and 3-D displacements of reflective markers were recorded. A custom model was used to calculate hip angles, which was used to define relevant dynamometer positions. Differences and correlation between torque in extended and flexed knee positions were calculated. In Part 2, 69 athletes performed isometric and concentric hip extensions (60 and 350 deg/s) without fixing the knee while torque and dynamometer position were recorded. Torque in each condition was analysed over the range of motion defined in Part 1, and was related to the maximal horizontal force in sprinting as measured using a radar during 40m acceleration sprints.
RESULTS: Based on kinematic analysis, dynamometer range of motion of interest was 50 to 0 deg, over which torque was analysed in all conditions. In Part 1, hip extension torque was 29 to 42% higher in the relatively more extended knee position than in relatively more flexed knee position at all velocities ($p<0.01$). The torque measured in the two knee positions significantly correlated in all conditions ($r=0.62$ to 0.89, $p < 0.025$), with the weakest correlation at 350 deg/s. In Part 2, isometric and concentric torque at 60 deg/sec significantly correlated to horizontal force in sprinting ($r=0.53$, $p<0.01$, and $r = 0.48$, $p<0.01$, respectively), however, this association was not significant at 350 deg/s ($r=0.22$, $p=0.06$).
CONCLUSION: In isometric and at slow concentric contractions, evaluating hip extension torque in ~90 deg flexed knee position provides valuable information for elite athletes from sprint-based sports. However, at high velocity, hip extensors should be tested in a relatively extended knee position.

## NEUROMUSCULAR AND AUTONOMIC RECOVERY AFTER A SINGLE SPRINT INTERVAL SESSION

LLORIA-VARELLA, J., RAVEL, A., KORAL, J., BUSSO, T.

*UNIVERSITÉ JEAN MONNET SAINT-ETIENNE*

INTRODUCTION: Sprint Interval Training (SIT) is known to be a very effective approach for improving both the anaerobic and anaerobic pathways in very short periods of time (1). However, since high-intensity exercise creates a large accumulation of physiological stress, the time required to fully recover after a SIT session needs to be considered for practitioners and coaches aiming to optimize training prescription. Previous works have reported impaired performance and delays in recovery of up to 24 to 72h for the neuromuscular system (2) and up to 48h for the cardiac parasympathetic reactivation (3). The aim of this study was to determine whether the neuromuscular and autonomic nervous systems would be impaired 24 and 48 hours after a single session of SIT.
METHODS: 21 healthy and recreationally active subjects (8 females) performed an 8x15s all-out session on a cycle ergometer with two minutes of recovery between repetitions after a familiarization session comprising 3x15s all-out sprints the week before. Blood lactate concentration ([LA−]b) was measured 3 minutes after the last sprint. A complete neuromuscular evaluation during both isometric and dynamic conditions was performed before (PRE), 24 (POST24h) and 48h (POST48h) after the session. Knee extensor maximal voluntary contraction (MVC), voluntary activation (VA), high- and low-frequency doublets (Db100 and Db10) as well as maximal force, velocity and power during two 7s sprint on cycle ergometer at two different loads were analyzed. Additionally, participants were asked to record their heart rate the previous and the three subsequent nights to the session to assess heart rate variability (HRV).
RESULTS: [LA−]b was 13.4 ± 2.5 mM after the session. No significant impairment at POST24h and POST48h was observed for the MVC ($p = 0.24$), Db10:Db100 ratio ($p = 0.15$) nor VA ($p = 0.08$). From a dynamic standpoint, no impairment was observed at POST24h and POST48h for maximal force ($p = 0.11$), velocity ($p = 0.88$) or power ($p = 0.63$). Finally, HRV did not reveal any significant changes the nights following the SIT session (rMMSD; $p = 0.17$).
CONCLUSION: In conclusion, despite of the great physiological stress accumulation, a single session of SIT did not induce significant fatiguing effects in either the neuromuscular or on the autonomic nervous system from 24h after its completion.
Key words: sprint interval training, neuromuscular fatigue, recovery, heart rate variability

## OP-MH08 Injury Prevention

### ATHLETES' PROTECTION FROM CONCUSSION IN DIFFERENT OLYMPIC COMBAT SPORTS. LET'S START FROM THE RULES

ARRIAZA, R., MARTÍNEZ DE QUEL, O., GÓMEZ, M., AUGUSTOVICOVA, D.
*UNIVERSITY OF A CORUÑA*

INTRODUCTION: In the past decade, sports-related concussions have drawn considerable attention from the public, the media, and sports medicine professionals. Epidemiological reports provide convincing evidence that numerous concussions occur at all levels of sport activity, but little is known about the differences in the level of protection that rules offer to the athletes in different sports, especially in those where risks are higher, as combat sports.
METHODS: A revision of the rules of the different Olympic combat sports (boxing, taekwondo, judo, wrestling, fencing and karate)was done, in order to compare the level of protection (in trms of protective equipement, level of impact allowed, umpires decisions in case of a concussion, and protective time to return to sports after a concussion) both in adults and in adolescent athletes.
RESULTS: Only two sports (boxing and taekwondo) allow concussion as a way to victory in a match, both in adults and in athletes over 16 years of age. Competition rules in karate restrain impact force in younger athletes to that which would no represent a significant energy transfer to the head of the athlete (i.e.: no displacement when receiving the hit). Protection period after a concussion ranges from 7 days in Judo to 30 days in boxing and Taekwondo, although only karate rules impose a longer period after a second concussion (3 months) and even longer after a third one (one year). Helmets are used in boxing for females and for under 18 year old boxers; they are used in taekwondo through all ages, as they are instrumented with contact sensors, as they are in fencing. Protection gloves are quite different in boxing, karate and taekwondo, both in size and weight. Rules in taekwondo and karate give extra points to hits in the head area compared to the body
CONCLUSION: In light of the obvious differences among the different combat sports, it is not possible to unify criteria regarding protective equipement, but probably a more uniform joint effort to establish protection criteria regarding time to return to sport should be set. Also, the fact that the head offers a higher score in karate and taekwondo, and that the goal of redeeming an oponent out of combat is clearly easier in boxing through head impacts than through body punches, clearly encourages using the head as target and increases the risk of concussions.

### FOAM-ROLLING AND NEUROMUSCULAR EXERCISES AS INTERVENTION TO PREVENT THE OCCURRENCE OF RUNNING-RELATED INJURIES IN RECREATIONAL RUNNING.

JUNGMALM, J., DESAI, P., BÖRJESSON, M., KARLSSON, J., GRAU, S.
*UNIVERSITY OF GOTHENBURG*

INTRODUCTION: Recent years have seen an increasing interest in research on the prevention of running-related injuries (RRIs). Interventions including, but not limited to, running training programs, running shoes, and foot muscle strength with varying effectiveness have been conducted (1, 2, 3). Some factors such as improved muscular strength, proprioceptive balance, and flexibility are pointed out as possible mechanisms in an injury prevention program. Conditioning exercises such as neuromuscular control and foam rolling exercises have been suggested to improve these factors. However, the effectiveness of a program consisting of neuromuscular control and foam-rolling exercises in combination has not yet been evaluated. Therefore, the aim of this study was to compare the cumulative injury incidence proportion (CIP) of RRIs between runners who received an injury prevention program with runners who did not receive a program, over the course of 18 weeks.
METHODS: We invited 433 recreational runners (n=203 female) to participate in the study. The intervention group (n=228) performed neuromuscular control and foam-rolling exercises twice a week for 18 weeks. The control group (n=205) received no treatment. Running volume and running-related pain were reported weekly using an online questionnaire. Compliance with the intervention program was defined according to the number of sessions (low=<18, intermediate=18-31, high=32-40). Time-to-event statistics were used to calculate the CIP at 18 weeks for both groups respectively, as well as for each intervention subgroup with regard to compliance.
RESULTS: The CIP for the intervention group was 23.0% (95%CI=17.8-29.4) and 27.1% (95%CI=21.4-33.9) for the control group. The CIP for intervention subgroups were 43.2% (95%CI=32.8-55.4), 16.0% (95%CI=9.0-27.8), 4.6 (95%CI=1.5-13.6) for the low, intermediate, and high group, respectively. In total, 100 RRIs were sustained.
CONCLUSION: Although no difference between the intervention group and the control group was observed, runners with higher compliance with the intervention were less likely to sustain an RRI compared with the control group. Therefore, despite the program was not effective in reducing the occurrence of RRIs on a group level, it may be beneficial for certain types of runners or beneficial if a certain dose (e.g. at least twice a week) is implemented.

### PHYSICAL LITERACY FOR SPORT INJURY PREVENTION – BUILDING THE BASE FOR ATHLETE DEVELOPMENT

PIKE, I., RICHMOND, S., BABUL, S., JACOB, J.

*UNIVERSITY OF BRITISH COLUMBIA/UNIVERSITY OF TORONTO*

INTRODUCTION: Participation in sport and recreation is a common mechanism for physical activity (PA) among youth. Decades of scientific literature documents participation in sport and PA resulting in positive health outcomes. Despite some literature supporting a relative decline in the number of youth participating in PA generally, studies suggest that over 80% of Canadian youth participate in at least one organized sport, annually. However, the landscape of sport participation in youth in Canada is changing. Increasingly, we note that there are two ends to the sport participation spectrum, one where athletes participate in intense amounts of PA and experience more frequent training, compared to youth at the other end who are less physically active, have low muscular strength and mastery of skills. This dichotomy paints a bleak picture for the physical literacy and overall health in youth, including the athletes that will form the base of athletic programs in the future. Further, and most importantly, literature supports an increase in the risk of sport-related injury at both ends of the spectrum.
The objective of this work was to highlight the similarities in physical literacy (PL) and sport injury prevention programming for athlete development, to develop a resource that supports the work of athlete development across sectors, and to discuss opportunities for collaboration for athlete development that includes injury prevention, across the athlete lifespan.
METHODS: Practitioners in both elite and recreational sport requested an accessible resource to support both athlete development and injury prevention. An on-line resource that provides evidence-informed injury prevention strategies using an integrated knowledge translation approach was co-created. A framework was used to guide a literature review of over 50 sport and recreational activities, across outcomes consistent with the public health approach to prevention. Key to the process of resource development was engagement with a team of stakeholders including athletes, coaches, and experts in physical literacy, injury prevention and public health.
RESULTS: The resource presents summaries of evidence on prevalence and risk factors, as well as effective interventions for sport injury that can be used across sporting activities. The resource presents both the scientific literature as well as resources that support the critical components of both physical literacy and sport injury prevention programming for youth, including neuromuscular training (NMT).
CONCLUSION: Active & Safe Central (www.activesafe.ca) is a resource that addresses an identified gap in access to evidence and resources for athlete development. The resource emphasizes the priority for both physical literacy and NMT for athlete development that includes sport injury prevention at an early age. Further, collaboration across sectors including education, elite and recreational sport, and public health is critical for a comprehensive approach to healthy athlete development.

### THE IDENTIFICATION OF PRIORITY TOPICS FOR RESEARCH AND COCHRANE REVIEWS ON INTERVENTIONS DESIGNED TO PREVENT SPORTS INJURIES: A THREE-PHASE INTERNATIONAL CONSENSUS PROJECT

MACMILLAN, G., HARRISON, S., CHESTERTON, P., PORTAS, M., HANDOLL, H., ELLIOTT, J., ATKINSON, G.

*TEESSIDE UNIVERSITY*

INTRODUCTION: Injury prevention is important for sustaining a physically active lifestyle, and to help maximise health and societal benefits. For the best use of research funding, time and efforts, it is important to identify research priority topics using formal mixed methods that involve researchers and end-users of research. Such approaches are rare in exercise science. In collaboration with the Cochrane Bone, Joint and Muscle Trauma Group, we conducted a three-phase project aiming to identify priority topics for Cochrane Reviews and primary research of interventions used to prevent lower and upper limb sports injuries in adults.
METHODS: After a rigorous formulation and piloting process, online surveys were completed by 357 sports participants (aged 16-84 years) from 29 countries, and by 227 people (aged 16-69 years) from 27 countries in roles that supported sports participants. Posed questions related to employed injury prevention strategies, reasons for use, potential drawbacks and future research topics. Recruitment was completed via social media outlets. For the subsequent three-round electronic Delphi study, a panel of 28 expert researchers were recruited by purposeful sampling with set criteria, e.g., publication records. In the first round, participants were asked to state in their opinion, the three most important topics for future injury prevention research. In the subsequent rounds, consensus ratings on a 1-9 GRADE scale were obtained to arrive at perceived priorities for future Cochrane Reviews. For each project phase, web-based platforms were used where opinions were collated and synthesised using formal content analysis methods.
RESULTS: Suggested topics were numerous and heterogeneous within, and between, each phase of the project. Sports participants deemed areas relating to individual (personalised) athlete approaches, nutritional interventions, and strength and conditioning interventions to be most important for future research, with 12%, 11% and 11% of total responses relevant to each respective theme. Sports support staff prioritised training load interventions (18%), strength and conditioning interventions (12%) and individual (personalised) athlete approaches (7%) to be priority topics. The response rates for Rounds 1, 2 and 3 of the eDelphi were 89%, 92% and 87%, respectively. The first round identified 74 priority topics. At the end of the final round, 85% of the participant cohort graded training load to be of critical importance (7-9 on the GRADE scale). Additionally, 65% and 60% of the participant cohort deemed neuromuscular training and psychological interventions to be of critical importance.
CONCLUSION: Common priority topics across the first two project phases related to individual athlete (personalised) approaches, nutritional interventions and strength and conditioning interventions. In the eDelphi study, training load interventions, neuromuscular training and psychological interventions were deemed to be the most important by experienced researchers.

### UNDERSTANDING HEAD IMPACT EXPOSURE IN MALE AND FEMALE AMATEUR OLYMPIC BOXERS

JONES, C., MELOTTI, L., BROWN, M.R., LOOSEMORE, M.

*SPORTS & WELLBEING ANALYTICS, SWANSEA UNIVERSITY, UNIVERSITY COLLEGE LONDON*

INTRODUCTION: Amateur boxing is a high-intensity intermittent combat sport, which results in the accumulation of sub-concussive head impacts during competition. It has been debated in a number of combat and collisions sports that the result of repetitive head impact exposure is associated with long term neurodegeneration. There is currently a gap in understanding the relationship between head impacts and neurological function due to a lack of quantification of forces that individuals are exposed to in competition. This study aimed to characterize impact exposure and the associated injury metrics of amateur male and female international boxers during an Olympic qualifying competition via an instrumented mouthguard monitoring system.
METHODS: Thirteen amateur international Olympic boxers took part in an Olympic qualifying event (29.8±5.5 yrs, 1.79±0.03 m, 70.5±11.9 kg). Head accelerations were measured using the PROTECHT instrumented mouthguard (IMG) system (Sports & Wellbeing Analytics, UK).

Linear and angular acceleration signals were filtered using a zero-phase lag 4th order Butterworth filter, with a low-pass cut-off frequency of 160 Hz. Head impact accelerations were compared across impact events, rounds, weight class and sex. Impacts were video-verified and classified according to event (jab, hook, movement, overhand and uppercut) and location (head and body). Multi-level linear models compared peak linear acceleration (PLA) and peak rotational acceleration (PRA) head impact values across striking events (jab, hook, movement, overhand and uppercut), rounds (1-3), weight class (light, middle and heavy) and sex (male v female).
RESULTS: IMG data was collected from 15 bouts and 45 rounds. A total of 1542 head impacts were identified and video verified, with mean values of 24.0±12.3 g and 2411±1627 for PLA and PRA. No differences were observed across sex or weight for PLA and PRA values ($p > 0.05$). Significant differences ($p < 0.05$) were observed between linear acceleration for striking events jab and hooks when compared to overhands ($p < 0.05$), but no differences were observed rotationally ($p > 0.05$). Head acceleration impacts recorded in rounds and bouts were 33±16 and 94±44, but no round or bout differences were observed across sex or weight categories ($p > 0.05$).
CONCLUSION: Characterisation of impact exposure identified no differences between male or female athletes or different weight categories. The overhand attributed higher linear intensity values compared with the jab and hook. Though no significant the female cohort and lighter weight cohorts attained greater impact volumes than the male and heavier cohorts, whereas the male and heavier cohorts attained greater striking magnitudes. The results provide the first evidence of head impact exposure of amateur international Olympic boxers in competition.

## Oral presentations

### OP-PN29 Supplements III

#### LOW DIETARY ACID LOAD IS ASSOCIATED WITH LOWER CORTISOL AND LEUKOCYTE RESPONSES TO EXERCISE AFTER A 12-WEEK DIET AND TRAINING INTERVENTION

HIETAVALA, E., IHALAINEN, J., MERO, A.

*UNIVERSITY OF JYVÄSKYLÄ*

INTRODUCTION: Physical exercise is considered a stressor that promotes an acute suppression of the immune system, which can be seen e.g., as an increased number of leukocytes. We investigated acute cortisol and leukocyte responses to endurance and strength training after a 12-week combined endurance and strength training and dietary intervention period.
METHODS: In all, 46 healthy, recreationally active men and women participated in the study and were randomly divided into low dietary acid load (L-DAL) and moderate dietary acid load (M-DAL) groups for 12 weeks. In L-DAL there were 9 men (age 32.0 ± 9.6 yr, body mass index 27.2 ± 3.1 kg/m2) and 13 women (34.3 ± 6.9 yr, 23.0 ± 3.5 kg/m2), and in M-DAL 12 men (31.3 ± 5.1 yr, 25.2 ± 2.1 kg/m2) and 12 women (32.0 ± 5.9 yr, 23.7 ± 3.5 kg/m2). L-DAL was advised to increase the consumption of fruits and vegetables (pre: 340 ± 180 g vs. post: 970 ± 560 g) and M-DAL was advised to limit their intake of fruits and vegetables (pre: 270 ± 180 g vs. post: 250 ± 210 g). The aim was that potential renal acid load (PRAL) of L-DAL was alkalogenic (pre: 7.19 ± 27.6 vs. post: -48.1 ± 34.6 mEq/d), whereas during M-DAL, PRAL was aimed to be acidogenic (pre: -30.4 ± 42.2 vs. post: 4.17 ± 17.3 mEq/d). The participants trained twice a week, and every standardized training session consisted of both endurance and strength training. Participants performed a submaximal cycling test (CT) with three 8 min workloads at 35%, 55% and 75% of their VO2max before (PRE) and after (POST) the intervention. All workloads were separated by 4-min rest periods, during which venous blood samples were collected (CT35, CT55, CT75). On the following 4 days after the cycling test, blood samples were obtained after an endurance training session (ET), a strength training session (ST) and on follow-up days 1 and 2 (F1 and F2).
RESULTS: In L-DAL, cortisol was lower during CT and on F1 at POST as compared to PRE (PRE vs. POST at F1: 348 ± 35 vs. 309 ± 31 nmol/l, $p<0.05$). Furthermore, in L-DAL, the total number of leukocytes was significantly lower during CT, after ET, after ST and on F1 at POST as compared to PRE (PRE vs. POST at CT35: 7.42 ± 1.26 vs. 6.51 ± 1.30, $p<0.01$; CT55: 8.09 ± 1.26 vs. 7.08 ± 1.19, $p<0.01$; CT75: 9.40 ± 1.67 vs. 7.89 ± 1.69, $p<0.01$; ET: 9.52 ± 2.57 vs. 7.99 ± 1.77, $p<0.01$; ST: 9.17 ± 2.14 vs. 7.89 ± 2.87, $p<0.05$; F1: 6.59 ± 1.22 vs. 5.77 ± 1.26 E9/l, $p<0.01$). This was due to a significantly lower neutrophil count in L-DAL during CT, after ET and on F1 at POST as compared to PRE. In M-DAL, lymphocytes were lower during CT and cortisol higher after ET at POST as compared to PRE.
CONCLUSION: The acute cortisol and leukocyte responses to exercise were suppressed after the training period especially in the group of lower dietary acid intake. These results suggest that increased intake of fruits and vegetables may suppress acute exercise-induced stress and immune response, and this effect may be sustained for up to 24 hours post-exercise.

#### THE EFFECTS OF 24-WEEK PREBIOTIC INTERVENTION ON MARKERS OF IMMUNITY AND UPPER RESPIRATORY AND GASTROINTESTINAL SYMPTOMS IN ELITE RUGBY UNION PLAYERS: A PILOT RANDOMISED CONTROLLED TRIAL

PARKER, C.J., JOHNSON, M.A., HUNTER, K.A., SHARPE, G.R., WILLIAMS, N.C.

*NOTTINGHAM TRENT UNIVERSITY*

INTRODUCTION: Elite athletes are exposed to physiological and psychological stressors that may impair immunity and increase the risk of upper respiratory (URS) and gastrointestinal symptoms (GIS). Gut microbes have a substantial influence on systemic immune function (Roberfoid et al., 2010). Dietary prebiotic galactooligosaccharides are effective at altering the gut microbiome and have been shown to reduce URS in academically stressed students (Hughes et al., 2011). Whether prebiotics could also reduce URS and GIS in elite athletes is unclear. Therefore, the aim of this study was to investigate the effect of a 24-week prebiotic intervention on markers of immunity and URS and GIS in elite rugby union players during a regular playing season.
METHODS: Thirty-three elite male rugby union players were randomised to receive 2.9 g/d of either Bimuno-galactooligosaccharide (B-GOS; n=16) or a maltodextrin placebo (PLA; n=17) for 24 weeks in a double-blind design. Daily URS and weekly GIS were self-reported using questionnaires. At baseline (B), 12 weeks (12W) and 24 weeks (24W) salivary immunoglobulin A (sIgA) and plasma C-reactive protein (CRP) and tumour necrosis factor alpha (TNF-α) were measured.
RESULTS: There was no between-group difference in URS incidence or severity, but the mean duration of episodes was shorter in B-GOS (7.4 ± 2.8 days) than PLA (9.8 ± 4.1 days) ($P = 0.04$). Area under the curve of weekly GIS scores were lower in B-GOS (Median [IQR], 50 [10.5-139.5]) than PLA (Median [IQR], 149 [69-208]) ($P = 0.03$). The number of symptom free weeks for GIS was higher in B-GOS than PLA ($P = 0.04$). SIgA secretion rate at B and 12W was not different between-groups however, at 24W it was greater in B-GOS (Median [IQR], 142

µg/min [94.9-155.0]) than PLA (Median [IQR], 86 µg/min [71.5-105.5]) (P = 0.01). Plasma CRP and TNF-α did not differ between groups across the study (P > 0.05).
CONCLUSION: Twenty-four weeks of a prebiotic B-GOS intervention reduced the duration of URS, the incidence and severity of GIS and enhanced sIgA secretory rate in elite rugby union players. These findings suggest that B-GOS has the potential to modulate immune function and reduce illness, which may improve an athlete's availability to train and compete.

## SIGNIFICANT IMPROVEMENTS IN COGNITIVE PERFORMANCE AND WELLBEING WITH A BIFIDOBACTERIUM LONGUM 1714-SERENITAS PROBIOTIC SUPPLEMENT – AN ATHLETE EXPERIENCE PROGRAMME

SORENSEN, K.1, KUPUSERAVIC, J.2, JACKMAN, J.S.2

*1 MEDICAL AFFAIRS, NOVOZYMES, CORK 2 SCIENCE TEAM, ART HEALTH SOLUTIONS, GATESHEAD*

INTRODUCTION: Intensive training is associated with changes in the composition of the gut microbiota in athletes. The implications of this may extend beyond physical health, affecting cognitive performance and mental wellbeing via the gut-brain axis [1]. Clinical studies have demonstrated strain-specific cognitive benefits of probiotic supplementation in healthy volunteers, yet real-world data in athletes is limited [1]. This athlete experience programme evaluated cognitive performance and wellbeing outcomes before and after 8 weeks of probiotic supplementation.
METHODS: Athletes volunteered or were referred to the experience programme by their nutritionist and/or coach, to receive a daily probiotic supplement containing Bifidobacterium longum 1714-Serenitas (1x10^9 colony-forming units) and B vitamins, for 8 weeks. Reaction time (Simple Reaction Time test), decision-making (adapted Stroop task), distractibility (adapted Flanker task) and perceived stress (Likert scale) were assessed via the Omics [TM] app at weeks 1, 3, 4, 6 and 8. Perceived sleep quality and energy levels were measured via an online survey prior to starting the programme and at week 9. Data analysis compared the Loading period (weeks 1-4) vs the Observation period (weeks 6-8), including paired samples T-test for cognitive performance data and perceived stress levels. Data are presented as percentage of athletes who improved and average percentage change over time.
RESULTS: 35 athletes completed the programme (75% aged 18-34 years, 25% aged 35-54; 81% male, 19% female; 61% team sports (football, rugby, netball, hockey), 39% individual sports (golf, cycling, athletics)). Significant improvements were observed for reaction time (63% of athletes; 4% average improvement, p=0.008) and decision-making (72% of athletes; 5% average improvement, p=0.006). 43% of athletes reported improvements in distractability, equating to a 3% average improvement, p=0.196 ns). Improvements in perceived stress were reported by 66% of athletes, with a 6% average improvement (p=0.015). Sleep quality and energy levels reportedly improved among 58% and 54% of athletes, respectively. 87% would recommend the 1714-Serenitas supplement to other athletes.
CONCLUSION: These real-world data suggest that supplementation with Bifidobacterium longum 1714-Serenitas was associated with improvements in cognitive performance, stress, sleep quality and energy levels in athletes, among whom marginal gains may significantly impact performance. Similar findings have been observed in pre-clinical and clinical trials of this strain without B vitamins [2,3], suggesting a strain-specific probiotic effect. Further research into the athletic applications of specific probiotic strains and their mode of action is warranted.

## THE USE OF TART CHERRY SUPPLEMENTATION BY SPORT SCIENCE PRACTITIONERS, SUB-ELITE AND ELITE ATHLETES: PRACTICES AND ATTITUDES

SABOU, V.1, WANGDI, T.1,2, O'LEARY, M.1, KELLY, V.3, BOWTELL, J.1

*1SPORT AND HEALTH SCIENCES, UNIVERSITY OF EXETER; 2SCHOOL OF HUMAN MOVEMENT AND NUTRITION, UNIVERSITY OF QUEENSLAND; 3SCHOOL OF EXERCISE AND NUTRITION SCIENCES, QUEENSLAND UNIVERSITY OF TECHNOLOGY*

INTRODUCTION: Tart cherry (TC) supplementation has been shown to accelerate post-exercise recovery, enhance endurance performance and improve sleep duration and quality. The efficacy of dietary supplements depends on using an effective supplementation protocol, which may not always be the case in applied practice. Therefore we investigated the use of TC supplementation by sport science practitioners, sub-elite and elite athletes and compared this use to evidence based practice.
METHODS: An online survey (Qualtrics, WA, USA) was completed anonymously by sport science practitioners (professionally registered and providing supplementation advice) and athletes competing at various levels . Frequency analysis was conducted for all questions and the results were presented as percentage of responses. Chi squared analysis was used to assess the impact of professional experience on TC recommendations for sport science practitioners and the influence of the competition level on TC supplementation practices for athletes.
RESULTS: Thirty-five practitioners completed the survey. TC supplements were recommended to athletes by 46% of the respondents (11% - previously recommended TC supplements; 26% have not previously recommended TC supplements but were planning on doing so in the future). Fifty percent of those recommending TC supplements indicated enhancing exercise recovery as their goal, while 26% indicated improved sleep quality/duration. Acute TC supplementation and daily TC use during multi-day competition with a 2-3 day pre-load were the most recommended protocols (28% and 18%, respectively). Fifty-two percent of respondents were unsure of the optimal daily total polyphenol dose. Professional experience level did not alter TC use recommendations (p>0.05). Eighty athletes (52.5% elite ) completed the survey. Twenty -three percent of the athletes used TC supplements and 13% planned to use them. Improved exercise recovery and sleep duration/quality were the most indicated goals (71% and 32% of the respondents, respectively). Thirty-nine percent of athletes were using TC supplements acutely, 32% were supplementing chronically, with the rest utilising a combination of strategies. One day pre and post-load protocols were common (34% and 42%, respectively). No differences in the TC supplementation practices of sub-elite and elite athletes were identified (p>0.05).

CONCLUSION: TC supplements were used by and were of interest to a high proportion of sport science practitioners and to a smaller but nonetheless notable proportion of athletes surveyed. The main goals of the respondents when using TC supplements (enhancing exercise recovery and sleep duration and quality ) only partially matched the current evidence base, with sleep applications being insufficiently evidenced at present. Further, practices of both groups rarely aligned with the protocols found to be effective within the literature in terms of both supplementation duration and polyphenol dose.

## IS-SH03 Current trends on Mental Health in Sport, FEPSAC Invited Symposium

### DUAL CAREER EXPERIENCES PREDICT MENTAL HEALTH OUTCOMES IN EUROPEAN STUDENT-ATHLETES

KEGELAERS, J.

*VRIJE UNIVERSITEIT BRUSSEL*

In recent years, there has been a sharp rise in academic and applied attention for mental health (MH) and well-being (WB) of athletes and their importance have been increasingly emphasized in light of the COVID-19 crisis and the Olympic and Paralympic games. Student-athletes form a commonly sampled subpopulation within mental health research. Nevertheless, a recent scoping review found that only limited attention has been directed towards examining the relationship between athletes' dual career (DC) experiences and their mental health. Therefore, as part of the Erasmus+ Sport project "Dual Careers for Mental Health" (DC4MH), we investigated athletes' DC experiences and MH/WB in six EU countries (Belgium, Denmark, Italy, Spain, Slovenia, Sweden). In total, 1175 student-athletes (age = 19.9, SD = 5.24; 51% female; 38% higher education) completed an online survey including, amongst others, the Mental Health Continuum Short Form (i.e. measuring General, Emotional, Social, and Psychological WB) and the newly developed DC experiences scale (i.e. measuring DC competencies, Negative DC experiences, and DC support).
Following Keyes' three category diagnosis of positive MH, 52% of student-athletes were categorized as "flourishing", 44% as "moderate MH", and 4% as "languishing". Significant linear relationships were observed between all dimensions of DC experiences and MH. Multiple linear regressions showed that DC competencies, negative DC experiences, DC support, Scandinavian background, resilience and MH literacy significantly predicted general WB (R2Adj = .49), emotional WB (R2Adj = .40), social WB (R2Adj = .38), and psychological WB (R2Adj = .42) in European student-athletes. DC competencies and resilience were the strongest predictors for general, emotional and psychological WB, while Scandinavian background was the strongest predictor for social WB. The study findings highlight the important connection between athletes' DC experiences and MH/WB. Developing a more detailed understanding of student-athletes' MH experiences can inform practitioners to develop research-based and contextually informed tools and initiatives focused on MH monitoring, MH literacy and psychological resilience-building strategies.

### 'RECALCULATING ROUTE': NARRATIVES OF ELITE ATHLETES IN THE ROAD TO TOKYO 2020 AND ITS IMPACT ON MENTAL HEALTH

ZAMORA SOLÉ, R.

*UNIVERSITAT AUTÒNOMA DE BARCELONA*

INTRODUCTION: The disruption of the Olympic cycle of Tokyo 2020 caused by the COVID-19 lockdown and the postponement of the Tokyo 2020 Olympic Games forced Olympic hopefuls to go through a series of uncertain and challenging phases. These, event and non-event, can be understood as two concurrent non-normative transitions that could have the potential to put mental health of elite athletes on risk. The aim of the present study is to explore the narratives of elite athletes during the different phases of the disruption of Tokyo 2020, understand how those evolve during time, and their impact on mental health.
METHODS: Eight elite athletes from a high-performance center in preparation for Tokyo 2020 (6 female and 2 male) took part in this longitudinal qualitative study. The data collection was done by a series of semi-structured online synchronous interviews that took place in three specific moments: during lockdown, in the beginning of the 'new normality' and in the pre-Olympic phase. The philosophical position of Interpretivism was used as a companion and extension of the thematic narrative analysis used for data analysis.
Results: Elite athletes define Tokyo 2020s preparation phase as a bumpy road that presented unclear conditions towards the final destination. During their road to Tokyo 2020, three specific time related narratives were identified: (a) lockdown: moving from threat to opportunity; (b) 'new normality': embracing uncertainty and (c) pre-Olympic phase: pulling the handbrake. Two more narratives, (d) giving up the control fallacies and (e) the adaptability as a distinction of being an athlete, were present during the whole preparation process and overlapped with the situational narratives. The overall preparation process showed that the influence of the environment (i.e., coaches, families) and psychological aspects such as resilience are a key protective factor when ensuring elite athletes' mental health.
Conclusions: The road to Tokyo 2020 has allowed us to identify that athletes possess a series of resources to recalculate their route in case of unexpected events and adapt to uncertain circumstances. In this sense, psychological protective factors, such as resilience and adaptability, should be included in career assistance programs as well as psychoeducation for the entourage. Future investigations should explore the experiences of the agents of the environment (i.e., coaches, families) in supporting athletes on non-normative transitions and to explore the post-Olympic transition in this disrupted Olympic cycle.

### EXPLORING BODY IMAGE DURING RETIREMENT FROM ELITE SPORT: PERSPECTIVES FROM RETIRED OLYMPIANS

PAPATHOMAS, A.

*LOUGHBOROUGH UNIVERSITY*

Pressure to be lean for athletic performance gains can lead athletes to adopt an unhealthy preoccupation with body weight and appearance. Athlete body dissatisfaction is prevalent across sports and can lead to disordered eating, negative affect, and poor mental health. Whether body image concerns persist into athletic retirement is a recent focus of research, with insights limited to survey-based data in sub-elite athletic samples. This is the first focused study to explore the meanings elite athletes ascribe to retirement body changes. We recruited 31 retired elite athletes, including 23 former Olympians, to participate in a semi-structured interview. Participants had been

retired for between 1 and 7 years (m = 3.9yrs). More than 25 hrs of interview data was transcribed verbatim and subject to a reflexive thematic analysis. We constructed 4 major themes to describe athlete experiences:1) A legacy of body-conscious culture 2) The struggle for "normal", 3) Loss of body as loss of self, 4) Holding on versus moving on. Athletes explained how the body surveillance culture of elite sport echoed into their post-sport lives. An Olympian identity is an embodied identity, so body changes represent a loss of the self. Accepting the inevitability of physical changes in retirement and finding new meanings and identities, eased body dissatisfaction for many, but the process was fraught with difficulties. Athletes' insights may support sport psychologists and elite sport organisations to devise strategies and policies to facilitate adaptation to body changes post-retirement.

## OP-SH18 Socio-ecological predictors of physical activity

### ARE MATURITY STATUS AND SEX DETERMINANTS IN A PHYSICALLY ACTIVE YOUNG POPULATION? INFLUENCE ON BODY COMPOSITION AND PHYSICAL FITNESS

MANZANO-CARRASCO, S., LÓPEZ-FERNÁNDEZ, J., MAJANO, C., LEÓN-JIMÉNEZ, M., ALONSO-CALLEJO, A.

*UNIVERSITY OF CASTILLA-LA MANCHA*

INTRODUCTION: Maturity cause changes in body composition and physical fitness in children, but it differs among children of the same chronological age as some individuals mature earlier or later than their peers. Evidence suggests that body composition and health in adulthood can be preceded by body composition and physical fitness during childhood and adolescence. Also, these parameters can be improved by physical activity. However, more evidence is needed to understand changes in body composition and physical fitness of active children and adolescents in different maturity states. Therefore, the study aimed to investigate the influence of maturity status and sex on body composition and physical fitness parameters in an active young population.
METHODS: 1682 active children and adolescents (aged 6-17) from rural areas engaged in extracurricular sports participated in this study. Participants were divided into four subsamples depending on sex (boys and girls) and sexual maturity status (prepubertal and pubertal). Data on body composition (body mass index, muscle mass, and fat mass) and physical fitness (20-m shuttle run test, handgrip strength, and vertical jump) were collected. Differences between groups were evaluated through two-way ANOVA (boys vs girls; prepubertal vs pubertal) and correlations were performed to evaluate the relationship between age and physical fitness parameters. The level of significance was set at $p<0.05$.
RESULTS: The results showed that pubertal athletes had higher body mass index, fat mass (kg) and muscle mass (kg) than the prepubertal in both sexes ($p<.05$). Boys had significantly higher muscle mass values than girls in both maturity groups ($p<.001$). In terms of physical fitness, the pubertal group performed significantly better in the 20 mSRT (stages), handgrip strength (kg) and countermovement-jump (cm) than the prepubertal group in both sex groups ($p<.05$). Boys reported significantly higher values in all physical fitness test than girls in both maturity groups ($p<.05$). Nevertheless, the relative data showed the opposite trend. Prepubertal group in both sexes showed a higher percentile value for all physical fitness parameters than the pubertal group ($p<.05$). It should be noted that prepubertal girls showed higher values in the 20 mSRT (pc) than prepubertal boys ($p<.001$).
CONCLUSION: This study suggests that absolute values of body composition and physical fitness improved in pubertal children, while percentile analysis reveals that pubertal children are less fit than prepubertal children. Furthermore, body composition and fitness showed a significant relationship with the maturation process. Thus, it is evident that extracurricular sports activities and physical education classes may not be sufficient to maintain fitness levels in pubertal adolescents.

### A STUDY ON THE FAMILY ENVIRONMENT AND THE IMPACT ON THE SCIENTIFIC FITNESS LITERACY OF CHINESE CHILDREN AND ADOLESCENTS DISTINGUISHING THE FIRST CAREGIVERS

PAN, X., ZHANG, Y., WANG, H., WU, D.

*CHINA INSTITUTE OF SPORT SCIENCE*

Scientific fitness literacy is a localised concept of physical literacy adapted to the Chinese context, measured and validated by the implementation of the National Survey on Fitness Activity. The family environment has a significant impact on psychology and behaviour of children and adolescents in sport. This study focuses on the impact of the home environment that distinguishes a childs first caregiver on SFL.
This study is based on data obtained from the 2020 pre-survey on the physical fitness activity status of children and adolescents by the General Administration of Sport of China . The valid samples recovered for each age group were 540 for ages 3-6, 522 for ages 7-9, 590 for ages 10-12, and 587 for ages 13-18. SPSS19.0 and AMOS22.0 were used for data analysis. The corresponding questionnaire was designed for four age groups(3 - 6, 7 - 9, 10 -12, 13 -18). After examining the reliability and validity of SFL in different age groups, and the best multiple analysis models for different age groups and different family environment sub-influencing factors on SFL were screened out using stepwise multiple regression analysis. we divided each age group into two comparison groups: parents as the primary caregivers (hereafter referred to as "PPC") and neither parent is the primary caregiver(hereafter referred to as "NPPC"), to investigate the differences and similarities in the SFL of children and adolescents by different caregivers.
For children in the 3-6-year-old NPPC group, most parental and family factors did not enter the model, suggesting that the development of childrens SFL shows little sign of any parental involvement and that the influence of the family environment is missing. The most significant sub-factors in 7-9-year-old PPC group is the childs screen time (television, various electronic devices), This phenomenon will become more pronounced as children and adolescents transition to adulthood. In the NPPC group, there is no logical explanation for the positive relationship between the number of electronics owned by households and SFL. We found that many sub-factors showed a lag in NPPC group compared to PPC group. For example, mothers played a role in the 3-6 year old PPC group, whereas it was at age 7-9 years in NPPC group that this factor started to enter the model. (mothers education). The same applies to the role of fathers ( 7-9 years PPC group, while 10-12 years NPPC group)and whether families are willing to pay for their children to attend sports classes(Across the PPC group at ages 7-9, 10-12, and 13-18, but only present in the 13-18 NPPC group model).

Comparing the different age groups, the influencing factors entering the regression model gradually decrease with age, the fewer interventions are available, and the harder it is to improve SFL by changing the family environment. Comparing the PPC and NPPC groups,the PPC group has a higher degree of explanation in the regression model than the NPPC group and more factors enter the model because the parents are not absent and both parents have an influence on their children by preaching and modeling. The PPC group therefore has more interventions and means at its disposal.

## A SOCIO-ECOLOGICAL EXAMINATION OF THE PRIMARY SCHOOL PLAYGROUND: PRIMARY SCHOOL PUPIL AND STAFF PERCEIVED BARRIERS AND FACILITATORS TO A PHYSICALLY ACTIVE PLAYGROUND DURING BREAK AND LUNCH-TIMES

GRAHAM, M.

*TEESSIDE UNIVERSITY*

Using Brofenbrenner's socio-ecological model as a conceptual framework, the objective of this study was to determine playground users (primary school staff and pupils) perceptions of the barriers and facilitators to a physically active school playground at an intra-personal (individual), inter-personal (social), environmental and policy level. Results from a series of qualitative interactions with children (n = 65) from years five and six (9 to 11 years old), and structured interviews with adult teachers (n = 11) revealed key differences in the child and adult perceptions of the playground and the purpose of break-times. A number of inter-related environmental boundaries and school policies were identified as restrictive to children's explorations and activity levels during 'free play' periods, which centred on resource availability, accessibility and health and safety. Further, traditional playground hierarchies act to promote and prevent physical activity engagement for different groups (e.g. gender and age). Finally, differences between the adult and child perception of the primary school playground were observed. Playground physical activity, during break-times appears to be affected by a number of variables at each level of the socio-ecological model. This study provides an opportunity for primary schools to reflect on primary school playground strategies and practices that are implemented at each level of the socio-ecological model to encourage a more effective use of the playground during school break-times.

## CREATING MOTIVATION ENVIRONMENT FOR ADOLESCENTS THROUGH RACKET SPORTS (RACKETLON) FOR LONG LIFE PARTICIPATION AND WELLBEING

GIAKOUVAKI, A., APOSTOLIDIS, N.

*NATIONAL AND KAPODISTRIAN UNIVERSITY OF ATHENS*

Introduction
The promotion of long life active participation in individual and team sports has a special influence on the specifics of the sport, the training process, sport environments, the form of competition and the experience of well-being. The aim of this study is to investigate the issue of intrinsic motivation and self - determination of adolescents who participate in racket sports such as Racketlon, to gain pleasure.
Methods
To determine the factors that motivate an individual to participate in a chosen leisure activity, the Participation Motivation Questionnaire (PMQ) which was introduced by Gill et al. (1983). The data were analyzed by descriptive statistics, factor analysis and one way ANOVA.
Results
The results of the factor analysis of the PMQ revealed the factors of achievement/status, team atmosphere, fitness, energy release, skill development, friendship and fun as basic motives for involvement. It is interesting that female participants have the same top four motives as males and that intrinsic motivation is equally important for both genders.
Discussion
One of the goals of Physical Education is that students acquire healthy and long-lasting sports as well as physical activity habits. This is an aspect that has led to the analysis of the benefits of leisure-time habits on students. When motivation is assessed regarding the participation in sport, the priorities and the processes of motivation should be understood so as to carry on and maintain physical activity. Individuals are motivated to sport because of internal factors, such as enjoyment, skill development and mastery, and external factors, such as rewards, improved health and wellbeing. Psychologists are interested in approaching the initial reasons why people get involved in sports as well as their commitment to participation. It has also been revealed that the motivation of participants in sporting competitions is different from that of participants in routine sport and recreational activities. Racketlon, as a complex sport, has a different approach as far as competition is concerned: winning in an individual Racketlon event is not as important as collecting points in all four events.

## MIGRATING TO A PHYSICALLY ACTIVE COUNTRY: CHANGES IN PHYSICAL ACTIVITY AND THE PERCEPTION OF THEIR CONTEXTUAL ATTRIBUTES

GONÇALVES, R., BATALAU, R., PALMEIRA, A.

*CIDEF - RESEARCH CENTRE FOR SPORT AND PHYSICAL EDUCATION*

Purpose: In the European Union (EU), 59% of the citizens claim that they never or seldom exercise or play sports, although there is a great difference between countries (e.g., 72% in Portugal vs. 30% in Sweden). So, migrating from a country to another may have different impacts on physical activity level (PA), but is understudied and may provide essential public health information. Therefore, the aim of this work was to analyze the association between emigration from an "inactive country" to an "active country" and PA, and the perception of contextual attributes for PA, in adults.
METHODS: In this cross-sectional study, 402 participants accessed an online survey. Of these, 83 finished met eligibility criteria: i) 18-65 years old; ii) have lived in an inactive country for at least 10 years; iii) migrated and now living in an active country for at least 6 months. An active country was defined as an EU country, where >8% "regularly" and <42% "never" exercise or play sport (EU averages, according to the Eurobarometer). A self-report assessed perception of contextual attributes for PA (NEWS-A) and PA (IPAQ-SF), in both contexts. Differences between contexts were examined through a paired sample t test. Effect sizes (r) were calculated, where values of .1, .3, and .5 repre-

sent a small, medium, and large effect, respectively. Pearson correlations and regression analysis assessed the associations among the variables.
Results: When participants emigrated from an inactive country to an active country, they increased their walking time (r=.55), moderate PA (MPA; r=.33), moderate-to-vigorous PA (MVPA; r=.21), and the total PA MET-min (r=.33) per week. The perception of walkability also changed, with eight dimensions increasing the perception of contextual attributes for PA when people migrated to an active country (r average =.43). While living in an inactive country, MVPA min/week and total PA MET-min/week were positively correlated with the perception of infrastructure and safety for walking (p≤ .028) and negatively correlated with crime (p≤ .004). These data suggest that people, in an inactive country, do not feel safe to be more active. These associations did not happen in the active country, where only the perception of lack of cul-de-sacs was positively correlated with MVPA min/week and total PA MET-min/week (p≤ .040), showing that more street connectivity awareness in the active country could explain the increase in PA. The regression analysis did not produce any significant results.
Conclusions: In our sample, migrating from an inactive country to an active country increased the PA and the perception of contextual attributes for PA. The correlations point to the possibility that PA promotion policies of the inactive countries constrain the integration of an active lifestyle in their populations. Future studies should investigate how their physical and psychosocial contexts may facilitate this, as well as individual factors such as motivation.

## 09:30 - 10:45

## Invited symposia

### IS-PN09 Glycogen metabolism in muscle: from bench to athletes

#### CARBOHYDRATE FEEDING OR RESTRICTION: FROM BENCH TO ATHLETES

MORTON, J.
*LIVERPOOL JOHN MOORES UNIVERSITY*

The aim of this talk is to present the current knowledge on how carbohydrate feeding or restriction affects exercise performance and adaptations to training. Recent findings on the differences between carbohydrate-intake before, during and after exercise and how this is related to glycogen content, substrate utilization and cell signaling pathways involved in oxidative adaptations within the muscles will be highlighted. The presentation will include considerations on how to translate laboratory findings to practical applications for endurance athletes in relation to various levels of carbohydrate intake around certain training sessions. James was the Head of Nutrition for Team Sky and Team Ineos between the period of 2015-2019, responsible for the implantation of the nutritional strategy underpinning 5 consecutive Tour de France victories, the philosophy of which was based on CHO periodisation.

#### EXERCISE, GLYCOGEN AND GLYCOGEN HANDLING PROTEINS IN SINGLE MUSCLE FIBERS

MURPHY, R.
*LA TROBE UNIVERSITY*

This talk will focus on the cellular abundance of glycogen and proteins required for glycogen regulation. Human muscle heterogeneity will be addressed by examining proteins in isolated single muscle fibres using western blotting, a technique pioneered by Robyn. To further provide knowledge around glycogen regulation, this talk will discuss muscle fibre type specificity of the array of glycogen handling proteins and presenting data obtained using micro-dissection techniques and discuss association of these proteins with glycogen. The manipulation of intramuscular glycogen content via exercise will form the basis of understanding how glucose uptake into muscle may be regulated and how the behaviour of glycogen handling proteins is affected by the exercise.

#### DOES SUBCELLULAR HETEROGENEITY IN GLYCOGEN METABOLISM IMPACT EXERCISE PERFORMANCE?

NIELSEN, J.
*UNIVERSITY OF SOUTHERN DENMARK*

Here the current knowledge on how the subcellular distribution of glycogen in skeletal muscle may impact exercise performance will be presented. Recent studies using quantitative microscopy have shown that the content of glycogen in skeletal muscle should be considered to be more than a global concentration of the cell, but also to be important local energy depots connected to specific energy requiring processes and related to distinct functions of the muscle fibers. The presentation will include recent findings ranging from studies conducted at isolated single muscle fibers to large-scale human interventions addressing aspects of spatial glycogen metabolism and their potential relationship to athletic performance. Joachim has been one of the leading investigators conducting quantitative microscopy with a focus on the subcellular distribution of glycogen.

## IS-BM04 Myocellular and neuromuscular aspects of blood-flow restricted (BFR) exercise

### MYOCELLULAR EFFECTS AND MECHANISMS OF ADAPTION WITH LOW-LOAD BFR RESISTANCE TRAINING

NIELSEN, J.

*UNIVERSITY OF SOUTHERN DENMARK*

Myocellular effects and mechanisms of adaption with low-load BFR resistance training
Blood-flow restricted (BFR) training has been established as a training modality capable of evoking significant improvements in mechanical muscle function (e.g., muscle strength) and skeletal muscle mass using low external exercise loadings (20-30%-1RM). Available data suggest that the training modality may serve as an effective alternative to traditional heavy-load resistance training when aiming to stimulate myocellular adaptations. However, the underlying physiological stimuli, upstream effectors and myocellular pathways responsible for the adaptive changes in myocellular morphology in response to BFR training remain elusive.
This presentation will review recent and novel evidence on myocellular adaptations and their underlying mechanisms with low-load blood-flow restricted training.

### NOVEL MRI TECHNIQUES TO ASSESS INTRAMUSCULAR FLUID SHIFTS IN ACUTE BFR EXERCISE

HADDOCK, B.T.

*RIGSHOSPITALET, COPENHAGEN UNIVERSITY HOSPITAL*

Apart from detailed anatomical imaging, recent advances in magnetic resonance imaging (MRI) include techniques capable of in vivo measurements of several physiological parameters. The application of blood flow restriction (BFR) when performing resistance training is known to alter muscle oxygenation and myocellular swelling. Novel quantitative MRI techniques allow rapid and accurate 3D measures of muscle oxygenation, macro-vascular blood flow, shifts in myocellular fluid content, and changes in extracellular fluid fractions. These in vivo measures of key parameters related to muscle oxygenation and myocellular swelling are of great interest in decoding the mechanisms behind the positive adaptations of BFR training.
This talk will present novel quantitative MRI data detailing the acute and post exercise physiological responses to established resistance exercise strategies using BFR versus free-flow (FF) loading conditions. Marked differences in these parameters are demonstrated between BFR and FF exercise conditions, which contribute to explain the anabolic potential of blood flow restricted muscle exercise.

### NEUROMUSCULAR PLASTICITY WITH ACUTE AND LONG-TERM BFR TRAINING: WHAT WE KNOW AND WHAT WE NEED TO KNOW

CENTNER, C.

*UNIVERSITY OF FREIBURG*

Numerous studies within the past two decades have demonstrated that an induction of a local hypoxic environment facilitates the adaptive responses of human skeletal muscle during low-load (LL) resistance training. Although positive adaptations following blood flow restriction (BFR) training have been reported on the level of both muscle structure and function, the underlying mechanisms behind these adaptations are not fully understood. Besides metabolic accumulation, recent evidence indicates that LL-BFR training may facilitate pronounced adaptations also at the neural level.
In this presentation, existing evidence on the acute and long-term effects of LL-BFR on central and peripheral neural markers will be summarized.

## IS-MH08 Epigenetics of Physical Activity and Healthy Ageing

### SEX-SPECIFIC EPIGENETIC DIFFERENCES IN RESPONSE TO EXERCISE TRAINING

EYNON, N.

*VICTORIA UNIVERSITY*

Males and females differ in nearly all complex traits, including both their normal and abnormal/aberrant (i.e. disease state) physiological responses, yet females have long been underrepresented in, or excluded from fundamental and clinical research. This has major implications for personalised and targeted health interventions and this is particularly true for exercise science. While sex differences have been variously attributed to sex chromosomes, hormones, differences in behaviour and environmental exposures, the Epigenetic basis for these differences remain to be elucidated.
Epigenetics determines how the cell uses its genetic information to perform its function, without changing the code of this genetic information. The epigenome is highly sensitive to environmental stimuli such as smoking, diet and exercise. The skeletal muscle epigenome is particularly sensitive to exercise, and exercise training programs caused widespread DNA methylation (an Epigenetic mark) shifts in genes that are relevant for skeletal muscle health.
The Gene SMART study, led by our group, is the first of its kind to comprehensively assess genetic and epigenetic markers that contribute to muscle health in a relatively large group (n = 200) of participants. Comprehensive phenotypic data and muscle biopsies have already been collected from 130 participants (n=100 males, and n=30 females) pre-and-post intense exercise. We combined the Gene SMART cohort and open access datasets and performed a powerful Epigenetic- Wide Association Study meta-analysis of sex in skeletal muscle, totalling n = 369 individuals (n = 217 males, n = 152 females). We first established a list of DNA methylation differences between males and

females, and explored their genomic context. We then integrated them with sex-biased gene expression, and inferred the potential downstream effects on skeletal muscle function.
Elucidating the exercise epigenome as well as the sex differences in molecular mechanisms is critical for developing deeper insight into the underlying mechanisms of exercise adaptations and facilitate the use of this information in future research and practice.

**THE EPIGENETIC LANDSCAPE OF PHYSICAL ACTIVITY AND HEALTHY AGEING**

SILLANPÄÄ, E.

*UNIVERSITY OF JYVÄSKYLÄ, FACULTY OF SPORT AND HEALTH SCIENCES, GERONTOLOGY RESEARCH CENTER..*

Human ageing is accompanied by a decline in muscle mass and strength, loss of physical independence as well as increased morbidity and mortality. The underlying molecular mechanisms behind these physiological changes remain poorly characterized. Physical activity is a cost-effective and simple intervention with great potential to decelerate the rate of cellular and molecular damage as well as the functional decline brought about by ageing.
As an interface between genome and external factors, epigenetics forms a fundamental link between genotype and environmental factors such as diet and exercise. DNA methylation, the most widely studied epigenetic mechanism, modifies gene function by responding to the internal and external environment. DNA methylation changes at specific CpG (cytosine nucleotide followed by a guanine nucleotide) sites are associated with chronological age. Ccollectively, data sharing through biobanks, as well as technological and statistical developments have offered promising tools for identifying epigenetic markers of biological age.
The novel epigenetic marks to measure ageing referred to as epigenetic clocks are weighted sums of DNA methylation at specific CpG sites. Epigenetic clocks are based on statistical models in which ageing phenotypes are predicted using genome-wide DNA methylation data, and optimal CpG sites are selected for the age predictor by the algorithm. Epigenetic clocks are able to predict both time-to-death and time-to-disease, making them fascinating tools to estimate effects of physical activity and other lifestyle habits on biological aging. Recently, the first epigenetic clock for muscle tissue, 'MEAT' (Muscle Epigenetic Age Test), was developed by the Eynon group, which emphasized the discrepancies in biological aging between tissues. Tissue-specific epigenetic ageing could provide insight on various exposures and their influence on health and morbidity.
This presentation will summarize recent studies that investigated associations between physical activity/function-related phenotypes and epigenetic aging in various tissues. Based on results from quantitative genetic models, common confounders such as genetic and social factors as well as other lifestyle habits will be discussed.

**THE ROLE OF MITOCHONDRIAL NON-CODING RNAS IN MUSCLE ADAPTATION TO EXERCISE**

LAMON, S.

*DEAKIN UNIVERSITY*

Mitochondrial adaptations play a central role in the beneficial effects of exercise. This is particularly relevant in metabolically active tissues such as skeletal muscle, which rely on the tight control of mitochondrial gene expression to ensure efficient mitochondrial function and adaptation. Despite the importance of mitochondrial signalling in exercise-induced adaptations, the molecular regulators of these responses are not yet fully elucidated.
Mitochondria retain a conserved genome from prokaryotic ancestors and mitochondrial gene regulation relies on communication between mitochondrial- and nuclear-encoded transcripts. Non-coding RNAs (ncRNAs) have regulatory roles in the modulation of gene expression. Emerging evidence demonstrates that regulatory ncRNAs, particularly microRNAs (miRNAs) and long ncRNAs (lncRNAs), localize within the mitochondria in diverse physiological and pathological states. These molecules present intriguing possibilities for the regulation of exercise-induced mitochondrial gene expression. Indeed, research suggests that all known miRNAs are encoded by the nuclear genome but can target mitochondrial genes, while lncRNAs can be encoded by the mitochondrial genome itself.
We used a human and a rat skeletal muscle model of aerobic exercise to investigate the role of mitochondrial miRNAs and lncRNAs in exercise adaptation. We first set up a new technique to extract human and rat skeletal muscle mitochondria with a high level of purity. To perform transcriptomic analyses of mitochondria-localised ncRNAs, we isolated intact mitochondria from cultured rat myoblasts and optimised a ribonuclease digestion approach to remove transcripts located exterior to mitochondria. We next determined optimal cDNA and adapter ligation conditions for the construction of small RNA sequencing libraries from low mitochondrial RNA input amounts. Human and rat RNA was then used to generate cDNA libraries for miRNAs and lncRNAs, respectively, which were sequenced using Illumina technologies. Mature human miRNA sequences were mapped to miRBase v22.0 and rate lncRNA sequences were mapped to the rat genome (Ensembl version 99).
Based on this, we identified over a profile of nuclear-encoded miRNAs localised within myoblast mitochondria pre- and post- an acute bout of aerobic exercise. Using the same approaches, we assess the whole mitochondrial transcriptome of purified human and rat skeletal muscle tissue, revealing the enrichment of numerous ncRNAs within the mitochondria subcellular compartment at rest and in response to exercise.
These results support our hypothesis that a level of ncRNA-mediated gene regulation takes place in the mitochondria. NcRNA-mediated regulation of the mitochondrial genome is therefore a relatively unexplored field that presents exciting possibilities to further our understanding of mitochondrial metabolism and exercise physiology.

## IS-AP09 Female athlete research - applications to performance, health and risk of injury (sponsored by Adidas)

### INSIGHTS INTO THE EFFECTS OF FLUCTUATING FEMALE HORMONES ON MUSCULOSKELETAL PROPERTIES AND INJURY RISK

LEGERLOTZ, K.

*HUMBOLDT UNIVERSITY BERLIN*

The effects of female sex hormones appear to be viewed and valued in light of weakening the women's body, with females being – be it consciously or unconsciously – viewed as less functioning, weaker or less well-adapted versions of men. In the context of the menstrual cycle, research often appears to start with the underlying – yet often implicit – assumption that female hormones, the menstrual cycle or menstrual bleeding are seen as something avoidable or undesirable. Consequently, it is assumed that female hormones or the menstrual cycle are responsible for higher rates of specific injuries or cycle-dependent reductions in performance. This deficit- and problem-oriented approach is mirrored in the underlying assumptions that often initiate research. For example, it is reflected by the mechanistic approach that has been applied to link female sex hormones such as estrogen to mechanical or functional weakness, interpreting physiological changes observed during the menstrual cycle as negative, and associating those changes with an increased risk of injury. Although the literature strongly suggests that there is an association of ACL ruptures with the preovulatory phase, this by itself does not explain why injury prevalence varies between phases, but it rather begs the question as to "why". It is crucial to not fall into the trap of mistaking a correlation for a causation, of overlooking the possibility that statistical effects can also be caused by a third variable, only hold true for some subgroups, or that further variables could be more relevant than the one regarded in one's own statistical model. Thus, to uncover the mechanism behind peaks in injury incidence during the menstrual cycle it is important to understand that it is not exclusively the estrogen level that varies with different phases of the menstrual cycle.
We would like to highlight that this deficit-orientated approach first may be affected by a biased view on exercising women, which may drive us to ask misleading research questions based on erroneous assumptions, and second by an oversimplification of a complex system, mistaking a correlation for a causality. We would like to show that if we change our assumptions and if we take other variables into account, we may come up with an alternative explanation regarding the observed association between the menstrual cycle and injury risk.

### INSIGHTS INTO THE EFFECTS OF HORMONAL CONTRACEPTIVES ON MUSCULOSKELETAL ADAPTATION AND INJURY RISK

HANSEN, M.

*AARHUS UNIVERSITY*

In elite sports, even small margins can be crucial in the medal race. In most countries, more than half of the young female population, including female athletes, use hormonal contraceptives. Nevertheless, knowledge is still sparse when it comes to the effects of all types of hormonal contraceptives on musculoskeletal tissues and cardiovascular parameters in relation to adaptation to training, performance and sports injuries.
Presently, oral contraception is the most widespread type of hormonal contraception. Oral contraceptives markedly change the sex hormonal profile since they suppress the endogenous sex hormone levels and induce daily fluctuations in synthetic sex hormones after ingestion of the oral contraceptive pill. Within the last years, the interest in non-genital effects of oral contraceptives in young females has risen, and both positive and negative effects of using oral contraceptives have been reported on markers of health, performance and injury risk. This suggests a need for sports specific and individualized approaches when guiding female athletes on the use of contraceptives. This presentation aims to provide the listener with an update based on the latest research findings in the field. Gaining the latest evidence within this field is relevant for researchers who include female participants in human trials, and for coaches and athletes who strive to optimize on all fronts.

### IMPROVING KNOWLEDGE AND COMMUNICATION ABOUT FEMALE HORMONAL CYCLES IN APPLIED SPORT SETTINGS

MCGAWLEY, K.

*MID SWEDEN UNIVERSITY*

Some research studies have suggested that prescribing certain types of training during specific phases of the menstrual cycle (MC) will lead to enhanced physiological adaptations, reduced health risks and improved performance. However, a recent systematic review and meta-analysis concluded that the quality of the existing evidence for organizing training around MC phases is generally quite poor, and that responses to phase-based training interventions vary between (and even within) individuals (McNulty et al. 2020). As such, general recommendations for training according to the MC are not considered appropriate. Similar findings have been presented in a related systematic review and meta-analysis that looked at the effects of hormonal contraceptive (HC) use on athletic performance, with a lack of high-quality scientific studies currently available and a great deal of between-study variation reported (Elliott-Sale et al. 2020). In both of these studies, individualised approaches are recommended.
In sports performance environments, an individualized approach to working with female athletes in relation to their hormonal cycles requires knowledge, resources and well-developed interpersonal relationships between athletes and coaches (Höök et al. 2021). However, a number of recent studies have reported that knowledge about the female hormonal cycle is typically poor among athletes and coaches (e.g., Solli et al. 2020; Larsen et al. 2020). Those topics poorly understood include the physical and psychological effects of hormonal fluctuations, typical MC symptoms, effects of HC use and the long-term health implications of amenorrhea, which is often normalised in weight-bearing and aesthetic sports. Moreover, athletes and coaches perceive female hormonal issues to be uncomfortable, awkward, embarrassing and taboo to talk about. A lack of MC monitoring and related documentation is also common, even at an elite level. Despite this lack of knowledge, avoided discussions and poor routines regarding female hormonal cycles, athletes and coaches have reported a desire to learn, communicate and monitor more. With organized structures and forums specifically relating to female hormonal issues currently lacking within applied sport settings, sports federations and athlete/coach development pathways, educational and communication models have been proposed to guide the process (Clarke et al. 2021; Höök et al. 2021).

This lecture will highlight recent advances in research relating to knowledge, communication and applied practice relating to female hormonal cycles, as well as frameworks for supporting female athletes in the pursuit of athletic excellence. While the science is complex and the application in sport settings is challenging, simple practices including monitoring, testing, feedback and continuous adjustment can have an impact on athlete performance, health and well-being.

#### HIGH-FREQUENCY BLOOD FLOW RESTRICTED RESISTANCE EXERCISE TO FAILURE INDUCES HIGHER CELLULAR STRESS IN MUSCLE FIBRES THAN A NON-FAILURE PROTOCOL

BJØRNSEN, T.1,2, HODY, S.3, RAASTAD, T.1,4, PAULSEN, G.2,4, WERNBOM, M.5, VÅRVIK, F.T.1,2, BERNTSEN, S.1, CUMMING, K.T.4,6

*1 UNIVERSITY OF AGDER . 2 NORWEGIAN OLYMPIC AND PARALYMPIC COMMITTEE. 3 UNIVERSITY OF LIEGE. 4 NORWEGIAN SCHOOL OF SPORT SCIENCES. 5 UNIVERSITY OF GOTHENBURG. 6 ØSTFOLD UNIVERSITY COLLEGE*

INTRODUCTION: High-frequency blood flow restricted resistance exercise (BFRRE) with sets performed to failure has been reported to induce pronounced cellular stress in both fibre types, with type I fibres being most affected (1). However, stress responses to frequent non-failure BFRRE protocols have not been investigated. Therefore, the purpose of the present study was to compare the effect of a failure vs. non-failure BFRRE protocol on the heat-shock protein (HSP) responses over a period of two 5-day-blocks of 7 BFRRE sessions, separated by 10 days of rest (RestWeek).
METHODS: Seventeen untrained men (25±6 yrs) had their legs randomly assigned to either failure- (FA; four sets to voluntary failure) or not to failure (Non-FA; 30-15-15-15 repetitions) protocol using unilateral knee extensions at 20% of 1 repetition maximum (1RM) with 30 seconds rest between sets. BFRRE was conducted with partial blood flow restriction (100 mmHg, 15cm wide cuff). Muscle samples obtained before, 2 h after the first session, during the RestWeek, and at 10 days post-intervention (Post10) were analyzed for αB-crystallin (αBc), HSP70 and myosin heavy chain by immunofluorescence and western blot (αBc and HSP70). Knee extension maximal voluntary isometric contraction (MVC) was measured up until Post10.
RESULTS: Two h after the first BFRRE bout, FA displayed a greater accumulation of αBc in the cytoskeletal fraction than Non-FA (FA: 11.4±12.5-fold vs. Non-FA 4.7±6.1-fold, p=0.007, Mean±SD), and both groups decreased αBc levels in the cytosolic fraction (FA: 24±19%, p<0.001; Non-FA 19±24%, p=0.001). FA also increased staining intensity (reflecting cytoskeletal-bound proteins) of αBc in type I fibres more than Non-FA 2h after BFRRE (FA: 161±194% vs. Non-FA: 81±118%, p=0.044), but not so in type II fibres (FA: 102±118%, p<0.001; Non-FA: 62±87%, p=0.017, no group difference, p>0.05). Staining intensity of HSP70 increased 2h after BFRRE in type I fibres (FA: 38±66%, p=0.009; Non-FA: 32±45%, p=0.028), and in type II fibres (FA: 26±53%, p=0.071; Non-FA:48±59%, p=0.001), with no group differences. FA increased cytoskeletal HSP70 at Post10 (FA: 87±185% vs. Non-FA 22±65%, p=0.057), and type I fibre staining intensity of HSP70 at RestWeek (FA: 122±231% vs. Non-FA: 28±41%, p=0.010), compared to Non-FA. In addition, only FA increased αBc staining intensity in type I fibres from baseline to RestWeek (FA:40±54%, p=0.017; Non-FA: 28±63%, p=0.131). MVC was decreased in both groups by ~30% 2h after BFRRE, and ~10% after the first block of BFRRE (RestWeek), but only FA had reduced MVC at Post3 and Post10 (5-8%, all p<0.05).
CONCLUSION: The high-frequency BFRRE protocols to failure and not to failure stressed both fibre types acutely and during short-term training, as evident by the HSP responses. Overall, the FA protocol induced greater stress responses compared to the Non-FA protocol, especially in type I fibres.

#### THE EFFECTS OF THREE DIFFERENT ECCENTRIC EXERCISE MODES ON TEMPORAL SYMPTOMS OF EXERCISE-INDUCED MUSCLE DAMAGE

CUTTELL, S.A.1, BAROSS, A.W.1, COSTELLO, J.2, MACHADO, L.1, KAY, A.D.1

*1: UON , 2: UOP*

INTRODUCTION: Greater symptoms of exercise-induced muscle damage (EIMD) are commonly reported after eccentric-based exercises than other contraction modes [1], which may confer a greater protective effect (repeated-bout effect) from EIMD symptoms in subsequent exercise bouts [2]. Various eccentric exercise modes are frequently investigated in research and used in athletic settings, therefore the purpose of this study was to compare the effects of downhill running (DHR), drop jumps (DJ) and isokinetic eccentric contractions (Isok) on functional, molecular and perceptual EIMD measures.
METHODS: Participants were randomised into either one of three experimental groups (DHR [N = 6], Isok [N = 6], DJ [N = 6]) with DHR (30 min, ~70%VO2max, 15% decline), Isok (100 unilateral isokinetic eccentric contractions at 50% MVC), and DJ (100 drop jumps from a height of 0.6 m; 5 sets of 20 jumps with 1 min rest between sets). Maximum voluntary isometric contraction of knee extensor force, perception of pain, and creatine kinase (CK) concentration were measured before and 24, 48, 72 and 96 hr after eccentric exercise using dynamometry, a visual analogue scale (VAS), and reflectance photometry, respectively.
RESULTS: A significant ($P \leq 0.05$) increase was detected in CK at all time points from baseline for DHR (Mean Δ 24hr = 75%, 48hr = 74%, 72hr = 34%, 96hr = 27%), DJ (Mean Δ 24hr = 82%, 48hr = 83%, 72hr = 65%, 96hr = 62%) and Isok (Mean Δ 24hr = 51%, 48hr = 29%, 72hr = 28%, 96hr = 13%). Similarly, there was a significant decrease in MVC at all time points from baseline for DHR (Mean Δ 24hr = 14%, 48hr = 10%, 72hr = 7%, 96hr = 5%), DJ (Mean Δ 24hr = 22%, 48hr = 4%, 72hr = 7%, 96hr = 6%) and Isok (Mean Δ 24hr = 14%, 48hr = 12%, 72hr = 15%, 96hr = 10%). Finally, VAS was also significantly increased across all time points from baseline for DHR (Mean Δ 24hr = 57%, 48hr = 62%, 72hr = 55%, 96hr = 8%), DJ (Mean Δ 24hr = 61%, 48hr = 60%, 72hr = 33%, 96hr = 25% from baseline) and Isok (Mean Δ 24hr = 25%, 48hr = 13%, 72hr = 9%, 96hr = 0%). There was no significant difference between groups in any measure.
CONCLUSION: The significant functional impairment, elevated CK and pain evident for several days following different eccentric exercise modes have important implications for exercise prescription, performance and injury risk in the days after unaccustomed eccentric exercise. However, the similar temporal responses are indicative that the specific mode of eccentric contractions (DHR, DJ, Isok) did not differentially influence the magnitude of functional, molecular or perceptual EIMD responses.

**REPEATED BOUT EFFECT: NEUROMUSCULAR AND CARDIORESPIRATORY RESPONSES DURING DOWNHILL WALKING IN RELATION TO MUSCLE FUNCTION LOSS**

CHALCHAT, E., MARTIN, V., PENAILILLO, L., BOURRILHON, C., MALGOYRE, A., LEPETIT, B., BOURDON, S., DUBOIS, R., SUBRY-AN, M., CHARLOT, K., SIRACUSA, J., GARCIA-VICENCIO, S.

*INSTITUT DE RECHERCHE BIOMÉDICALE DES ARMÉES / UNIVERSITÉ CLERMONT AUVERGNE, LABORATOIRE AME2P*

INTRODUCTION: It has been well established that performing a bout of unaccustomed, predominantly eccentric exercise may result in a long-lasting muscle function deficit (>24 h) and in a set of symptoms (e.g., muscle soreness, increased levels of circulating proteins). It is also well established that repeating the same bout within few weeks results in reduced loss of muscle function and symptoms of muscle damage compared to the initial bout. It has been suggested that neural, mechanical and cellular adaptations may explain the protection conferred by a single bout of eccentric exercise, called the "repeated bout effect" (RBE).
Currently, there is no consensus about how the adaptations involved in the RBE could affect neural (muscle activation) and mechanical (muscle/tendon elongation) behavior during a second bout of eccentric-biased exercise. Moreover, while it is well known that neural/mechanical behavior could affect running/walking economy, no study investigated cardiorespiratory changes for a given running/walking speed in a RBE context. The aim of the present study was to: 1) quantify any mechanical, neural or cardiorespiratory changes that occur between two identical eccentric biased exercises separated by two weeks; 2) explore whether these parameters were associated with muscle function loss or any muscle damage markers.
METHODS: 15 participants performed two sessions of 45-min loaded downhill walking (DW) separated by 2 weeks. Oxygen consumption (VO2), heart rate (HR), rating of perceived exertion (RPE), muscle architecture of the vastus lateralis (VL) and EMG activity of the VL, rectus femoris (RF), biceps femoris (BF), gastrocnemius medialis (GM), soleus (SOL) and tibialis anterior (TA) muscles were assessed during the downhill walking. Maximal voluntary contraction (MVC) torque, delayed-onset muscle damage (DOMS), knee range of motion (ROM), creatine kinase (CK) and myoglobin (Mb) were assessed before (PRE), within 1h (POST) and 4h after the exercises (POST), and the days after the two sessions (24h, 48h, 72h and 168h).
RESULTS: MVC torque measured 24h after the DW was reduced by 22.8 ± 11.7 % and 7.4 ± 8.2 % for the first (DW1) and the second (DW2) DW. DOMS, ROM, Mb, and CK were also significantly reduced after DW2 compared to DW1 ($p < 0.01$). Muscle activation (RF and SOL EMG activity), cardiorespiratory (HR and VO2) and subjective (RPE) responses were significantly decreased during DW2 compared to DW1 ($p < 0.05$). Muscle architecture analyses are in progress.
CONCLUSION: As expected, we found a reduced loss of muscle function and symptoms of muscle damage after the second bout compared to the initial bout of downhill walking. Protective adaptations conferred by the first bout induce a lower perceived exertion and cardiorespiratory responses when the same exercise is repeated within few weeks. Neural and mechanical adaptations could partly explain the lower perceptual and physiological responses during a second bout of eccentric biased exercise.

**EFFECTS OF A STANDARD VS. A MODIFIED RESISTANCE TRAINING PROGRAM TARGETING INTRAMUSCULAR CONNECTIVE TISSUES ON MUSCLE ARCHITECTURE, ECHOGENICITY AND ISOMETRIC STRENGTH**

CSAPO, R., GUMPENBERGER, M., WESSNER, B.

*UNIVERSITY OF VIENNA*

INTRODUCTION: Older muscles typically present a fibrotic phenotype, possibly related to a blunted cellular response of the network of intramuscular connective tissue (IMCT) to physical loading1. A recent study testing various acute exercise stimuli indicated that plyometric jumps and foam rolling may provoke a greater expression of IMCT-related genes than conventional resistance exercise2. To follow up on these findings, a longitudinal study comparing conventional and IMCT-targeted resistance training programs based on cellular, imaging-based and functional parameters is currently being conducted. Here, the first data on muscle architecture, ultrasound echogenicity and isometric strength are reported.
METHODS: Nine (4 males, 66.3 ± 3.0 yrs, 171.1 ± 6.1 cm, 73.8 ± 10.4 kg) and 10 (3 males, 67.7 ± 4.3 yrs, 168.8 ± 7.5 cm, 68.9 ± 12.5 kg) older subjects were assigned to a conventional (CONV-G) and IMCT-targeted (IMCT-G) training group, respectively. Both groups engaged in 16 weeks of full-body resistance training 3 times/week. Targeting the knee extensor muscles, CONV-G performed 2-4 sets of 15-10 repetitions of leg extensions at 60-85% of 1-RM in all sessions. In the IMCT-G, one weekly session was dedicated to leg extensions as in CONV-G, but in the other two sessions plyometric jumps (2-4 sets, 20-12 jumps) were performed on a specific trampoline device (Tramp Trainer TT). All sessions in the IMCT-G were concluded with foam rolling (1-2 sets, 10 passes) on all sides of the thigh. Ultrasound (SonoSite Micromaxx) and isokinetic dynamometry (Contrex MJ) were used to measure vastus lateralis fascicle pennation angles and echogenicity as well as isometric knee extension strength before, halfway through (8 weeks) and at the end of the intervention. Time × group ANOVAs were used for statistical analyses.
RESULTS: Pennation angles increased from 7.4 ± 1.6° pre-training to 8.2 ± 1.7° (week 8) and 8.9 ± 1.5° (week 16) ($F(2,34) = 5.43$, $p = 0.009$). Mean echo intensities increased non-significantly from 93.7 ± 20.3 to 95.7 ± 19.7 (week 8) and 98.0 ± 22.6 (week 16). Isometric knee extension strength increased in both groups by 22.0 ± 21.6% at week 8 and 29.9 ± 22.3% at week 16 ($F(2,34) = 26.36$, $p < 0.001$). For none of the outcome parameters, significant between-group differences or interaction effects were found.
CONCLUSION: Plyometric jumps and foam rolling acutely induce a strong expression of genes encoding the biosynthesis of various matrix metallopeptidases2. However, incorporation of these stimuli into a standard resistance training program failed to provoke significant changes in muscle echogenicity, indicative of adipose and fibrous tissue infiltrations. Despite an 88% difference in conventional, heavy-weight resistance training volume, both CONV-G and IMCT-G training were similarly effective in increasing pennation angles and muscle strength.

## OP-PN38 Physiology II

### IS CEREBRAL DEOXYGENATION RATE DURING PURE NITROGEN BREATHING AN ADDITIONAL METRIC OF HYPOXIC SENSITIVITY?

CITHERLET, T.1, RABERIN, A.1, SCHORDERET, F.1, HERSEL, F.1, MONNIER, Y.1, MANFERDELLI, G.1, MILLET, G.P.1

*1: UNIVERSITY OF LAUSANNE*

INTRODUCTION: Hypoxic chemosensitivity is a key parameter of adaptation to hypoxia and is generally assessed by measuring the hypoxic ventilatory response (HVR), for example by performing the Richalet test (RT). There are other HVR tests such as the pure nitrogen breathing test (N2T) performed only at rest. Most studies on hypoxic chemosensitivity have focused on cardiorespiratory parameters, but cerebral oxygenation responses may also be of interest. Accordingly, the present study aimed to investigate the relationship between cerebral deoxygenation and HVR during RT and N2T.
METHODS: Twenty-eight healthy participants (Mean ± SD; age 26 ± 2 years; height 175 ± 11 cm; weight 70 ± 12 kg) underwent RT and N2T. In the RT, participants performed four 4-min stages on a cycle-ergometer: resting in normoxia, resting in hypoxia (FIO2 = 0.115), exercising in hypoxia, exercising in normoxia. Exercise intensity was set at 30% of normoxic peak oxygen uptake. In the N2T, participants were exposed in a lying position to a series of 10 periods of pure N2 breathing (random 1-8 consecutive breaths). Minute ventilation ($\dot{V}E$), pulse oxygen saturation (SpO2), and cerebral deoxyhemoglobin (HHb) in the prefrontal cortex were continuously monitored by metabolic cart (Ergocard CPX Pro), pulse oximeter at the earlobe (Nonin), and near-infrared spectroscopy (PortaLite), respectively. In both tests, HVR was calculated as $\dot{V}E$ plotted against SpO2 (HVRRT and HVRN2T, respectively). The linear regression of the slopes of each HHb increase during N2 exposures (S(HHB)N2T) was used as an index of cerebral deoxygenation rate.
RESULTS: HVRRT was similar to HVRN2T (0.469 ± 0.264 vs. 0.484 ± 0.365 L/min/%/kg, P = 0.97). A significant inverse correlation was observed between S(HHB)N2T and HVRRT (R2 = 0.34, P = 0.001). S(HHB)N2T was also correlated to the nadir SpO2 value measured during N2T (P = 0.03) and to the normoxia-to-hypoxia increase in resting $\dot{V}E$ during RT (P = 0.03).
CONCLUSION: The inverse correlation between S(HHB)N2T and HVRRT (i.e., meaning the smaller the cerebral deoxygenation rate during breathing N2, the higher the HVR during the RT) suggests that cerebral deoxygenation might be a potential predictive metric of hypoxic sensitivity. Indeed, a good HVR is known to play a pivotal role in the adaptation to hypoxia and our results indicate that it is accompanied by better preservation of brain oxygenation in the prefrontal cortex. The correlations between S(HHB)N2T and both SpO2 nadir during N2T and normoxia-to-hypoxia increase in resting $\dot{V}E$ during RT strengthen the present assumption. Further studies are requested to evaluate if this easy-to-set-up N2T could be implemented along with HHb measurement as a complementary or alternative measurement to RT. It would also be of interest to assess its potential application to screen high-altitude travelers for AMS risk.

### WHAT PARAMETERS DEFINE MAXIMAL APNEA DURATION?

DECLERCQ, L.

*GHENT UNIVERSITY*

INTRODUCTION: The current world record of static breath-holding is set at an astonishing 11 min 35 s in male and 9 min 2 s in female. In order to accomplish such apnea performances, individuals must be able to store large amounts of oxygen and conserve this oxygen efficiently during apnea. Additionally, they should be able to withstand hypoxia (low oxygen levels) and hypercapnia (high carbon dioxide levels) in blood and tissues. Previous research has already gained some insights in the fascinating physiological responses to breath-holding, but a lot of pieces are still missing to the puzzle. The aim of this study is therefore to explore the determining physiological parameters in order to perform longer apneas and to investigate why men can perform longer apneas than women.
METHODS: 28 physically active individuals (23 ± 3 years old), 16 males (180 ± 6 cm; 73.2 ± 7.5 kg) and 12 females (168 ± 8 cm; 64.3 ± 5.8 kg), naïve to apnea participated in this study. All subjects were medically screened for contra-indications. Lung function tests were performed and hemoglobin mass (Hb mass) was determined using the optimized CO-rebreathing method. ANOVA was used to compare differences in apnea duration, Hb mass and vital capacity (VC) between male and female subjects. Linear regressions were used to examine the relation between apnea duration, Hb mass and VC.
RESULTS: Male subjects had an average breath-hold time of 199 s ± 46 s while female subjects could hold their breath on average for 148 s ± 53 s ($p = 0.011$). Hb mass was on average 853.9 ± 106.6 g in men and 618.2 ± 69.1 g in women ($p < 0.001$). Also VC was higher in men with a mean value of 6.1 ± 0.7 L versus a mean value of 4.7 ± 0.6 L in women ($p < 0.001$). Both Hb mass ($p = 0.011$; $R^2 = 0.186$) and VC ($p = 0.001$; $R^2 = 0.336$) showed a significant positive correlation with maximal apnea duration.
CONCLUSION: A higher Hb mass and greater lung volume seems to lead to longer apnea durations. Since men exhibit a higher Hb mass and VC, we expect men to have higher oxygen (O2) storage and carbon dioxide (CO2) buffer capacity which contribute to a longer apnea duration.

### EVIDENCE FOR VOLUME-DEPENDENT CROSS-LEARNING DURING 10 WEEKS OF UNILATERAL HEAVY RESISTANCE TRAINING

HAMARSLAND, H., HAMMARSTRÖM, D., HAFSMO, M., VARPESTUEN, T., ELLEFSEN, S.

*INLAND UNIVERSITY OF APPLIED SCIENCES*

INTRODUCTION: Unilateral training protocols allow one individual to undergo two different treatments within the same timeframe, allocated to each of the two limbs. The benefit of such designs includes increased statistical power, due to within-individual comparisons, with accompanying reductions in required resources. Despite of this, training interventions seldom employ unilateral designs, which is likely due to potential cross-learning effects between the two limbs, whereby training of one limb induces gains in strength in the contralateral limb, as reported in a number of studies. Although the presence of such cross-learning effects is widely accepted, it has proven difficult to conclude on this perspective, due to several methodological issues with previous studies. The goal of the current study was to investigate the potential cross-learning effects during a 10-week unilateral training intervention with two different training volumes or lack thereof.

METHODS: Healthy untrained subjects (♂:12, ♀:27, 24.4±3.9 yrs) participated in a 10-week whole-body training intervention, wherein the legs were exposed to either of three interventions, i) no training, ii) three sets of 10RM resistance training (RT), or iii) six sets of 10RM RT, performed three times per week in a contralateral manner (leg press and knee extension). For these interventions, participants performed either of five combinations: 0-3, 0-6, 3-6, 0-0 and 3-3. Muscle strength was assessed as 1RM (leg press and knee extension) and isokinetic strength (0°/sec, 60°/sec and 240°/sec), performed 4 times during the initial 3 weeks of training and 2 times in week 11. Average weighted mean changes after familiarization were used in analyses. Muscle mass was assessed as mid-thigh muscle thickness (m. vastus lateralis and m. vastus intermedius, ultrasound) in weeks 1, 3, 7 and 11. Group * Time effects were evaluated using mixed-effects models.
RESULTS: Strength development in non-trained legs showed an interaction effect with the training volume performed by the other leg (group * time P=0.011), increasing 6.9 % in 0-6 (95% CI: 1.7, 12.4) and 2.0 % in 0-3 [-2.8, 7.0] compared to 0-0. This was not seen in the 3-set leg (group * time P=0.110). For muscle thickness, neither non-trained legs nor three-set legs displayed contralateral spillover from the trained leg (non-trained legs, group * time P=0.728; three-set leg, group * time P=0.728).
CONCLUSION: In contralateral training designs, cross-learning may affect strength outcome in non-training control limbs, but not muscle mass. The extent of the contralateral training effect seems to be influenced by the prescribed training volume in the trained limb.

**COMPARISON OF AEROBIC FITNESS PARAMETERS WITH DIFFERENT PATTERNS OF VAGAL REACTIVITY FOLLOWING THE ORTHOSTATIC TEST AT REST IN HEALTHY MEN**

GARCIA, G., KOBAYASHI, L., GUIMARÃES, F., MORLIN, M., NETO, R., PORTO, L., CRUZ, C., MOLINA, G.
*UNIVERSITY OF BRASÍLIA – UNB*

INTRODUCTION: The vagal tank theory is still a metaphor and its applicability in the sports field is not yet fully understood. In human aerobic performance, higher resting vagal activity can lead to saturation vagal activity with a reduction in performance. So, the degree of vagal reactivity (VR) after the orthostatic test (OT) may be a better index and thus make the vagal tank theory more applicable in this area. Therefore, this study aimed to compare the aerobic fitness parameters in men with different VR patterns after the OT at rest.
METHODS: Sixty-three healthy men were evaluated after the OT, and a maximal cardiopulmonary exercise test (CPX) was realized in the sequence. Volunteers were divided into two subsamples of VR based after an OT: low VR (GLRV n = 21), aged 28.5 ±6.2 years, and body mass index (BMI) of 24.4 ± 2.5 kg/m2, and high VR (GHRV n = 21), aged 23.6 ±3.7 years and BMI of 23.3 ± 2.5 kg/m2. The first group was characterized with VR values ≤ 1st tertile and the second group with VR values ≥ 3rd tertile. A Polar RS800® was used to record the RR-interval series at rest for 5 minutes in the supine (sup) and orthostatic (ort) positions. The heart rate variability was analyzed by Kubios software, and the vagal marker was assessed by the pNN50 index. The VR (ΔpNN50) was calculated by subtracting pNN50ort from pNN50sup. The aerobic fitness parameters derived from CPX were: Oxygen Uptake (VO2), velocity associated with VO2 (V-VO2) at the anaerobic threshold (AT), respiratory compensation point (RCP), maximum effort (MAX), and the total time of effort (EXT-time). If the data met the normality assumptions or not (Shapiro-Wilk test), the inferential analyses were run either with the independent t-test or the Mann-Whitney test with a two-tailed $p \leq 0.05$.
RESULTS: We observed a higher value of VR on the GHVR [ΔpNN50: -49.5 (-54.4 - -42.0)%] compared GLVR [ΔpNN50: -7.1 (-12.5 - -1.5)%] ($p < 0.01$). We did not observe any difference between groups (GHVR vs GLVR) on VO2AT [21.5 (19.8 - 24.2) vs 19.9 (17.1 - -24.9) ml.kg-1.min-1] , VO2RCP (39.3 ± 6.6 vs 37.9 ± 7.8 ml.kg-1.min-1) and VO2MAX (47.8 ± 7.6 vs 45.4 ± 7.9 ml.kg-1.min-1) ($p \geq 0.28$). However, GHVR presented higher values of V-VO2 at the AT [V-VO2AT: 6.3 (6.1 - 6.5) km/h], RCP (V-VO2RCP: 9.8 ± 1.5 km/h) and MAX (V-VO2MAX:13.1 ± 1.3) compared GLVR [V-VO2AT: 5.6 (5.2 - 6.0)km/h; V-VO2RCP: 8.7 ± 1.0km/h; V-VO2MAX: 11.2 ± 0.9 km/h] ($p \leq 0.01$). We also observed differences in EXT-time on GHVR (662.2 ± 51.2 seconds) compared GLVR (609.0 ± 58.5 seconds) ($p < 0.01$).
CONCLUSION: The aerobic fitness parameters as V-VO2 (AT, RCP, and MAX) and EXT-time were higher on GHVR than GLVR, despite the same value of VO2 (AT, RCP, and MAX). These results clarify the relationship between higher levels of VR and different classical markers of aerobic fitness. Therefore, this study suggests that the greater VR after the OT, the better its running economy and performance despite the similar VO2 values at AT, RCP, and MAX in healthy men.

**CANNABIS WITH PREDOMINANT THC, BUT NOT CBD, REDUCES CYCLING PERFORMANCE IRRESPECTIVE OF INHALATION METHOD**

CHEUNG, C.P., BAKER, R.E., BURR, J.F.
*UNIVERSITY OF GUELPH*

INTRODUCTION: Cannabis is amongst the most widely used recreational substances in the world, primarily for the psychotropic effects of the cannabinoid delta-9-tetrahydrocannabinol (THC), and purported anti-inflammatory, analgesic, anxiolytic, and sleep-promoting effects of the cannabinoid cannabidiol (CBD). Recreational, collegiate, and elite level athletes have reported cannabis and cannabinoid use for a variety of reasons, including perceived ergogenic benefit. However, the effects of cannabis and isolated cannabinoids on exercise performance are poorly characterized. The current study assessed the effects of inhaling cannabis on cycling performance. We further tested the impact of accentuated levels of cannabinoids (THC or CBD) and the method of inhalation.
METHODS: 14 Healthy participants (9M, 5F; VO2max: 50.6±7.6 mL/kg/min) completed 10-min submaximal intensity cycling, followed by a self-paced 20-min functional threshold power test (FTP). Tests were performed under 1) control conditions, 2) after smoking cannabis high in THC (S-THC), 3) after inhaling vaporized cannabis high in THC (V-THC) and 4) after inhaling vaporized cannabis high in CBD (V-CBD) using a dry-flower vaporizer. Indirect calorimetry was performed, and ratings of perceived exertion were recorded throughout exercise.
RESULTS: During submaximal cycling, heart rate was greater in both THC conditions, regardless of inhalation method, compared to control and V-CBD (Control: 116±24bpm, S-THC: 130±18bpm, V-THC: 134±16bpm, V-CBD: 115±19bpm; all $p \leq 0.05$). Oxygen consumption [VO2 (Control: 1764±209mL/min, S-THC: 1838±246mL/min, V-THC: 1688±184mL/min, V-CBD: 1700±217mL/min)] and carbon dioxide production [VCO2 (Control: 1475±226mL/min, S-THC: 1562±208mL/min, V-THC: 1416±177mL/min, V-CBD: 1415±214mL/min) were higher during S-THC compared to both V-THC and V-CBD (lowest common p=0.05). During the 20-minute FTP, average power output was lower in THC conditions compared to control and V-CBD conditions (Control: 218±72W, S-THC: 208±72W, V-THC: 203±73W, V-CBD: 216±72W; each $p \leq 0.05$). Despite reduced average power during the FTP in S-THC and V-THC, there were no differences in heart rate, oxygen consumption, or ratings of perceived exertion across conditions (all $p > 0.05$).
CONCLUSION: These findings suggest that inhalation of cannabis containing the psychotropic cannabinoid THC, reduces cycling performance irrespective of inhalation method. This likely occurs due to a reduction in gross efficiency, evidenced both by accentuated physiological responses to a fixed submaximal workload, and similar responses to a near-maximal effort, despite reduced power output. Additional-

ly, cannabis predominantly containing the non-psychotropic cannabinoid CBD appears to have no effect on cycling performance or the physiological and perceptual responses to exercise.

## OP-MH16 Breast cancer/colorectal cancer

### EFFECTS OF LIFESTYLE INTERVENTIONS ON CARDIOMETABOLIC HEALTH IN NON-PHYSICALLY ACTIVE BREAST CANCER SURVIVORS AT RISK OF RECURRENCE: A RANDOMIZED CONTROLLED TRIAL

NATALUCCI, V.1, FERRI MARINI, C.1, LUCERTINI, F.1, ANNIBALINI, G.1, VALLORANI, L.1, SISTI, D.1, SALTARELLI, R.1, FLORI, M.2, CATALANO, V.3, ROCCHI, M.B.L.1, STOCCHI, V.4, EMILI, R.3, BARBIERI, E.1

*1 UNIVERSITY OF URBINO; 2,3 OSPEDALE SANTA MARIA DELLA MISERICORDIA; 4 UNIVERSITY SAN RAFFAELE*

INTRODUCTION: Impaired cardio-metabolism, fat accumulation, and low-grade chronic inflammation are associated with an increased risk of breast cancer (BC) development and recurrence [1-3]. Moreover, adjuvant treatments for BC negatively impact maximal oxygen uptake (VO2max) [4]. Interventions aiming at improving metabolic syndrome and cardiorespiratory fitness in BC survivors (BCS) are needed to reduce the risk of comorbidities and improve BC outcomes. This randomized controlled trial assessed the effects of a 12-week aerobic exercise intervention on metabolic syndrome related risk factors and VO2max in non-physically active BCS.
METHODS: 41 BCS (women; stages 0-II; non-metastatic; age 51.6±7.0 years; non-physically active) with a risk factor for recurrence due to metabolic or endocrine disorders underwent a 12-week lifestyle intervention based on nutrition and exercise. Women were randomly allocated to an intervention (IA) or a control (CA) arm. In addition to counselling on diet habits and physical activity, which were provided to both arms, IA performed a 12-week remotely (1 session/week) and on-site (2 sessions/week) supervised aerobic exercise training program having progressive increases in exercise intensity (40%-70% of heart rate reserve) and duration (20-60 min). Participants estimated VO2max, %fat mass (%FAT), glycemia (GLY), LDL, and triglycerides (TRI) were assessed before (t0) and after (t1) the lifestyle interventions. A repeated measure MANOVA (α=0.05), followed by univariate ANOVAs, were used to assess the effects of time (t0 and t1, repeated measure), intervention (IA and CA), and their interaction on VO2max, %FAT, GLY, LDL, and TRI.
RESULTS: Significant multivariate effects were found for time ($p<0.001$) and its interaction with intervention ($p=0.019$), whereas no significant multivariate effect was found for intervention ($p=0.401$). Univariate analyses showed a significant effect of time on LDL (t0=132.7±30.7, t1=122.3±26.9, $p=0.003$) and %FAT (t0=31.7±7.1, t1=29.9±6.5, $p<0.001$) levels of both groups, which decreased, while no significant changes over time were found on VO2max ($p=0.342$), GLY ($p=0.875$), and TRI ($p=0.348$) levels. The interaction between time and intervention was significant only on the VO2max levels ($p=0.037$), which increased in IA (t0=31.0±6.7, t1=32.5±6.0) and slightly decreased in CA (t0=31.7±4.5, t1=31.1±4.7), whereas no significant differences were found between IA and CA GLY ($p=0.407$), LDL ($p=0.080$), TRI ($p=0.441$), and %FAT ($p=0.128$) changes over time.
CONCLUSION: Lifestyle interventions attenuated metabolic syndrome risk factors by reducing LDL and %FAT. However, only a structured and supervised exercise prescription improved VO2max in BCS, supporting the inclusion of supervised clinical exercise programs into BCS treatment and survivorship care plans.

### EFFECTS OF HEAVY-LOAD STRENGTH TRAINING DURING (NEO-)ADJUVANT CHEMOTHERAPY ON MUSCLE STRENGTH AND MUSCLE CELLULAR OUTCOMES IN WOMEN WITH BREAST CANCER

VIKMOEN, O.1, STRANDBERG, E.1,2, DEMMELMAIER, I.2,3, BERNTSEN, S.2,3, NORDIN, K.2, RAASTAD, T.1,3

*1 NORWEGIAN SCHOOL OF SPORT SCIENCE, 2 UPPSALA UNIVERSITY, 3 UNIVERSITY OF AGDER*

INTRODUCTION: (Neo-)adjuvant chemotherapy for breast cancer has deleterious effects on skeletal muscle mass, muscle cells, and muscle function (1,2). Physical exercise during treatment may counteract some of these negative effects. However, the effects of strength training (ST) only are not well documented. The aim of the current study was to investigate if heavy-load ST during (neo-)adjuvant chemotherapy treatment counteracts deleterious effects on skeletal muscle fiber CSA, myonuclear content and satellite cell number in women diagnosed with breast cancer.
METHODS: Women diagnosed with stage I-III breast cancer were randomly allocated into a strength training intervention group (INT, n=23) and a waiting list control group (CON, n=17). The INT group performed supervised heavy-load ST twice a week over the course of chemotherapy treatment (approximately 16 weeks) whereas the CON group was encouraged to continue with their usual activities. Testing of muscle strength and collection of muscle biopsies from m. vastus lateralis was performed before the first cycle of chemotherapy (T0) and after the end of chemotherapy treatment (T1).
RESULTS: One repetition maximum increased in the intervention group in both chest press (10.2±8.2%, $p<0.01$) and leg press (11.1±7.7, $p<0.01$) from T0 to T1 whereas no significant changes occurred in the control group. The percent change from T0 to T1 was different between groups ($p<0.01$).
Preliminary data from a subset of the muscle biopsies showed no significant change and no differences between groups in muscle fiber cross-sectional area (CSA) (INT n=6, CON n= 4), myonuclear content (INT n=13, CON n= 5) or satellite cell content (INT n=11, CON n= 8) in neither muscle fiber type 1 nor muscle fiber type 2.
CONCLUSION: The ST program was effective in increasing the muscle strength in women treated for breast cancer during (neo-)adjuvant chemotherapy treatment. There were, however, no changes in muscle fiber CSA or other cellular outcomes after strength training. Both the lack of reduction in muscle fiber CSA during chemotherapy in the control group and the lack of increase in the intervention group contrasts with a previous study that reported reduced muscle CSA after usual care and increased muscle CSA after strength training combined with high-intensity interval training (1). In fact, in our data, there was a tendency to a negative effect of ST on muscle CSA, myonu-

clear content, and satellite cell content. However, our results are preliminary, and results might change when analyzes of all biopsies are finished.

**IMPACT OF A SELF-DETERMINATION THEORY-BASED EXERCISE INTERVENTION ON COLORECTAL CANCER PATIENTS' PSYCHOLOGICAL AND BEHAVIORAL OUTCOMES DURING ADJUVANT CHEMOTHERAPY: A PRELIMINARY QUALITATIVE REPORT**

JIMÉNEZ-LOAISA, A., ROMERO-ELÍAS, M., GONZÁLEZ-CUTRE, D., RUIZ-CASADO, A., FERRIZ, R., BELTRÁN-CARRILLO, V.J.
*UNIVERSITY OF CASTILLA-LA MANCHA*

Introduction
Physical activity (PA) improves survival, reduces death, and entails physical and psychological benefits in colorectal cancer (CRC) patients throughout oncological treatment. However, such exhaustive toxic regimens have side effects that reduce patients' quality of life and their PA levels [1]. Given these circumstances, the development of appropriate programs to support motivation towards PA in these patients represents an important challenge to address by researchers and healthcare professionals. In this qualitative study, we explore the effects of a 6-month exercise program grounded on self-determination theory (SDT) on basic psychological needs satisfaction and different psychological and behavioral consequences in CRC patients under adjuvant chemotherapy. Theoretical frameworks such as SDT could help to optimize exercise interventions and their health outcomes [2].
Methods
Sixteen CRC patients enrolled in a motivational exercise program participated in the study (Mage = 64, SD = 11.58). The sample also included six relatives and the whole oncology team (three oncologists and two nurses) of the hospital where the program was delivered (Hospital Universitario Puerta de Hierro, Spain). The intervention (FIT-CANCER) consisted of three 60-min sessions per week (face-to-face and online modality), and began with the start of patients' chemotherapy. Sessions were designed including motivational techniques from SDT with the purpose of satisfying patients' needs for autonomy, competence, relatedness, and novelty. Qualitative data were collected through semi-structured interviews and observation (field notes), and were analyzed following thematic analysis.
Results
The CRC patients felt their needs for autonomy, competence, relatedness, and novelty were satisfied during the SDT-based exercise program, giving rise to positive psychological and behavioral outcomes during the chemotherapy process. Among these, patients reported enhanced self-esteem, better mood and optimism, greater vitality and well-being, and increased sociability due to their participation in the program. Additionally, patients showed a high engagement with the exercise program, and increased their knowledge about physical exercise after participating on it.
Conclusion
Our results highlight the importance of implementing motivational exercise programs to enhance patients' functioning and well-being during the chemotherapy treatment.

**EFFECTS OF EXERCISE ON SYSTEMIC INFLAMMATION IN PATIENTS WITH BREAST CANCER: A RANDOMIZED CONTROLLED TRIAL**

THOMSEN, S.N., FRYDENBERG, H., HUSØY, A., FLOTE, V.G., CHRISTENSEN, J.F., SIMONSEN, C., PEDERSEN, B.K., THUNE, I.
*COPENHAGEN UNIVERSITY HOSPITAL - RIGSHOSPITALET, COPENHAGEN, DENMARK*

INTRODUCTION: Exercise training has been proposed as a means to regulate systemic inflammation during and after cancer treatment. However, the effects of exercise on systemic inflammation remain uncertain in patients with breast cancer. The aim of this study was therefore to evaluate the effect of exercise on systemic inflammation in patients with breast cancer.
METHODS: This study is a secondary analysis of a multicenter randomized controlled trial (EBBA II, NCT02240836). Women 18-75 years of age with newly diagnosed stage I-II breast cancer were eligible. Included patients were randomized 1:1 to standard care plus exercise (EX) or standard care alone (CON) stratified by menopausal status. Standard care consisted of surgery potentially followed by radiation, chemotherapy, and endocrine therapy. The exercise intervention was initiated 3 weeks after surgery and consisted of supervised, group-based, aerobic high-intensity interval training as well as strength training for 60 min 2x/week combined with home-based, moderate-intensity, aerobic training for 150 min/week for 12 months. Blood samples were collected before surgery, at 6 months and at 12 months and analyzed for plasma concentrations of C-reactive protein (CRP), interleukin (IL) 1β, IL-6, IL-8, IL-10 and tumor necrosis factor-α (TNF-α). Intention-to-treat analyses of between-group differences in changes from pre-surgery to 12 months were performed using linear mixed-effects models. Subgroup analyses were performed for patients receiving adjuvant chemotherapy. To increase model compliance, outcomes were analyzed on log-scales and estimated differences were back-transformed and reported as relative ratios (RR) with 95% confidence intervals (CI).
RESULTS: Among 491 breast cancer patients (age: 55±10 yrs, BMI: 25.5±4.7 kg·m2) 52% received chemotherapy, 80% received radiation, and 56% received endocrine therapy. Preliminary analyses show between-group differences for CRP (RR: 1.08, 95%, CI: 0.87 to 1.33, P= 0.50), IL-1β (RR: 0.99, 95%CI: 0.78 to 1.25, P= 0.94), IL-6 (RR: 1.03, 95% CI: 0.92 to 1.15, P= 0.63), IL-8 (RR: 0.97, 95%CI: 0.89 to 1.04, P=0.37), IL-10 (RR: 1.04, 95%CI: 0.94 to 1.14, P=0.50), or TNF-α (RR: 1.02, 95%CI: 0.97 to 1.07, P=0.50). In the subgroup analyses of patients receiving chemotherapy, we found a larger reduction in IL-10 in EX compared with CON (RR: 1.15, 95%CI: 1.01 to 1.32, P=0.046), whereas no between-group differences were found for CRP (RR: 1.15, 95%CI: 0.88 to 1.51, P= 0.32), IL-1β (RR: 0.94, 95%CI: 0.69 to 1.28, P= 0.68), IL-6 (RR: 1.07, 95%CI: 0.92 to 1.25, P= 0.36), IL-8 (RR: 0.97, 95%CI: 0.89 to 1.06, P= 0.52) or TNF-α (RR: 1.04 , 95%CI: 0.97 to 1.12 , P=0.27).
CONCLUSION: Among these breast cancer patients, a 12 months exercise intervention post surgery has no effect on systemic CRP, TNF-α, IL-1β, IL-6 or IL-8 but may reduce IL-10 in patients receiving chemotherapy.

## OP-AP09 Strength training

### THE EFFECT OF A FOUR-WEEK STRENGTH AND POWER PROGRAM ON SPRINT PERFORMANCE IN COURT-BASED WHEELCHAIR ATHLETES

DINEEN, A.1, WARNE, J.1,2

*1> SETANTA COLLEGE, THURLES, TIPPERARY, IRELAND. 2> DEPT. OF APPLIED SCIENCE, TECHNOLOGICAL UNIVERSITY DUBLIN – TALLAGHT CAMPUS, IRELAND*

INTRODUCTION: It is well documented that strength and power training has positive effects on sprinting performances in able-bodied athletes, but there is a lack of evidence investigating if the same could be said for wheelchair athletes. Therefore, the purpose of this study was to investigate if a four-week strength, power and resisted sprint training program improved maximal strength, power and sprint speed performance in male court-based wheelchair athletes, post a COVID-19 detraining period.
METHODS: Sample size calculations identified that 10 participants were needed for this study (determined from a similar explosive strength intervention in wheelchair athletes measuring acceleration over 20m (Ozmen et al., 2014), where effect size was dz = 1.03). Therefore, five national and seven international level male wheelchair athletes, with strength training experience were recruited for the study (Age; 29 ± 11 years, Mass; 79.44 ± 15.36 kg, Wingspan; 178.21 ± 13.14 cm, Training Age 6 ± 3 years). Participants Pre and Post strength and power intervention testing consisted of 3RM bench press, 2.5m, 5m and 10m sprint times and seated medicine ball throw for distance. The training intervention consisted of three training sessions per week, two gym-based session and one resisted sprints session. The gym based sessions were 60 – 75 minutes in duration, consisting of one heavy strength day, and one ballistic day. The resisted sprint program consisted of resisted sprints using an (EXER-GENIE® speed trainer, Thousand Oaks, CA, USA), set at a light resistance of 3 – 6kg. Analysis included a Wilcoxon S-R test (sprints), and a paired t-test (Med ball throw and 3RM), $\alpha = 0.05$.
RESULTS: We identified improvements in 2.5 m (Pre Median 0.96 sec vs Post Median 0.90 sec, $z = 2.46$, $p = 0.014$), 5m sprint (Pre Median 1.90 sec vs Post Median 1.79 sec, $z = 3.07$, $p = 0.002$), 10m sprint (Pre Median 3.45 sec vs Post Median 3.34 sec, $z = 2.94$, $p = 0.003$), Seated medicine ball throw (mean increase 12.64cm; 95%CI [5.42 to 19.85cm], $p = 0.003$, Cohen's dz = 1.11 [Large]) and 3RM bench press (mean increase 6.04kg; 95% CI of difference [4.70 to 7.39kg], $p \leq 0.001$, Cohen's dz = 2.85 [Very Large]).
CONCLUSION: The results of this four-week intervention show that heavy strength, power and resistance training was sufficient in improving maximal strength, power and sprint speed performances in court-based wheelchair athletes, post a COVID-19 detraining period. This supports previous work in this area that suggests that heavy strength training along with explosive strength be it from ballistic strength exercises or resisted sprint work should be utilised more with wheelchair athletes to promote an increase in sprint acceleration.
REFERENCE: Ozmen, T. et al. (2014) 'Explosive strength training improves speed and agility in wheelchair basketball athletes', Revista Brasileira de Medicina do Esporte, 20(2), pp. 97–100. doi: 10.1590/1517-86922014200201568.

### NEUROMUSCULAR ADAPTATIONS TO LONG TERM VS PERIODIC INCLUSION OF ISOMETRIC TRAINING

LUM, D., JOSEPH, R., ONG, K., TANG, J., SUCHOMEL, T.

*SINGAPORE SPORT INSTITUTE*

INTRODUCTION: The inclusion of isometric training (ISO) has been reported to improve strength and the performance various sports related skills (Lum and Barbosa, 2019; Lum et al., 2021). However, no study has compared the adaptations to long term (>24 weeks) and periodic inclusion of ISO. The aim of the study was to compare the effects of including isometric training for consecutive 24 weeks (CISO) against a periodic inclusion (PISO) of this mode of training, on strength and dynamic performances.
METHODS: 24 elite floorball athletes (age: 23±2.7 years, stature: 1.74±2.08 m, body mass: 72.7±14.4 kg) were randomly assigned to the control (CON), CISO, or PISO group. Athletes completed 20-m sprint, countermovement jump (CMJ) and isometric mid-thigh pull (IMTP) during pre-test and were tested on week 6, 12, 18 and 24. All groups performed a similar strength training program twice per week. However, two sets of squats were replaced with isometric squat in CISO for all 24 weeks, but only on weeks 1-6 and 13-18 for PISO.
RESULTS: A significant main effect for time was observed for 5-, 10-, and 20-m sprint time, CMJ height, peak force, peak power, time to take-off, modified reactive strength index, IMTP peak force, relative peak force and force at 200 ms (P= <0.001-0.037). CISO resulted in greater improvement in 5-m sprint time than CON at week 24 (P=0.024, g=1.17). Both CISO and PISO resulted in greater improvements in 10-m sprint time than CON at various time points (P=0.007-0.038 and 0.038, g=1.07-1.44 and 1.18, respectively). CISO and PISO resulted in greater improvements in 20-m sprint time than CON at week 6 (P=0.007 and 0.025, g=1.65 and 1.40, respectively). While no significant difference in percentage change in CMJ height between groups, a small to large effect was observed in favour of CISO as compared to CON (P=0.179, g=0.90) and PISO (P =0.542, g=0.49) at week 24. Similarly, no significant difference in the change in all IMTP measures. However, a moderate effect in favour of CISO and PISO as compared to CON was observed for IMTP peak force (P =0.413, g=0.58 and P=0.560, g=0.56, respectively) at week 24.
CONCLUSION: The current results support the findings of previous studies, indicating that the inclusion of ISO is beneficial to both strength and dynamic performance as compared to dynamic resistance training alone. However, while CISO seems to result in greater positive effect on 20-m sprint and CMJ performance, there was no clear difference on its effect on maximal strength as compared to PISO.

### THE EFFECTS OF DIFFERENT VELOCITY LOSS THRESHOLDS DURING BENCH PRESS TRAINING WITH LIGHT LOADS

RODILES-GUERRERO, L.1,3, SÁNCHEZ-VALDEPEÑAS, J.1,2, CORNEJO-DAZA, P.J.1,2, PÁEZ-MALDONADO, J.1,3, CANO-CASTILLO, C.1, BACHERO-MENA, B.1,3, SÁNCHEZ-MORENO, M.1,4, PAREJA-BLANCO, F.1,2

*1 PHYSICAL PERFORMANCE & SPORTS RESEARCH CENTRE, UNI PABLO DE OLAVIDE, SEVILLE; 2 FACULTY OF SPORT SCIENCES, UNI PABLO DE OLAVIDE, SEVILLE; 3, 4 UNIVERSITY OF SEVILLE, SEVILLE*

INTRODUCTION: In recent years the practicability of velocity-based training (VBT) approach for monitoring and real-time prescription of resistance training (RT) intensity and volume has been demonstrated [1,2]. In this regard, it has been shown that higher velocity loss (VL) thresholds (25-50%) maximized muscle hypertrophy, while lower VL thresholds (<25%) evoked positive neuromuscular-related adaptations using an intensity-matched design training, from 70 to 85% one-repetition maximum (1RM), in the bench press (BP) exercise [2]. However,

it is currently unknown if these findings could be extrapolated to lower intensities. Therefore, this study aimed to compare the effect of four VL thresholds – 0% (VL0), 15% (VL15), 25% (VL25) and 50% (VL50) – on strength gains during the BP exercise using intensities ranging from 40% to 55% 1RM.
METHODS: Forty-seven males were randomly and assigned to four groups: VL0 (n=10), VL15 (n=13), VL25 (n=12) and VL50 (n=12) that followed an 8-week (16 sessions) VBT program in BP. A progressive loading BP test was performed before (Pre) and after (Post) training. From this test the following variables were calculated: a) average mean propulsive velocity (MPV) attained against all absolute loads common to Pre- and Post-training (AV); b) average MPV attained against absolute loads that were lifted equal or faster than 0.8 m·s−1 at Pre-training (AV≥0.8); c) average MPV attained against absolute loads that were lifted slower than 0.8 m·s−1 at Pre-training (AV<0.8); d) 1RM.
RESULTS: No significant group × time interactions were noticed for any of the variables analyzed (all P>0.05). Significant time effects were observed for all variables (all P<0.001). All groups showed significant improvements in 1RM, AV, AV<0.8 (P < 0.001-0.05). The VL15, VL25 and VL50 interventions showed significant gains in AV≥0.8 (P < 0.001-0.05), but this was not found for VL0.
CONCLUSION: These findings indicate that after an 8-week VBT program carried out in the BP using light loads (40% to 55% 1RM), a VL threshold of 15% provides a sufficient training stimulus to improve strength performance to a similar magnitude than higher VL thresholds (25% and 50%), despite the considerable differences in the training volume accumulated by each group.

**EFFECT OF SIX WEEKS' IN-SEASON HIGH VS. MODERATE-INTENSITY RESISTANCE TRAINING ON STRENGTH, POWER AND MUSCLE SORENESS IN MALE ACADEMY SOCCER PLAYERS**

MCQUILLIAM, S.1, CLARK, D.1, ERSKINE, R.1, BROWNLEE, T.2
*1. LIVERPOOL JOHN MOORES UNIVERSITY, 2. UNIVERSITY OF BIRMINGHAM*

INTRODUCTION: Strength and conditioning (S&C) coaches in youth soccer actively seek to improve sport specific actions, such as acceleration, sprinting and jumping, through a variety of training methods, of which resistance training (RT) is a central component [1]. However, recently published research suggests that soccer S&C coaches typically implement three sets of eight repetitions at a moderate intensity, when aiming to develop strength in-season. Further, from this PhD project, two limiting factors reported by S&C coaches for incorporating RT into their programmes are time constraints and concerns regarding delayed onset muscle soreness (DOMS) following RT. The aims of this study were to investigate the impact of high- vs. moderate-intensity RT vs. pitch-based soccer training only on changes in strength, power, and speed, and to compare DOMS between training groups in male academy soccer players (ASP).
METHODS: Twenty-two ASP (18±1 years-old) were assigned to either a high-intensity RT (HRT: n=8), moderate-intensity RT (MRT: n=7) or a soccer training-only control group (CON: n=7). HRT completed 2x4 parallel back squat (PBS) repetitions at 90% single-repetition maximum (1RM), while MRT performed 3x8 PBS repetitions at 80% 1RM, both once a week for six-weeks in-season alongside regular soccer training. CON performed pitch-based soccer training only for six weeks. All groups completed the following pre- and post-training assessments: 3RM PBS; bilateral vertical and horizontal countermovement jump (CMJ) height/distance; squat jump (SJ) height; and 20m sprint. DOMS was assessed via visual analogue scale after each training session throughout the six-week period.
RESULTS: HRT and MRT experienced similar increases compared to CON in absolute PBS 3RM (+16±8% vs. +27±16% vs. +2±3%, p<0.001), SJ height (+6±6% vs. +11±7% vs. -7±6%, p=0.001), CMJ height (+8±3% vs. +10±6% vs. -4±10%, p=0.008) following training. Further, there was a greater increase in PBS 3RM relative to body mass following HRT than MRT and CON (+23±8% vs. +16±14% vs. +3±4%, p=0.001) and horizontal CMJ distance improved in HRT but not in MRT or CON (+11±5%, +7±7% and +2±4%, respectively, p=0.011). Sprint time did not change in any group (p>0.05). HRT volume was 58±15% lower than that of MRT (p<0.001) and DOMS measured throughout training did not differ between groups (p=0.487).
CONCLUSION: These findings suggest that one HRT session a week is an efficient method to improve lower-limb strength and power in ASP in-season compared to MRT and pitch-based soccer training only. Importantly, HRT achieved this with 58% less training volume than MRT, and similar DOMS to soccer training alone, thus highlighting the effectiveness of HRT and supporting its incorporation into a standard in-season ASP training programme.

**THE INFLUENCE OF ASSISTED AND RESISTED VARIABLE RESISTANCE BACK SQUAT ON SUBSEQUENT COUNTER MOVEMENT JUMP PERFORMANCE**

VAN ENIS, A.J.1, KAY, A.D.2, BLAZEVICH, A.J.3, KOKKOTIS, C.4, SIDERIS, V.5, TSATALAS, T.6, MINA, M.A.1
*1: UOD (DERBY, UK), 2: UON (NORTHAMPTON, UK), 3: ECU (PERTH, WA) 4: D.U.TH (KOMOTINI, GREECE), 5: ASP*

INTRODUCTION: Back squat warm-up activities using elastic band (EB) resistance in combination with free weight resistance (FWR) can improve subsequent countermovement jump (CMJ) performance (1), a phenomenon termed post-activation performance enhancement (PAPE). However, these improvements are reported using a traditional EB attachment site that creates additional downwards resistance (RES) with no data available of alternative positioning that would create upwards EB assistance (ASS). Therefore, the aim of this study was to compare the influence of two EB attachment sites (RES and ASS) with FWR alone following a task-specific comprehensive warm-up on subsequent CMJ performance.
METHODS: Fifteen active males (age = 25.5 ± 3.5 y, height = 1.7 ± 6.2 m, mass = 80.5 ± 9.9 kg) volunteered to participate in this study and completed three conditions (FWR, RES, ASS) in a randomised order each separated by at least 48 h. During each condition the participants

completed baseline 1 (BL1) CMJ measures and then performed a task-specific comprehensive warm-up consisting of 5 mins of cycling, two sets of 5 bodyweight squats, 5 continuous CMJs at 70% of perceived maximum and finally, maximal CMJs were performed every 30s until 3 consecutive jumps were within 3% of jump height. This was followed by baseline 2 (BL2) CMJs and participants then performed 3 back squats of either RES, ASS or FWR at 85% 1-RM with 35% of load generated during the ASS and RES EB conditions. CMJs were then performed 30 s, 4 min, 8 min and 12 min later.
RESULTS: Significant ($p < 0.05$) increases in the ASS condition from BL1 in jump height (4.6-11.8%) and power (3.3-8.0%) occurred at 30 s, 4 min, 8 min, 12 min and from BL2 in jump height (3.9-6.9%) and power (3.0-4.6%) at 30 s, 4 min were observed. Similar significant increases were observed in the RES condition in jump height from BL1 (4.7-10.3%) and power (2.4-6.5%) at 30 s, 4 min, 8 min, 12 min and from BL2 in jump height (4.1-5.3%) and power (2.7-4.0%) at 30 s, 4 min, 8 min. Again, significant increases were observed in the FWR condition in jump height from BL1 (4.5-9.0%) and power (3.0-5.4%) at 30 s, 4 min, 8 min and from BL2 in jump height (3.5%) and power (1.8%) but only at 30 s.
CONCLUSION: The implementation of EB variable resistance during back squats utilising either the ASS and RES attachment sites elicited greater increases in jump performance compared with the FWR condition. The different attachment methods of the EB during back squats alter the loading characteristics allowing the lifter to operate at near maximal levels for a greater proportion of the lift providing a greater stimulus, which may potentially explain the greater and prolonged increase in subsequent jump performance.

### PRINCIPAL COMPONENT ANALYSIS OF DYNAMIC AND KINEMATIC PREDICTORS OF MAXIMUM VERTICAL JUMP ON TRAINED AND UNTRAINED PERFORMERS

RODRIGUES, C.1,2, CORREIA, M.1,2, ABRANTES, J.3, BENEDETTI, M.4, NADAL, J.5
*1 FACULTY OF ENGINEERING, UNIVERSITY OF PORTO; 2 INESCTEC, PORTO; 3 ULHT, LISBON; 4 UFPE, RECIFE; 5 UFRJ, RIO DE JANEIRO*

INTRODUCTION: Muscle stretch-shortening cycle (SSC) is a common element at several sports with reversible action on lower limbs at countermovement (CM) namely in running and jumping [1]. At lower limbs, muscle SSC has been assessed on maximum vertical jumps (MVJ) due to its standard protocol, experimental control, and accessibility on long CM at countermovement jump (CMJ) and short CM at drop jump (DJ) for comparison with squat jump (SJ) without CM [2,3]. Nevertheless, high dimensionality, strong correlation and time dependence of dynamic and kinematic data on MVJ point for the need of dimension reduction while preserving maximum explained variability. Also, according to the objective of strength training it is determinant to detect principal factors to be trained [4].
METHODS: For this reason, we applied principal components analysis (PCA) to dynamic and kinematic predictors of MVJ on trained and untrained male performers. Trained group (T) is composed by nT=16 athletes of the Portuguese national volleyball team (21.4±3.1)yrs, (85.2±5.8)kg mass and (1.93±0.04)m height, and untrained group (U) composed by nU=6 students of sports and physical education degree, without specific sports records or injuries, ages (21.5±1.4)yrs, (76.7±9.3)kg mass and (1.79±0.06)m height.
Each group performed a total of 3 SJ, CMJ and DJ, with acquisition of ground reaction forces (GRF) by an AMTI BP2416-4000CE force plate at 1000 Hz and Mini Amp MAS-6. Best repetition of SJ, CMJ and DJ was selected for each subject based on flight time method and vertical GRF was used to obtain 51 dynamic and kinematic predictors of MVJ. Selected variables were grouped on four communities of (i) time-force-impulse (t-F-I), (ii) force-velocity-power (F-v-P), (iii) force-displacement-work (F-z-W) and (iv) global (t-F-I-v-P-z-W) community of whole-body center of gravity. PCA was applied to each community and results were compared among T and U groups.
RESULTS: Differences were detected with higher number of principal components (PC) of scree value above 1 at T in relation to U group, with T group presenting higher PC at CMJ and DJ than SJ, whereas explained variance presented higher values at U group (i) 96.9%, 96.7%, 92.4%; (ii) 97.0%, 97.5%, 98.0%; (iii) 93.4%, 99.6%, 97.6%; (iv) 97.7%, 100%, 100% at SJ, CMJ, DJ than T group (i) 92.0%, 89.3%, 89.7%; (ii) 90.2%, 95.5%, 93.6%; (iii) 85.5%, 84.6%, 89.5%; (iv) 92.8%, 95.6%, 95.5%. Differences were also detected on first two PC loads at (i) - (iv) factors for U and T groups on SJ, CMJ and DJ.
CONCLUSION: PCA conduced to differences at explained variances on (i) - (iv) factors with the need of larger number of PCs on T than U group to explain the same variance corresponding to higher variable complexity at T in relation to U group.

### ALTERED LOADING ABSORPTION AFTER DROP JUMP AND DROP LANDING IS RELATED TO LOWER MUSCULAR PRE-ACTIVATION TIME, IN ATHLETES WITH CHRONIC ANKLE INSTABILITY

ACHIARDI, O., CASTILLO, T., HERNÁNDEZ, J., ROBERT, J., SEPÚLVEDA, C.
*PONTIFICIA UNIVERSIDAD CATÓLICA DE VALPARAÍSO*

INTRODUCTION: Chronic Ankle Instability (CAI) is a condition characterized by neuromuscular, range of motion, and postural control deficits that predispose athletes to reinjure. Previous data have shown altered landing strategies in people with CAI when compared to healthy controls. Whether these adaptations are related to ankle muscles activation patterns, has not been documented. This knowledge would be of much use for programing physical rehabilitation protocols to prevent the progression of CAI. Thus, our purpose was to determine the relationship between ground reaction force (GRF) parameters and muscle pre-activation time (PaT), among subjects with and without CAI, after a drop jump (DJ) and a drop landing (DL).
METHODS: 30 young volunteers were classified in two groups (CAI, n = 15; Control (CON), n = 15) according to the recommendations of the International Ankle Consortium. Groups were similar in height, body mass and gender distribution. Each participant performed 5 DJ and 5 DL from a platform of 40 cm height, landing on a force plate recording GRF and synchronized to surface electromyography (sEMG) signals from tibialis anterior (TA), peroneus longus (PL) and peroneus brevis (PB). The GRF signals were low pass filtered (20 Hz), normalized to body weight, and then processed to calculate the maximal GRF (FMax) and the loading rate (LR) from the time of initial contact to when FMax was achieved. Signals from sEMG were band pass filtered (10-450 Hz) and then processed (RMS 20 ms, 10 ms overlap) and compared to initial contact time to calculate PaT. Comparisons among groups were performed using Mann-Withney test, and correlations using Spearman test. A p value <0.05 was considered as significant.
RESULTS: FMax was larger for CAI after DJ (CAI 3.4±0.6 N/N vs CON 3.0±0.3 N/N; $p<0.01$) but was not different from CON after DL. LR was larger for CAI after both DJ (CAI 35.7±13.3 N/N*s vs CON 24.5±10.0 N/N*s; $p<0.01$) and DL (CAI 41.3±10.4 N/N*s vs CON 35.0±5.9 N/N*s;

p<0.01). PaT was smaller in PB for CAI after DJ (CAI 187.1±199.2 ms vs CON 374.4±325.2 ms; p<0.01) and DL (CAI 166.9±176.1 ms vs CON 437.3±348.5 ms; p<0.01). TA PaT was larger for CAI after DL (CAI 152.0±77.9 ms vs CON 114.1±30.3 ms; p<0.01) but was not different from CON after DJ. No differences were found in PL PaT in both jumps. Moderate negative correlations were found for LR with PB PaT after DJ (r=-0.42; p<0.01) and DL (r=-0.31; p=0.02), and with PL PaT after DJ (r=-0.46; p<0.01). Fmax had a small negative correlation with PB PaT after DJ (r=-0.26; p=0.04), and a small positive correlation with TA PaT after DL (r=0.27; p=0.04).
CONCLUSION: Subjects with CAI exhibit less GRF absorption after dropping from a medium altitude, which is related to a lower PaT from relevant muscles around the ankle. This condition might contribute as a major risk factor for ankle reinjure. Patients with CAI might benefit from including loading absorption strategies derived from muscular control in their rehabilitation protocols.

### ARE FOOT POSTURE AND MORPHOLOGICAL DEFORMATION ASSOCIATED WITH ANKLE PLANTAR FLEXION PERFORMANCE AND VERTICAL DROP JUMP KINETICS ?

TOURILLON, R., SIX, A., FOURCHET, F.

*SWISS OLYMPIC MEDICAL CENTER, LA TOUR HOSPITAL, MEYRIN, SWITZERLAND*

INTRODUCTION: The human foot is composed of passive elastic and active components that allow energy absorption and generation during jumping [1]. Previous studies have shown that individuals with a stiffer foot medial longitudinal arch displayed greater isokinetic ankle plantarflexion peak torque and vertical stiffness during a vertical drop jump task (VDJ) [2,3]. However, the degree of relationships between these tasks and various foot posture and morphological deformation measurements are not clearly understood. Therefore, we hypothesized that foot morphological deformation will be associated with ankle plantarflexion performance and VDJ kinetics whereas foot posture will not. We also hypothesized that the association with foot morphological deformation in 3 dimensions will be greater than 1 or 2 dimensions.
METHODS: In thirty-height healthy participants (n=18 females, 29.2±5.0yrs, body mass index (BMI) 22.8±2.7), we assessed the foot posture using the Foot Posture Index and the foot morphological deformation in 1, 2 and 3 dimensions using the Arch Height Index Measurement System [4]. Ankle plantarflexion performance in different contraction modes was assessed in prone position using an isokinetic dynamometer whereas kinetic variables during eccentric and concentric VDJ subphases were analyzed using two force platforms. A principal component analysis (PCA) was applied to the ankle plantarflexion and kinetics performance data. To understand the relationship between the identified principal components (PCs) and foot morphological deformation outcome a Pearson product moment correlation (r value) was used.
RESULTS: PCA revealed 12 PCs that captured more than 99% of the variability within the data. On these PCs, only 2 were found with correlations ≥ 0.4 with VDJ jump height performance (PC1 : r = 0.47; PC2 : r = 0.79). PC1 was made up of 12 variables whereas PC2 was made up of 11 variables highlighting 4 clusters of participants with different performance strategies and neuromuscular capacities. However, no PCs identified within the ankle plantarflexion and kinetics performance data showed a clear correlation (r <0.3) with foot posture or foot morphological deformation outcomes.
CONCLUSION: While foot posture and foot morphological deformation remain of interest in characterizing foot morphology across individuals, these parameters may not influence ankle plantarflexion performance and VDJ kinetics. These findings highlight the lack of clinical relevance of static and passive foot evaluations in predicting dynamic foot function. Further studies should focus on the validation of specific dynamic foot measures (eg. active stiffness, strength) in order to help clinicians at understanding the role of the human foot at enhacing lower limb and ankle performance.

### OP-BM14 Muscle Tendon Function

### INCREASING PRELOAD INCREASES MUSCLE FASCICLE STRETCH AMPLITUDES BUT NOT RFE DURING MAXIMAL VOLUNTARY ECCENTRIC DORSIFLEXION CONTRACTIONS

TECCHIO, P.1, RAITERI, B.J.1, HAHN, D.1,2

*1 RUHR UNIVERSITY BOCHUM, BOCHUM, GERMANY 2 UNIVERSITY OF QUEENSLAND, BRISBANE, AUSTRALIA*

INTRODUCTION: Muscle fascicle kinematics can be decoupled from muscle-tendon unit (MTU) kinematics due to MTU compliance, so that muscle fascicles can even shorten during MTU lengthening [1]. Understanding how preload affects decoupling during MTU lengthening contractions is important for residual force enhancement (rFE) studies as the magnitude of rFE increases with increasing stretch amplitude [2]. Therefore, this study aimed to evaluate how different preloads (PL) affect fascicle stretch amplitudes during maximal voluntary eccentric MTU contractions of the human tibialis anterior (TA) and the rFE elicited by these contractions.
METHODS: Participants (n=4) were in a reclined sitting position (~68° recline, ~90° knee flexion) with their right foot attached to a modified footplate that was connected to a dynamometer crank arm. After a standardized warm-up, participants performed 3 maximal voluntary fixed-end reference contractions at shank-footplate angles of 5° dorsiflexion (REFS) and 35° plantarflexion (REFL) in a randomized order. Three maximal voluntary MTU lengthening contractions per condition were then performed from REFS to REFL at 40°/s in a randomized order at 0% (PL0), 50% (PL50), and 100% preload (PL100) of the REFS peak torque. Participants received real-time visual feedback of their ankle joint torque, which they attempted to keep within two predefined torque ramps that were 2.5% above and below a target torque, and were instructed to contract as hard and fast as possible when the dynamometer crank arm started moving. Participants held each contraction for 4 sec after the end of the crank arm rotation. Torque, crank arm angle, and TA muscle activity were recorded at 2 kHz using a 16-bit ADC and TA muscle architecture changes were recorded using B-mode ultrasound at 50 fps.

RESULTS: Muscle activity amplitudes (REFL: 0.58±0.20 V, PL0: 0.54±0.19 V, PL50: 0.53±0.23 V, PL100: 0.48±0.21 V), net active torques (REFL: 47.8±26.1 Nm, PL0: 52.4±26.8 Nm, PL50: 49.1±24.6 Nm, PL100: 46.4±22.8 Nm) and fascicle lengths were similar across conditions (REFL: 68±12 mm, PL0: 68±13 mm, PL50: 68±14 mm, PL100: 69±14 mm) during a 1-sec hold phase from 2.5 sec after the end of stretch. Fascicle stretch amplitudes during the dynamometer-imposed rotations increased with increasing preload (PL0: 17±2 mm, PL50: 21±1 mm, PL100: 25±1 mm). rFE reported as percentage of REFL did not increase with increasing preload (PL0: 11.2±10.2%, PL50: 4.7±6.9%, PL100: -0.9±13.9%).
CONCLUSION: Preliminary results suggest that: i) a greater preload increases fascicle stretch amplitudes during in vivo MTU lengthening, and; ii) greater fascicle stretch amplitudes do not increase rFE following maximal voluntary eccentric dorsiflexion contractions.

## PLANTAR FLEXION SHORTENING PERFORMANCE IS ENHANCED AFTER ECCENTRICALLY INDUCED PRELOAD COMPARED TO A TORQUE-MATCHED FIXED-END CONTRACTION PRELOAD

GÖCKING, T.1, HOLZER, D.2, SEIBERL, W.1

*1. UNIVERSITÄT DER BUNDESWEHR MÜNCHEN, NEUBIBERG, GERMANY; 2. TECHNISCHE UNIVERSITÄT MÜNCHEN, MUNICH, GERMANY*

INTRODUCTION: In stretch-shortening cycles (SSCs) an eccentric muscle action is directly followed by a shortening contraction. The work during the shortening phase of SSCs exceeds the work of shortening contractions without preceding stretch [1]. Several factors influence this so-called SSC-effect [2]. One of the most discussed mechanisms is related to the preload before shortening. We are interested if the same amount of preload differently affects work during shortening if the preload was either produced by a fixed-end contraction with increased intensity or by eccentrically-induced force enhancement.
METHODS: Electrically stimulated ankle plantar flexor torque was assessed during preloaded shortening and SSC contractions (range 25° at 40°/s), with a (low) intensity evoking ~ 30% of the maximum voluntary torque (N=14; ongoing ultrasound-based analysis of muscle dynamics). To match identical preload before shortening, a second stimulation intensity (high) was used to reach identical eccentric preload torque values measured in SSCs. Three different protocols are presented: 1) preloaded shortening with constant low intensity (SHO); 2) shortening with high stimulation intensity during preload and low stimulation intensity during the shortening phase (SHO-matched); 3) SSC with constant low intensity (SSC). Repeated-measures ANOVA determined differences in torque before shortening and mechanical work during shortening between conditions ($\alpha$=.05).
RESULTS: Torque of SHO-matched and SSC at the onset of shortening were identical (p=.974). Compared to SHO, shortening work during SSC and SHO-matched was 1.9 (± 0.5) and 1.8 (± 0.4) times increased (p<.001), respectively. Additionally, work during shortening in SSC was higher than during SHO-matched (p=.001).
CONCLUSION: Stretch-induced history dependent effects possibly play a more significant role for shortening work in SSCs beyond just increasing the torque at the beginning of the shortening. Increased preload substantially impacts the work during shortening, apparent in conditions with higher intensity for fixed-end preload (SHO-matched) compared to constant low stimulation intensity (SHO). But when the same amount of increased preload was eccentrically induced (SSC), even higher work was performed in the successive shortening. The same amount of preload torque in SHO-matched and SSC should result in the same amount of tendon-based passive-elastic recoil effects. However, during fixed-end preload the contractile unit initially shortens, whereas during eccentric preload the muscle lengthens and triggers mechanisms of (residual) force enhancement [2]. Despite identical amount of preload, the mechanisms of force enhancement, likely related to titin [3], seem to counteract force depressing effects during shortening, leading to the additionally increased work.

## IN VIVO EXAMINATION OF THE LINK BETWEEN MUSCLE ARCHITECTURE AND MUSCLE FUNCTION

WERKHAUSEN, A., GLØERSEN, Ø.N., NORDEZ, A., PAULSEN, G., BOJSEN-MØLLER, J., SEYNNES, O.R.

*NORWEGIAN SCHOOL OF SPORT SCIENCES*

INTRODUCTION: The links between sarcomere arrangement and force production, suggest relationships between muscle architecture and function [1]. However, recent theoretical considerations debate the links [2] and the few studies investigating the actual relationships in vivo are not all in agreement. While e.g. rate of torque development has been linked to pennation angle, fascicle length was not related to explosive torque [3], but to isokinetic joint work [4]. Thus, we examined relationships between muscle architecture and muscle function, and assessed the agreement of methods to measure muscle architecture.
METHODS: Three different ultrasound-based approaches were used to assess the relationships between vastus lateralis fascicle length, pennation angle and thickness, and the mechanical output of the muscle (i.e. force and work) in twenty-one healthy participants. Muscle architecture was analysed in panoramic ultrasound scans at rest with the knee fully extended and in regular scans at an angle close to maximum torque (60º), at rest and during maximum contraction. Isokinetic and isometric strength tests were used to estimate maximum muscle force and work production at various velocities. Pearson correlation coefficient was used to assess the relationships (P<0.05).
RESULTS: Measurements of fascicle length, pennation angle and thickness obtained with different methods correlated mostly moderately with each other (r=0.40-.074). Fascicle length measured at 60º at rest was significantly correlated with force produced during high velocity knee extension (400ºs-1, r=0.46) and with joint work during isokinetic knee extension (r=0.44 at 200ºs-1 and r=0.57 at 100ºs-1), but we did not find significant correlations between fascicle length or pennation angle and any other measure of force production or muscle work. Muscle thickness was significantly correlated to maximum force for all measurement methods (r=0.44-0.73).
CONCLUSION: Correlations between fascicle length and muscle mechanical output were stronger for the measurement at rest with the muscle close to optimal length, suggesting that the slack in full knee extension and the measurement under contraction attenuate the functional significance of architecture. Overall, these findings highlight the limitations of current methodological approaches to measure fascicle length and pennation angle in vivo, which may explain ambiguous findings on their relationship with function in previous studies. They also challenge our current interpretation of static architecture measurements as predictor for muscle performance.

## FORCE REDEVELOPMENT AFTER STRETCH-SHORTENING CYCLES AND ITS RELATION TO RANGE AND SPEED OF MUSCLE ACTION

HOLZER, D.1, PATERNOSTER, F.1, SCHWIRTZ, A.1, SEIBERL, W.2

*[1] TECHNICAL UNIVERSITY OF MUNICH, [2] UNIVERSITY OF THE BUNDESWEHR MUNICH*

INTRODUCTION: Stretch shortening cycles (SSC) are the most common muscle action in sports or daily locomotion. During the concentric phase of a SSC, muscle force, work and power are increased when compared to pure shortening contractions (CON) [1]. This is called the SSC-effect and is discussed to be related to elastic energy preservation, reflex activity, preactivation and history dependence of muscle action [2]. To better understand potential history dependent effects present during SSCs, this work focused on the redevelopment of isometric post-shortening force after SSC compared to CON muscle action, where differences between SSC and CON contractions cannot be explained by all other proposed mechanisms [2].
METHODS: Eleven subjects performed submaximal plantar flexion contractions on a dynamometer using electrical nerve stimulation, including isometric, lengthening, CON and SSC contractions at 60% of individual maximum (velocities: 40/120°/s; ROM: 15/25°). Additionally, two synchronized ultrasound probes and 3D motion capturing were used to control kinematics and muscle-tendon unit behavior. Variables of interest were muscle force and rate of force redevelopment (RoFR) after shortening.
RESULTS: The SSC-effect was confirmed in all tested conditions. At the end of shortening, forces following SSC contractions were higher than after CON ($p<0.001$), yet both reduced compared to the isometric reference condition ($p<0.001$). RoFR post-shortening was significantly increased in fast conditions ($p<0.001$) with a tendency of an increased RoFR in SSC contractions when compared to CON ($p=0.065$). 2s post-shortening forces were decreased by 7-15% when compared to the isometric reference in all conditions ($p<0.01$) with no difference between CON and SSC ($p=0.4$). For fast contractions, statistical parametric mapping (SPM) revealed increased forces after SSCs up until 0.28-0.4s post-shortening when compared to CON ($p<0.02$).
CONCLUSION: Following SSC and CON contractions, forces were reduced compared to an isometric reference [3]. The increased forces at the end of shortening following SSC compared to CON could still be explained by changed muscle-tendon interaction during shortening. However, the lasting differences in post-shortening force during the isometric holding between fast CON and SSC contraction (same muscle length and contraction intensity) indicate history dependent effects. Thereby, our results suggest that range of motion seems to be less relevant for high RoFR than the speed of the muscle action. Both the less depressed forces post shortening as well as the better RoFR could be beneficial in consecutive SSC contractions by possibly influencing mechanical efficiency.

## STRETCH-SHORTENING CYCLES OF THE VASTUS LATERALIS VARY WITH ERGOMETER ROWING INTENSITY IN HIGHLY TRAINED ROWERS: AN EMG AND ULTRASOUND CROSSOVER TESTING

HELD, S., RAITERI, B., RAPPELT, L., HAHN, D., DONATH, L.

*GERMAN SPORT UNIVERSITY COLOGNE*

INTRODUCTION: A rowing cycle involves leg flexion and subsequent leg extension. This flexion-extension cycle enhances power output by about 10% compared with leg extension only [1], which is thought to occur because rowing cycles induce active stretch-shortening cycles (SSCs) of the knee extensors at the muscle fascicle level. SSCs enable up to 50% higher muscle force, work, and power output during the shortening phase compared with isolated muscle shortening [2]. However, it remains unknown whether rowing cycles cause active muscle fascicle stretch as the knee extensors have long in-series elastic tissues that can decouple fascicle and muscle-tendon unit (MTU) length changes [3]. Thus, the present study examined muscle fascicle kinematics of the vastus lateralis (VL) during rowing cycles at two rowing intensities and at the same rowing intensity with two techniques.
METHODS: Fifteen young, sub-elite, male rowers (19.5 ±1.6yr; 1.94 ± 0.06m; 91.9 ±5.4 kg; 2,000-m time-trial personal best: 456 ±33W; weekly training volume: 17.8 ±4.1h; rowing experience: 7.5 ±2.8yr) performed 60-s rowing intervals on an ergometer using a traditional style at a low (LiR) and high intensity (HiR) and a micro-pause style at a low intensity (MpR). Muscle activity amplitudes, knee joint angles, and muscle fascicle length changes from the left-sided VL were quantified using surface electromyography, inertial measurement units, and B-mode ultrasound imaging, respectively.
RESULTS: All rowing conditions showed active fascicle stretch during late knee flexion ($p \leq 0.001$, SMD $\geq 0.72$) and subsequent active fascicle shortening throughout knee extension. Active fascicle stretch duration, amplitude and velocity (rANOVA: $p \leq 0.001$, $\eta p2 = 0.49$) were not significantly different (post-hoc: $p \geq 0.17$; SMD $\leq 0.26$) between LiR and MpR, but were significantly increased during HiR (post hoc: $p \leq 0.001$; SMD $\geq 0.70$). The percentage of rowing cycles that involved active fascicle stretch (rANOVA: $p \leq 0.001$, $\eta p2 = 0.95$; post-hoc: $p \leq 0.001$, SMD $\geq 0.87$) was also significantly higher for HiR (98.3 ±12.9%) compared with both LiR (65.0 ±48.1%) and MpR (68.3 ±46.9%).
CONCLUSION: Rowing involves SSCs of the VL at both the MTU and muscle fascicle levels, but the amount of active stretch differs between rowing intensities, with the longest, largest, and fastest active stretch occurring during HiR. SSC-based mechanisms may therefore contribute more to rowing performance during HiR than LiR or MpR.

### OP-MH18 Brain and cognition (AGUEDA)

#### ASSOCIATION OF INFLAMMATORY MARKERS WITH GRAY MATTER VOLUMES IN COGNITIVELY NORMAL OLDER ADULTS: THE ROLE OF CARDIORESPIRATORY FITNESS. THE AGUEDA TRIAL.

OLVERA-ROJAS, M.1, SOLIS-URRA, P.1, MORA-GONZALEZ, J.1, TOVAL, A.1, GARCÍA-RIVERO, Y.2, RIVAS-NAVAS, D.2, PEÑA-GONZÁLEZ, C.2, ORTEGA, F.B.1,3, ESTEBAN-CORNEJO, I.1

*1.UNIVERSITY OF GRANADA; SPORT AND HEALTH UNIVERSITY RESEARCH INSTITUTE ; 2.INSTITUTE OF BIOSANITARY RESEARCH OF GRANADA ; 3.UNIVERSITY OF JYVÄSKYLÄ*

INTRODUCTION: Inflammatory markers are chronically elevated during aging. At this stage, inflammation has been associated with higher prognosis of neurodegenerative disorders, cognitive decline, and brain damage. This, in turn, might indicate a link between age-related inflammatory changes and neuropathological processes, including gray matter reductions. Conversely, cardiorespiratory fitness (CRF) is involved in the protection against chronic diseases associated with low-grade inflammation. Thus, we aim (i) to examine the association of interleukin-6 (IL-6) and C-reactive protein (CRP) levels with total gray matter volume in cognitively normal older adults; and (ii) to examine whether CRF may attenuate this relationship.
METHODS: This study included cross-sectional data from 77 older adults aged 65-80 years (54% females) participating in the AGUEDA randomized controlled trial. Plasma IL-6 levels were determined by an enzyme-linked immunosorbent assay (ELISA) and plasma levels of CRP were determined by nephelometry. All T1-weighted images were collected on a 3.0 T Siemens Magnetom Prisma Fit scanner. Gray matter volume was calculated using Diffeomorphic Anatomical Registration Through Exponentiated Lie algebra (DARTEL). CRF was assessed using the 6-minutes walking test. Model 1 was controlled for sex, age and years of education, and model 2 was additionally adjusted by CRF. Alphasim and Hayasaka were calculated for the statistical threshold.
RESULTS: IL-6 was negatively associated with gray matter volume ($p<0.001$) in the left inferior temporal gyrus ($k=132$; $t=-3,57$) in model 1. After CRF adjustments, this association was attenuated ($k=88$; $t=-3,49$). IL-6 was not positively related to gray matter volume in any region of the brain. In addition, CRP was not positively or negatively related to gray matter volume in any brain region.
CONCLUSION: The present study shows IL-6, but not CRP, may negatively influence gray matter volume in the left inferior temporal gyrus in cognitively normal older adults. CRF could partially attenuate the association between IL-6 and gray matter volume. Exercise-based randomized controlled trials will help to determine whether exercise-induced changes in these inflammatory markers might influence brain structure in older adults.

#### METABOLIC RISK AND GRAY MATTER VOLUME IN COGNITIVE NORMAL OLDER ADULTS (AGUEDA TRIAL): THE MODERATING ROLE OF MUSCULAR STRENGTH

SOLIS-URRA, P.1,2, MORA-GONZALEZ, J.1, FERNANDEZ-GAMEZ, B.1, OLVERA-ROJAS, M.1, TOVAL, A.1, MARTINEZ-BARBERO, J.P.3, CONTRERAS-RODRIGUEZ, O.4, ERICKSON, K.I.5, GÓMEZ-RÍO, M., ESTEBAN-CORNEJO, I.1

*1UNIVERSITY OF GRANADA; 2*

INTRODUCTION: Metabolic risk is associated with poorer brain health in older adults. Current evidence reveals a positive and important role of muscular strength for lower metabolic risk and higher gray matter brain volumes, separately, although this last association has been scarcely explored. Muscular strength may moderate the relationship between metabolic risk and brain volumes, but this has not been investigated. Thus, the aim of the present study is: (i) to determinate whether gray matter brain volumes change according to metabolic risk in cognitively normal older adults, and (ii) to test the moderating role of muscular strength on this association.
METHODS: Eighty cognitively normal older adults aged 65 to 80 years from the AGUEDA trial were included in a cross-sectional analysis. We calculated the metabolic risk considering waist circumference, triglycerides, high density lipid cholesterol, glucose, and blood pressure levels. A dichotomic variable was computed to indicate low (0-1 factors) or high (2-5 factors) metabolic risk. T1-weighted images were collected using a 3.0-Tesla Siemens Magnetom Prisma Fit scanner. Maximal muscular strength was determined by a handgrip dynamometer, using the average of the maximum value achieved with each hand. A whole voxel-based morphometric analysis was performed to determinate the differences in gray matter brain volumes between the low vs. high cardiometabolic risk participants, including age, sex and educational level as covariates. Alphasim and Hayasaka correction were applied to cluster size thresholding. The between-group significant eigenvariate values were then extracted to test the moderating role of muscular strength on the association between those values and the cardiometabolic risk using the Johnson-Neyman technique. This technique highlights the specific cut points of the moderator (muscular strength) in which the association between the predictor (cardiometabolic risk) and the outcome (gray matter brain volumes) appears or disappears.
RESULTS: Participants at high cardiometabolic risk had lower gray matter volumes compared to those at low risk in six clusters ($p<0.001$): superior frontal gyrus ($k=70$ and 159, for left and right), left inferior frontal gyrus ($k=89$), left postcentral gyrus ($k=146$), right superior temporal gyrus ($k=330$) and left cerebellum crus I and declive ($k=1029$). Moderation analysis revealed that the low vs high metabolic risk differences in gray matter brain volumes were moderated by muscular strength ($p<0.05$; >30.5 to < 48.5 kg) in all of the brain cluster mentioned above, except for the superior temporal gyrus and the cerebellum declive.
CONCLUSION: The present study demonstrates that cognitively normal older adults at high cardiometabolic risk have lower gray matter volume in several cortical regions and cerebellum, compared to those at low metabolic risk. In addition, muscular strength moderates the association between cardiometabolic risk and the gray matter brain volumes in those regions.

**THE ASSOCIATION BETWEEN GAIT VARIABILITY PARAMETERS AND GRAY MATTER VOLUME IN COGNITIVELY NORMAL OLDER ADULTS: A CROSS-SECTIONAL ANALYSIS FROM THE AGUEDA TRIAL.**

MARTIN-FUENTES, I.1, RUIZ-MALAGON, E.J.2, SOLIS-URRA, P.1, FERNANDEZ-GAMEZ, B.1, SCLAFANI, A.1, BELLON, D.1, KRAMER, A.F.3,4, ORTEGA, F.B.1, MORA-GONZALEZ, J.1, ESTEBAN-CORNEJO, I.1

*1 PROFITH ; UNIVERSITY OF GRANADA. 2 IMUDS UGR. 3. BECKMAN INSTITUTE, UNIVERSITY OF ILLINOIS, USA. 4. CENTER FOR COGNITIVE AND BRAIN HEALTH, DEPARTMENT OF PSYCHOLOGY, BOSTON,USA.*

INTRODUCTION: Greater gait variability is a predictor of dementia, and it has been associated with a higher risk of falls and frailty in the elderly. There is growing evidence on the relationship between gait parameters and gray matter volume in the brain. For example, inter-steps inconsistency, defined by poorer equilibrium control, uncoordinated movements, and greater sway, has been shown to be correlated with less gray matter volume in the brain in older adults with mild cognitive impairment. However, there is still a need to examine such associations in cognitively normal older adults. Thus, the aim of this study was to examine the associations between gait variability parameters and gray matter volume in cognitively normal older adults.
METHODS: Sixty-five cognitively normal older adults aged 65-80 years (37 women) participated in this cross-sectional analysis from the AGUEDA trial. The Optogait system (Microgate, Italy) was used to assess gait variability parameters. Participants walked back and forth across a track made up of two bars (i.e., a transmitting and a receiving optical signal bar) set 1-meter apart at their maximum walking pace for 5 minutes, recording a minimum of 150 steps. The bars were 5-m long (5 segments of 1-m each), and two cones were placed 2-m apart at each end of the track, so the participants had to turn around the cone and walk through the track again. The coefficient of variation (CV) of stride length (cm), stride time (sec), cadence (steps/min) and double steps support time (sec) were calculated as gait variability parameters. A 3.0 T Siemens Magnetom Prisma Fit scanner was used to acquire T1- weighted structural brain images. The gray matter volume was determined by voxel-based brain morphometric analysis. The associations between gait variability parameters and gray matter volume were assessed by individual general linear models (one model for each gait parameter) with age, sex, and years of education as covariates. The clusters were reported after applying AlphaSim spatial extent threshold and Hayasaka corrections.
RESULTS: Main results showed a negative association ($p<0.001$) between cadence and gray matter volume in the anterior cingulate cortex ($k = 152$; $t = -3.6$). In addition, stride length, stride time and double steps support time were not negatively related to gray matter in any brain region, after applying corrections. There were no statistically significant positive associations between any gait variability parameter and gray matter volume in any region of the brain.
CONCLUSION: Greater cadence variability, but none other gait parameter, was associated with less gray matter volume in the anterior cingulate cortex. This result suggests that poor gait performance and impaired gait regulation may negatively influence gray matter volume in the aging brain. Further experimental studies should examine the impact physical activity could have over gait variability, and in turn, gray matter volume in the elderly.

**AN UPDATE ON THE RESISTANCE STRENGTH EXERCISE PROGRAM FROM THE AGUEDA (ACTIVE GAINS IN BRAIN USING EXERCISE DURING AGING) TRIAL**

FERNANDEZ-GAMEZ, B., SOLIS-URRA, P., OLVERA-ROJAS, M., FONTALBA-MEDINA, R., FERNÁNDEZ ORTEGA, J., FERNANDEZ ESCABIAS, M., GRANADA-MAIA, J., PRIETO LARA, C., JIMÉNEZ-PAVÓN, D.

*1.UNIVERSITY OF GRANADA, 2.UNIVERSITY OF CADIZ*

(co-authors: Mora-Gonzalez, J., Esteban-Cornejo, I.
INTRODUCTION: The aim of the present study is to provide an update on the exercise program implemented in the AGUEDA trial, a randomized controlled trial investigating the effects of a resistance training program on brain health in cognitively normal older adults.
METHODS: A total of 85 cognitively normal older adults aged 65 to 80 years were randomized into an exercise or a control group. Participants from exercise group performed upper and lower limb exercises using elastic bands and theirs own body weight as main resistance. The exercise load was based on the execution time, the resistance of the elastic bands (seven ascending intensities), and the exercises difficulty (three levels). The exercise program lasted 24 weeks and included 3 sessions/week. Participants perceived maximal perceived exertion (RPE) using perceived exertion scale from 1 to 10 and intrinsic motivation, using Feeling Scale from -5 to 5, were recorded each session.
RESULTS: Of the 44 participants from the exercise group, 29 (19 females) have already completed the 24 weeks of exercise, accumulating a total of 2,016 training sessions with a 96.5% attendance rate. The mean total duration of these sessions was 70±4 min; specifically, 7.63±1 min dedicated to the warm-up, 57.2±3 min to the main part, and 5.42±1 min to the cool-down. The mean RPE achieved was 5.41±1. Pre- and post-session intrinsic motivation scores were 3.07±0 and 3.34±0 (difference's $p<0.001$), respectively.
CONCLUSION: The present study details the progress made in the resistance strength exercise program of the AGUEDA trial so far. This may serve public health professionals who wish to implement such evidence-based program and test its brain health effects in cognitively normal older adults.

**IDEAL CARDIOVASCULAR HEALTH AND MEMORY PERFORMANCE IN COGNITIVELY NORMAL OLDER ADULTS: PRELIMINARY RESULTS FROM THE AGUEDA TRIAL**

BUSTAMANTE-ARA, N.1,4, SOLIS-URRA, P.1, COCA-PULIDO, A.1, OLVERA-ROJAS, M.1, MOLINA-HIDALGO, C.2, COSTA-RODRÍGUEZ, C.1, CARRERA-MUÑOZ, I.3, ORTEGA, F.B.1, MORA-GONZÁLEZ, J.1, ESTEBAN-CORNEJO, I.1

*1.UNIVERSITY OF GRANADA, SPAIN; 2. UNIVERSITY OF PITTSBURGH, PITTSBURGH, PA; 3.HOSPITAL UNIVERSITARIO VIRGEN DE LAS NIEVES, GRANADA. SPAIN; 4. ACCDIS, PONTIFICIA UNIVERSIDAD CATÓLICA DE CHILE, CHILE.*

INTRODUCTION: Physical activity contributes to maintaining cardiovascular and brain health during aging. Increasing numbers of Ideal Cardiovascular Health (ICVH) factors has been associated with a lower risk of dementia and lower rates of cognitive decline[1]. Particularly, ICVH factors could influence memory (subjective and objective) in healthy older adults, which is closely related to a higher risk of developing dementia [2]. Our objective was to examine the associations of individual and combined ICVH factors with subjective and objective memory performance in cognitively normal older adults.
METHODS: We analyzed baseline (cross-sectional) data of 71 cognitively normal older adults aged 65 to 80 years from the AGUEDA trial. The 7 ICVH factors proposed by The American Heart Association [3] were classified as "ideal" or "not ideal": smoking, body mass index (BMI), physical activity, diet, cholesterol, blood pressure, and glucose. The Subjective Cognitive Decline (SCD) was defined by obtaining ≥5

points in the subjective memory decline scale [4], plus no impairment in the Montreal Cognitive Assessment test. Visual memory was assessed by Rey-Osterrieth Complex Figure (ROF) and episodic memory by Rey Auditory Learning Verbal Test (RALVT). Sometimes variables were inverted so that a high score indicated a better performance (i.e., retroactive interference and proactive interference). Sex, age, and educational level were included as covariates in the models.
RESULTS: Among 71 participants, the mean age was 70.8 (SD 3.7) years, 58% women. The mean ICVH score was 3.2 (SD 1.2), higher in women than men (p=.01). 17% of participants had more than 5 ICVH factors. Individual ideal criteria and the ICVH score were not associated with SCD score (Rho:-.065, p=.60). Individual ICVH factors were not associated with objective memory performance (i.e., visual or episodic memory), except for blood pressure. Ideal blood pressure was associated with better performance in episodic memory (Coefficient:1.16, IC95% .08 to 2.24 for retroactive interference). In addition, participants with ≥5 ICVH factors showed similar performance in visual and episodic memory compared to those with <5 ICVH factors (all p>0.05).
CONCLUSION: ICVH factors were not associated with subjective memory performance. Except for blood pressure, ICVH individual factors or ICVH score may not influence visual and episodic memory in cognitively normal older adults. Future, more extensive studies should examine the influence of ICVH on memory performance and other cognitive indicators during aging.

## Oral presentations

### OP-SH11 Socio-ecological factors and sport participation

#### CAN ECOLOGICAL LANDSCAPE BE A USEFUL CONCEPT FOR UNDERSTANDING PHYSICALLY INACTIVE CHILDRENS RELATIONSHIP TO PHYSICAL ACTIVITY IN EVERYDAY LIFE?

HÖGMAN, J., AUGUSTSSON, C., WAGNSSON, S.
*FACULTY OF ARTS AND SOCIAL SCIENCES*

To understand how physically inactive children relate to physical activity (PA) there is a need to utilize concepts allowing for a structured ideographic approach. Bronfenbrenners (2005) various theoretical models has been widely utilized within sport and health science. A common critique has been that the model, often illustrated as concentric circles, is too static and, thus, not accounting for the complexity of how culture informs human development (Vélez-Agosto, 2017).
In order to push bioecological thinking forward and to develop a more dynamic perspective, we use the concept 'ecological landscape'. Our purpose here is to make visible how barriers and openings within various ecological systems interact and, thus, create a unique landscape for every individual child's relationship with PA. The concept ecological landscape refers to the sum of the relationships between an individual child and its multidimensional environment. It is grounded in field theory (Lewin, 1952), bioecological theory (Bronfenbrenner, 2005) and integrates sociocultural perspectives (Veléz-Agosto et al., 2017). We consider the relationship between children and PA to be shaped by barriers and openings in the ecological landscape. These barriers and openings are derived from various ecological systems and are of different nature (both culture, nature and mixtures of these). Together they create a landscape that characterizes the path to PA. Experiences of the barriers and openings are created in interaction with the child and its unique characteristics. Thus, the landscape is subjectively constructed and unique to each child. The landscape is ecological because the child and its environment is inevitably intertwined. If one of the parts changes, so does the other. Learning always involves change in perception. To equip a child with resources, competences, and beliefs means that the landscape will change and new openings will be visible.
The potential in using the concept of ecological landscape lies in the ability to qualitatively, and at an appropriate level of abstraction, make visible how aspects of the inactive child's relationship with the environment influence behavior. This makes it possible to start from a subjective position and investigate the weight of various influences. A further potential is to use the concept as a methodological tool that may open up for participatory action research. In the research process, inactive children may develop an increased awareness of their own ecological landscape.

#### THE MUTABILITY OF SPORTS PARTICIPATION AND THE EMERGENCE OF INFORMAL SPORTS AMONG NORWEGIAN YOUNGSTERS

JOHANSEN, P.F., THURSTON, M., GREEN, K.
*INLAND NORWAY UNIVERSITY OF APPLIED SCIENCES*

Introduction
Despite a growing body of evidence suggesting that establishing wide sporting repertoires during youth is related to ongoing engagement in sports, little is known about how youngsters' sporting careers develop during the teenage years. In particular, there is a lack of knowledge about developments in forms of participation. By providing detailed analysis of cohorts of young Norwegians as they progressed through lower-secondary school and into upper-secondary school (13–16-year-olds), this study provides insights into how different sporting forms wax and wane during a particularly important period typically marked by heavy drop-out and drop-off from sports.
METHODS: Data were obtained from a longitudinal cohort study of Norwegian youngsters attending 11 lower secondary schools. Annual surveys were conducted from grade 8 through grade 9 to grade 10. Appropriate analyses for repeated measures and between-subjects were used to examine changes in sports participation frequency and sporting forms over time as well as differences in participation between the sexes respectively.

RESULTS: The results showed the cohort sustained their sports participation rates over the three years. Girls' sports participation declined slightly but significantly overall. For boys, there were no significant changes. Nor were there any significant differences in sports participation frequencies between sexes at age 15–16. While team games decreased for all between grades 8 and 10, the decrease was only significant for football and handball among girls and hockey for boys. Strength training increased significantly in popularity among both boys and girls over the three-year period.
Discussion
We suggest that the reasons for the relatively stable and high sports participation rates observed are due to mutable participation patterns where the youngsters shifted and changed between different sporting forms. The observed patterns suggest a convergence between the sexes, contributing to narrowing gender gaps in sports participation. Growth in the popularity of strength training across the whole sample underlines the increasing centrality of health and fitness and informal sports through the life-stage of youth for both sexes. The findings then, suggests that drop-out from organized, club-based sport does not necessarily signal drop-out from sport per se, it might also signal an intensification of the trend towards more informal activities. That being said, organized sport has not faded into the participatory background. Our data suggest that boys remain more likely than girls to sustain involvement in sports typically done in organised forms, while girls on the other hand, reported more pronounced shifts towards less organized orientations towards participation. This may throw some light on the steeper decline in organized sports participation among girls compared to boys during youth.

## ELITE ATHLETES AND PARENTHOOD - FINANCIAL CONDITIONS, (SUPPORT) STRUCTURES AND FAMILY PLANNING

HELLBORG, A.

*MALMO UNIVERSITY*

Elite athletes as parents have received greater attention in recent years, which has raised questions regarding the possibilities of combining an elite career with family life. Research in this area has increased during the 2000's. Palmer and Leberman's study (2009) of mothers found that balancing time between family and elite sports was difficult; this is also found in other studies (Andreasson et al, 2018). Time seems to be a key issue when committing to a sporting career and having children. The purpose of this study is to explore and analyse elite athletes' view of combining elite sports and parenthood from a financial and structural perspective. As analytical tools Mills ideas of personal troubles and public issues is relevant as well as theories surrounding parenthood and gender equality.
An online survey directed to active elite athletes was used. The survey consisted of questions about financial conditions, support and the structuring of their sporting activities. I received 27 answers from athletes who had children and 11 from those who did not have children. The results show that about half of those who have children say that their financial situation has been worse since they had children. Two thirds do not feel they have support from their national association. There is a lack of support for bringing children to competitions, which was an expressed wish for some. About half of the respondents said that the association need more knowledge about combining elite sports and parenthood.
Both groups have elite sporting colleagues that have had children during their career. Those who do not have children express that it will be important to try to plan when to have children, so it does not collide with important competitions. This is something that those who had children did not say to the same extent.
The conclusion is that the associations are not offering support to the elite athletes, according to the athletes. The athletes wish there were more support to bring children to competitions but also for the association to show support for their situation. Some even expressed that the association were uninterested in their situation. The athletes' wish for support can be perceived as an opinion that combining elite sports with parenthood is a public issue that the association need to help them with. However, the lack of support they receive may be interpreted as a perception of this situation as a personal trouble that the athletes have to figure out for themselves (cf. Mills, 1971/2002). There may be a gap in the perception of this situation between athletes and the associations.

## LIKE FATHER, LIKE DAUGHTER - A QUALITATIVE STUDY OF FATHER-DAUGHTER DUOS IN PROFESSIONAL SOCCER

ERIKSTAD, M.K., HAUGEN, T., SEGBERG, U., GRANLI, E., JOHANSEN, B.T.

*UNIVERSITY OF AGDER*

Introduction
Wilson, Wilson, and Baker (2018) have noted that there are many anecdotes of sporting talent that runs in families. Nevertheless, there is a lack of studies concerning the dynamics within such families where expertise passes down through generations. The purpose of the study was therefore to investigate the perceived role and importance of fathers in father-daughter duos in professional soccer.
Method
Informants consisted of two Norwegian father-daughter duos in soccer (n = 4). Both fathers had played for the Norwegian national team, and their daughters are current professional players that have represented Norway at U-23 national team level or higher. Individual semi-structured interviews were conducted by telephone. All informants were asked about their own sport development, as well as questions about fathers' involvement in their daughter's career. Interviews were verbatim transcribed and thematic analyzed.
Results
All informants described a developmental pathway consisting of large amounts of play and practice activities throughout development, with increased emphasis on deliberate forms of practice from adolescence. Informants also highlighted factors that contributed to understand their play and practice involvement, including access to local soccer fields and influential coaches and siblings. Furthermore, four themes related to paternal influence on daughter's careers emerged: 1) role models (e.g., transmitting values and daughters being inspired to achieve what their dad had achieved), 2) active involvement (e.g., fathers playing with and/or coaching their daughter), 3) expert advice (fathers using their own experience and expertise to advise), and 4) support (e.g., emotional support, avoiding pressure).
Discussion
While notions have been made about multiple sporting generations, the present study is to our knowledge the first to investigate the perceived role and importance of fathers in professional father-daughter duos. Informants highlighted paternal influence that were enabled by their experience as former professional athletes, including providing expert advice and their daughters being inspired by their

achievements. Furthermore, findings also included paternal involvement that may be applied by parents without previous professional sport careers, including playing sport with their child and providing support.

**INFLUENCE OF THE SOCIAL AND SPORTING CONTEXT ON THE DEVELOPMENT OF SPANISH PARALYMPIC ATHLETES**

CERRADA-NOGALES, J.A., FERNÁNDEZ-GONZÁLEZ, A., RODRÍGUEZ, M., GIMÉNEZ, F.J., ABAD, M.T.
*FACULTY OF EDUCATION, PSYCHOLOGY AND SPORTS SCIENCES. UNIVERSITY OF HUELVA.*

Introduction
Whether an athlete reaches the highest level in any discipline will be determined by many factors. In the performance of Paralympic athletes, it is of paramount importance to understand the sporting context (Blauwt and Lezzoni, 2014) as they face numerous social and environmental barriers (Díaz et al., 2019) that limit the sporting participation of people with disabilities (Díaz et al., 2019).
Method
The sample consists of 28 Spanish Paralympic women who have participated and won at least one medal in a Paralympic Games held in the 21st century (Sydney 2000, Athens 2000, Athens 2004, Beijing 2008, London 2012, Rio 2016 and Tokyo 2020). This is a qualitative research as the interview was used as an instrument for the collection and analysis of information.
Results
Among the results referring to the sporting context, most of the sportswomen interviewed were influenced by a family member or friend, or by medical recommendation in order to gain confidence and independence due to their disability. Regarding the social context, the sportswomen interviewed acknowledged the great help they received from their families during the training process, as well as from their friends, but to a lesser extent. On the other hand, they emphasized that at no time did their family and friends put any kind of pressure on them.
Conclusions
Most of them highlighted the figure of the coaches because of the constant motivation they receive from them. However, some of the women interviewed stated that the coaches, in some cases, gave them stress and anxiety. On the other hand, the closest social environment (family and friends) is essential during the training stages for the athletes as they exert a strong influence. In addition, there is the psychological support that they have given them in the hardest stages, especially in high performance.

### OP-MH24 Exercise therapy

**EFFECTS OF A HOME-BASED WHOLE-BODY HIGH-INTENSITY INTERVAL TRAINING ON NEUROMUSCULAR AND CARDIORESPIRATORY FITNESS**

KLASS, M., SCOUBEAU, C., FAORO, V., CARPENTIER, J., BAUDRY, S.
*UNIVESRSITÉ LIBRE DE BRUXELLES*

INTRODUCTION: Developing effective home-based exercise interventions is important for people living far from fitness or rehabilitation facilities, more so in the context of social-distancing during the COVID-19 pandemic (1). Therefore, the present study investigated the neuromuscular and cardiorespiratory fitness adaptations to a home-based, video-directed, high-intensity interval training using only body weight as resistance (WB-HIIT).
METHODS: Twenty-seven healthy adults (23 ± 1 years) were assigned to the WB-HIIT group (N=14) or to a control group (maintenance of habitual lifestyle) and took part to pre- and post-intervention evaluations. The neuromuscular assessments included 3 repetition maximum (3RM) leg press, knee extensor maximal isometric voluntary contraction (MVC), voluntary activation (VA; using the interpolated twitch method) and muscular endurance (quantified by the time to task failure [TTF] at 30% MVC). Maximal oxygen consumption (VO2max) and aerobic power (Wmax) were determined during an incremental cyclo-ergometer test. The 8-week WB-HIIT (3 sessions/week) consisted in a 3-min warm-up followed by 4 bouts of 30 s all-out whole-body exercises (squats, lunges, mountain climbers, jumping jacks, modified burpees…) interspaced with 30 s of active recovery. The training sessions were performed at home by means of videos containing oral directives for each exercise and simultaneous demonstration. Heart rate (HR) was recorded during sessions using a HR monitor and the Polar Beat app.
RESULTS: None of the parameters changed significantly in the control group. Maximal and mean HR recorded during the WB-HIIT sessions were respectively 88 ± 5 % and 74 ± 5 % of maximal HR. The VO2max (+5%; P=0.03) and Wmax (+7%; P=0.01) increased significantly after WB-HIIT. The 3RM and MVC torque increased by 14% (P<0.001) and 8% (P=0.04), respectively. VA tested during the MVC did not change significantly (P=0.27) after WB-HIIT. However, there was a negative correlation (r= -0.77; P<0.01) between subjects' initial VA level and VA change (%), and a positive correlation (r=0.74; p<0.01) between VA change (%) and MVC torque increase (%). Finally, TTF was improved by 26% (P=0.025) after WB-HIIT.
CONCLUSION: The home-based WB-HIIT, performed during the pandemic period, induced improvements in cardiorespiratory fitness as well as in isometric strength, 3RM and muscular endurance. The negative relation between initial VA and VA change suggests a greater effect in subjects with lower initial VA, which resulted in a positive impact on maximal torque.

**THE IMMEDIATE EFFECT OF EXERCISE INTENSITY ON MOOD AND PERCEIVED EXERTION OF ADULTS WITH DEPRESSIVE DISORDER**

KAFRAMANI, E.M., KARNAROU, K., PSYCHOUNTAKI, M., NIKOLAIDOU, M.E.

*NATIONAL AND KAPODISTRIAN UNIVERSITY OF ATHENS*

INTRODUCTION: Numerous studies have shown that exercise is effective at reducing depressive symptoms. However, because of the heterogeneity of exercise programs, optimal exercise intensity has yet to be established (1). Moderate intensity has been suggested as an ideal solution (2), but, both low and high intensity exercise interventions have produced positive outcomes, rendering results equivocal (3). This study aimed at investigating the immediate effect of a single bout of interval training at different intensities.
METHODS: Fifteen participants (12F, 39.7±14.1 years), that suffered from mild to moderate depression (Beck-II scores: 17-22) and, who were assessed with a high physical activity level (IPAQ) (4), participated in a low (~50-60% HRmax) and a moderate-to-vigorous (MTV) intensity exercise session (~70-80% HRmax). Participation order was randomly counterbalanced with a period of 3-4 days apart. Both sessions included interval training with load corresponding to body weight and of 45 min duration. Before and right after cessation of exercise, participants completed the profile of mood state questionnaire (POMS) and the Borg rate of perceived exertion scale. Furthermore, heart rate was recorded (Polar M430) for 5 min before and throughout execution of both sessions and was used to determine HR levels at rest and at 1st and 2nd min of recovery phase. Two-way RM ANOVAs (time x exercise intensity) and paired t-tests were performed to test for possible differences.
RESULTS: A significant main effect of time was found since immediately post both exercise sessions, participants' mood (PRE: 18.8±2.6, POST: -8.9±1.3; P<0.001) and perceived rate of exertion scores (PRE: 14±0, POST: 10±1; P<0.001) were improved. Exercise intensity did not have a significant effect either on mood (LOW: 3.6±20.5, MTV: 6.3±20.2; P<0.05) or perceived rate of exertion (LOW:12±3, MTV:13±4; P<0.05). Exercise intensity did not significantly differentiate HR responses at recovery (1st min: LOW: 20±8, MTV: 16±8 bpm; P<0.05; 2nd min: LOW: 25±8, MTV: 21±12 bpm; P<0.05), whereas HR levels at rest were similar between intensities (LOW: 80±12, MTV: 79±12 bpm; P<0.05). No significant interaction was found in any parameter.
CONCLUSION: Present results support previous studies reporting a significant decrease of depressive symptoms after moderate intensity training. It has been suggested that the effect of exercise on depression is independent of the dose, intensity or type of exercise (1) and the improvement in mood and rate of perceived exertion after the low intensity session suggests it. The similar rate of cardiac recovery evidenced in both intensities lends further support. In conclusion, a single bout of low or MTV exercise intensity seems to have a beneficial effect on mild-to-moderate depressed adults.

**LONG TERM PHYSICAL ACTIVITY IMPROVES THE QUALITY OF LIFE AND ENRICHED ENVIRONMENT ATTENUATES DEPRESSION, IN ELDERLY**

FIORILLI, G., DI MARTINO, G., BUONSENSO, A., CENTORBI, M., CALCAGNO, G., DI COSTANZO, A., DI CAGNO, A.

*UNIVERSITY OF MOLISE*

INTRODUCTION: Physical activity is progressively being recognized as a key element in the whole management of successful aging. Nevertheless, only a prolonged engagement in regular exercise might allow the expected benefits. Moreover, the gradual multy-sensory deterioration, by providing less stimulation to the areas of the brain, accelerates the decline in elderly. Environmental factors and active lifestyles seem to positively influence the neurodegenerative processes, promoting adherence and compliance, decreasing stress and the risk of depression (Zhang, S., et al 2021). The purpose of this study was to show the effects of physical activity programs on the quality of life and depression of an over-50 age sample assessed after 6, 12 and 24 months.
METHODS: One hundred and seventy-eight subjects (aged 62.12 ± 7.88) were randomly assigned to two experimental conditions: Aerobic and Strengthening training in standard environment (AS) and Low-impact Exercise (LE) in enriched environment, 3 days per week. Before and after intervention, quality of life (SF-36) and depressive disorder (GDS) assessment questionnaires were administered.
RESULTS: The univariate analysis showed no significant differences after 6 and 12 months in SF-36 for both the experimental groups, while only AS showed a significant improvement after 24 months (f=11.14; p= 0.001). Conversely, regarding GDS, a significant improvement in depression scores, after 6 months, were found in LE groups (f=8.922; p= 0.001) and these values remain constant up to 24 months while AS did not show significant differences between among 6,12 and 24 months.
CONCLUSION: High level of fitness, gained after AS, improved a good perception of quality of life estimated on the scales of physical, emotional and social functioning, vitality, psychological well-being, which correlated with health, but only after a long-term adherence to exercise (Choi, J et al 2021).
Regarding changes in depression, the results suggested that an exercise program organized in an enriched environment is more effective in attenuating depressive symptoms than a traditional program. Exercise training organized in a context which offers many opportunities for physical activity, with sensory and intellectual stimulations, might improve the depressive symptoms.

### PHYSIOLOGICAL AND PERCEPTUAL DIFFERENCES BETWEEN NORMOBARIC HYPOXIA AND TERRESTRIAL ALTITUDE: A RANDOMIZED CONTROLLED CROSSOVER STUDY

HOHENAUER, E.1,2,3,4, FREITAG, L.1, COSTELLO, T.J.5, KUENG, T.2, TAUBE, W.3, HERTEN, M.1, CLIJSEN, R.1,2

*1 UNIVERSITY OF APPLIED SCIENCES AND ARTS OF SOUTHERN SWITZERLAND, LANDQUART, SWITZERLAND 2 THIM UNIVERSITY OF APPLIED SCIENCES, LANDQUART, SWITZERLAND 3: UNIVERSITY OF FRIBOURG, FRIBOURG, SWITZERLAND*

INTRODUCTION: Much hypoxia research has been carried out in a hypobaric environment but investigations between normobaric hypoxia (NH) and hypobaric hypoxia (HH) are lacking [1]. Therefore, the aim of this study was to investigate, if there is a difference between NH and HH and to compared it to normobaric normoxia (NN) on a) cognitive performance, b) physiological and perceptual response during sub-maximal exercise and c) on the autonomic nervous system, stress response and self-perceived ratings under rest.
METHODS: Healthy volunteers (n=10 females, n=10 males, 27.6±6.2 yrs) underwent 4 experimental sessions. In NN, participants were tested in the laboratory at ∼550m whilst under NH, an altitude of ∼3000m was simulated. During terrestrial altitude, participants spend two days (HH1 and HH2) at ∼3000m in the Swiss alps. The participants conducted in each condition a cognitive performance test (CPT) and a submaximal step-test (modified Harvard step-protocol). During the CPT, cerebral tissue oxygenation index (cTOI) and cognitive performance outcomes (throughput, accuracy and reaction time) were assessed. During the submaximal step-up test, heart-rate (HR), SpO2, quadriceps femoris muscle oxygenation index (mTOI), perceived exertion, mean arterial pressure, lactate and dyspnea were collected. At rest, salivary cortisol, HR-variability (HRV), symptoms of acute mountain sickness (AMS) and sleep quality were assessed.
RESULTS: During CPT, cTOI was higher in NN vs NH (ΔcTOI 5.03±1.4%, p=0.001) and higher in NN vs HH1 (ΔcTOI 5.14±1.4%, p=0.001) with no differences between NH and HH1 and HH2. Δaccuracy, Δreaction time didn't change between groups during CPT. During the step task, SpO2 was higher in NN vs all hypoxic conditions (ΔSpO2 NN vs NH: 6.0±0.6%, p<0.001, ΔSpO2 NN vs HH1: 7.8±0.6%, p<0.001, ΔSpO2 NN vs HH2: 6.3±0.6%, p<0.001). SpO2 was also higher NH vs HH1 (ΔSpO2 1.7±0.6%, p=0.008). HR was lower in NN vs NH (ΔHR 5.4±2.6 bpm, p=0.04) and lower in NN vs HH2 (ΔHR 11.2±2.6 bpm, p<0.001) during the step-task and lower in NH vs HH2 (ΔHR 5.8±2.6 bpm, p=0.03). At rest, parasympathetic- and sympathetic nervous system were more negatively affected in HH2 vs NH (p<0.05) whereas symptoms of acute mountain sickness were higher at HH1 vs all other conditions (p<0.01 for all).
CONCLUSION: In conclusion, this study demonstrates, that the physiological responses to systemic, moderate hypoxia are different between NH and HH. SpO2, cardiovascular and HRV were more negatively affected in HH compared to NH. Nevertheless, this study also shows the different inter-individual responses to hypoxic environments which should be investigated in future studies under controlled and standardized conditions.

### FEASIBILITY AND ACCEPTABILITY OF AN ADAPTED PHYSICAL ACTIVITY TOOL (MATCH) TO PREVENT IATROGENIC DECLINE DURING HOSPITALIZATION IN OLDER ADULTS: IS THE TYPE OF CARE UNIT AN ISSUE?

AUBERTIN-LEHEUDRE, M.

*UNIVERSITÉ DU QUÉBEC À MONTRÉAL*

INTRODUCTION: In older adults, hospitalization leads to iatrogenic decline, which accelerates the spiral of autonomy loss. Implementing physical activity (PA) as clinical care would be a solution to counteract this deleterious process. Previously, we showed that MATCH, an adapted and unsupervised PA program, seemed feasible, acceptable and effective in geriatric assessment units (GAU) and even in covid-19 units. Nevertheless, the reasons for hospitalization of older adults are diverse, leading them to be admitted to different geriatric care units. Thus, we aimed to evaluate the implantability, feasibility, and acceptability of MATCH in 3 geriatric units (post-acute care (PAC) vs. rehabilitation unit (RU) vs. GAU).
METHODS: All patients admitted to the 3 geriatric units during the study period were assessed by the physician to verify eligibility and to prescribe the MATCH PA program. Inclusion rate, prescription rate, and time to implementation as well as adherence and acceptability but also physical performance were assessed.
RESULTS: Of the 390 patients admitted, 140 were eligible. Among these patients, 114 (RU: n=41; GAU: n=43; PAC: n=30) accepted the care MATCH. The median time to implementation was acceptable and similar between the 3 units (day: RU:2.59 vs. PAC:3.27 vs. GAU:1.26). Rehabilitation health professionals found the MATCH program adequate for patients admitted on the 3 units (% of adequacy: RU:71.4 vs. PAC:75 vs. GAU: 73.7). Although the patients were free to do their exercises, more than half of them did the exercise prescription twice a day (% of patients: RU:85.6 vs. PAC:69.9% vs. GAU:91.2%). The walking goal was achieved at 100% by all patients from the 3 units. Finally, grip strength (Jamar+), functional capacity (SPPB), lower limb strength (takaï equation via 10 rep chair test) and muscle endurance (30 sec chair test) improved significantly for all the patients independently of the unit.
CONCLUSION: Implementing MATCH during hospitalization appears to be feasible and acceptable in addition to increase physical health of older adults, independently of the type of unit care. A randomized controlled trial is needed to confirm our promising results regarding this pragmatic exercise tool .

### IS-BM05 The Accurate Assessment of the Neuromuscular System in Sports Science

#### THE ORIGINS AND IMPLICATIONS OF BIAS IN SURFACE ELECTROMYOGRAMS

VIGOTSKY, A.

*NORTHWESTERN UNIVERSITY*

Surface electromyograms (sEMG) are the primary measure used to draw inferences regarding neuromuscular excitation. In doing so, investigators assume that sEMG amplitude accurately represents the degree of a target muscle's electrical activity. In this talk, I will discuss the validity of this assumption, especially as it pertains to bipolar sEMG. First, I will review the biophysics of muscle fiber action potentials and how they give rise to the interference sEMG. From first principles alone, one can see how biases in—or systematic effects on—the sEMG amplitude may present themselves and influence inferences when, for example, comparing sEMG amplitudes between muscles. For instance, the angle of pennation appreciably affects sEMG amplitude due to how the action potentials travel through space relative to the electrodes. Next, I will discuss experimental evidence demonstrating how biases can arise in sEMG experiments and the extent to which these biases can affect inferences. Such evidence indicates that muscle length changes and other nonstationarities have massive effects on observed amplitudes, even for identical neural input. Finally, I relate this evidence to applications of sEMG amplitudes in sports science, including comparisons between exercises and during highly dynamic movements—inferences from bipolar sEMG are often untenable, considering the biases described. Yet, hope is not lost! In closing, I will present why there is reason to believe more advanced methods, including high-density sEMG, can help overcome several of these biases to enable more accurate inferences concerning neuromuscular excitation in sports science.

#### IS THE VARIABILITY IN EMG SIGNALS JUST NOISE?

HODSON-TOLE, E.

*MANCHESTER METROPOLITAN UNIVERSITY*

One of the key aims when recording an EMG signal in any experiment, is to maximise the physiological content and minimise non-physiological signal components. In doing so we often talk about minimising 'noise' in recorded signals. In signal processing, the term noise be used to reflect these unwanted signal modifications. It can also be used to mean that recorded signals are random or unpredictable, and at first glance an EMG signal may appear to contain such random variation.In many examples human movement (and other natural phenomena) we find that variability in the measure of interest (e.g., stride length or speed) can in fact show clear patterning, or structure, when assessed as a function of time. This structure indicates a temporal organisation to the variability (structure), that is non-random and is considered to contain useful information related to the underlying system control. Structure in the fluctuations of a person's stride times or pedal cycle durations can be generated by simple mechanical mechanisms or by the neural command signals reflected in EMG signals. For example, we can consider structure in raw EMG signals may reflect fluctuations in the firing rates of recruited motor units and therefore may not be as 'noisy' as they first appear.
Recently developed methods of quantifying signal structure provide measurements of features of signal structure in a physical time scale (e.g., milliseconds, or number of pedal cycles), which is usefulfor physiological interpretation and comparison to other biomechanical or physiological measures. Here we will therefore explore the application of a sample entropy-based measure of signal structure, entropic half-life (EnHL), to assess EMG signals, focusing on those recorded during cycling on a stationary cycle ergometer. This will include discussion of the potential for signals recorded from high-density surface EMG arrays to be assessed using such techniques to improve understanding of underlying motor control strategies.

#### WHAT WE NEED TO KNOW FOR DETECTING HIGH-DENSITY SURFACE EMGS IN SPORTS SCIENCE

VIEIRA, T.

*POLITECNICO DI TORINO*

The first two lectures will present considerations for the valid application of surface electromyography. The first talk will deal with the sources of bias undermining the assumption that the amplitude of surface electromyograms (EMGs) is a proxy of muscle excitation. The second talk will focus attention on the possibility of overcoming these sources of bias when sampling surface EMGs from multiple skin locations. At this point, we expect one to acknowledge high-density technology may be the most accurate means of assessing the timing and the degree of muscle excitation. However, the open issue remains: How can high-density surface EMGs of high quality be collected in the highly dynamic conditions inherent to sports science? Addressing this question requires:
I) The ability to discriminate signals of high quality from signals of low quality
The quality of surface EMGs is not directly related to the bias discussed in the first talk, but to the signal-to-noise ratio (SNR). Ideally, the surface EMG contains a collection of action potentials generated within the target muscle. How well these action potentials are represented in the surface EMG depends on how much noise is present in the signal, with noise being broadly defined as fluctuations in the skin electric potential associated with non-physiologic sources under direct control of the experimenter. The SNR, and thus the signal quality, scales with how much greater the amplitude of action potentials is relative to variations in the skin electric potential resulting from the movement of cables, inappropriate cleansing of the skin and power line interference. Overcoming bias is possible only when the collected EMG has a sufficiently high SNR.
II) A minimally encumbering, robust system for acquiring high-density EMGs
Valid inferences for sport necessitate that subjects be allowed to move freely with surface EMGs. Otherwise, wearing an encumbering, acquisition system would itself constitute a source of bias. In addition to facilitating movement, systems for the acquisition of high-density EMGs in dynamic conditions should be robust to the sources of noise described in the previous point. Thus, the ideal acquisition system

should eliminate cables connecting electrodes to the amplifiers, use miniaturize, lightweight acquisition modules, and employ a wireless communication protocol.
In this talk, I will cover the two points above. I will discuss the meaning of sufficient quality, providing didactic examples on how high-density surface EMG helps discriminate signal quality and overcome bias. I will then show the high-density acquisition system that we recently developed, suitable for sports science applications, and illustrate how it has been used for the detection of high-quality, high-density EMGs from elite athletes during the challenging 100 m sprint.

### EFFECT OF CAFFEINE ON TIME TO EXHAUSTION, TIME PERCEPTION AND PERCEIVED FATIGUE IN ACTIVE SUBJECTS

WEIPPERT, M., GUBE, M., BRUHN, S., SCHRÖDER, T., TILLMANN, M., BEHRENS, M.

*UNIVERSITY OF ROSTOCK*

INTRODUCTION: Caffeine (CAF) has been shown to improve endurance performance probably due to its effects on the central nervous system resulting in a decreased effort perception. Although effort perception is considered an important determinant of endurance performance and a contributor to perceived fatigue, further aspects related to perceptual-discriminatory, affective-motivational, and cognitive-evaluative dimensions might play a role (Venhorst et al., 2018). Therefore, we investigated the effect of oral CAF ingestion on endurance performance, perceived fatigue, and its determinants.
METHODS: For this purpose, 35 recreationally active subjects (17 females, age: 23 ± 4 yrs) participated in a randomized, counterbalanced cross-over study. Peak power output was determined in a familiarization session. Subsequently, the effect of 6 mg*kg-1 of CAF, compared to placebo (PLA), on time to exhaustion (TTE), perceived fatigue, perceptual-discriminatory (effort, exercise-induced bodily sensations), affective (valence, arousal, dominance), and cognitive-evaluative determinants (action crisis, attentional focus) as well as time perception (i.e., time production precision) and heart rate during cycling at 65% peak power was investigated. Data were analysed with repeated measures ANOVAs and paired t-tests.
RESULTS: No effect of CAF was found on TTE ($p = 0.552$, Cohen's $d = 0.235$), perceived fatigue, as well as its perceptual-discriminatory, affective, and cognitive-evaluative dimensions. In contrast, time production precision was better during CAF at the beginning and did further improve with increasing perceived fatigue, while it decreased during PLA (interaction of time × condition: ($p = 0.020$, $\eta^2 = 0.163$). There were no significant differences in mean heart rate between CAF and PLA ($p = 0.402$, Cohen´s $d = 0.506$).
CONCLUSION: While TTE, perceived fatigue, and its determinants were not affected by a dose of CAF during constant-load exhaustive cycling in recreationally active subjects, precision of time perception during exercise was improved. This might be explained by improved general attention following CAF ingestion. Further investigations are needed to clarify whether CAF can thereby positively affect pacing behaviour and performance in time trial paradigms.

### QUANTIFICATION OF CAFFEINE AND ITS MAIN METABOLITE PARAXANTHINE FROM DRIED BLOOD SPOTS (DBS) AFTER DIFFERENT FORMS OF ORAL CAFFEINE ADMINISTRATION

TUMA, C., BRAUN, H., THOMAS, A., THEVIS, M.

*GERMAN SPORTS UNIVERSITY COLOGNE*

INTRODUCTION: Caffeine is a widespread ergogenic aid used in mass sport as well as in competitive
sport. To alter athletic performance, it is used in many forms: as caffeinated drinks, caffeine anhydrous or caffeinated chewing gums. Studies have already shown a difference in plasma pharmacokinetics after consumption of caffeinated chewing gum and caffeine capsules (Kamimori et al., 2002). Over the last years the number of caffeine containing supplements in diverse administration forms have significantly increased. Consequently, the aim of the study is to investigate their different mechanisms of action. For this purpose, the influence of five different administration forms on the caffeine and paraxanthine blood concentration were analyzed.
METHODS: 200 mg caffeine in five application forms was administered to 16 healthy young adults in a randomized cross-over design: capsule, tablet, drinking ampule, chewing gum and pouches. Samples were taken in form of 20 µl Dried Blood spots (DBS) at 16 different points in time in a two-hour time frame after caffeine administration. Samples were analyzed by a validated UHPLC-MS/MS method. Area under the curve (AUC), maximum concentration (cmax), time to maximum concentration (tmax) and change from baseline to cmax (Δcmax) were calculated using Excel 2019 . Shapiro-Wilk test for normality of data, parametric and non-parametric tests were calculated using SPSS 28.
RESULTS: Data evaluation show highly intra- and interindividual differences depending on baseline concentration and administration form. Classification of three groups based on baseline caffeine concentration were made. One-way ANOVA analysis revealed significant differences ($p<.001$) between group 1 (baseline concentration < 1 µg/ml) and group 3 (baseline concentration > 10 µg/ml).
Tukey post-hoc analysis showed a significantly increased cmax in three out of five administration forms and a significantly increased AUC in all administration forms for higher baseline concentration (group 3) ($p < .05$) .
Total cmax is highest after tablet ingestion (405 ± 155µg/ml) and tmax is shortest after pouche administration (31 ± 19 min).
Steadily increasing paraxanthine concentrations demonstrate a constant rise in metabolization rate of caffeine shortly after ingestion.
CONCLUSION: The results of this study support recent findings that caffeine absorption and metabolism vary depending on administered form of caffeine. It confirms that absorption is fastest, when already beginning through buccal mucosa.
Baseline caffeine concentration significantly influences the rate of caffeine absorption and maximal caffeine concentration after the ingestion of 200mg caffeine.
These findings should be taken into consideration whenever athletes use caffeine to enhance sports performance.

## APPLE PUREE AS A NATURAL FRUCTOSE SOURCE PROVIDES AN EFFECTIVE ALTERNATIVE FOR FUELLING HALF-MARATHON RUNNING PERFORMANCE

REYNOLDS, K.M., JUETT, L.A., JAMES, L.J., MEARS, S.A.

*LOUGHBOROUGH UNIVERSITY*

INTRODUCTION: Carbohydrate intake during endurance exercise in an effective and recognised strategy to improve performance. A natural, food first approach is attractive as it may appeal to athlete dietary choices and help overcome potential health concerns associated with artificial fructose sources. However, data on meaningful performance outcomes and associated gastrointestinal (GI) upset to food-based carbohydrate supplements in runners are limited. We aimed to examine half-marathon running performance and GI comfort of two different fructose sources (natural and artificial) ingested during exercise, as part of a glucose-fructose supplement.
METHODS: Eleven healthy runners (two female, nine male, 32 ± 8.4 y, 1.75 ± 0.08 m, 67.1 ± 7.9 kg) completed a familiarisation (eight miles) and two half-marathon races (13.1 miles) on a flat out and back L-shaped loop. In total 60 g of carbohydrate was consumed (24 g at 0, and 12 g at 3.1, 6.1 and 9.1 miles) with a 2:1 glucose:fructose ratio. Fructose was provided through pure crystalline fructose (GF) (artificial fructose source) or apple puree (AP) (natural fructose source), with additional maltodextrin added to achieve the desired glucose:fructose ratio. Water was provided ad libitum at the same time points. Spilt times and overall GI comfort (0-10 scale) was assessed at 0, 3.1, 6.1, 9.1 and 13.1 miles. Blood and urine samples, and other subjective measures were collected pre and post run. Participants were blinded to the study aim and were told the study was to investigate the effect of different carbohydrate sources, both providing an optimal dosage.
RESULTS: There was no difference in half marathon performance between trials (AP 89:52 ± 09:33 min; GF 88:44 ± 10:09 min; P=0.684) and there was no difference in pacing over the splits (P=0.264), or mean heart rate (AP 171 ± 2 beat/min; GF 175 ± 1 beat/min; P<0.001). GI comfort was not different between trials (post: AP 5±3, GF 3±2, P=0.305), but did increase over time (P<0.001). There was no difference in voluntary fluid intake (AP 409 ± 206 mL; GF 294 ± 149 mL; P=0.094), sweat rate (P=0.707), dehydration accrued (P=0.507) or plasma volume change (AP -0.2 ± 7.2%; GF 2.2 ± 6.4%; P=0.349) between trials. Plasma osmolality increased pre- to post-race (AP 0.290 ± 0.003 to 0.294 ± 0.002 mosmol/kg; GF 0.290 ± 0.002 to 0.294 ± 0.003 mosmol/kg; time effect P<0.001) in both trials, but was not different between trials (interaction effect P=0.935). Similarly, plasma albumin, creatine kinase, creatinine, glucose, myoglobin and ureic acid were not significantly different between trials (interaction effect P≥0.215), but increased pre- to post-race (P<0.001).
CONCLUSION: Apple puree as a natural fructose source was as effective as artificial fructose in supporting half-marathon running performance without increasing GI symptoms.

## SHATAVARI SUPPLEMENTATION IN POSTMENOPAUSAL WOMEN IMPROVES HANDGRIP STRENGTH AND UPREGULATES PROTEINS AND PATHWAYS INVOLVED IN SKELETAL MUSCLE ADAPTATIONS TO TRAINING STIMULI.

OLEARY, M.

*UNIVERSITY OF EXETER*

INTRODUCTION: Shatavari is an understudied but widely available herbal supplement that contains steroidal saponins and phytoestrogenic compounds. One previous study showed that shatavari enhances strength gains in young men engaged in resistance training (Anders et al. doi: 10.3390/ jfmk5010004). We hypothesised that shatavari may be of particular benefit for postmenopausal muscle health since estradiol deficiency contributes to sarcopenia in women.
METHODS: In a randomised double-blind trial, 20 postmenopausal women (68.5 ± 6 years) ingested either placebo (N = 10) or shatavari (N = 10; 1000 mg/d, equivalent to 26,500 mg/d fresh weight shatavari) for 6 weeks. Handgrip and knee extensor strength were measured at baseline and at 6 weeks. Vastus lateralis (VL) biopsy samples were obtained. Functional and immunoblotting data are presented as difference scores (Week 6—baseline, median ± interquartile range). Tandem mass tag global proteomic analysis of skeletal muscle samples was conducted. Data were normalised to total peptide amount and scaled using a reference sample across experiments. Data were filtered using a 5% FDR. Log2 transformed fold change (week 6 vs baseline) was calculated and Welch's t-test was performed to compare placebo (N = 5) and shatavari (N = 7) samples. Over-representation analysis (ORA) of significantly upregulated proteins was conducted in Reactome (v79). Quantitative pathway enrichment analysis was performed using Reactome Pathway Analysis with Down-weighting of Overlapping Genes (PADOG).
RESULTS: Handgrip (but not knee extensor) strength was improved by shatavari supplementation (shatavari +0.7 ± 1.1 kg, placebo −0.4 ± 1.3 kg; p = 0.04). Myosin regulatory light chain phosphorylation, a known marker of improved myosin contractile function, was increased in VL following shatavari supplementation (immunoblotting; placebo −0.08 ± 0.5 a.u., shatavari +0.3 ± 1 arbitrary units (a.u.); p = 0.03). Shatavari increased the phosphorylation of Aktser473 (Aktser473 (placebo −0.6 ± 0.6 a.u., shatavari +0.2 ± 1.3 a.u.; p = 0.03) in VL. 76 VL proteins were found to be differentially expressed between placebo and shatavari. ORA demonstrated that shatavari upregulates proteins and pathways involved in protein translation (p <0.0001) and the metabolism of RNA (p = 0.006). PADOG indicated that shatavari upregulates pathways involved in elastic fibre formation (p = 0.03), transmission across chemical synapses (p = 0.04), integrin cell surface interactions (p=0.02) MAPK signalling (p=0.01) and integration of energy metabolism (p=0.01).
CONCLUSION: Shatavari may improve muscle function and contractility via myosin conformational changes. Proteomic analyses indicate that shatavari may support muscle adaptation responses to exercise stimuli, via protein synthetic, neural and integrin-MAPK mediated force sensing and transduction mechanisms. Further investigation of its utility in conserving and enhancing musculoskeletal function is warranted.

## POTENTIAL ANTI-FATIGUE EFFECTS OF HERBAL PREPARATION (HEMOHIM) WITH KOREAN MEDICINAL PLANTS

SEO, J.1, BAE, J.2, JIANG, S.1, SHIN, C.1, AHN, S.1, SUNG, Y.1, KIM, D.1, SONG, W.1,3

*1 DEPARTMENT OF PHYSICAL EDUCATION, INSTITUTE OF SPORT SCIENCE, SEOUL NATIONAL UNIV., KOREA; 2 INSTITUTE OF SPORTS & ARTS CONVERGENCE, INHA UNIV., KOREA; 3 INSTITUTE ON AGING, SEOUL NATIONAL UNIV., KO*

INTRODUCTION: Nowadays, deterioration of quality of life due to chronic fatigue has been one of the major health problems in the community. Fatigue can be defined as a subjective experience, and includes such symptoms as physical and mental tiredness. Previous studies reported that fatigue is involved with decrease in physical fitness. Interests in strategies that help to delay the onset of fatigue and improve exercise performance are also increasing. HemoHIM is a mixture containing traditional Korean medicinal plants, including Angelica gigas Nakai (Apiaceae), Cnidium officinale Makino (Umbelliferae), and Paeonia lactiflora Pallas (Paeoniaceae). The herbal preparation has been proved effective in exercise performance and fatigue level in an animal study before. Therefore, the purpose of this study was to evaluate the effects of HemoHIM on fatigue level and exercise performance in healthy adults.

METHODS: 96 people with fatigue were recruited in the randomized, placebo-controlled, double-blind clinical trial. They were randomly assigned to the HemoHIM group (HG: n=48) and the placebo group (PG: n=48). Each subject consumed HemoHIM or placebo every day for 8 weeks. In visit-1 (week -2), VO2 max was measured by performing a cycle ergometer test to assess the eligibility. The subjects meet the criteria were then randomly assigned to either HG or PG in visit-2 (week 0). Each subject visited the laboratory 4 times. Body composition, vital signs, dietary intake, fatigue level (Fatigue severity scale, FSS), cardiorespiratory endurance (cycle ergometer test), muscle strength (grip strength), biochemical markers, and adverse events were measured at each visit.
RESULTS: There were no significant differences between groups in the characteristics at the baseline. HemoHIM significantly decreased the total score of the FSS compared to the PG on visit-3 (week 4, p=.019), and this decrease was maintained until visit-4 (week 8, p=.002). The exercise distance to exhaustion in HG was significantly increased compared to the PG (p=.040). In addition, HemoHIM also significantly increased lactate immediately after the ergometer test (p=.011) and 30-minute after the test (p=.036) compared to the PG. However, there were no significant differences in body composition, vital signs, dietary intake, and muscle strength between groups before and after intervention.
CONCLUSION: One of the adaptations to training is increased tolerance to lactate, which is the ability to continue exercise in the condition of increasing lactate level in the blood. In this study, the significant increase in lactate levels immediately after the ergometer test is considered to be identical to the training effect. In addition, the decrease in FSS score and the increase in exercise distance suggested the delay in the onset of fatigue. Therefore, this study showed that HemoHIM induces anti-fatigue effects, specifically in the lactate tolerance. This study may have potential applications in the nutritional supplement industry in the future.

### IS-MH09 Exercise, fitness, and brain health during childhood: from healthy to clinical population

#### CHILDHOOD FITNESS AND COGNITION: THE MODERATING ROLES OF INTRA- AND INTER-INDIVIDUAL DIFFERENCES IN COGNITIVE AND ACADEMIC PERFORMANCE

KAMIJO, K.

*CHUKYO UNIVERSITY*

Accumulating evidence has shown the beneficial effects of regular physical activity (PA) and the associated improvements in physical fitness on cognitive and academic performance in children. However, several recent large-scale randomized controlled trials have failed to find such beneficial effects, leaving room for doubt on the causal link between childhood fitness and cognition. To identify possible factors underlying the lack of consensus in the literature, our group has focused on intra- and inter-individual differences in cognitive and academic performance.
In the first study (Ishihara et al., 2020), we reanalyzed data from three randomized controlled trials, in which the effects of a PA intervention on cognitive performance were examined, with a cumulative total of 292 participants (9–13 years). This study aimed to examine whether the effects of PA interventions on cognitive performance are moderated by baseline performance. The results indicated that cognitive improvements resulting from PA interventions were greater in children with lower baseline cognitive performance.
In the second study (Ishihara et al., 2021), we analyzed data from a two-year longitudinal study, to investigate the association between changes in aerobic fitness and academic performance of 469 junior high school students by focusing on intra-individual variability in school grades. This study specifically examined whether improvements in aerobic fitness had differential effects on an individual's worst and best grade points. The results indicated that improvements in aerobic fitness were associated with an improvement in the worst grade points, however, no such longitudinal association was observed for the best grade points.
Collectively, these findings suggest that the beneficial effects of PA interventions and fitness improvements are moderated by intra- and inter-individual variability in cognitive and academic performance. In other words, if baseline performance is too high (i.e., the cognitive task or academic test is too easy), the beneficial effects of PA interventions and fitness improvements might not be detected. Based on these findings, this presentation will describe the current limitations and future directions in childhood exercise-cognition studies.

#### SELECTIVE ASSOCIATIONS OF PHYSICAL FITNESS COMPONENTS WITH BRAIN STRUCTURE AND FUNCTION IN CHILDHOOD OBESITY: IMPLICATIONS FOR ACADEMIC PERFORMANCE

ESTEBAN-CORNEJO, I.

*UNIVERSITY OF GRANADA*

Obesity is a major public health concern for developed and developing countries. Over the past years, childhood obesity has more than doubled worldwide. Beyond the consequences of obesity on physical health, childhood obesity may compromise brain health by influencing both brain structure and function. Indeed, obesity has been associated with detectable structural differences in the brain, as well as with worse executive function and academic performance, as compared to normal-weight children. Parallelly, physical fitness might have a positive impact on brain health, resulting in better academic performance, and may thus attenuate the negative effect of overweight and obesity on brain during childhood. Thus, examining the potential benefits of physical fitness for brain health in the context of overweight and obesity during early stages of life is of critical relevance. Using data from a Spanish study of children with overweight/obesity (i.e., ActiveBrains Project), we examined how different components of physical fitness associate with brain structure (global and regional gray matter volume, surface and cortical thickness, global and regional white matter volume, and global and regional white matter microstructure) and brain function (hippocampal functional connectivity), and whether these associations had academic implications.
In a sample of around 100 overweight/obese children aged 8-11 years, we found that fitter children had bigger brains. Specifically, cardiorespiratory and motor fitness were related to total gray matter volume, without academic implications. Similarly, we also found that cardiorespiratory and motor fitness were independently associated with greater gray matter volume of numerous cortical and subcortical brain structures, coupled with better academic performance. When focused on cortical thickness and surface area, cardiorespiratory and motor fitness were also related to cortical thickness, but not surface area, and in turn to intelligence.

White matter tissue may be also modified by physical fitness. In this case, muscular strength seems to be the fitness component more susceptible and selective to influence white matter, but not gray matter indicators. Muscular strength was associated with global white matter volume, and with regional white matter volume and integrity. Indeed, regional white matter volume was also related with better academic performance. Lastly, in term of functional connectivity, cardiorespiratory and motor fitness, but not muscular strength, were independently related with better hippocampal functional connectivity, and in turn, to academic performance.
Thus, physical fitness components seem to selectively influence brain structure and function, coupled with academic implications in children with overweight/obesity. This presentation will guide future studies on fitness, exercise and brain health in childhood obesity.

**COGNITIVE EFFECTS OF EXERCISE IN CHILDREN BORN PRETERM: NEUROCOGNITIVE MECHANISMS OF MARTIAL ARTS**

LUDYGA, S., MÜCKE, M., GERBER, M., PÜHSE, U.
*UNIVERSITY OF BASEL*

Due to advances in medical care, mortality rates of babies born very preterm decreased over the last decades. However, babies that survive the preterm birth face severe neurodevelopmental disabilities and impairments in motor skills across different developmental stages. These problems are related to pronounced deficits in executive function that can be detected at the transition from childhood to adolescence. Structured exercise programs have been found to benefit executive function in term-born and typically developing individuals, with a tendency to induce greater benefits in children with worse performance on cognitive tasks. This indicates a potential of exercise to reduce executive function deficits in children born preterm, but a paucity of studies in this field question whether exercise-induced effects apply to this population.
Using case-control matching, we examined the roles of different aspects of physical fitness to preterm birth-related deficits in executive function and response inhibition in particular. Motor skills rather than aerobic fitness mediated the impairments in response inhibition in children born very preterm. On a neurocognitive level, this mediating effect was explained by motor skills influencing a cognitive control process that contributed to deficits in behavioral performance. Due to the indication that motor skills are a pathway by which response inhibition can be improved, we conducted randomized controlled trials to investigate the effects of a motor-demanding martial arts program on this cognitive function in children born preterm and peers born at term. Following 12 weeks of training, improvements in response inhibition were detected among both groups. Even though the magnitude of the gains were similar between children born preterm and peers born at term, the neurocognitive mechanisms differed. Martial arts training elicited benefits for response inhibition by reducing a specific cognitive control deficit associated with preterm birth. In contrast, children born at term improved this cognitive function by a change towards more effective conflict monitoring.
Our findings highlight aspects of physical fitness that promise improvements in executive function, when targeted by structured exercise. Both children born preterm and those born at term can expect beneficial effects for this cognitive domain after a period of martial arts training. However, the pathway by which martial arts benefit aspects of executive function differ between these groups. These findings broaden the understanding of mechanisms underlying exercise-induced effects in children with typical and atypical cognitive development.

### IS-AP10 Exploring the heterogeneity of human responses to exercise and physical inactivity

**INDIVIDUAL RESPONSE TO EXERCISE TRAINING (OR LACK THEREOF): SEEMINGLY OBVIOUS BUT SCIENTIFICALLY ELUSIVE**

HECKSTEDEN, A.
*SAARLAND UNIVERSITY, INSTITUTE OF SPORTS AND PREVENTIVE MEDICINE*

Interindividual variability in the relation between the levels of physical exercise and fitness seems obvious (“talent”, “trainability”) and the large variation in observed responses after experimental changes in exercise levels is in line with casual observation. However, it is important to keep in mind that observed variation does not necessarily reflect true difference between individuals. In fact, the only certain component of observed variation in training response is measurement error. A control group enables a plausible discrimination between measurement error (present in either group) and eventual training induced variation (present in the training group only). This is the consideration that is generally taken into account today. In contrast, it is frequently overlooked that training induced variation may be due to true differences between subjects and / or limited repeatability of individual responses. Importantly, the repeatability of training responses on the individual level is still unknown, presumably due to the challenges associated with replicated study designs when investigating long-term adaptive responses.
Taking other lines of evidence into account, the results of twin or family studies and animal breeding experiments let meaningful interindividual variation in training response seem highly plausible. On the other hand, the multitude of modifiable moderators affecting the response to physical exercise leads to suspect considerable within-subject variation. Finally, the difficulty of standardizing exercise “dose” (as compared to e.g., pharmaceutical interventions) must be considered when interpreting variability in responses.
This talk aims to provide an overview of what is known (or not) about interindividual variability in the response to changes in the level of physical exercise and raise some potentially interesting points.

**INDIVIDUAL VARIABILITY IN SKELETAL MUSCLE MASS AND FORCE LOSS AFTER BED REST**

FERNANDEZ-GONZALO, R.
*KAROLINSKA INSTITUTET*

Interindividual differences in physiological responses to an intervention have received great attention in the last decades. However, some approaches used to analyze individual variability do not account for the variability explained by technical and/or random errors, and thus not biological variability alone. To tackle these limitations, the inclusion of a control group is crucial. Alternatively, the use of cross-over designs can be very helpful, since they offer the advantage of controlling for genetic factors influencing the individual response.
A unique opportunity to address individual variability upon bed rest responses is the Planica bed rest program, where three studies were performed using identical pre- and post-bed rest tests under strictly controlled conditions and using a cross-over design.

This talk will describe the analysis of the individual responses in skeletal muscle outcomes after bed rest using data from these three studies with similar protocols (PlanHab; FemHab; LunHab). Subjects participated in three cross-over campaigns within each study: normoxic and hypoxic bed rest, and hypoxic ambulation (used as a control). Individual variability (SDIR) was investigated as √(SDExp2–SDCon2), where SDExp and SDCon are the standard deviations of the change score (i.e., post - pre) in the experimental (normoxic and hypoxic bed rest) and the control (hypoxic ambulation) groups. Significant SDIR was detected for knee extension torque, and thigh and calf muscle area. The individual variability reported here had a high degree of repeatability and it was partly driven by baseline values. The use of orthogonal partial least squares (OPLS) regression analysis is also presented to explore if changes in the investigated variables could predict calf muscle area alterations. This analysis indicated that 43% of the variance in calf muscle area could be attributed to changes in all the other variables.
In summary, this talk presents a validated methodology to report clinically relevant individual variability in muscle mass and force alterations after bed rest, as well as tools to examine the repeatability and potential moderators of interindividual responses. The data originating from this study may serve as one of the cornerstones to develop (bio)markers of the individual response, which would offer new tools to improve health management of astronauts and to optimize individual programs to counteract the negative effects of unloading both during space missions and here on Earth.
The information conveyed in this talk should be of interest and use to skeletal muscle physiologists with an interest in muscle atrophy, unloading, and inactivity. In addition, the methodological approach presented here could serve as an example of how to examine individual variability in physiological outcomes after an intervention and help to understand the limitations and possibilities of different methodological tools.

**INTER-INDIVIDUAL VARIATION IN ASTRONAUTS IN RESPONSE TO THE SPACEFLIGHT ENVIRONMENT AND THE ROLE OF LONG-TERM HEAD-DOWN BED REST STUDIES IN UNDERSTANDING IT**

SCOTT, J.

*FRANCE*

Exposure to the spaceflight environment results in profound multi-system physiological adaptations in which there appears to be substantial inter-individual variability (IV) between International Space Station (ISS) crewmembers. However, the routine performance of 'countermeasure' exercise on ISS renders it impossible to separate the effects of the spaceflight environment alone from those associated with exercise, whilst differences in exercise programs, spaceflight operations constraints, and environmental factors further complicate the interpretation of IV. In contrast, long-term head-down bed rest (HDBR) studies isolate, by means of a control group, the effects of mechanical unloading from those associated with countermeasure exercise interventions, as well as controlling many of the factors that may contribute to IV.
This presentation reviews the available evidence of IV in response to the spaceflight environment and discusses factors that may complicate its interpretation. Individual data from two, 60-d HDBR studies are presented, which demonstrate that, despite the highly standardized experimental conditions, marked quantitative differences still exist in the response of the cardiorespiratory and musculoskeletal systems between individuals. The statistical concept of "true" and "false" individual differences and its potential application to HDBR data is also discussed. It is concluded that it is currently not possible to evaluate IV in response to the ISS spaceflight environment and countermeasure exercise. However, with highly standardized experimental conditions and the presence of a control group, HDBR is suitable for the investigation of IV in the physiological responses to gravitational unloading and countermeasures. Such investigations may provide valuable insights into the potential role of IV in adaptations to the spaceflight environment and the effectiveness of current and future countermeasures.

### OP-PN35 Immobilisation and fatigue

**THE IMPACT OF BETA2-AGONIST INGESTION ON MUSCLE AMINO ACID KINETICS AND INSULIN SENSITIVITY DURING SHORT-TERM FOREARM IMMOBILIZATION IN HEALTHY, YOUNG VOLUNTEERS**

DIRKS, M.L., JAMESON, T.S.O., ANDREWS, R.C., DUNLOP, M.V., ABDELRAHMAN, D.R., MURTON, A.J., WALL, B.T., STEPHENS, F.B.

*UNIVERSITY OF EXETER, UNIVERSITY OF TEXAS MEDICAL BRANCH, GALVESTON, TX, USA*

INTRODUCTION: Short-term muscle disuse, e.g. during recovery from (sports) injury or surgery, leads to negative muscle amino acid balance and consequently muscle atrophy. Although the underlying mechanisms remain to be elucidated, disuse is accompanied by the rapid development of anabolic resistance (AR, i.e. blunted muscle protein synthesis (MPS) following protein intake) and insulin resistance (IR, i.e. impaired insulin-stimulated glucose uptake). Short-acting beta2-agonists cause hypertrophy by increasing MPS and reducing muscle protein breakdown (MPB), and stimulate muscle glucose uptake. The aim of this work was to determine the impact of salbutamol ingestion on muscle amino acid kinetics and insulin sensitivity during short-term disuse. Twenty healthy individuals (age 23±1, BMI 24.0±0.6 kg·m-2) underwent 2 days of forearm cast immobilization. During immobilization, participants orally ingested placebo (PLA; n=9, 5M/4F) or salbutamol (SAL; 4 mg Ventolin; n=11, 6M/5F) four times daily, and a fully-controlled eucaloric diet (1.2 g·kg-1·day-1 protein (~10-15en%), 50-55en% carbohydrates, 30-35en% fat). Before and after immobilization, whole-body glucose disposal rate (GDR), forearm glucose uptake (FGU, i.e. direct measure of muscle insulin sensitivity), and amino acid kinetics were measured under fasted and hyperinsulinaemic-hyperaminoacidaemic-euglycaemic clamp conditions (50 mU·m2·min-1 Actrapid; 1.38 mL·kg-1·h-1 10% Primene) using arteriovenous forearm balance and intravenous L-[ring-2H5]phenylalanine (phe) infusion. During clamps GDR was unchanged in PLA, but increased 18±9% in SAL (P<0.05). In contrast, immobilization decreased insulin-stimulated FGU by 34±19% (from 52±5 to 29±7 umol·min-1; P<0.05), with no difference between groups. Both forearm phe net balance (NB) and rate of disappearance (Rd, i.e. proxy for muscle amino acid uptake) increased during clamps (P<0.05; NB and Rd from -20±4 to 19±6 and from 19±4 to 46±7 umol·min–1·100 mL forearm volume–1, respectively; all clamps) but were not affected by immobilization or treatment. Phe rate of appearance (Ra, i.e. proxy for muscle amino acid release) increased over twofold during fasting and clamps following immobilization in PLA (clamp: from 13±5 to 33±7 umol·min–1·100 mL forearm

volume–1; P=0.062), an effect completely suppressed in SAL (clamp: from 29±8 to 31±6 umol·min–1·100 mL forearm volume–1; P>0.05). Salbutamol enhances insulin-stimulated whole-body glucose disposal but not in inactive muscle, suggesting that this is mediated by contraction. In contrast to previous work, immobilisation did not significantly reduce forearm amino acid uptake, perhaps due to potent stimulation by insulin and amino acids. However, salbutamol inhibited the efflux of amino acids from muscle, suggesting inhibition of MPB and/or stimulation of MPS, and reversal of anabolic resistance. Further research is required to determine the intracellular mechanisms involved and whether salbutamol prevents muscle disuse atrophy.

**METHODS: RESULTS: CONCLUSION: DOES HUMAN SKELETAL MUSCLE POSSESS A NEGATIVE MEMORY OF MUSCLE WASTING?**

TURNER, D.

*NORWEGIAN SCHOOL OF SPORT SCIENCES*

INTRODUCTION: Immobilization (IMM) evokes a significant loss of skeletal muscle (SkM) size and function. Research has demonstrated an epigenetic memory of SkM strength and hypertrophy, where these parameters are further enhanced when strength training is reencountered. Despite this evidence of a positive memory, it is still currently unknown if a negative memory of muscle wasting exists. The present study therefore aimed to determine whether SkM is compromised to a greater extent after repeated atrophy.
METHODS: Young healthy males and females (25.6±4.8 yrs, BMI 25.9±5.8) underwent 2 weeks of unilateral limb IMM (30-degrees knee flexion) twice. Each IMM period were interspersed by 7 weeks of recovery. Before and after each IMM period, leg lean mass (DXA), cross-sectional area (CSA, B-mode ultrasound) of the vastus lateralis (VL) and rectus femoris (RF) together with isometric knee extension torque (dynamometry) across 3 knee flexion angles (90-, 60- and 30-degrees) were assessed. SkM biopsies were obtained for future analyses of DNA methylation and gene transcription. Paired t-tests enabled detection of significant changes ($p<0.05$) after IMM (n=6). All data are presented as mean ± SD.
RESULTS: IMM induced a 3.1 ± 2.9% reduction of leg lean mass in the IMM leg (9.70 ± 2.85 vs. 9.41 ± 2.75 kg, p=0.06) and a 2.2 ± 1.8% increase in the non-IMM leg (9.71 ± 3 vs. 9.88 ± 2.91 kg, p=0.05). Across the 2 participants analyzed thus far, repeated immobilization (RIM) also led to a reduction in the IMM limb (5.5 ± 2%, 10.29 ± 4.59 vs. 9.78 ± 4.54 kg) with no difference in the non-IMM limb (-0.1 ± 0.5%, 10.22 ± 5 vs. 10.20 ± 4.94 kg). VL CSA decreased by 10.4 ± 5% after IMM (n = 6, 24.02 ± 5.37 vs. 21.47 ± 4.73 cm2, p=0.01) with no change in RF CSA (0.1 ± 3.6%, 5.87 ± 1.11 vs. 5.86 ± 1.09 cm2, p=0.95). For the only participant analyzed thus far, VL CSA decreased to a similar extent after IMM (13.5) and RIM (13.7%). For RF however, CSA increased (2.3%, 6.72 vs. 6.87 cm2) after IMM and decreased after RIM (4.6%, 7.14 vs. 6.81 cm2). Knee extension torque reduced by 18.1 ± 11.3% (241 ± 75 vs. 198 ± 69 N, p=0.01), 7.8 ± 12.7% (240 ± 80 vs. 216 ± 64, p=0.16), 2.3 ± 17.9% (147 ± 48 vs. 142 ± 52, p=0.82) at 90-, 60-, 30-degrees, respectively (n=6). When relativized to recovery, RIM also induced a similar reduction in muscle strength at 90- (24.37 ± 2.8%, 252 ± 50 vs. 191 ± 45 N), 60- (18.8 ± 14.6%, 241 ± 102 vs. 203 ± 118 N) and 30-degrees (26 ± 11.6%, 137 ± 52 vs. 104 ± 54 N, n=2).
CONCLUSION: Overall, SkM is significantly compromised after IMM-induced atrophy. To date however, it is still currently unknown if there is a greater loss of SkM after RIM. Furthermore, studies on the molecular mechanisms underpinning SkM wasting are scarce. Future research should employ unbiased genome-wide analysis to determine the transcriptional and epigenetic response of repeated atrophy.

**BRAIN OXYGENATION DURING COGNITIVE PROCESSING IS ALTERED WITH 60 DAYS BEDRIDDEN PHYSICAL INACTIVITY**

ABELN, V.1, MUEHLER, F.1, BRAUNSMANN, L.1, STUCKENSCHNEIDER, T.

*<1> GERMAN SPORT UNIVERSITY COLOGNE; <2> CARL VON OSSIETZKY UNIVERSITY OLDENBURG*

INTRODUCTION: Regular physical activity elicits central angiogenesis and neurogenesis and may, thus, support cognitive performance and brain health. Training interventions have shown to decrease neuronal activity (decreased hemodynamic response) during executive cognitive processing in prefrontal areas, which is suggested to reflect more efficient information processing (Voelcker-Rehage, Godde, & Staudinger, 2011). Studies investigating adverse effects of physical inactivity are scarce due to ethical reasons and mainly include injured individuals or observational data. Investigating the effects of inactivity on healthy subjects, however, would provide important information about the timely onset of degradation processes. 60-day bedrest is hypothesized to impair information processing compensated by increased neuronal activity (=higher oxygenated (O2Hb) and lower deoxygenated hemoglobin (HHb) concentrations assessed by functional near-infrared spectroscopy (fNIRS)).
METHODS: 24 participants (aged 33.3 ± 8.9 years, 8 females) spent 60 days in strict bedrest (group BED). fNIRS was used to monitor hemodynamic changes within the prefrontal cortex at rest and during attentional auditory and visual cognitive tasks on day -2 before, 3, 50 during, and +2 and +13 after bedrest. A control group (CTRL, n= 9, aged 32.5 ± 10.0 years, 3 females) completed the same test battery without bedrest. ANOVA for repeated measures (Bonferroni corrected) with the factors time, group and their interaction were calculated for O2Hb and HHb, as well as reaction time (RT) and accuracy (ACC) of the cognitive tests.
RESULTS: RT revealed a main effect of time ($p< .001$). BED and CTRL groups tend to differ in their progressions (time*group p= .045) and only CTRLs showed a significant decrease on day +13 compared to -2 (p= .014). ACC did not change over time, between groups or conditions. For O2Hb, the time*group interaction ($p< .001$) indicated higher relative prefrontal O2Hb concentration during attentional processing on day 50 of bedrest compared to day -2 (p= .001) and to day +13 after bedrest (p= .033) within the BED group and compared to day 50 of the CTRL group (p= .026). No difference was observed for HHb.
CONCLUSION: Attentional task performance was slightly affected during 60 days of bedrest reflected by increased O2Hb concentration (higher neuronal/oxygen demand). The adverse effects of physical inactivity were recovered on hemodynamic level two days after bedrest, but remained on behavioral level even thirteen days after bedrest. This may indicate that hemodynamic alterations are not the cause but consequence of cognitive impairments.

### FATIGUE INDUCED BY A SIMULATED COMPETITION IN ELITE WORLD-CLASS FENCERS

VARESCO, G., PAGEAUX, B., GOISBAULT, M., MARTINENT, G., DORON, J., JUBEAU, M.

**NANTES UNIVERSITÉ, LABORATORY MOVEMENT - INTERACTIONS - PERFORMANCE.*

INTRODUCTION: Fencing is an open-skilled, asymmetric combat sport characterized by high-intensity bouts and requires high levels of coordination, power, and accuracy. However, the performance-specific fatigue of fencing remains to be elucidated1. In the present study, we evaluated the neuromuscular and mental aspects of fatigue induced by a competition in elite world-class athletes.
METHODS: Changes in countermovement jump height, knee extensors maximal isometric force, rate of force development (RFD), voluntary activation and contractile response to muscular electrical stimulation were measured in 12 male world-class fencers (epee n = 6 ; foil n = 6). Measurements were performed before and after the first match, and after a 5-matches simulated competition. Perceived fatigue and effort were evaluated with 10-cm visual analog scales (VAS), and the perceived workload was assessed with the NASA-TLX scale.
RESULTS: Jump height did not change significantly after one or five matches (P = 0.108). Maximal force, RFD and voluntary activation were not significantly different after match 1 but significantly decreased after match 5 compared with baseline (-13 ± 12%, P < 0.001; -9 ± 19%, P < 0.025; -15 ± 16%; P = 0.003, respectively). Finally, contractile responses did not change significantly along the simulated competition (P = 0.337). Perceived fatigue increased from baseline (3.9 ± 2.5 cm) after match 1 (5.6 ± 2.0 cm, P = 0.026) and match 5 (7.3 ± 2.1 cm, P < 0.001), and was greater following match 5 compared to match 1 (P = 0.001). Similar outcome after match 1 and match 5 were also found for perception of effort (6.6 ± 1.8 cm vs. 6.8 ± 1.6 cm, P = 1.000) from the VAS scale, and perceived mental (75 ± 13 vs. 70 ± 20, P = 0.259) and physical demand (68 ± 13 vs. 76 ± 14, P = 0.158) from the NASA-TLX.
CONCLUSION: In elite world-class fencers, there was no evidence of neuromuscular alterations after a single match. The observable impairments at the end of the competition were moderate regarding maximal force and RFD. Those changes were mainly due to impairments in voluntary activation. The moderate neuromuscular impairments suggest that elite world-class fencers can cope well with the physical demand of a 5-matches simulated competition. However, feelings of tiredness and lack of energy (perception of fatigue) increased along the five matches and was high at the end of the simulated competition. The perceived physical and mental demand of the match, along the perception of effort, remained constantly elevated throughout the competition. These results suggest that elite fencing is characterized by an important mental demand that could lead to the induction of mental fatigue overtime.

### EFFECT OF A SUSTAINED COGNITIVE ACTIVITY ON COGNITIVE PERFORMANCE FATIGUE, PERCEIVED FATIGUE AND PREFRONTAL CORTEX ACTIVATION

GUBE, M., WEIPPERT, M., BRUHN, S., MITTLMEIER, T., BEHRENS, M.

*UNIVERSITY OF ROSTOCK*

INTRODUCTION: Sustained cognitive activities (SCA) can lead to the phenomenon of fatigue and have been shown to impair endurance performance and motor control during different tasks. In general, cognitive task-induced state fatigue can be defined as psychophysiological condition that is characterized by a decrease in a cognitive performance measure and/or an increased perception of fatigue. However, the temporal development and possible dynamics of cognitive performance fatigue and perceived fatigue during a SCA were rarely studied. To better understand the effect of a SCA on the development of state fatigue, perceived fatigue, its potential determinants, cognitive performance and prefrontal cortex activation were investigated over time.
METHODS: In a randomized, counterbalanced cross-over design, 30 subjects (female: 15; age: 23 ± 2.9 years; BMI: 20.5 ± 3.1 kg*m-2) completed a SCA task (60 min digital Stroop task) and a control task (60 min watching a neutral video). In both sessions, activation of the prefrontal cortex was measured with functional near-infrared spectroscopy (fNIRS). To record the development of perceived fatigue and other possible contributors (e.g., affective valence, stress, perceived mental effort, arousal, boredom, motivation) during the SCA, visual analogue scales were used to quantify these aspects in regular time intervals (1, 15, 30, 45, 59 min). Reaction time and accuracy recorded during the Stroop task were used as cognitive performance measures. Data were analysed with repeated measures ANOVAs.
RESULTS: Significant interactions were observed for perceived fatigue (VAS mental fatigue) ($p = .000$; $\eta p2 = .186$), affective valence ($p = .000$; $\eta p2 = .215$), stress ($p = .015$; $\eta p2 = .100$) as well as prefrontal cortex activation ($p = .044$; $\eta p2 = .133$). Main effects of condition were shown for perceived fatigue, perceived mental effort and stress ($p \leq .018$; $\eta p2 \geq .179$). Time effects were found for perceived fatigue, perceived mental effort, affective valence, stress, motivation and boredom ($p \leq .000$; $\eta p2 \geq .109$). Furthermore, a significant main effect of time was found for the cognitive performance measure reaction time ($p = .000$; $\eta p2 = .211$) during the Stroop task.
CONCLUSION: Changes in perceived fatigue, its potential determinants affective valence and stress, and prefrontal cortex activation indicated a clear discrimination between conditions. Increased activation of the prefrontal cortex during the Stroop task, compared to the control condition, together with improvements in reaction time with constant accuracy during the Stroop task may suggest a compensatory mechanism that contributed to maintain cognitive performance over time. The changes in perceived fatigue and its potential determinants could be assumed to be a premature protective signal against expected cognitive performance fatigue.

### OP-MH22 Vascular function

### EFFECT OF DIFFERENT MODES OF EXERCISE ON VASCULAR FUNCTION OF RECESSIVE FEMALE UNIVERSITY STUDENTS WITH FAMILY HISTORY OF HYPERTENSION

ZHANG, P.

*BEIJING SPORT UNIVERSITY*

INTRODUCTION: Due to sedentary behavior, physical inactivity and high caloric diet and other unhealthy lifestyle habits, atherosclerotic cardiovascular disease (ASCVD) has become the main disease threatening the health of women and the leading cause of death of women in China. Sedentary lifestyle and insufficient exercise are life pattern of many university students, especially in females, which result in overweight and obesity and other health problems. This paper probes into characteristics of changes in vascular function among female univer-

sity students with family history of hypertension after different modes of exercise with same energy expenditure, instruct them to do exercise scientifically and prevent hypertension and ASCVD.
METHODS: Forty-five young women (20.6±1.7yrs) with family history of hypertension (without training experience) participated in the study that was approved by IRB at Beijing Sport University. All of them were overweight (China cutoff point body mass index≥24kg/m2). They were evenly randomized to control (CT) group, high-intensity interval exercise (HE) group and moderate-intensity continuous exercise (ME) group. The exercise began after two hours of the meal. The ME group did exercise 40 min at the intensity of 65%-75%HRmax. The HE group performed an interval running session consisting of 4×4 min bouts (running at the intensity of 85%-95%HRmax 4 min, interspersed by 3-min rest). The energy expenditure was similar between those two groups. The pulse wave velocity (PWV) and ankle brachial index were determined at the time points of pre-exercise, immediately after exercise, then every 5 minutes till 40 minutes.
RESULTS: (1) Immediately after exercise, the HE group demonstrated significantly decreased level of PWV (867.00±84.33 vs 972.50±93.05cm/s, P<0.01). During recovery period, from 5 to 40 min, the level of PWV in HE group increased gradually. 40 min after exercise, participants in HE group still had a significant lower PWV level compared with the baseline (4.4%, P<0.01). (2) Participants in the ME group had a significant reduction in the PWV level (12.3%, P<0.01) immediately after exercise. 40 min after exercise, PWV level in ME group returned to the baseline. (3) During recovery period, compared with CT group, participants in ME and HE groups had significant lower PWV level from 5 min to 25 min (P<0.05). There were no significant differences in PWV level between ME group and HE group neither immediately after exercise nor during recovery period.
CONCLUSION: Both moderate-intensity continuous exercise and high-intensity interval exercise could reduce arterial stiffness and ameliorate vascular elasticity of overweight young women with family history of hypertension, which were beneficial to prevent hypertension and ASCVD in early life. It was suggested that high-intensity interval exercise may result in a greater stimulus for vascular adaptations when compared to moderate-intensity continuous exercise.

**PRELIMINARY RESULTS OF THE PHYSICAL ACTIVITY AND CAROTID ATHEROSCLEROTIC PLAQUE HEMORRHAGE (PACAPH) PROJECT**

MURA, M., DEHINA-KHENNICHE, L., WEISS-GAYET, M., JOSSET, L., RIVOIRE, E., THOMAS, A., ARSICOT, M., DELLA-SCHIAVA, N., MILLON, A., PIALOUX, V.

*UNIVERSITÉ CLAUDE BERNARD LYON1*

INTRODUCTION: Carotid atherosclerotic plaque instability is one of the major causes of ischemic strokes. Instable plaques are hemorrhagic and contain large content of infiltrated monocytes (MC). In recent cross-sectional studies, our team demonstrated that atherosclerotic patients practicing moderate physical activity (PA) have less intraplaque hemorrhage and less pro-inflammatory circulating MC than non-active ones.
The objective of this study is to determine the effect of an individualized home-based PA intervention on carotid atherosclerotic plaque instability.
METHODS: The PACAPh study is a longitudinal, interventional, monocentric, randomized, controlled study. 80 asymptomatic patients will be recruited with carotid stenosis >50%, without indication of surgery or intercurrent inflammatory diseases. Patients are randomized 1:1 either in the control or in the PA group. The control group follows its usual care. Patients of the PA group receive a connected wristlet for daily step count, and a PA instructor call them twice a month to set new daily step goals, in order to increase the daily step count. In both groups, fitness, MC subsets and kinetic of blood clot formation are assessed.
RESULTS: 52 patients were included (72.1±1.4y/o). To date, 37 patients completed the protocol. PA group increases their VO2 plateau from 13.0±0.8 to 15.8±1.0 mL/min/kg while the control group remains stable (13.6±1.1 to 13.9±1.1 mL/min/kg). Maximal strength of quadriceps is unchanged in both groups. Quality of life slightly improves in the PA group (EQ-5D-5L), and sedentary declines in the PA group.
CONCLUSION: Fitness results suggest that the PA intervention increases the active behavior of patients while limiting sedentary behavior. With addition inclusion, we should be able to analyze the effects of this PA intervention on biological markers, such as MC subsets, kinetic of blood clot formation or blood rheology.

**ACTIVE STRETCHING TRAINING IN PATIENTS WITH CHRONIC VENOUS INSUFFICIENCY: A PILOT RANDOMIZED CONTROLLED TRIAL.**

MENEGATTI, E.1, MANDINI, S.2, PAGANI, A.3, MANDINI, B.2, FABBRI, M.2, MAZZONI, G.2, FOGLI, M.2, ZAMBONI, P.3, GIANESINI, S.3

*UNIVERSITY OF FERRARA <1> <2> <3>*

INTRODUCTION: Chronic venous insufficiency (CVI) is the most common vascular pathology which affect up to 50% of the general population in the industrialized counties [1]. The progression of CVI depend on different risk factors: genetic background, female sex, hormone, obesity and sedentary lifestyle [2]. Musculoskeletal disorders are often associated with more severe clinical stages of CVI, especially foot static disorder [3] affecting body posture. The aim of the study was to investigate the effect of active stretching (AS) training on venous function and quality of life in patients with CVI. The secondary objective was to evaluate the changes in postural outcomes.
METHODS: A prospective two-arm pilot randomized controlled trial was conducted. Of a total of 25 eligible patients, 5 were excluded, while 20 were included and randomly assigned to AS training, performed twice a week for 3 months (0/10 M/F; mean age 62.9±9 y), or to a control group (C) (2/8 M/F; mean age 54.5±15.5 y) who did not receive any exercise indication.
At baseline and after 3 months leg volume, air plethysmography (APG), quality of life (QoL) with disease specific validated questionnaire (VVSymQ), ankle range of motion (ROM), postural deformities using the optoelectronic body posture machine were recorded.
RESULTS: At the end of the training in the AS group a significant leg volume reduction was detected (from 2340±239mL to 2239±237mL (4.3%); p<.0001), whereas in the C group no significant volume changes was found. Among APG parameters, the ejection fraction rate (EF%) increased significantly from 49.3±9.3% to 61.1±14.5%, p<.005. A moderate-strong correlation between EF% and ankle ROM variation was found (R2=0.6790; p<.003). In AS group a significant improvement in venous symptomatology was measured, the VVSymQ total score decreased from 11.1±2.7 to 3.7±0.8, p<.0001; while in the C group no significant changes were recorded. Finally, the postural outcomes related to lower back and pelvis such as pelvic tilt, pelvis torsion, and lordotic angle significantly improved only in the AS training group (p<.04, p<.01, p<.01 respectively).
CONCLUSION: The proposed AS training impacts on venous function improving APG parameters related to musculoskeletal pump efficiency. In addition, the amelioration of postural outcomes confirms the AS action on the lower back and pelvis misalignments. This pilot study

paves the way for future investigations in this field, opening a further possibility in the management of CVI patient by means of appropriate exercise programs.

### EFFECTS OF ANTIHYPERTENSIVE MEDICATION ON THE BLOOD PRESSURE RESPONSES TO AEROBIC EXERCISE IN HYPERTENSIVE INDIVIDUALS

RAMIREZ-JIMENEZ, M.1, MORALES-PALOMO, F.2, MORENO-CABAÑAS, A.2, ALVAREZ-JIMENEZ, L.2, ORTEGA, J.2, MORA-RODRIGUEZ, R.2

*1 UNIVERSIDAD DE CÁDIZ. 2 UNIVERSIDAD DE CASTILLA-LA MANCHA*

INTRODUCTION: Hypertension is the most important risk factor for death and cardiovascular disease, affecting more than 1.1 billion people worldwide and leading to 9.4 million deaths every year. Endurance aerobic training, is effective at lowering resting systolic blood pressure (SBP) by 2–8 mmHg depending on the initial hypertension level. Especially during exercise, SBP rises above resting levels, as cardiac output increases to meet the oxygen and nutrient demands from contracting muscles. Individuals with hypertension at rest, show an exaggerated SBP response to submaximal and maximal exercise in comparison to normotensive individuals. The hypertension during exercise is concerning since those hypertension peaks could further damage the already eroded vasculature of hypertensive middle-aged individuals. In fact, a recent metanalysis reveals that hypertension during moderate exercise intensity is independently associated with higher risk for cardiovascular events and mortality.
Many individuals with diagnosed resting hypertension are successfully treated with antihypertensive medication (AHM). However, the ability of AHM to reduce hypertensives responses during exercise has been recently questioned. The objective of this study was to investigate if the systolic blood pressure (SBP) response to a maximal graded exercise test (GXT) is influenced by antihypertensive medication (AHM).
METHODS: Thirty-one hypertensive individuals with metabolic syndrome under AHM treatment targeting the renin-angiotensin-aldosterone system (RAAS) were recruited. By using a randomized, double-blind, placebo-controlled, crossover design, participants completed two trials: 1) AHM trial in which participants were tested under their habitual antihypertensive medication treatment and, 2) placebo trial (PLAC) in which participants were analyzed after 72-hours of AHM withdrawal and substituted by placebo. In each trial, plasma renin activity (PRA), aldosterone concentration and SBP responses at rest and during GXT were measured. A two-factor ANOVA was used to determine statistically significant differences between trials (i.e., medication and intensity as factors).
RESULTS: There was an interaction between medication and intensity on SBP responses (P=0.049). Bonferroni post-hoc analysis revealed that AHM reduced SBP at resting conditions (128±11 vs 134±12 mmHg, P=0.001). However, medication did not affect SBP at any of the incremental exercise intensities, ranging from 40 to 100% of the peak power output, resulting in similar peak SBP in AHM and PLAC trials (211±25 vs 206±25 mmHg respectively, P=0.088). An adequate RAAS blockade is suggested by the increase in PRA (P<0.001) and the decrease in aldosterone to renin ratio (P=0.007) observed in AHM in comparison to PLAC.
CONCLUSION: The present data suggest antihypertensive medication is effective inhibiting the RAAS activity and lowering resting SBP. However, AHM seems to be not effective lowering SBP during incremental aerobic exercise until exhaustion.

### PHYSICAL ACTIVITY, GENETIC PREDISPOSITION FOR CARDIOVASCULAR DISEASE, AND ALL-CAUSE MORTALITY: THE FINNISH TWIN COHORT

JOENSUU, L.1, WALLER, K.1, KANKAANPÄÄ, A.1, PALVIAINEN, T.2, KAPRIO, J.2, SILLANPÄÄ, E.1,2

*1, UNIVERSITY OF JYVÄSKYLÄ; 2, UNIVERSITY OF HELSINKI*

INTRODUCTION: Current paradigm in the field of exercise science is that physical activity (PA) reduces the risk of premature death (1). To complement the evidence-base, more research is called to assess the role of PA in participants with different underlying attributes, such as genetic predispositions (2). We assessed if PA mitigates the risk of all-cause mortality despite genetic liability for CVD.
METHODS: All-cause mortality was followed for 19.7±8.1 years among 5,344 participants (mean age at baseline 48.9±9.6 years, 55% women) from the older Finnish Twin Cohort. Genetic predisposition for coronary heart disease (CHD), high systolic (SBP) and diastolic blood pressure (DBP) were assessed with polygenic risk scores (PRSs). PA during leisure-time was assessed longitudinally with a structured questionnaire in 1975, 1981 and 1990 and quantified into a mean value of metabolic equivalent hours per day (meanMET h · day-1). Cox proportional hazards model was used to estimate associations between PRSs, PA and all-cause mortality, adjusted for family relatedness, ten principal components of ancestry, age, sex, body mass index (BMI), smoking, binge drinking, fruit, and vegetable consumption.
RESULTS: During the follow-up 1,314 (25%) participants died. In models adjusted for family relatedness, ancestry, age, sex, and BMI, one standard deviation increase in CVD PRSs was associated with 8–12% higher risk of all-cause mortality: CHD (Hazard Ratio 1.11, 95% Confidence Interval 1.04–1.17), SBP (1.08, 1.03–1.14), DBP (1.12, 1.07–1.19). When meanMET was added to the model, statistically significant main effects with 4% lower risk of mortality were observed despite the genetic liability for CVD. However, the associations were attenuated and non-significant after further adjustments for other lifestyle factors.
CONCLUSION: We examined among the first studies the associations between PA during adulthood and mortality in adults with known genetic predisposition for CVD. Genetic predisposition for CVD and lifestyle factors showed independent main effects with all-cause mortality. The favorable associations observed between PA, genetic risk for CVD, and all-cause mortality were attenuated when other lifestyle factors were also considered. The clustering of healthy lifestyles might partially explain the frequently observed favorable associations between PA and mortality. These findings provide information for research-based health policy making and suggest that promoting overall healthy lifestyles might mitigate the risk of all-cause mortality despite the genetic liability for CVD.

## OP-AP08 Plyometric Training

### COMPARISON OF COMPLEX TRAINING WITH TWO DIFFERENT ORGANIZATIONS ON LOWER LIMB NEUROMUSCULAR PERFORMANCES

BOURGEOIS, H., DUCHATEAU, J., BAUDRY, S.

*UNIVERSITÉ LIBRE DE BRUXELLES - FACULTÉ DES SCIENCES DE LA MOTRICITÉ*

INTRODUCTION: Complex training combines high-load strength exercises with plyometric ones to improve explosive performance (1). These two exercises can be either alternated set by set (contrast loading; CL) or performed separately by blocks, with all sets of high-load exercises preceding plyometric ones (block training; BT). It has often been suggested that the heavy exercise in CL may have an acute potentiating effect on the following plyometric exercise and hence further increases the explosive performance after a training program (2). The objective of this study was to determine whether the use of different load organizations influenced neuromuscular performance?
METHODS: Forty-seven young men (age range: 23.6 ± 2.8 years) involved in explosive sports were assigned to either a control group (CON, n = 13), CL group (n = 17) or BT group (n = 17). The training program lasted 8 weeks (2 sessions/week) with all training variables (volume, intensity, rest) being identical between the two training groups. The strength exercises consisted of a 6-s maximal isometric half-squat and calf exercises, and the plyometric exercises of different jump types (vertical and horizontal jumps performed in bipodal and unipodal conditions and from different heights). The number of sets per training session was increased progressively during the training program from 6 to 10 sets. Before and after the training or control period, maximal height in squat jump (SJ), drop jump (DJ, 40 cm height) and its associated reactivity index (jump height/contact time) were assessed, as well as the maximal isometric force (MVC) and one repetition maximum (1RM) for the half-squat exercise.
RESULTS: Before training, none of the variables differed between groups. After training, both training groups showed an increase in SJ height (CL: +13.5%, BT: +16.2%, $p < 0.001$), 1RM (CL: +13.9%, BT: +11.2%, $p<0.01$), and MVC (CL: +4.8%, $p = 0.05$, BT: +11.1%, $p<0.001$), without significant changes in the CON group. The BT group experienced a greater increase in MVC than the CL group ($p<0.05$), and only the BT group showed an increase in DJ height (+13%, $p<0.05$) and reactivity index (+10%, $p<0.05$).
CONCLUSION: Our results confirm that CL and BT are effective for improving isometric and dynamic strength and jump performances (3). The lesser efficacy of CL could reflect a greater accumulation of fatigue which have counteracted the potentiating effect of the maximal isometric contraction on the following jump exercise (4), although the effect of fatigue in CL and BT remains a matter of debate (5). In conclusion, the present results indicate that both training organization improved explosive performance with a trend towards a greater efficacy for the BT organization.

### THE INFLUENCE OF PLYOMETRIC TRAINING ON COLLEGIATE DANCERS

DAMICO, A., KELSEN, V.

*SALEM STATE UNIVERSITY*

INTRODUCTION: Plyometric training is an effective method for improving jumping and leaping ability. Whether it can improve the performance of collegiate dancers, who perform a considerable amount of jumping and leaping in their normal training, is unknown. Therefore, the purpose of this study was to examine whether plyometric training can influence dancers' jumping ability, compared to activities normally performed in dance training.
METHODS: This six-week training study included 14 collegiate dancers (age: 21.1 ± 2.4 yr). Nine participants followed a plyometric training program, while five completed a volume-matched dance training program, with common propulsive dance maneuvers selected to resemble the plyometric exercises that would be performed in the plyometric training group. Each group trained twice per week for the duration of the study. Changes in the squat jump, countermovement jump, and broad jump were used as outcome measures. The first three weeks of training were a series of beginner-level jumps (80 touches per session) and the final three weeks progressed to intermediate-level jumps (100 touches per session). Data were assessed using a two-tailed T test, and the alpha level was set to .05.
RESULTS: Plyometric training resulted in significantly greater improvements in broad jump (25.7 ± 6.1 cm) compared to dance training (4.5 ± 4.3 cm) ($p=.03$). No significant differences were observed between plyometric training and dance training in the countermovement jump ($p=.56$), or the squat jump ($p=.22$).
CONCLUSION: These findings suggest that replacing some portion of traditional dance training with a volume-matched plyometric program may result in improvements in broad jumping for collegiate dancers, but not vertical jumping. Collegiate dancers seeking to improve their ability to leap horizontally may benefit from incorporating plyometric exercise.

### A 4-WEEK BLOCK OF HIGH-DENSITY BODYWEIGHT EXERCISES WITH WHOLE-BODY ELECTROMYOSTIMULATION DOES NOT IMPROVE JUMP AND STRENGTH PERFORMANCE: A TWO-ARMED RCT

RAPPELT, L., MICKE, F., HELD, S., DÖRMANN, U., KLEINÖDER, H., DONATH, L.

*GERMAN SPORT UNIVERSITY COLOGNE: DEUTSCHE SPORTHOCHSCHULE KOLN*

INTRODUCTION: The combination of whole-body electromyostimulation (WB-EMS) training and jumping exercises both conducted twice weekly over the duration of 8-14 weeks has been found to increase maximal strength in lower extremities, sprinting and jumping performance [1, 2]. In elite sports, however, the mesocycles of training are often organized according to block periodization. Further, since EMS cannot improve the coordinative aspect of sport-specific movements, the functional transfer into a sport-specific context may be more pronounced when performing dynamic rather than static exercises with superimposed EMS. Thus, this randomized controlled trial aimed at

elucidating whether a 4-week block of either high-density static or dynamic WB-EMS followed by a 4-week block of realization consisting of plyometric exercises is suitable to increase maximal strength and jumping performance in young and physically active adults.
METHODS: Twenty-six trained adults (13 female, 20.8 ± 2.2 years, 69.5 ± 9.5kg, 9.7 ± 6.1h of training/w) were randomly assigned to either a static (STA) or volume-, load- and work-to-rest-ratio-matched dynamic training group (DYN). Before (PRE), after 4 weeks (thrice weekly) of WB-EMS training (MID) and a subsequent 4-week block (twice weekly) of plyometric training (POST), maximal voluntary contraction (MVC) during leg extension (LE), leg curl (LC) and leg press (LP) and jumping performance (SJ, Squat Jump; CMJ, counter-movement-jump; DJ, drop-jump) were assessed. Further, mean perceived effort (RPE) was additionally rated for each session.
RESULTS: Neither rANOVA nor pairwise comparison resulted in significant effects for MVC, SJ and CMJ. The reactive strength index of DJ was significantly higher in STA compared with DYN at MID (162.2 ± 26.4 vs. 123.1 ± 26.5 cm・s-1, p = 0.002, SMD = 1.48) and POST (166.1 ± 28.0 vs. 136.2 ± 31.7 cm・s-1, p = 0.02, SMD = 1.00). Further, DYN rated the perceived effort significantly higher than STA (6.76 ± 0.32 vs. 6.33 ± 0.47 a.u.,, p = 0.013, SMD = 1.06).
CONCLUSION: A high-density block of dynamic or static bodyweight training with complementary WB-EMS is not suitable for increasing maximal strength and jumping performance in young and physically active adults. Therefore, a lower training volume with higher training intensity over a longer training period may induce higher adaptations.

## EFFECT OF INTER-REPETITION REST DURATION ON PERFORMANCE DURING 50 MAXIMAL REPEATED COUNTERMOVEMENT JUMPS

JANIKOV, M.T., OMCIRK, D., PÁDECKÝ, J., MALECEK, J., JONÁŠ, M., TUFANO, J.J.

*CHARLES UNIVERSITY*

INTRODUCTION: To be effective, the plyometric exercises must be performed with fast movement velocity, but also with sufficient volume without too much fatigue. To achieve this balance, manipulating inter-repetition rest duration might be effective in delaying fatigue onset and allowing for a greater training volume. Therefore, the aim of the present study is to examine the effects of various inter-repetition rest durations on repetitive countermovement jump (CMJ) performance.
METHODS: Nine physically active men (27.1 ± 3.20 yrs, 1.79 ± 0.06 m, 84.0 ± 10.19 kg) participated in this study. Five visits, separated by at least 48 h, consisted of standardized warm-up and a set of 50 maximal CMJs without arm swing performed continuously (R0c; whereby the end of one jump immediately transitioned into the next jump) or intermittently with 0 (R0; where they landed, stood upright, and then began the next countermovement), 4 (R4), 8 (R8), and 12 (R12) seconds of inter-repetition rest. The start of the rest period was defined as a moment when a subject returned to the upright standing position. The subjects held a wooden dowel in the high bar back squat position, and two linear position transducers (GymAware PowerTool, Kinetic Performance, Australia) were used to measure jump height (JH) and time to peak concentric velocity (TTPV). The strings of the linear position transducers were attached to each end of the wooden dowel, and the average of values recorded by two devices was used for analysis for each variable. The subjects were instructed to use self-selected countermovement depth and to perform all jumps with the intention to jump as high as possible. The results were grouped into 5 groupings of 10 repetitions (G1-G5). Two-way repeated measures ANOVA and Post-Hoc pairwise comparisons were used to compare the mean values of each repetition groupings in IBM SPSS Statistics for Windows, v. 22 (IBM Corp., Armonk, NY, USA).
RESULTS: There were significant main effects ($p<0.05$) for condition and groups of repetitions in addition to a condition*repetitions interaction for JH and TTPV. JH decreased and TTPV increased throughout R0. Similar results were seen in R0c, however, TTPV was not different between G1 and G2, as well as between G3 and G4. JH was significantly decreased in G3, G4, and G5 compared to G1 in R4, as well as in G3 compared to G1 in R12.
CONCLUSION: Rest period manipulation significantly influenced the fatigue onset in repeated CMJs, measured as change of JH and TTPV. Significant decreases of performance occurred in the first 20 jumps in R0 and R0c conditions. On the other hand, increase of rest duration in R4 delayed significant decreases in performance. Furthermore, no decrease of performance was seen throughout the 50 jumps in the R8 condition, meaning that 8-seconds is likely enough to enable high-volume jump training without decreases in performance.

## EFFECTS OF PLYOMETRIC TRAINING IN SOCCER PLAYER'S KICKING PERFORMANCE: A META-ANALYSIS

ZHANG, Y.1, LI, C.1, GÓMEZ, M.2, MEMMERT, D.3, LI, D.1

*1 BEIJING SPORT UNIVERSITY, 2 POLYTECHNIC UNIVERSITY OF MADRID, 3 GERMAN SPORT UNIVERSITY COLOGNE*

INTRODUCTION: Kicking ability is a fundamental skill in the sport of soccer, notably when attempting to score goals. Increased probabilities of winning are related to high standards of kicking performance. Assessing kicking performance and recognizing factors that influence this component of play is critical to the success of soccer games. A great deal of research examines the effects of plyometric training (PT) on soccer kicking performance. Nonetheless, available studies produced inconsistent results, and the literature has not yet been systematically reviewed. Therefore, the impacts of PT on kicking performance remain unclear. This meta-analysis aimed to determine the pooled effect size of PT on kicking performance in soccer players depending upon the related factors (i.e., age, gender, skill level, and duration of intervention).
METHODS: This meta-analysis was carried out according to the PRISMA guidelines. Searches for this study were conducted in four electronic databases: Web of Science, PubMed, Medline, and Scopus. Peer-reviewed studies must have included when they met all of the following criteria: 1) participants were healthy soccer players; 2) the PT intervention was utilized in the experimental group; 3) the regular soccer training program was applied in the control group; 4) the outcome was kicking performance, including kicking speed or kicking distance; 5) the paper was in English.
RESULTS: A total of seventeen studies yielding 18 effect sizes with n = 568 participants were finally included in the meta-analysis. A random-effects model was used to calculate Hedge's g with 95% confidence intervals, which showed that PT had a large-sized positive effect on soccer kicking performance (g = 0.974, 95% CI [0.607, 1.340], $p < 0.001$). Subgroup analyses were performed (i.e., age, gender, skill level, intervention duration), demonstrating no significant differences. In concrete terms, when assessing kicking performance between the

groups (over 18 years of age vs. under 18, male vs. female, elite vs. non-elite), no difference was observed between the groups (p = 0.153-0.827). Similarly, the over-7-week PT intervention has the same effect on kicking performance as the under-7-week one (p = 0.726).
CONCLUSION: The study demonstrates that PT is an effective method to improve soccer players' kicking performance, which plays a crucial role in the overall success of the games. As for the soccer players, coaches, and strength and conditioning professionals, the PT includes a certain value in practice. Therefore, besides well-known training methods like power training in the weight room, PT could be incorporated into the overall strength and conditioning programs for soccer players to reach high standards of kicking performance.

### OP-PN39 Physiology III

#### REBOUND CEREBRAL HAEMODYNAMICS DURING SPRINT-BASED EXERCISE

WEAVER, S.R.C., SKINNER, B.D., RENDEIRO, C., MCGETTRICK, H.M., LUCAS, S.J.E.
*UNIVERSITY OF BIRMINGHAM*

INTRODUCTION: Exercise-induced increases in blood flow is thought to induce beneficial adaptive responses in the cerebrovasculature. Compared to the sustained blood flow elevations observed with continuous, moderate intensity exercise, interval-based approaches exhibit more complex patterns in flow. Short, supramaximal-intensity exercise (e.g. 30-second sprints) suppresses middle cerebral artery velocity (MCAv) during the bout, but is followed by a subsequent elevation at the onset of recovery. These changes are closely linked to exercise-induced hyperventilation driving hypocapnia at high intensities. This study aimed to examine the role that exercise intensity plays in this post-interval bout rebound response. It was hypothesised that higher intensities would elicit the greatest rebound in early sprint bouts, while lower intensity efforts would induce more consistent responses across multiple bouts.
METHODS: Eight physically active participants (5 female) completed four separate sprint-interval sessions at 80%, 120%, 160% and 200% of maximal power output (Wmax), in a randomised order. The exercise protocol involved 4 x 30-s sprint bouts, interspersed with 4.5-minutes of active recovery at 50 W. MCAv was assessed by transcranial doppler, alongside measures of breath-by-breath end-tidal carbon dioxide (PETCO2). Data were exported and passed through automated feature selection to detect the minimum point during each bout and the maximum point during rebound (first 1-minute of active recovery). All data were analysed using linear mixed effects modelling.
RESULTS: MCAv values within the 80% Wmax visit (97.7 ± 32.3 cm/s) were significantly higher than those in visits at any other intensity (120%: 96.0 ± 33.5 cm/s; 160%: 90.7 ± 30.0 cm/s; 200%: 83.8 ± 27.9 cm/s; all $p < 0.01$), while MCAv in 200% Wmax visits was significantly lower than in all other visits ($p \leq 0.03$). Across the four bouts, regardless of intensity and minimum/maximum point, MCAv was significantly greater for bout 1 (102.0 ± 31.8 cm/s) than in any other bout (Bout 2: 91.4 ± 31.8 cm/s; Bout 3: 88.0 ± 29.6 cm/s; Bout 4: 85.7 ± 29.8 cm/s; all $p < 0.01$). While not significant, rebound responses (maximum – minimum point) were seen to increase across repeated bouts at 80% (Δ39.2 cm/s in bout 1 vs. Δ44.1 cm/s in bout 4). Whereas at 200% the opposite trend was seen, with a decline in rebound magnitude from bout 1 (Δ52.3 cm/s) to bout 4 (Δ38.8 cm/s). Across all intensities and bouts PETCO2 responses were seen to mirror those in MCAv.
CONCLUSION: Acute sprint bouts across a range of intensities and for multiple bouts induce MCAv rebound responses. The amplitude and pattern of these responses over repeated efforts appears to feature an intensity-dependent component, with submaximal intensity sprint efforts showing a more sustained elevation during the bouts and for the rebound response post bouts. These findings indicate that submaximal intensities should be incorporated into interval-based exercise interventions to maximise adaptive stimuli.

#### EFFECTS OF SPRINT INTERVAL TRAINING, CONTINUOUS TRAINING AND BLOOD FLOW RESTRICTION IN ACTIVE YOUNG MEN

FU, Y.
*SHANGHAI UNIVERSITY OF SPORT*

INTRODUCTION: To examine the effects of sprint interval training (SIT), continuous training (CT) and continuous training combined with blood flow restriction (BFR) (CT+B), with equal estimated energy expenditure between CT and CT+B, on body composition, aerobic and anaerobic performance.
METHODS: 45 young healthy active men (age: 19.70±1.01 yr, height: 178.36±5.67 cm, body mass: 71.23±8.47 kg) volunteered to participate in this study. Prior to training participants were familiarized to training procedures and undertook baseline test, including weight, body fat percentage, 2000m rowing performance (duration, maximal oxygen uptake and maximal heart rate) and Wingate test (maximal anaerobic power and average anaerobic power) were measured in baseline test. On the basis of baseline test, all subjects were matched into one of four groups (control, SIT, CT or CT+B). Participants in three training groups completed 12 supervised rowing sessions over 4-weeks period, sessions were separated by a minimum of 48 hours. The SIT group (n=12)performed 20s all out sprints with 160s (1:8 work-rest ratio) of low cadence， nine bouts per session. CT and CT+B groups performed continuous rowing at an intensity of 25% of peak power output either without (CT, n=12) or combined with BFR (CT+B, n=12). In CT+B group, and cuffs were applied as high up as possible on the proximal portion of each thigh and were inflated for 20 s to a pressure of 100% arterial occlusion pressure, nine bouts per session as same as SIT. The control group did not participate in additional training sessions. Subjects were encouraged to maintain their physical activity and diet patterns throughout the programs. Post-training measures were identical with the baseline test.
RESULTS: The body fat percentage of SIT (-1.03±1.28%, P=0.012), CT (-1.06±0.68%, P＜0.001) and CT+B (-0.90±1.15%, P=0.02) were significantly decreased after intervention; the 2000m time-consuming in SIT group (-0.31±0.19min， $P < 0.001$), CT group (-0.36±0.29 min, P = 0.001) and CT+B group (-0.40±0.20 min, $P < 0.001$) were significantly reduced; maximal oxygen uptake of the SIT (5.02±3.73 ml/kg/min, P = 0.03) and CT+B (1.88±4.63 ml/kg/min, P = 0.017) groups were significantly increased; maximal anaerobic power in the SIT group (48.42±37.74W, P = 0.001) and the CT+B group (38.17±39.09W, P = 0.001) increased significantly; average anaerobic power in CT group (42.25±44.50W, P = 0.007) and CT+B group (39.33±29.18W, $P < 0.001$) increased significantly after intervention; and there was no significant difference between groups after intervention among above indicators ($P>0.05$).
CONCLUSION: 4-week SIT, CT, and CT+B interventions can equivalently improve body composition and endurance performance in active young men; however, SIT and CT+B are more effective in improving cardiorespiratory fitness than CT. Continuous training combined with intermittent blood flow restriction can be used as an alternative to improving cardiorespiratory fitness and body composition.

### SUSTAINED SLEEP RESTRICTION REDUCES RESISTANCE EXERCISE PERFORMANCE BUT NOT MARKERS OF MUSCLE PROTEIN METABOLISM IN RESISTANCE-TRAINED FEMALES

KNOWLES, O.E., DRINKWATER, E.J., ROBERTS, S.S.H., ALEXANDER, S.E., TREWIN, A., ABBOTT, G., GARNHAM, A., LAMON, S., AISBETT, B.

*DEAKIN UNIVERSITY*

INTRODUCTION: Female athletes sleep less and report more sleep problems than males (1). Resistance exercise is an important component of athletic training programs yet inadequate sleep reduces muscle strength in males (2). The implications for females are unknown. This study investigated the effect of sustained sleep restriction on repeated resistance exercise performance, anabolic and catabolic hormone levels, molecular markers of skeletal muscle protein synthesis and degradation and perceived fatigue and training stress in females.
METHODS: Ten healthy, resistance-trained, eumenorrheic females aged 18-35 years underwent nine nights of sleep restriction (SR; 5-h time in bed) and normal sleep (NS; > 7-h time in bed), in a randomised, cross-over fashion with a minimum 6-week washout. Participants completed resistance exercise sessions on days 3, 5, 7 and 9 of each trial, with blood samples collected pre- and post-exercise to assess hormonal responses. Muscle biopsies were collected pre- and post-exercise on day 3 and 9 to assess circadian and muscle protein metabolism-related gene and protein content via PCR and Western blot, respectively. Exercise performance was assessed using volume-load, reactive strength index and mean concentric velocity with rating of perceived exertion recorded post-exercise. Participants completed awakening saliva sampling and the multi-component training distress scale daily.
RESULTS: Volume-load decreased (<1%, $p < 0.05$) with SR. Mean concentric velocity per set was slower during SR for lower body (up to 15%, $p < 0.05$), but not upper body, compound lifts. SR increased total training distress by 84% ($p < 0.005$) and session perceived exertion by 11% ($p < 0.005$). SR increased the salivary cortisol awakening response (by 42%, $p < 0.005$), yet had no impact on the plasma testosterone, cortisol and IGF-1 response to exercise. SR reduced pre-resistance exercise plasma sex-hormone binding globulin (by 18%, $p < 0.005$) and increased pre-resistance exercise free androgen index (by 35%, $p < 0.01$) on day 3 only. SR had a limited effect on the expression levels of the markers of protein synthesis, protein degradation and circadian-related gene and proteins in skeletal muscle.
CONCLUSION: Nine nights of sleep restriction reduced resistance exercise quality more than quantity and increased perceived effort and training distress at the same relative intensity of exercise. However sleep restriction did not impact the expression of the markers of muscle protein synthesis and degradation, which may be explained by the resistance-trained status of participants. Markers of exercise quality and internal load may be more sensitive than volume-load, to advise coaches of the negative effects of SR on resistance exercise. Further research is needed to demonstrate a protective effect of resistance exercise on skeletal muscle health with inadequate sleep.

### EFFECT OF INCREASED TRICEPS SURAE CONTRACTION VELOCITY ON WHOLE-BODY METABOLIC RATE AND MUSCLE ACTIVITY DURING CYCLIC PLANTARFLEXION CONTRACTIONS

SWINNEN, W., HOOGKAMER, W., DE GROOTE, F., VANWANSEELE, B.

*KU LEUVEN*

INTRODUCTION: Almost 100 years ago, Fenn (1923) demonstrated that the heat liberation of a muscle during concentric contraction was higher than during isometric contractions [1]. Fenn's results were the first of many that led to the general understanding that isometric muscle contractions are energetically cheaper than concentric muscle contractions. While researchers often use this knowledge to explain differences in whole-body metabolic rate during full-body exercises, the evidence is primarily based on single fiber studies. Here, we quantify the effect of increasing triceps surae concentric contraction velocity on whole-body metabolic rate and triceps surae muscle activity during cyclic contractions.
METHODS: Fourteen participants lay prone on a dynamometer and performed cyclic plantarflexion contractions at three different ankle angular velocities: 1) isometric with ankle angle at 10° plantarflexion (PF); 2) isokinetic at 30°/s with the ankle rotating from 5° PF to 15°PF and 3) isokinetic at 60°/s with the ankle rotating from 0° PF to 20° PF. During each condition participants generated torque during 1/3s to reach a target torque (25% of MVC) followed by 2/3s of rest. The conditions were randomized and cyclic contractions were sustained for 6 minutes in each condition. We collected whole-body metabolic rate, triceps surae and tibialis anterior muscle activations and in-vivo gastrocnemius medialis muscle fascicle kinematics.
RESULTS: As expected, increasing ankle angular velocity resulted in faster gastrocnemius medialis contraction velocities and more positive muscle mechanical work per cycle. While mean and peak plantar flexion torques per cycle were not different across ankle angular velocity conditions, net whole-body metabolic rate increased with increasing ankle angular velocity. Compared to the isometric condition, net metabolic rate was 50% and 113% higher in the 30°/s and 60°/s condition respectively. The increase in net whole-body metabolic rate should reflect an increased triceps surae muscle metabolic rate, which depends on muscle activity . Indeed, we found greater mean and peak triceps surae muscle activation with increasing ankle angular velocity. Interestingly, the increase in activation of gastrocnemius lateralis was most prominent (+100% at 60°/s vs. isometric) whereas the relative increase in soleus activation was smaller (+57% at 60°/s vs. isometric). The differences in relative increase may reflect the difference in muscle fiber type distribution with the soleus containing more slow twitch muscle fibers than the gastrocnemius lateralis [2].
CONCLUSION: We provide evidence that slower muscle contractions are metabolically cheaper at the whole-body level . In addition, our results indicate that when synergistic muscles contract faster we rely more on muscles with greater distributions of fast twitch fibers.

### WHOLE BODY-ELECTROMYOSTIMULATION TRAINING INCREASED FGF21 IN PARKINSON PATIENTS

CENTORBI, M., BUONSENSO, A., SOLIGO, M., MANNI, L., DI COSTANZO, A., CALCAGNO, G., CASAZZA, G., PARISI, A., FIORILLI, G., DI CAGNO, A.

*UNIVERSITÀ DEGLI STUDI DEL MOLISE*

INTRODUCTION: Parkinsons disease (PD) patients are unable or unwilling to adhere to traditional exercise programmes, due to physical and mental limitations. Therefore, it is needed to find a training methodology for them that provides an immediate feeling of well-being and enhances their motivation and perseverance. Whole Body-Electromyostimulation superimposed on voluntary movements is a time-

efficient and non-invasive training modality. The aim of this study was to find the most suitable and effective WB-EMS training methodology for this population.
METHODS: Twenty-five subjects (age 72.08 ± 6.07) were randomly assigned to three study arms: 20 min-Strength based WB-EMS training (85 Hz, with 4s on/4s off, 350 µs) (SG), 20 min-Endurance based WB-EMS training (7 Hz, 350 µs, continuous pulse duration) on a rowing machine (EG), and CG who did not carry out any training. For both the interventions the CE-certified medical EMS equipment Miha Bodytec, (Gersthofen, Germany) was used. Primary outcome variables included physical and cognitive performances, neurotrophic factors (BDNF, FGF21) and α-synuclein levels.
RESULTS: The RM-ANOVA showed significant improvements of both EG and SG in arm curl ($p = 0.003$) and sit to stand test ($p= 0.004$ and $p= 0.030$ respectively). The 6-minute walking test improved significantly ($p< 0.001$) better in the EG compared with the SG ($p= 0.004$) and in Tinetti balance and gait test EG showed higher balance and walking ability than in pre-intervention ($p< 0.001$) and better than SG ($p= 0.002$). With regard to cognitive performances, results showed improvements in general cognitive function (MMSE) both in EG ($p= 0.002$) and in SG ($p= 0.010$). Regarding the perception of fatigue (PFS-16), EG reported a lower fatigue than SG ($p= 0.013$) and CON ($p< 0.001$); in addition, the CON reported a higher perception of fatigue than pre-intervention ($p= 0.032$). The main result was that, after EG training, higher serum levels of FGF-21 ($p= 0.023$) and lower serum levels of α-synuclein were observed ($p= 0.037$). The FGF plays a crucial role in the survival of neurons as well as in neuroinflammation and mitochondrial dysfunctions caused by abnormal aggregation of α-synuclein [Liu,2021].
CONCLUSION: FGF21, in fact, reduces the accumulation of α-synuclein, reducing its toxicity and the loss of dopaminergic neurons. WB-EMS training resulted an effective and well-tolerated training without adverse events or side effects for Parkinsons patients [Fiorilli,2021]. Endurance training combined with WB-EMS was more effective than strength training in improving physical and cognitive performances, and the level of FGF21.

#### RELATIONSHIPS BETWEEN FUNDAMENTAL TRAINING VARIABLES AND ENDURANCE PERFORMANCE IMPROVEMENT IN RECREATIONAL MALE CYCLISTS

LEHMANN, N., TAUBERT, M., JUNKEREIT, D.

*OTTO VON GUERICKE UNIVERSITY MAGDEBURG*

INTRODUCTION: The question of how to optimize training regimens to maximize endurance performance has attracted much attention in recent years. Our current knowledge mainly comes from retrospective analyses of the training undertaken by elite endurance athletes, suggesting that high total training volumes (VOL) and high proportions of low-intensity training (LIT, typically ≥ 75%) are key to success [1 ]. The importance of training at moderate (MIT) and high intensities (HIT) has also been highlighted [1 ]. However, it is not clear whether training characteristics shown to be effective in elite athletes can also be considered best practices for recreational athletes [2]. The few studies addressing this problem to date were either cross-sectional, or if longitudinal, their sample sizes were typically small and the training period short.
METHODS: We analyzed powermeter data from a randomly selected sample of n = 69 recreational male cyclists (Mage = 42.9 ± 11.64 y, MCP = 3.90 ± 0.64 W/kg, MVOL = 24.85 ± 12.22 h/month) available from a public repository. Inclusion criteria were availability of power output data over a period of at least 24 months, interruptions of training of no longer than 4 months, and a minimum of 50 realized training sessions. Performance- and training-related data for each individual were quantified using the implementations of the Banister model and critical power (CP) in the Golden Cheetah software. The historical maximum of CP (CPmax) was defined as the reference point for later statistical analyses. Specifically, CPmax and its changes over a period of 12 months were used as dependent variables in several (partial) correlation and regression analyses.
RESULTS: Median (IQR) values of relative training intensity distribution were: LIT: 56.28% (50.98,62.92), MIT: 32.19% (26.36,35.84), HIT: 10.43% (8.37,14.16). Cross-sectional analyses of data from the time window of 12 months before CPmax revealed that VOL significantly predicted CPmax, $r = .39$, $p < .001$, as did the relative proportion of LIT, $r = .53$, $p < .001$ (corrected for VOL) and the ratio of LIT to MIT+HIT, $r = .52$, $p < .001$ (corrected for VOL). Longitudinal analysis revealed, however, that absolute yearly VOL was not associated with residualized CP change (corrected for CP baseline and age). Instead, we found that the percentage increase in yearly VOL (corrected for absolute VOL of the baseline year) was significantly correlated with residualized CP change, $r = .44$, $p = .004$. We will also present results of more complex regression models (relative weights analysis) aiming at ranking the predictors according to their statistical importance.
CONCLUSION: Our data indicate that best practice training recommendations derived from elite athletes do also hold true for ambitious recreational athletes. Specifically, the importance of high and progressively increasing VOL and high proportions of LIT became apparent.

#### THE REPRODUCIBILITY OF PACING DURING 20-MIN TIME-TRIALS ON ZWIFT®

MATTA, G., EDWARDS, A., ROELANDS, B., HETTINGA, F., HURST, P.

*CANTERBURY CHRIST CHURCH UNIVERSITY*

INTRODUCTION: Although the reproducibility of performance (i.e., mean power output) during laboratory- and field-based cycling time-trials is well established [1], only few studies investigated the reproducibility of pacing [2, 3], especially in virtual environments [4]. The purpose of this study was to analyse the reproducibility of pacing (i.e., distribution of power output) during time-based 20-min cycling time-trials on the virtual-reality cycling software, Zwift®.
METHODS: Forty-four cyclists (11 women, 33 men; 37 ± 8 years old, 180 ± 8 cm, 80.1 ± 13.2 kg) were recruited and performed 3x 20-min time-trials on Zwift®. To determine the reproducibility of pacing, mean power output per 2-min time-intervals was normalised to overall mean power output during each time-trial. Typical errors (TE; which constitutes the variability of the measure) derived from log-

transformed data and changes in the mean normalised power outputs between time-trials 1-2 and 2-3 were calculated for each 2-min time-interval; two-way repeated-measures ANOVA ($P < 0.05$) was used to analyse differences between 2-min time-intervals.
RESULTS: We found higher variability (evidenced by higher TE) of normalised power output at the start and end of each time-trial (TE = 5.06% and 4.36% for intervals 0-2 min and 18-20 min, respectively), in comparison to the remaining time-intervals. There was a main effect of time ($F = 18.32$, $P < .001$, ES = .31) and mean normalised power output decreased from time-interval 2-4 min to 12-14 min (all $P < .047$) and increased during 18-20 min in comparison to all previous time-intervals (all $P < 0.001$), except from 0-2 min ($P = .359$). However, pacing was not different between time-trials ($F = 1.31$, $P = .249$, ES = .03).
CONCLUSION: Our findings indicate that pacing is consistent throughout repeated time-trials, although there might be higher variability—evidenced by the higher TE—at the start and end, in comparison to the middle parts. Our results are likely to be used in assisting coaches and athletes in their virtual training monitoring and the development of new remote-study designs by sports scientists. This is particularly important in the current COVID-19 pandemic, where cyclists might rely upon virtual training.

## LOW INTENSITY TRAINING (LIT) IN CYCLISTS DURING PYRAMIDAL TRAINING: SHORTER, DAILY LIT SESSION SEEMS SUPERIOR FOR THRESHOLD POWER COMPARED TO LONGER 3-DAY LIT BLOCKS: A WORK-LOAD MATCHED RCT

RÖHRKEN, G., HELD, S., KEUFEN, P., KONCZALLA, L., SPERRLICH, B., DONATH, L.
*SPORTHOCHSCHULE KÖLN*

INTRODUCTION: Low-intensity training (LiT) is an essential training stimulus to improve performance and contributes to more than 80% of the weekly time- and session-related training volume in recreational and elite athletes. However, the density, distribution and duration of LiT sessions during a weekly training schedule still remains debatable. Thus, we aimed at elucidating whether shorter LIT training session on a daily basis result in superior threshold power compared to longer LIT training session within 3-day blocks.
METHODS: Twenty-one moderately trained cyclists (age = 33.9 ± 7.8 years, sex = 4 female, 17 male, 20 minute time trial performance = 3.7 ± 0.7 W/Kg, weight = 76.5 ± 13,9 Kg, training volume = 10.9 ± 2.27 h/week) were either assigned to the DenseLIT(DL)- or StretchLIT(SL)-group, using the minimization method (Strata: Gender, age, fitness level, training volume). DenseLIT accumulated 80% of their weekly LiT training volume in a three-day window with longer LIT sessions, whereas the Stretch-LIT group used a more weekly balanced approach with shorter daily LIT sessions. Both groups applied a pyramidal training intensity distribution (TID), and used two training mesocycles, each with three weeks of increasing training loads and one recovery (first cycle), or test week (last cycle). At the end of the eight-week intervention period, an incremental cycling (+50 W/5min.) test was conducted to assess submaximal performance surrogates at the lactate thresholds (iAT, P2, and P4) and peak performance.
RESULTS: rANOVA revealed significant time*mode interaction effect ($p \leq 0.05$; $\eta p2 \geq 0.18$) for iAT, P2 and P4. Subsequent pairwise post hoc testing revealed notably larger pre to post performance inprovements in StretchLiT (iAT (+30±28W; $p < 0.01$, SMD = 0.52), P2 (+37±33W; $p < 0.01$, SMD = 0.64) and P4 (+40±37W; $p < 0.01$, SMD = 0.58) compared to non-significant effects in DenseLIT (iAT (-5±21W; $p = 0.42$, SMD 0.01), P2 (+11±18W; $p = 0.07$, SMD = 0.17) and P4 (+12±25W; $p = 0.15$, SMD = 0.18). The training volume in both groups was workload matched (DenseLIT = 28191 ± 4165 Trimp vs. StretchLiT = 22474 ± 8983, $p = 0.25$).
CONCLUSION: StretchLiT show superior performance improvements in iAT, P2 and P4 performance with moderate effects , whereas DenseLIT display only trivial or no effects. Thereby, a continuous stretched out training regime seems to induce superior effects compared to a three-day dense LiT program in an eight-week intervention period of moderately trained cyclists.

## HIGH-INTENSITY INTERVAL TRAINING IN CYCLING: ACUTE RESPONSE AND CHRONIC ADAPTATIONS

QUITTMANN, O.J., GRANDJEAN, M., APPELHANS, D., ABEL, T.
*GERMAN SPORT UNIVERSITY COLOGNE*

INTRODUCTION: High-Intensity Interval Training (HIIT) was highlighted as a safe intervention that allows for multiple health benefits across the lifespan [1]. Previous research indicated variables for characterizing HIIT protocols and categorized four types of HIIT: long intervals (LI, > 60 s), short intervals (SI, ≤ 60 s), repeated sprint training (RST) and sprint interval training (SIT) [2]. It is commonly assumed that the acute physiological response corresponds to the adaptational effect. While recent meta-analyses compared the chronic adaptations to LI and SIT [3], there are several promising HIIT protocols that deserve closer attention at both levels. Hence, this systematic review aims to compare the effects of various HIIT protocols on (1) the acute response and (2) chronic adaptions in cycling.
METHODS: PubMed and Web of Science were used to find studies in the timespan from 2013 until the date of the search (15th of February 2021). Inclusion criteria were the comparison of different HIIT protocols, cycling as exercise modality and participants with a mean maximal oxygen uptake ($\dot{V}O_2max$) ≥ 45 ml/min/kg. Risk of bias was assessed by using the PEDro scale. Results were summarized for the acute response (time ≥ 90% $\dot{V}O_2max$, lactate concentration, perceived exertion and power) and chronic adaptations (time trial performance, $\dot{V}O_2max$ and lactate threshold) while indicating the participants' performance levels.
RESULTS: A total of 31 studies (23 acute, 14 chronic, 6 both) with a mean PEDro score of 5.4 ± 0.9 and a total sample size of N = 544 were included. The majority of acute studies applied a crossover design, while longitudinal studies were exclusively group-based. The highest times ≥ 90% $\dot{V}O_2max$ were reported for intervals with varied work intensity and protocols that combined SI and LI. SI demonstrated a substantially higher acute response compared to LI while differences in chronic adaptations appeared to be rather small and tended to favor SI in highly-trained/professional athletes. When compared to SI and LI, SIT and RST demonstrated considerably lower improvements in aerobic endurance parameters, whereas anaerobic and sprint parameters were effectively improved.
CONCLUSION: The results indicate that HIIT protocols that are associated with a higher acute response may not necessarily lead to superior chronic adaptations. Whereas SI and LI seem to be equally effective for improving endurance performance, SIT and RST are more adequate for improving sprint performance. In accordance with previous research [3], the reported performance improvements decreased with increasing training status. Limitations arise from the design of longitudinal studies and the applied matching procedures. Future studies are

encouraged to perform crossover interventions and include measures of glycolytic capabilities to holistically examine the adaptational effect of various forms of HIIT.

**LESS IS MORE—CYCLISTS-TRIATHLETE'S 30 MIN CYCLING TIME-TRIAL PERFORMANCE IS IMPAIRED WITH MULTIPLE FEEDBACK COMPARED TO A SINGLE FEEDBACK**

BAYNE, F.

*LONDON SOUTH BANK UNIVERSITY*

Purpose: The purpose of this article was to (i) compare different modes of feedback (multiple vs. single) on 30 min cycling time-trial performance in non-cyclist's and cyclists-triathletes, and (ii) investigate cyclists-triathlete's information acquisition.
METHODS: 20 participants (10 non-cyclists, 10 cyclists-triathletes) performed two 30 min self-paced cycling time-trials (TT, ~5–7 days apart) with either a single feedback (elapsed time) or multiple feedback (power output, elapsed distance, elapsed time, cadence, speed, and heart rate). Cyclists-triathlete's information acquisition was also monitored during the multiple feedback trial via an eye tracker. Perceptual measurements of task motivation, ratings of perceived exertion (RPE) and affect were collected every 5 min. Performance variables (power output, cadence, distance, speed) and heart rate were recorded continuously.
Results: Cyclists-triathletes average power output was greater compared to non-cyclists with both multiple feedback (227.99 ± 42.02 W; 137.27 ± 27.63 W; $P < 0.05$) and single feedback (287.9 ± 60.07 W; 131.13 ± 25.53 W). Non-cyclist's performance did not differ between multiple and single feedback ($p > 0.05$). Whereas, cyclists-triathletes 30 min cycling time-trial performance was impaired with multiple feedback (227.99 ± 42.02 W) compared to single feedback (287.9 ± 60.07 W; $p < 0.05$), despite adopting and reporting a similar pacing strategy and perceptual responses ($p > 0.05$). Cyclists-triathlete's primary and secondary objects of regard were power (64.95 s) and elapsed time (64.46 s). However, total glance time during multiple feedback decreased from the first 5 min (75.67 s) to the last 5 min (22.34 s).
Conclusion: Cyclists-triathletes indoor 30 min cycling TT performance was impaired with multiple feedback compared to single feedback. Whereas non-cyclist's performance did not differ between multiple and single feedback. Cyclists-triathletes glanced at power and time which corresponds with the wireless sensor networks they use during training. However, total glance time during multiple feedback decreased over time, and therefore, overloading athletes with feedback may decrease performance in cyclists-triathletes.

INTRODUCTION: The loss of strength and flexibility is a frequent challenge in patients following total knee arthroplasty (TKA). Despite the lack of clear guidelines for the postoperative rehabilitation protocols, such protocols typically include bilateral strength training of the lower limbs. Training intensities are therefore calculated from the bilateral one repetition maximum. However, based on the theory of the bilateral deficit, a reduced bilateral force production compared to the summed unilateral force production from the same homologous muscles [1], this might underestimate the muscle's capacity [2]. Therefore, the aim of the study was to analyze the effects of unilateral compared to bilateral strength training following unilateral TKA on knee extensor strength and flexibility.
METHODS: Twenty-two patients were randomly assigned to a unilateral (UL: n=11, 6 males, 62.5+/-9.7 y, BMI: 32.4+/-7.3) or bilateral (BL: n=11, 4 males, 59.1+/-6.1 years, BMI: 29.8+/-3.9) inpatient rehabilitation training group. All patients participated in a 3-week routine physical therapy including flexibility, proprioception water aerobics, treadmill training, and ergocycle training. Additionally, depending on the training group assignment, patients performed unilateral (operated leg only) or bilateral leg press, knee extension, knee flexion, and calf raise exercises. Main outcome measures were isometric leg extension strength of the separate legs and maximum flexion of the operated knee before and after the training. Effects were tested by mixed multi factorial ANOVAs and post-hoc tests.
RESULTS: Both groups increased their isometric leg extension strength of the operated leg (from 17.5 +/- 6.3 to 21.9+/-6.4 kg) and the non-operated leg (from 21.2+/-5.0 to 24.9+/-5.4 kg). The increases were significantly greater ($p<0.05$) for the non-operated leg in the UL-group (+27.5% vs. +11.6%). Knee flexion increased in both groups (from 101.81+/-13.67° to 109.5+/-14.4°) with greater changes ($p<0.05$) in the UL-group (+10.7 vs. +4.5%).
CONCLUSION: Unilateral strength training following TKA led to similar strength benefits in the operated leg and even greater benefits in the strength in the non-operated leg and the flexibility of the operated knee compared to bilateral strength training. The greater intensity over the whole range of motion during unilateral strength training seems to provide a greater stimulus to increase flexibility than bilateral strength training without any negative effects during therapy. Hence, unilateral strength training in postoperative rehabilitation is a promising alternative to standard bilateral rehabilitation programs.

### INFLAMMATORY MARKERS IN EARLY SYMPTOMATIC KNEE JOINT OSTEOARTHRITIS: A CASE-CONTROL-PILOT STUDY

HEFFERNAN, S.M.1, MCCARTHY, C.2,3, EUSTACE, S.4, WALDRON, M.1, DELAHUNT, E.2, DE VITO, G.2,5

*SWANSEA UNIVERSITY, UK1; UNIVERSITY COLLEGE DUBLIN, IRELAND2; MATER MISERICORDIAE UNIVERSITY HOSPITAL, IRELAND3; CAP-PAGH NATIONAL ORTHOPAEDIC HOSPITAL, IRELAND4 ; UNIVERSITY OF PADOVA, ITALY5*

INTRODUCTION: Osteoarthritis (OA) is characterised by the failure of normal biological processes to repair following damage. This can be due to abnormalities in movable joint structures and manifests symptomatically as pain and reduction of physical function [1]. These can be caused by sports injury or post-traumatic osteoarthritis [2]. Traditionally, OA was considered a “wear and tear” disorder, however it is now recognised as an inflammatory condition, pre-seeded by molecular modifications [3]. Early diagnosis of OA is essential to optimising treatment and clinical outcomes. A recent set of clinical assessment criteria have been recommended for use in patients with early OA, with further research into biochemical markers being advocated [4]. The aim of our study was to evaluate select inflammatory markers in individuals with early knee OA (eKOA) and asymptomatic controls (matched for age, anthropometrics and physical function).
METHODS: Twenty six eKOAs were recruited (females, n = 13; age = 60.2 ± 5.4yrs, height = 1.73 ± 0.11m, body mass = 77.8±12.8kg, DXA-fat = 33.9 ± 8.5%). The inclusion criteria were as follows; pain for >1 year, Knee Injury and Osteoarthritis Outcome Score (KOOS) pain score of greater than 50 and Kellgren and Lawrence grade ≤ 2. Twenty-three asymptomatic individuals (females, n = 14; age = 59.9 ± 5.5yrs, height = 1.71 ± 0.09m, body mass = 72.6 ± 11.3kg, DXA-fat = 30.4 ± 8.2%) were recruited as a comparator group. The Timed Up and Go Test and the 6 Minute Walk Test were used to evaluate participant’s physical function. Participants’ blood was drawn into serum separator tubes, centrifuged and stored at -80oC. Serum levels of IL-1α, IL-1 β, IL-2, IL-4, IL-6, IL-8(CXCL8), IL-10, hsCRP and TNF-α were quantified using a multiplex assay quantified on a V-plex®Sector Imager 2400 (Meso Scale Discovery, Rockville, MD, USA).
RESULTS: Expectedly KOOS pain differed between the groups (mean = 99.2 ± 2.0 AU vs 69.2 ± 13.8 AU; $p < 0.001$). Only IL-6 was higher in eKOA ($p = 0.001$, $\eta p2 = 0.229$; by 0.197pg/mL, 34.5%). This difference had moderate discriminative accuracy (AUC = 0.751, 95% CI = 0.610-0.891, $p = 0.003$), an accurate positive rate of 84% (false positive rate = 64%) and a cut-off below 0.627pg/mL. Among eKOA, IL-6 did not correlate with KOOS pain ($p = 0.501$; $r = -0.151$).
CONCLUSION: Inflammation plays a pivotal role in the progression of KOA, however is sparsely investigated in eKOA, with little structural or functional defects. Our results illustrate that circulating IL-6 could be used as a potential biomarker of early knee OA. Future work should seek to verify this results in a larger sample and further investigate IL-6 related molecular pathways in eKOA.

### WHOLE BODY VIBRATION FOR CHRONIC PATELLAR TENDINOPATHY: A RANDOMIZED EQUIVALENCE TRIAL.

RIEDER, F., WIESINGER, H.P., HERFERT, J., LAMPL, K., HECHT, S., NIEBAUER, J., MAFFULLI, N., KÖSTERS, A., MÜLLER, E., SEYNNES, O.

*PARACELSUS MEDICAL UNIVERSITY SALZBURG*

INTRODUCTION: Whole body vibration (WBV) triggers an anabolic response in various tissues, including tendons [1]. However, the clinical effectiveness of this exercise regime against tendinopathy remains unexplored. Therefore, in this waitlist-controlled equivalence trial, we tested the effectiveness of WBV as a treatment of patellar tendinopathy against conventional heavy slow resistance training (HSR).
METHODS: Thirty-nine patients were randomized to either 3 months of WBV training (n = 13), HSR training (n = 11), or a waitlist control (WLC) group (n = 15). In a partly cross-over design, 14 patients of the WLC group were redistributed to one of the two intervention groups (5 in WBV, 9 in HSR). Pre- and post-intervention testing included pain assessments (VAS), functional limitations (VISA-P), knee extension strength and tendon morphology, as well as tendon material and mechanical properties. Follow up measurements (VAS, VISA-P) were performed in the WBV and HSR groups six months after the intervention.
RESULTS: Comparisons with the WLC group revealed significant improvements in VISA-P and VAS scores after HSR (41%, $p = .003$ & 54%, $p = .005$) and WBV (22%, $p = .022$ & 56%, $p = .031$) training. These improvements continued until follow-up (HSR: 43% & 56%; WBV: 24% & 37%). Pre-post improvements in VAS scores were equivalent between WBV and HSR groups but inconclusive for the VISA-P score and all pre-test to follow up comparisons. The mid-tendon cross-sectional area was reduced after both WBV (-5.7%, $p = .004$) and HSR (-3.0%, $p = .006$) training, although the equivalence test was inconclusive.
CONCLUSION: Whole body vibration improved symptoms typically associated with patellar tendinopathy. This type of intervention is as effective as HSR against pain, although equivalence could not be confirmed for other variables. The beneficial responses to WBV treatment persisted for 6 months after the end of the intervention.

### BIOMECHANICAL ANALYSIS OF THE PATTERNS OF FEMALE FUTSAL PLAYERS WITH AND WITHOUT KNEE PAIN. CROSS-SECTIONAL STUDY.

FERRÁNDEZ-LALIENA, L.1, VICENTE-PINA, L.P.1, SÁNCHEZ-RODRÍGUEZ, R.1, ORANTES-GONZÁLEZ, M.E.2, HEREDIA-JIMÉNEZ, J.M.3, LUCHA-LÓPEZ, M.O.1, TRICÁS-MORENO, J.M.1

*1. UNIVERSIDAD DE ZARAGOZA, 2.UNIVERSIDAD PABLO DE OLAVIDE , 3. UNIVERSIDAD DE GRANADA*

INTRODUCTION: Knee injury incidence and especially anterior cruciate ligament (ACL) injuries in womens soccer is very high and higher than in mens soccer (1). The high sports casualty and recurrence rate justifies the need to work on injury prevention identifying and reversing the main biomechanical and neuromuscular risk factors (2,3). A cross-sectional study is proposed to identify the relationship between biomechanical risk patterns established by the bibliography (4).
METHODS: A sample of 16 female futsal players (23,94 ± 5,03 years) was selected. They were divided into three groups: ACL intervention (LCA), knee pain (KP) and no knee injury (NI). A 3D capture system of 12 infrared cameras (Qualisys A.B, Gotegorg, Sweden) was used. Visual3D software was then used to create an 8-segment biomechanical model for the calculation of biomechanical variables. A pressure platform system was used to detect the peak torque of the braking reaction force. Specific tests were performed. A contrast of variables between groups was performed using Students t-test and an analysis of the effect size using Cohens d. A linear regression model was constructed using ANOVA. A 95% confidence level was established.

RESULTS: Eight KP players, one with LCA, and another group of 8 NI players were analysed. The contrast between groups did not significant results, although relevant differences appeared when analysing the effect size. The KP group presented a biomechanical adjustment towards greater knee valgus (d=0.64), contralateral trunk displacement (d=0.86), contralateral pelvic drop (d=1.04), and greater plantar flexion at the moment of maximum impact on the force platform ($p<0.05$). Moreover, a regression model was defined which fixes the knee valgus variable in 99% ($p<0.01$) as a function of the variables trunk displacement, pelvis drop, hip rotation, knee rotation and ankle valgus.
CONCLUSION: The biomechanical pattern may be different between futsal players with knee pathology and players without injury, being knee valgus a conditioned variable and definable from other biomechanical variables.

## OP-SH08 Teacher Education

### INITIAL TEACHER EDUCATION - A PHYSICAL EDUCATION PRESERVICE TEACHERS PERCEPTION

AMORIM, C., RIBEIRO-SILVA, E.
*UNIVERSITY OF COIMBRA*

Introduction
This study explores physical education preservice teachers' (PSTs) perceptions of initial teacher education (ITE) and its input to their professional life and teachers' identity, at the end of their teaching practicum. The aim was to explore PSTs' perceptions concerning different features of the teaching profession, investigate the value attributed to the teaching practicum, and examine PSTs' identity as teachers.
Methods
The sample was composed of 157 PSTs in the Master's in Teaching PE, who just completed their teaching practicum. Data was collected using the 'Questionnaire for student teachers' (Ezer et al.,2010) . The close-ended questions determined perceptions concerning five features of the teaching profession and ITE, such as agents of training, components of teacher education, roles of teachers, motivation for teaching, and conceptions of teaching and learning. The statements regarding motivation for teaching were associated with subcategories of self-efficacy, commitment to the practice of teaching, intrinsic and extrinsic motivation. The statements in conceptions of teaching and learning were associated with subcategories of traditional and constructivist approaches to teaching and to learning. The open-ended questions described significant changes during the teaching practicum and what made PSTs feel like teachers. Quantitative data was statistically analysed through SPSS 26, and qualitative data were analysed using thematic content analysis.
Results and Discussion
Findings revealed that PSTs consider the cooperating teacher the principal agent of training (1.55±1.14); the teaching practicum as the most important component of initial teacher education (1.57±1.18); it is the teachers' role to deliver universal values (2.34±1.43); motivation for teaching is the relationship established with children (5.52±.64); and the teaching profession requires lifelong learning and development (5.63±.66). The most valued statements regarding motivation for teaching were related to intrinsic motivation (5.15±.57). The PSTs showed a constructive approach to teaching (5.20±.48) and to learning (5.07±.56). Through their open-ended questions, the most significant change was their self confidence, and the teacher and pupil relationship made them feel like teachers. PSTs place the student at the centre of the teaching and learning process, which requires learning and lifelong development within the teaching profession. PSTs consider the cooperating teacher as the most important agent of training during ITE and, therefore, decisive in their professional identity formation.
Conclusion
The analysis of the results regarding perception of learning and teaching revealed a preference for a constructivist approach. The present findings allow us to improve ITE programs.

### TEACHER EDUCATORS' PROFESSIONAL IDENTITY DEVELOPMENT: AN EXPLORATORY STUDY WITH UNIVERSITY-BASED PHYSICAL EDUCATION TEACHER EDUCATORS

AMARAL-DA-CUNHA, M.
*UNIVERSITY OF MAIA*

Introduction
Gee (2000-2001, p.99) defines identity as, 'being recognized [by oneself and others] as a certain «kind of person», in a given time and context'. Research literature over the last two decades highlights the importance of identity in teaching practice and teacher professional learning (Beauchamp & Thomas, 2009; Beijaard et al, 2004; Day et al., 2006; Rodgers & Scott, 2008). Teacher educators (school and university-based) are an occupational group experiencing increased scrutiny by international policy makers and researchers (Tryggvason, 2012; White, 2018). However, limited related literature falls within the development of a professional identity for university-based teacher educators (Izadinia, 2014; Pereira et al., 2015; Yamin-Ali, 2017), rendering it difficult to identify and define them. Thus, addressing university-based teacher educators' complex work in current higher education contexts requires identifying the issues influencing their professional

identity development (Hinostroza-Paredes, 2021; Mannes, 2020). Taking Gee's (2000-2001) discursive notion of identity - constructed through language and talk, this study addresses this lack of consideration by exploring who university-based teacher educators are.
Methods
Ten individuals supervising school placements from Portuguese Physical Education Teacher Education Programme at a private university took part in semi-structured interviews. An inductive qualitative analysis was undertaken for data analysis. An informed consent form seeking approval to use the data collected to inform the study was completed by the participants. Pseudonyms were assigned to ensure anonymity and confidentiality.
Results
There were two overarching themes: Issues of teaching identity, including experience, participation, interaction, reflection, and performance; and Constraints in the work context, namely personal, institutional, and social.
Discussion
The findings revealed that, a university-based teacher educator is someone whose identity is developed from, (i) previous professional experiences and roles; (ii) one's active participation in the school placements' syllabus; (iii) informal interactions with the faculty-tutors peers; (iv) research and reflexion of one's practices; and (v) the performance of the role itself. The constraints in developing a professional identity were: (i) responsibility in preparing effective teachers for the future; (ii) workload and conciliating other professional roles; (iii) lack of recognition by the stakeholders; (iv) professional instability; (v) preservice teachers' lack of commitment and assessment; (vi) balancing educational experiences in cooperating schools; (vii) lack of time to establish meaningful pedagogical relationships; and (viii) management of conflicts. Recommendations were offered for a continuing development of teacher educators' professional identity.

### TEACHING SKILLS OF EXPERIENCED ELEMENTARY SCHOOL TEACHER IN PHYSICAL EDUCATION CLASSES—FOCUSED ON INVOLVEMENTS WITH STUDENTS IN CLASSES AND ACTIVATION WITH VERBAL COMMUNICATION OF STUDENTS—

UMEMURA, T.1, TAKASE, J.2, TAKAHASHI, M.3, KAWAMOTO, T.4, MURAKAMI, M.5, NAKAJIMA, T.2

*1 HOKUSHO UNIVERSITY, 2 HOKKAIDOU UNIVERSITY OF EDUCATION, 3 TOKAI UNIVERSITY, 4 SAPPORO ELEMENTARY SCHOOL AFFILIATED TO HOKKAIDO UNIVERSITY OF EDUCATION, 5 SAPPORO HUSHIMI ELEMENTARY SCHOOL*

INTRODUCTION: Teachers teaching skills have been identified through many previous studies. Furthermore, teachers' teaching skills in physical education classes have been examined by systematic observation instrumentation. Recently, it is required verbal and non-verbal communication with others through physical activities in physical education classes. It suggested the importance of active learning with communication in the government curriculum guidelines (Ministry of education, 2015). Therefore, teachers' teaching skills are essential for the acceleration of group work using verbal communication in physical education classes. However, teachers' teaching skills in physical education classes have been investigated mostly by quantitative research using observation methods and the student evaluation in physical education classes. The purpose of the study was to examine the teaching skills of experienced teachers in physical education classes.
Methods
we investigated involvement with children of experienced elementary school teachers in physical education classes. Participants were four experienced elementary school teachers and 5th and 6th graders (81boys and 90 girls) who always take their physical education classes. In the approach, we analyzed the contents of experienced teachers' speeches and the content of descriptions on students' cards. Each text data was analyzed through text mining (NVivo). Additionally, the communication date was measured by Hitachi Business Microscope to confirm group communication conditions by teacher's involvement. The Business Microscope described their communication networking figures.
Results and Discussion
Resultantly, it was suggested there were common characteristics of experienced teachers from the contents of teacher speeches in classes, student cards, and communication networks. From the experienced teacher's speeches, there were various and many questions for students. Nakajima (2017) showed that experienced teacher has asked about tasks and encouraging explanation instead of presenting the answer. Therefore, it would be predicted experienced teachers involve students in various questions and attempt to encourage thinking to learn tasks. In addition, there were more specific descriptions that related to learning tasks from students' cards after classes. Umeno (1997) indicates students could be motivated to learn tasks by doing questions from the teacher constantly. Similarly, students' awareness of learning tasks would be presented in the descriptions by constant questions from an experienced teacher. Moreover, it was shown that the group communication among the experienced teachers was active. Due to this result, experienced teachers could be promoted collaborative learning in each learning group.

### OPPORTUNITIES OR CONSTRAINTS THROUGH PHYSICAL EDUCATION AND SPORTS PAST EXPERIENCES.

GOMES, L.1, RAMOS, M.2, CLARO, J.1, MARTINS, J.3,4, CARREIRO DA COSTA, F.1

*1: CIDEFES, UNIVERSIDADE LUSÓFONA 2: ISCTE-IUL, CIES-IUL, 3: LABORATÓRIO DE PEDAGOGIA, FACULDADE DE MOTRICIDADE HUMANA E UIDEF, INSTITUTO DE EDUCAÇÃO, UNIVERSIDADE DE LISBOA, 4: CENTRO INTERDISCPLINAR*

Schools and Physical Education (PE) have been recognized as important environments for promoting a physically active lifestyle (Pate et al., 2006). Literature supports that through the experiences, teachers develop stable emotional characteristics, which contribute to structure their values (Haynes et al., 2016). The study analyses teachers experiences in PE and how these experiences relate to the value they attribute to PE and sports and whether they are facilitators or obstacles promoting active lifestyles.
Methods
A mix method study was adopted. A questionnaire (Carreiro da Costa & Marques, 2011) about the experience in PE, perceptions about PE status was applied to 297 teachers (58 male). From this sample, 24 teachers were selected for 3 focus groups depending on their experiences in PE (good, bad experiences or both). MaxQda was used for the inductive qualitative data analysis.
Discussion
Teachers who have had good experiences in PE in school value the role of PE and sports. They refer the teacher, the curriculum, and a high self-perception of competence as the factors that have contributed to building positive experiences. Teachers who have had bad experiences do not value the importance of PE or sports. The teachers, curriculum, specific equipment, traumatic experiences, and a low level of self-competence are explanatory factors of negative attitudes towards PE.

Conclusions
These results support the importance of the earliest good experiences in PE to generate attitudes that value and support PE and sports value. They have demonstrated that PE and sport are still peripheral core subjects in schools. It is crucial that PE teachers and sports coaches, in addition to their work, should function in the school, with subject teachers, parents, and the community, promoting the role and importance of school and PE in promoting active lifestyles.

### CP-MH02 COVID-19: Aerobic fitness and physical activity

#### EXERCISE INTOLERANCE POST-COVID-19 – IS IT ALL DECONDITIONING? A REVIEW

SCHWENDINGER, F., KNAIER, R., RADTKE, T., SCHMIDT-TRUCKSÄSS, A.
*UNIVERSITY OF BASEL*

INTRODUCTION: Exercise intolerance is a chief complaint of patients with post-COVID-19 symptoms and is concomitant with low cardiorespiratory fitness.[1-3] There is a growing body of literature investigating potential underlying mechanisms of this complaint.[2,3] Due to the variety of studies, it is however difficult for researchers and clinicians to capture the big picture. We thus aimed to perform a narrative review on the contribution of the pulmonary system, cardiovascular system, as well as the periphery to low cardiorespiratory fitness post-COVID-19.
METHODS: We systematically searched the databases Medline, EMBASE, and L.OVE Coronavirus Disease by Epistemonikos through January 2022. After deduplication and screening, we ended up with 32 relevant studies examining adult patients post-COVID-19 using cardiopulmonary exercise testing.
RESULTS: The prevalence of restrictive lung disease seemed to decrease with recovery time. Already in the first months after the active phase of COVID-19, traditional spirometry parameters (forced expiratory volume in 1s, forced vital capacity, the ratio between the two) were within the normal range in most patients. However, median diffusive lung capacity using carbon monoxide was low even up to one year post-COVID-19 (1 to 5 months, n = 12: 76 [74, 79] % of pred.; >5 months, n = 6: 86 [78, 87] % of pred.). Chronotropic incompetence and small stroke volume are cardiovascular parameters that may contribute to low cardiorespiratory fitness, especially during the first months post-COVID-19. Yet, the available evidence is inconsistent.
CONCLUSION: The absence of major pulmonary and cardiac limitations points toward the periphery including vasculature and musculature as a central component of low cardiorespiratory fitness. Contrary to the conclusions of many studies, deconditioning is not the sole mechanism of low cardiorespiratory fitness post-COVID-19. Hence, cardiopulmonary exercise testing with measures of all three organ systems seems of major importance to identify relevant organ limitations in patients post-COVID-19.

#### REDUCED AEROBIC EXERCISE CAPACITY AND PULMONARY DIFFUSING CAPACITY AFTER HOSPITALISATION FOR COVID-19

RASMUSSEN, I., BERG, R., CHRISTENSEN, R.
*CENTRE FOR PHYSICAL ACTIVITY RESEARCH – RIGSHOSPITALET, COPENHAGEN, DENMARK*

INTRODUCTION: A large proportion of patients suffer from persistent and invalidating symptoms after recovery from coronavirus disease 2019 (COVID-19), which among other things may both be due to changes in lung function and in aerobic capacity. function.
METHODS: 28 patients admitted to hospitals were recruited for this investigator-blinded randomized study with a 12-week HIIT intervention. Patients will be block-randomised to either supervised HIIT exercise group or standard care (control group). This study is currently ongoing, and therefore these data will be evaluated based on baseline data. Patients underwent a standardized assessment including measurements of lung function and a maximal oxygen consumption test (VO2max). Expected lung function values was calculated based on summary equations according to height, age and sex. Normal standards for aerobic work capacity (VO2max (ml/min/kg)) in men and women with special reference to age was used to compare COVID-19 patients to healthy subjects.
RESULTS: 28 patients (58.1 ± 10.4 years; 64.3% male) who have been admitted to the hospital (median hospitalization stay: 6.5 days) completed baseline and were included in this analysis. Abnormalities were noted in diffusing capacity % predicted (81.6 + 19.2) and in total

lung capacity (88.5 + 15.7). The mean peak oxygen uptake was 22.8 ± 7.6 ml/min/kg. 24/28 (85.7%) COVID-19 patients showed to have lower exercise capacity than the general population, which is associated with higher all-cause mortality and cardiovascular events.
CONCLUSION: Reduced diffusing capacity was the most common abnormality of lung function followed by restrictive ventilatory defects and the patients showed lower exercise capacity compared to the general population. The findings indicate the need for a rehabilitation strategy for COVID-19 patients.

**IMPACT OF THE MRNA COVID-19 VACCINATION ON AEROBIC EXERCISE CAPACITY IN YOUNG ACTIVE HEALTHY SUBJECTS.**

*FACULTY OF MOTOR SCIENCES, ULB*

INTRODUCTION: A clear understanding of the COVID-19 vaccination side-effects in the general population, including young heathy adults, is still emerging. For athletes, previous studies reported 21% of myalgia in younger individuals after the first dose of the Pfizer/BioNTech vaccine which increased to 37% after the second dose [1]. However, a clear understanding of the COVID-19 vaccination effects on aerobic exercise performance would be of interest for adequate training adaptation in athletes.
1. Polack FP et al. N Engl J Med. 2020
METHODS: 18 healthy and active subjects (age: 18-35 years) referred to the Laboratory on 3 occasions: before (baseline) and 7 to 21 days after the first and the second dose of nucleic acid anti-COVID19 vaccines (Pfizer/BioNTech or Moderna). After a clinical examination, all subjects underwent an eight minutes submaximal (below the first ventilatory threshold (VT1)) steady-state exercise test on a cyclo-ergometer with concomitant gas exchange, cardiac output (Q), heart rate (HR) and stroke volume (SV) measurements (inert gas rebreathing technique, Innocor). After HR recovered to resting levels, a classical cyclo-ergometric incremental cardio-pulmonary exercise test (CPET) was performed until exhaustion. Oxygen consumption (VO2) and CO2 output (VCO2), ventilation (VE), electrocardiogram, blood pressure (BP) and finger pulsed oximetry (SpO2) were measured continuously during CPET.
RESULTS: During the steady-state submaximal exercise, at identical VO2 and Q, HR was increased and SV was decreased in the post-vaccination period as compared to baseline (respectively, HR:112±17 beat/min vs 104±21 beat/min, $p<0.05$ and SV: 117±36 ml vs 130±36 ml, $p=0.01$). This positive chronotropic effect was more pronounced after the second dose than after the first dose of vaccine ($p<0.05$). However, no alteration of CPET parameters were observed after vaccination with identical maximal VO2, VE, HR respiratory exchange ratio, O2pulse, BP, SpO2, VE/VO2, VE/VCO2 but also identical VT1 levels (all pNS).
CONCLUSION: Although no altered aerobic exercise capacity and performance are observed after the first and the second dose of mRNA vaccine in young heathy volunteers, an exacerbated chronotropic response during submaximal steady-state endurance exercise was observed. This is of importance for HR based training intensity titration to avoid under-training after vaccination. However, further investigations are needed to clarify the clinical relevance of this observation.

**THE IMPACT OF ONLINE-BASED GROUP RESISTANCE TRAINING ON PHYSICAL HEALTH AND EXECUTIVE FUNCTION IN OLDER INDIVIDUALS DURING COVID-19 PANDEMIC**

TOTTORI, N.1, NAKANO, D.2, HASEGAWA, T.3, FUJITA, S.3

*RITSUMEIKAN UNIVERSITY*

INTRODUCTION: The coronavirus disease 2019 (COVID-19) has spread worldwide, influencing lifestyle behavior. A decrease in physical activity has led to a decrease in physical and psychological health such as muscle mass and cognition in older individuals, therefore, the development of exercise at home was necessary. Resistance exercise is shown to be an effective method to increase muscle mass and muscular strength. In addition, resistance exercise promotes cognitive function in older individuals (Cassilhas et al., Med Sci Sports Exerc, 2007). However, little is known about the online-based resistance exercise on body composition and executive function. The aim of this study was to investigate the effects of online-based group resistance training using an elastic band on physical health and executive function in older individuals during the COVID-19 pandemic.
METHODS: Forty-one Japanese older subjects (age, 69 ± 1 years) were recruited for this study and randomly allocated to the exercise group (EX; n = 21) and control group (CON; n = 20). EX group participated in the online-based group training program through the video conference application (Zoom) connected by the 10.2-inch tablet three times per week for 12 weeks. This program consisted of 14 exercises using the elastic band for exercising the whole body. Before and after the intervention, dual-energy x-ray absorptiometry was used to measure the fat-free mass and fat mass. The isometric knee extensor and flexor torques were measured using a BIODEX dynamometer. In addition, the executive function was assessed by the Digit Span Backward test as working memory, Stroop test as inhibition, Trail Making test as cognitive flexibility, and Rey-Osterrieth complex figure as long-term episodic memory.
RESULTS: No significant differences were observed for the fat-free mass, fat mass, and knee extensor/flexor torques. The percent change from baseline in knee extensor torque was higher in EX group than in CON group ($P < 0.05$) while no significant change was observed in both groups. Regarding to executive function, EX group significantly improved the number of correct answers and longest level of sequence of two correct answers out of three trials in the Digit Span Backward test ($P < 0.05$ for both). In addition, EX group significantly improved the number of correct answers in the Color-Word version of Stroop test ($P < 0.05$) while no significant interaction was observed by repeated two-way analysis of variance. No significant change was observed in all executive function tests of the CON group.
CONCLUSION: The results of this study reveal that the online-based resistance training improved several executive functions meanwhile no improvement in body composition and muscular strength. These findings suggest that implementation of online-based training has a positive benefit for the executive function in elderly people during stay-at-home requests like COVID-19 restriction.

**THE EFFECTS OF EXERCISE THERAPY MODERATED BY SEX IN REHABILITATION OF COVID-19**

RAUSCH, L.K.

*UNIVERSITY OF INNSBRUCK*

INTRODUCTION: Pulmonary rehabilitation serves as a key component in the recovery of COVID-19 and standardized exercise therapy programs in pulmonary rehabilitation have been shown to significantly improve physical performance and lung function parameters in post-acute COVID-19 patients. However, it has not been investigated if these positive effects are equally beneficial for both sexes, especially considering a more severe physical impact of COVID-19 in men when compared to women. Therefore, the purpose of this study was to analyze outcomes of a pulmonary rehabilitation program with respect to sex differences, in order to identify sex-specific pulmonary rehabilitation requirements.

METHODS: Data of 233 patients (40.4% females) were analyzed before and after a three-week standardized pulmonary rehabilitation program. Patients were admitted to rehabilitation due to post-acute COVID-19 illness and staged using the COVID-19 Severity Scale by Huang et al. (2021). Lung function parameters were assessed as part of the clinical routine using spirometry (ICmax, maximal inspiratory capacity) and body plethysmography (FVC, forced vital capacity; FEV1, forced expiratory volume in the first second) and functional exercise capacity was measured by the Six-Minute Walk Test (6MWT). For the comparison of lung function and walking parameters by sex, Welch-ANOVA was used, as results of Levenes test suggested significant heteroscedasticity ($p < 0.05$). When comparing post-treatment 6MWT, FEV1 and FCV to corresponding reference values, paired t-tests were used.
RESULTS: At post-rehabilitation, ICmax, FVC, FEV1 and 6MWT has been improved in both sexes. Females showed a significantly smaller improvement in FEV1 and ICmax ($F = 5.86$, $\omega 2 = .02$; $p < 0.05$) than males. There was no statistically significant difference in FVC and 6MWT performance improvements between men and women. After the rehabilitation stay, females made greater progress towards reference values of 6MWT ($T(231) = -3.04$; $p < 0.01$) and FEV1 ($T(231) = 2.83$; $p < 0.01$) than males.
CONCLUSION: Sex differences in the improvement of lung function parameters seem to exist when completing a three-week pulmonary rehabilitation program and should be considered when personalizing standardized exercise therapies in pulmonary rehabilitation.

### CP-AP10 Physical performance in team sports

#### THE DEVELOPMENT AND VALIDATION OF A SKINFOLD-THICKNESS PREDICTION EQUATION IN HIGH LEVEL FUTSAL ATHLETES

MATIAS, C.N.1,2, SANTOS, D.A., GIRO, R.1, CAVACA, M.L.1, FALEIRO, J.1, OLIVEIRA, M., DUQUE, P., VICENTE, F., PEREIRA, P., TEIXEIRA, V.H., TEIXEIRA, F.J.1

*1BETTERY LIFELAB, BETTERY S.A., LISBOA, PORTUGAL; 2CIDEFES - UNIVERSIDADE LUSÓFONA, LISBOA, PORTUGAL;*

INTRODUCTION: Specific and practical approaches to estimate fat mass (FM) in athletes are warranted, especially regarding team sports athletes, i.e. futsal players. Assessing skinfold (SKF) thickness and body girth is a simple field technique to evaluate FM, especially when performed by an ISAK (The International Society for the Advancement of Kinanthropometry) certified practitioner. The aim of this study was to develop and cross-validate an anthropometric equation for FM estimation in a sample of male futsal players using ISAK SKF and body girth as variables vs. the dual X-ray absorptiometry (DXA) fat mass (%) output.
METHODS: Using a cross-sectional design, a total of seventy-nine young (18-37 y) professional and semi-professional futsal male players were recruited.
Players were assessed for weight (kg), height (cm), ISAK SKF (mm) and girths (cm) by a certified level 1 ISAK-accredited anthropometrist. The FM (%) output used as criterion was obtained by DXA according to standard procedures. Stepwise regression analysis was performed to evaluate the prediction errors regarding FM and a mathematical model was developed accordingly. Validation procedures for the developed models were performed according to the PRESS method.
RESULTS: Predictive variables included 3 SKF, 1 girth, and age. The resulting model for futsal athletes presented was:
FM (%) = -4.712 + 0.200 * ΣSKF + 0.171 * Waist + 0.025 * age
[where ΣSKF is the sum of triceps, abdominal and thigh SKF in mm, Waist is circumference in cm, and age in years].
The accuracy for the developed model was observed by the high coefficient of determination ($r2 \geq 0.81$).
The validation procedure was performed including the regression parameters, correlation concordance coefficient (CCC), and agreement analyses between the FM estimated from the new developed model and the reference method (DXA). No differences between methods were observed with a high correlation being reported ($r2 \geq 0.80$). The precision and accuracy of the methods was 0.906 and 0.997, respectively, with a CCC of 0.9037 (moderate strength of agreement). From the Bland Altman analysis, no trend was observed between the mean and the difference of the methods.
CONCLUSION: The high costs and the lack of portability of the DXA equipment precludes its use in most clinical/field settings. Using an easy to perform, safe and reliable method according to the ISAK protocols, our findings deliver a new valid and accurate model for FM (%) estimation in professional and semi-professional futsal players.

#### EFFECTS OF REPEATED-SPRINT TRAINING UNDER HYPOXIC ENVIRONMENT ON TEAM-SPORT-SPECIFIC SPRINTING ABILITY

LI, F., CHOW, B.C.

*DEPARTMENT OF SPORT, PHYSICAL EDUCATION AND HEALTH, HONG KONG BAPTIST UNIVERSITY*

INTRODUCTION: The purposes of this study were to examine the acute and delayed effects of repeated-sprint training volume on the improvement of the sprinting ability.
METHODS: This was single-blind, randomized control trial. Participants were randomly assigned into four groups for 4-w (RSH4) and 2-w (RSH2) repeated-sprint training under hypoxia; or under normoxia by 4 w (RSN4) and by 2 w (RSN2). Each training session was consisted of 3 sets of 5x5-s sprints at 20% maximum breaking load interspersed with passive recovery at exercise:recovery ratio of 1:5, 2 training sessions/week. In experimental groups (RSH4 & RSH2), the normobaric hypoxia was set at the FIO2 of 13.5%, simulating altitude of 3500 m approximately. In control groups (RSN4 & RSN2), training conducted under normoxic environment. Identical sprinting tests were conducted before (pre, baseline), immediately after (post, acute effect), and 4 w after (4-w-post, residual effect) the intervention. Data collection of 9-12 participants in RSH4, RSH2, and RSN2 were completed and analysed temperately for COVID pandemic.
RESULTS: The characteristics of 32 Participants were with age 20.5 ± 1.7 y, body height 174.9 ± 5.1 cm, body mass 70.9 ± 8.2 kg, and VO2max 56.8 ± 6.5 ml.kg-1.min-1. There was a significant time ($F = 11.85$, $p < 0.001$, $\eta 2 = 0.49$) effect on the distance covered in Yo-Yo test, with pre (1172.5 ± 365.3 m) were significantly lower than that of post (1300.6 ± 410.5 m, $p < 0.001$) and 4-w-post (1286.5 ± 440.9 m, $p = 0.033$) level. Peak velocity of anaerobic test showed a significant time effect ($F = 5.63$, $p = 0.009$, $\eta 2 = 0.29$), with pre (4.75 ± 0.27 m.s-1) were significantly lower than that of post (4.86 ± 0.23 m.s-1, $p = 0.037$) and 4-w-post (4.89 ± 0.23 m.s-1, $p = 0.044$) level. Peak power of anaerobic test showed a significant time effect ($F = 4.12$, $p = 0.027$, $\eta 2 = 0.23$), with pre (1024.5 ± 123.0 w) were significantly lower than that of post (1065.1 ± 150.0 w, $p = 0.026$) and 4-w-post (1071.2 ± 123.6 w, $p = 0.018$) level. Mean power of anaerobic test showed a signifi-

cant time effect (F = 6.76, p = 0.004, η2 = 0.33), with pre (669.8 ± 70.1 w) were significantly lower than that of post (693.5 ± 86.4 w, p = 0.047) and 4-w-post (704.9 ± 67.3 w, p = 0.001) level. Fatigue index of anaerobic test showed a significant time effect (F = 4.63, p = 0.019, η2 = 0.26), with pre (70.4 ± 8.4 %) were significantly higher than that of post (65.9 ± 7.2 %, p = 0.014) and 4-w-post (65.3 ± 8.5 %, p = 0.005) level. Total work of IEP test showed a significant time effect (F = 8.21, p = 0.002, η2 = 0.38), with pre (273.7 ± 26.1 w) were significantly lower than that of post (283.2 ± 24.9 w, p = 0.002) level. No other significant effects were founded.
CONCLUSION: There were effects of repeated-sprint training on the improvements of sprinting ability, delaying until 4 w after training. The specific sprinting abilities affected by training were sprinting when simulated team-sport intermittent exercise, as well as aerobic and anaerobic ability of sprinting.

### EVOLUTION OF THE PHYSICAL CHARACTERISTICS OF THE FRENCH WOMENS RUGBY SEVEN AND UNION: A TEN-YEAR LONGITUDINAL ANALYSIS

IMBERT, S., DELFORGE, E., BOISSIÈRE, J., JONCHERAY, H., VINCENT, J., DAUSSIN, F.N.

*UNIVERSITÉ DE LILLE ; LIGUE DES HAUTS-DE-FRANCE DE RUGBY ; LABORATOIRE SPORT, EXPERTISE, PERFORMANCE, UNITÉ DE LA RECHERCHE, INSTITUT NATIONAL DU SPORT, DE LEXPERTISE ET DE LA PERFORMANCE*

INTRODUCTION: Rugby union and rugby sevens are demanding and intermittent team sports with collisions, high intensity runs interspaced with periods of low intensity activity. While the physical characteristics development of elite male rugby union and rugby seven players have been widely described, much less is known about female international players. This present study aims to assess physical changes over time of women's rugby union players (backs and forwards) and women's seven players.
METHODS: Anthropometric and physical performance of French rugby union and seven women players were monitored at least two times per years by the French Rugby Federation. The best performance of each French international player over a two-year period was identified. Finally, a total of six hundred and thirty-one samples was obtained. Anthropometric data (height, mass and fat mass), physical performance (10, 20 and 50m sprint, maximal aerobic speed, counter movement Jump test, maximal bench press and rowing repetition) were monitored.
RESULTS: Specific evolution of anthropometric characteristics and physical performances was observed within rugby union positions and rugby seven.
Rugby union forwards improved their sprint ability (10m, 20m and 50m) regularly from 2009 to 2020 ($p<0.01$) while body weight, body fat, and age did not change over the years. Height, maximal aerobic speed, counter movement jump, maximal bench press and rowing repetition increased over the years ($p=<0.01$).
Rugby union backs have improved their sprint ability (10m, 20m, 50m), maximal aerobic sped, counter movement jump, maximal rowing repetition increased over the years ($p=<0.01$). The anthropometric characteristics evolved and the players become taller and increased their weight ($p<0.05$).
Seven players improved their explosivity (10m, $p<0.05$), maximal aerobic speed, maximal bench press and rowing repetition increased over the years while the speed over 20m and 50m, and the counter movement jump performances remained unchanged. The anthropometric characteristics evolved and the players become taller and lighter ($p<0.05$).
CONCLUSION: These results highlight the evolution of the woman rugby player profile over the last decade. It suggests that the coaches should adapt the references values used to identify or developed talent over the years.

### MATCH PHYSICAL DEMANDS DIFFERENCES BETWEEN STARTERS VS NON-STARTERS (SUBSTITUTES) IN SPANISH PROFESSIONAL SOCCER LEAGUE

PONCE-BORDÓN, J.C., LOBO-TRIVIÑO, D., LÓPEZ DEL CAMPO, R., RESTA, R., GARCÍA-CALVO, T.

*UNIVERSIDAD DE EXTREMADURA FACULTAD DE CIENCIAS DEL DEPORTE*

INTRODUCTION: A substitution is when a player is brought on to the pitch during a match in exchange for an existing player, during a stoppage in play. The soccer player who has been substituted takes no further part in a match. Research has showed that total distance, high-intensity running distance covered and the number of sprints were greater for non-starter compared to starter players (Lorenzo-Martínez et al., 2020; Padrón-Cabo et al., 2018). The aim of this study was to investigate the match physical demands differences between players who completed the entire match, players who were replaced (i.e., starters, ≥75 minutes played) and those that were substituted into (i.e., non-starter) soccer matches.
METHODS: The sample included the team match observations of all the matches played over four consecutive seasons (from 2015/16 to 2018/19) in the first (Liga Santander; n = 2,950) Spanish soccer leagues. Match physical demands data were obtained using an optical tracking system called ChyronHego® (TRACAB, New York, US). Relative total distance (TD/min.) and distance covered > 24 km·h-1 per minute (VHIRD/min.) were analyzed. The players were divided into three different groups: players who completed the entire match, players who were replaced, and substitute players. Linear Mixed Models (LMM) were applied to analyze the differences in match physical demands (i.e., distances covered) between players that started and those that were substituted. In addition, the effect of age and playing position soccer players were considering.
RESULTS: Results showed that TD covered per minute was greater in substitutes players (114.79 m/min.) than players who completed the entire match (111 m/min.) and players who were replaced (113.59 m/min.). Also, distance covered at more than 24 km·h-1 was greater in substitutes players (12.91 m/min.) than players who completed the entire match (3.11 m/min.) and players who were replaced (4.34 m/min.). In addition, there was a significant difference between playing position and age soccer players.
CONCLUSION: The present study showed that significant physical performance differences during soccer matches in Spanish LaLiga exist between starters and non-starters soccer players.

### ACUTE PHYSIOLOGICAL RESPONSE TO 5V5 FOOTBALL IN FEMALE FOOTBALL PLAYERS

RANDERS, M.B., PANDURO, J., ERMIDIS, G., VIGH-LARSEN, J.F., YOUSEFINAN, F., SØGAARD, K., KRUSTRUP, P., MOHR, M.

*UNIVERSITY OF SOUTHERN DENMARK*

INTRODUCTION: Physiological response to various football formats has been investigated intensively and are well understood in male football players, whereas investigations in female football playersare sparse. Studies in female football players have indicated that anaerobic energy turnover in female football players are lower than in male players (Krustrup et al., 2005; 2021). This study therefore aims at describing the acute physiological response to 5v5 football in female football players.

METHODS: 10 well-trained female football players (height: 169±5 cm, weight: 67.0±8.0 kg, fat% 24.8±7.6%) participated in 5v5 indoor football match organized as 4x12 min periods on an indoor 40x20 m wooden floor pitch. Heart rate was monitored during the session (Polar Team Pro) and blood lactate was evaluated prior to the match and after the 2nd and the 4th period. Muscle biopsies were collected from m. vastus lateralis at rest and at the end of the 4th period. Data are presented as means ± SD. Data were analyzed using t-test and one-way ANOVA with repeated measures. A significance level of 0.05 was chosen.
RESULTS: Average and peak heart rate were 166±14 and 189±11 bpm during the match. Average heart rate was higher during the first 12 min period than the following three periods (172±13, 165±16, 163±15, 163±14 bpm, P<0.05). Time spent with heart rate higher than 90% of maximal heart rate was 28±27%.
Blood lactate increased from 1.8±0.4 mmol/L prior to the match to 2.7±1.2 and 3.1±1.6 mmol/L after the 2nd and 4th period (P<0.05) with no difference between after the 2nd and 4th period.
Muscle lactate was 4.8±2.3 mmol/kg dw pre-match and increased to 8.8±3.9 mmol/kg dw after the match. No change was observed in muscle ATP (21.7±1.6 vs. 21.0±2.4 mmol/kg dw; P>0.4), whereas PCr was 73.0±8.3 mmol/kg dw pre-match and decreased to 57.0±12.6 mmol/kg dw after the match (p<0.05). Muscle glycogen was 343±73 mmol/kg dw pre-match and was lowered to 265±70 mmol/kg dw. after the match (p<0.05).
CONCLUSION: Heart rate was high during 5v5 with periods with near maximal intensity during indoor 5v5 football for female football players. Anaerobic energy turnover was, however, modest indicated by moderate drops in muscle glycogen and PCr and small increases in muscle and blood lactate and are similar to that observed in male footballers (Panduro et al., 2022, In review).

**ACTIVITY PROFILE AND PHYSICAL PERFORMANCE OF MATCH PLAY IN KORBALL PLAYERS: A PILOT STUDY**

WAWRZYNIAK, S., WEGRZYN, M., CHODOR, W., RUBAJCZYK, K.
*WROCŁAW UNIVERSITY OF HEALTH AND SPORT SCIENCES*

INTRODUCTION: Korfball is a non-Olympic team game played by hand within a rectangular field of play whereby two mixed teams try to shoot a ball into the korf (basket) of the opposite team. The sport's main characteristics encompass all-around skills, cooperative play, controlled physical contact, gender equality, players' right to protected ball possession and scoring from 360° around the korf (IKF, 2020). The best korfball players must perform both attacking and defending, about 72 times during a match, for about 24 minutes. The average match score in the Korfball League is 24 goals and a team needs 85 - 120 chances to create them (Crum, 2021). Previous investigations of movement profile were performed in netball, floorball, or the other non-Olympic sports but no similar studies exist in korfball. Therefore, this study aims to quantify match demands and the player load of all playing positions in korfball on elite level players.
METHODS: Twenty-two participants were elite korfball players from the Polish National Team (n=11, 24 ± 4.1 years, 167 ± 3.6 cm, 61.3 +8.7 kg for female, n = 11, 26.8 ± 6.2 years, 187.5 ± 3.4 cm, 88.5 +9.1 kg for men) who were investigated for a total of 3 completed matches. All athletes wore a Catapult Vector 7 unit containing a 10Hz LPS tag and 100Hz inertial 124 sensors (tri-axial accelerometer, gyroscope and magnetometer) connected wirelessly to the ClearSky LPS (Catapult Sports, Melbourne, Australia). The male players were divided into two subgroups of position to analyze the results: rebounder (MR) (n=5) and mixed (MM) (n=6). The following speed categories were used: walking (0 to 6 km / h), low intensity running (LIR; 6.1 to 12 km / h), medium intensity running (MIR; 12.1 to 15.4 km / h), high intensity running (HIR; 15.5-28.5 km / h) and sprint (>18.4 km/h). All values are presented as mean ± standard deviation (SD) with 95% confidence intervals.
RESULTS: The mean total distance covered in three full matches no differed substantially between gender in mixed positions (2149 ± 296 m for female, 2483 ± 233 m for MM and 2239 ± 220 m for MR). Running profiles characterized the match demands for typical korfball were identified regardless of sex (sprint and HIR <2%, MIR~16%, LIR ~40 %, walking ~42%). Nevertheless, mean change-of-directions jumps and acceleration/deceleration profile were different in each subgroups.
CONCLUSION: The results of these studies identify a descriptive movement match-profile that characterizes the motor demands for korf-ball players. The coeducational nature of korfball seems to differentiate the requirements for players according to the gender and role on the court.

**CHANGES IN THE ENERGY METABOLISM OF PLAYERS DURING A SOCCER GAME**

OGOH, S., OUE, A., WATANABE, H., SAITO, S., DORA, K., OGOH, N., OSUGA, M., HASEGAWA, T.
*TOYO UNIVERISTY*

INTRODUCTION: Energy metabolism required for exercise can be broadly classified into aerobic (endurance) and anaerobic (including muscle strength) energy metabolism, which are important factors in a soccer competition. However, exercise characteristics, such as the interval time in a soccer game, are complicated, and the ratio of aerobic and anaerobic energy metabolism is believed to greatly vary among individuals or players' positions in soccer. Moreover, quantifying the anaerobic energy metabolism is difficult in the game by measuring the running speed using global positioning system (GPS). Therefore, this study aimed to identify aerobic and anaerobic energy metabolism of each player using laboratory tests and evaluated physical activity and fatigue (accumulated anaerobic energy consumption) in each player using a GPS device during the course of the game.
METHODS: This study was conducted on 17 soccer players (mean age, 16.5 ± 0.6 years) from the women's youth professional soccer team in Japan (Chifure AS Elfen Saitama). In the laboratory tests, the anaerobic thresholds of each athlete were evaluated to identify their aerobic and anaerobic metabolic characteristics. During the treadmill exercise tolerance test, the individual ventilatory threshold and the required oxygen uptake (O2 demand) at each running speed were determined using a respiratory metabolism device (ARCO-2000N, manufactured by Arco System) (1, 2). Additionally, the running speed of each player in the soccer game was continuously measured using a GPS device to quantify the anaerobic energy metabolism during the game using respiratory data.
RESULTS: The ratio of anaerobic energy to the total energy consumed during the game was calculated for each player, which ranged from 20% to 40%. Furthermore, the ratio of aerobic to anaerobic energy metabolism varied among individuals, and this variation was partly due to the player's positions during the soccer game.
CONCLUSION: Changes in anaerobic energy metabolism during the game were visualised within an individual, which indicated that the sprint ability (the ability to recover from fatigue) can be evaluated during the game. Moreover, different characteristics of energy metabolism in soccer and player positions were presented, suggesting that this analysis may help evaluate the individual physical characteristics required for each position in soccer as well as the training effect in games.

### CP-BM07 Biomechanics of jumping and squatting

#### EFFECT OF SURFACE ENVIRONMENT ON FRONT SQUAT OF CROSSFIT ATHLETES

KIM, J.1,2, JANG, Y.1,2, PARK, J.1,2, RYU, J.1,2, PARK, S.1,2, YOON, S.1,2

*1 KOREA NATIONAL SPORT UNIVERSITY, SEOUL, KOREA 2 BIOMECHANICS LAB & MOTION INNOVATION LAB, SEOUL, KOREA*

INTRODUCTION: The CrossFIT is the one of popular fitness program consisting mainly of a mix of aerobic exercise, bodyweight exercise and Olympic weightlifting (1). Korean CrossFit gyms(Boxes) are inevitably very sensitive to soundproofing since they are located in collective buildings. Thus floor of the boxes in Korea is made of thickened and softened and it is unstable. As such, it is thought that the unstable ground environment of the Korean box can increase the risk of injury for CrossFit athletes (2 & 3). Therefore, the purpose of this study was to verify the effect of surface environment on Front Squat which is the most frequently used in CrossFit exercise.
METHODS: Ten CrossFit athletes who have more than 5 years athletic career and had no experience of musculoskeletal injuries on lower extremities in the last six months(age: 32.30±3.05 yrs., height: 173.70±5.12 cm, body mass: 82.40±6.31 kg, 1RM: 160±13.80 kg) participated in this study. All subjects were asked to perform front squat with 80% of 1 RM on hard surface(HS) and soft surface(SS). To investigate kinematics and kinetics differences between HM and SS, a three-dimensional motion analysis was performed using eight infrared cameras(sampling rate: 100 Hz) and seven channel of EMG(sampling rate: 1,000 Hz). A paired t-test was conducted to verify the differences and statistical significance set as $\alpha$=.05.
RESULTS: From the results of this study, no significant differences between SS and HS were found during ascending phase of front squat. Ankle joint range of motion in horizontal plane revealed greater in SS than that of HS during descending phase indicating increased possibility injury factors in SS (4) ($p<.05$). Also significantly greater quadriceps muscle activation was found in HS than that of SS during descending phase ($p<.05$). For the muscle activation ration (Gluteus maximus /Quadricepts), higher the ration was found in SS than that of HS during decending phase indicating Gluteus maximus is dominant in SS ($p<.05$).
CONCLUSION: The findings of this study suggests that performing front squat on SS may increase the risk of lower body injury. Therefore, new open boxes in Korea need to use hard surface with less risk of injury if it is possible.

#### THE COMBINATION OF PLYOMETRIC TRAINING WITH OTHER TRAINING METHODOLOGIES TO IMPROVE THE VERTICAL JUMP

LEÓN-MUÑOZ, C., RAMIREZ-CAMPILLO, R., SÁEZ-DE-VILLARREAL-SÁEZ, E.

*UNIVERSIDAD PABLO DE OLAVIDE*

INTRODUCTION: vertical jumping (VJ) performance is determined by a complex interaction among several factors including maximal force capacity, rate of force development, muscle coordination, and stretch shortening cycle(1). Enhancement of vertical jump performance is a common goal since the capacity to jump higher than an opponent may be advantageous in team competitions and in many individual sports (2). Various training methods have been applied to improve VJ performance. Such methods include plyometric (PL) training, resistance training, weight lifting (WL) training, and electrical stimulation etc. (3;4;5;6). Because of the multifaceted nature of VJ performance, a single training method approach may not be as effective as combining training methods to provide variation in stimulus and to increase the overall training adaptation (7). Therefore, the objective of this meta-analysis was to investigate the effects of a plyometric training program combined with other methodologies on vertical jump performance.
METHODS: After an electronic database search (PubMed and WoS), a total of 36 articles were included in the meta-analysis and were reviewed to analyze the impact of Plyometrics combined with other methodologies on vertical jump performance. Studies were included if they met the following criteria: 1) Studies with experimental groups performing a combination of training methods (e.g., plyometric combined strength). 2) Inclusion of control group. 3) At least one measure related to physical fitness (e.g., vertical jump tasks) before and after the training intervention. 4) Study design: multi-arm trials.
RESULTS: twenty-nine studies provided data for CMJ performance, involving 40 experimental and 33 control groups (pooled n = 933). Results showed a moderate effect of trained participants on CMJ performance (ES = 0.63; 95% CI = 0.49 to 0.77; $p < 0.001$; $I2 = 9.2\%$; Egger's test p = 0.133; Figure X) when compared to controls. Sixteen studies provided data for SJ, involving 20 exp. and 16 control groups (pooled n = 430). Results showed a moderate effect of trained participants on SJ (ES = 0.77; 95% CI = 0.45 to 1.10; $p < 0.001$; $I2 = 60.0\%$; Egger's test p = 0.797; Figure X) when compared to controls. Eight studies provided data for countermovement jump with arms performance, involving 9 exp. and 8 control groups (pooled n = 282). Results showed a moderate effect of trained participants on CMJA performance (ES = 1.01; 95% CI = 0.31 to 1.70; p = 0.005; $I2 = 85.8\%$; Figure X) when compared to controls. Five studies provided data for DJ performance, involving 9 exp. and 7 conTROL groups (pooled n = 237). Results showed a small effect of trained participants on DJ performance (ES= 0.46; 95% CI = 0.114 to 0.77; p = 0.005; $I2 = 26.3\%$; Figure X) when compared to controls.
CONCLUSION: Combining several elements into one training session seems to be an interesting idea in training modality. This meta-analysis showed that combined strength training programme was useful to increase jumping.

#### VALIDITY OF TIME OF FLIGHT DURING SINGLE-LEG JUMPS MEASURED WITH SMARTPHONE ACCELEROMETERS COMPARED TO FORCE PLATFORMS

GALLINA, A., LIM, M.A., CABRAL, H.V.

*UNIVERSITY OF BIRMINGHAM*

INTRODUCTION: Single leg jump height has recently been shown to be more effective than hop distance in the identification of deficit in lower limb muscle strength after anterior cruciate ligament reconstruction (1). However, not all clinics have access to specialised equip-

ment such as force platforms and contact mats, which are needed to estimate jump height (2). A possible alternative may be to measure the time of flight using the accelerometers embedded in smartphones. In this study we aimed to determine whether smartphone accelerometers provide a valid measure of time of flight during single leg jump when compared to a force platform.
METHODS: Twenty healthy participants (8 females, 27±4 years old, 173±1 cm, 72±1 kg) without current pain or recent lower limb injuries performed 5 single-leg jumps. Participants stood on their dominant leg, jumped as high as possible, landed on the same leg, and stabilized as quickly as possible. A force platform was used to collect ground reaction forces at 250 Hz. Body acceleration was collected using a smartphone that the participants held firmly on their chest in landscape mode, so that the X-axis of the smartphone accelerometer was mostly aligned with the gravity vector. Smartphone data were collected at 100 Hz using the MATLAB Mobile app. Vertical ground reaction forces and smartphone acceleration were exported and analysed in Microsoft Excel. For the force platform data, the start and end of each jump were identified as the time instant when the ground reaction force reached 50% of the participant's body weight. Similarly, in the acceleration data the start and end of each jump were identified when the acceleration reached 50% of the gravitational acceleration. The time of flight was calculated as the difference between the end and start of each jump and averaged across the 5 repetitions. Validity between the two systems was calculated using Intraclass Correlation Coefficient. The presence of a systematic bias was assessed using a paired T-test.
RESULTS: Time of flight measured with smartphones was approximately 20 ms longer than the time of flight measured with a force platform (305±46 vs 327±49 ms, $p<0.001$). Intraclass correlation coefficient demonstrated excellent validity (ICC = 0.988, CI: 0.969-0.995).
CONCLUSION: Our results provide preliminary evidence that the time of flight measured with smartphone accelerometers is highly valid when compared to the time of flight estimated from a force platform. The systematic bias implies that measures obtained using the two systems cannot be directly compared, and the use of different thresholds may reduce this bias. The wide availability of smartphones, the use of a free app, and the ease-of-use of the software for data analysis are promising factors for the implementation of this objective measure of motor performance in practice.

## POST-ACTIVATION POTENTIATION WITH SHORT HIGH INTENSITY ENDURANCE TRAINING AND PLYOMETRIC TO IMPROVE JUMPING PERFORMANCE

RODRÍGUEZ-BARBERO, S.1, RODRIGO-CARRANZA, V.1, GONZÁLEZ-RAVÉ, J.M.1, GALÁN-RIOJA, M.A.1,2, GONZÁLEZ-MOHÍNO, F.1,3

*1. UNIVERSITY OF CASTILLA-LA MANCHA, SPORT TRAINING LAB, TOLEDO, SPAIN*

INTRODUCTION: The ability to exert muscle power is critical for successful results in sports [1]. Exercises (e.g., sprint or heavy load exercises) performed in the warm-up have shown improvements in the subsequent performance [2]. The phenomenon of acute performance enhancement is called post-activation potentiation (PAP) and it increases acutely muscle power and performance [3]. The purpose of this study was to analyze the effects of high- vs low- intensity cycling exercises combined with plyometrics on vertical jump performance.
METHODS: Twenty-four physically active men participated were randomly divided into two groups and one control group (CON). One group performed short high intensity cycling efforts [5 x 10s ("all-out")/50s rest] (IT) and the other group performed low intensity continuous effort [5 min (75% of HRmax)] (CT). Both experimental groups performed 3 sets of 10 plyometric jumps with 1 min rest between sets after the cycling efforts. CON performed both days a warm-up activity of 13 minutes of low intensity cycling at 60% of HRmax. Before the warm-up, a countermovement jump (CMJ) (baseline) was performed in a platform Kistler Quattro-Jump (Kistler, Switzerland). Finally, after the warm-up, a CMJ was measured at 1, 3, 6 and 9 min rest.
RESULTS: CMJ showed differences regarding the time of measurement ($F = 39.103$, $p \leq 0.001$, partial $\eta 2 = 0.488$) and time x condition effects ($F = 17.536$, $p \leq 0.05$, partial $\eta 2 = 0.155$). CMJ height improved by 7.11, 7.23, 10.19 and 11.21% in IT and by 11.72, 15.08, 14.97 and 13.77% in TC at 1, 3, 6 and 9 min respectively compared to baseline.
Mean power showed differences regarding the time of measurement ($F = 9.585$, $p \leq 0.001$, partial $\eta 2 = 0.197$), but not with time x condition effect. Power increased by 5.18% in IT at 6min and by 7.92, 8.18 and 7.01% in CT at 1, 3 and 6 min compared to baseline.
CONCLUSION: The results suggest that IT is the most effective warm-up method for induce optimal PAP at 7 – 10min [3]. IT delays more time to produce potentiation than CT, maybe due to two causes. The principal cause, IT produces greater neuromuscular fatigue and requires more recovery time to optimal PAP effect. The other reason, CT causes less fatigue and PAP effect is shown after the end of the conditioning activity, being reduced after 7 min.

## COMPARISON OF KINEMATIC DATA OF JUMPING MOTION USING MARKER-BASED AND MARKERLESS MOTION CAPTURE

MASAKI, K.

*HOKUSHO UNIVERSITY*

INTRODUCTION: Three-dimensional motion analyze are a widely used method in the field of biomechanics. The standard method for 3D motion analyze is an optical marker-based motion capture system. The reliability of kinematic data obtained using marker-based motion capture has been questioned due to its sensitivity to marker placement and soft tissue artefact. Markerless motion capture systems are free from these errors associated with marker-based systems and may be able to measure kinematics more reliably. Theia3D markerless motion capture system (Theia Markerless Inc, Kingston, ON, Canada) has shown similar patterns and high reliability of lower limb joint angles in gait. However, its reliability in large joint motions such as skiing has not been confirmed. The purpose of this study was to compare the lower limb joint angles and center of mass (COM) positions measured by Theia 3D markerless and marker-based motion capture systems.
METHODS: Nine healthy adult males (mean age 21.6 ± 1.2 years, height 172.7 ± 6.8 cm, weight 65.6 ± 3.1 kg) participated in this study. They performed a side box jump (box height 300 mm, 795 mm between boxes), a ski mogul training exercise. The motion was recorded simultaneously using ten video cameras (RX0-II, Sony) for Theia 3D and 12 infrared optical motion capture cameras for marker-base motion capture (MAC3D, motion analysis Co.). Video data were processed using Theia 3D software, marker-based data were processed using marker-based capture software, and both sets of data were compared. The analysis was performed during the period of ground contact with the right-side platform. Grounding and release were defined as maximal plantar flexion of the right ankle joint just before grounding and release, and were time-normalized. Mean joint angles of each of the three right lower limb joints (hip, knee, and ankle joints) and COM were calculated. We used Pearsons product rate correlation coefficient for relative reliability, and Bland-Altman analysis for absolute reliability for both systems.
RESULTS: The relative reliability of the lower limb joint angles ranged from r = 0.59 to 0.99. The absolute reliability was 2.4 ± 0.6 ° on average for the 95% confidence interval of the minimum detectable change (MDC95). The relative reliability of COM was r = 0.97 to 0.99. The

average MDC95 was 0.82 ± 0.3 cm. Similar to comparisons in gait, the two systems produced very similar measurements in side-box jumps, with small differences in measurements and similar waveform patterns.
CONCLUSION: The results suggest that it is possible to measure not only walking but also jumping, landing, and other sports movements, as well as in the field, which were previously difficult to perform. Since this study was conducted on males in their 20s, results may differ depending on age, gender, health status, and clothing. Theia 3D was suggested to reduce the limitations of applied movements such as jumping and landing, as well as the measurement environment.

### ASYMMETRIC LOADING STRATEGIES DURING SQUATS FOLLOWING ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION: A LONGITUDINAL INVESTIGATION THROUGHOUT REHABILITATION WITH CURVE ANALYSES

STRONG, A., MARKSTRÖM, J.L., SCHELIN, L., HÄGER, C.K.

*COMMUNITY MEDICINE AND REHABILITATION*

INTRODUCTION: Kinetic loading asymmetries during bilateral squats have been reported following anterior cruciate ligament reconstruction (ACLR). Evidence is however limited to discrete value data extracted at specific knee angles from cross-sectional studies where side-to-side strategies are presented only at group level. It is therefore unclear whether loading asymmetries occur throughout the entire squat, whether they change during rehabilitation and how they are distributed between sides.
METHODS: Bilateral bodyweight squats were performed by 24 individuals (13 females) post-ACLR on three occasions: 1) Early rehab - 2.9 (1.1) months; 2) Mid-rehab - 8.8 (3.1) months; 3) Return to sport (RTS) - 13.1 (3.6) months; and 29 asymptomatic controls (22 females) on one occasion. Motion capture and two force plates were used to calculate time-normalized curves of vertical ground reaction forces and hip, knee, and ankle moments. Outcomes were compared between sides and groups, and over time, using functional t-tests with p-values adjusted by the interval-wise testing procedure. Individual knee loading strategies, i.e., under-/overloading of the ACLR side, were classified when asymmetry in favour of the respective side exceeded the 95% pointwise confidence interval of controls during at least 50% of the squat.
RESULTS: At Early rehab, ACLR had significantly greater (adjusted $P < .05$) asymmetry in knee flexion moment than controls during the time-normalized interval of 15-100% of the eccentric phase and the entire concentric phase, as well as ankle flexion moment during 56-65% of the concentric phase. At Mid-rehab, ACLR had significantly greater asymmetry than controls for knee flexion moment during 41-72% of the eccentric phase and for ankle flexion moment during 56-69% of the concentric phase. No significant between-group differences were found at RTS. At RTS compared with Early rehab, ACLR significantly reduced asymmetry for hip (21-46%, eccentric phase), knee (27-58%, concentric phase), and ankle flexion moment (21-57%, eccentric phase). Individual asymmetry strategies for knee flexion moment at Early rehab were mainly due to individuals underloading the ACLR side (46%) rather than overloading (4%). At RTS, however, more individuals overloaded (25%) than underloaded (17%) the ACLR side.
CONCLUSION: Curve analyses revealed significant kinetic loading asymmetries throughout bilateral bodyweight squats for our ACLR group compared with controls at Early rehab and Mid-rehab, but not at RTS. Significant reductions in hip, knee and ankle flexion moment asymmetry from Early rehab to RTS showed modifications during rehabilitation. An expected underloading strategy was evident for almost half of the ACLR participants at Early rehab, but an overloading strategy was the main reason for knee flexion moment asymmetry at RTS. Loading asymmetries during bilateral tasks should thus not be assumed due to underloading of the ACLR side, but may depend on an overloading strategy, particularly late in rehabilitation.

### A COMPARISON OF MEAN AND PEAK POWER BETWEEN THE PUSH PRESS, PUSH JERK AND SPLIT JERK WEIGHTLIFTING DERIVATIVES

SORIANO, M.1,2, JIMÉNEZ-ORMEÑO, E.1, GARCÍA-RAMOS, A.1,3, LAKE, J.4, MCMAHON, J.2, COMFORT, P.2

*1 CAMILO JOSÉ CELA UNIVERSITY, MADRID, SPAIN; 2 UNIVERSITY OF SALFORD, MANCHESTER, UK; 3 UNIVERSITY OF GRANADA, GRANADA, SPAIN; 4 UNIVERSITY OF CHICHESTER, CHICHESTER, UK*

INTRODUCTION: Weightlifting overhead pressing derivatives such as the push press (PP), push jerk (PJ) and split jerk (SJ) are used by practitioners to enhance the athletes ability to generate high power outputs (1). The PP, PJ, and SJ involve the dip and thrust phases. It is during the thrust phase where the highest power outputs have been recorded (2,3). However, to the authors knowledge, the differences in peak and mean power between these exercises have not been compared to date.
METHODS: Twelve well-trained participants (9 males and 3 females, weightlifting experience: 2.1 ± 1.1 yrs; 1RM PP: 75.5 ± 19.7 kg; 1RM PJ: 84.8 ± 19.7 kg; 1RM SJ: 92.9 ± 20.1 kg) performed a testing session to obtain the mean and peak power of the three exercises. Participants randomly performed one set of three repetitions of each exercise. A load of 75% 1RM of each exercise was selected as previously referred as the load at which the power outputs are maximized during weightlifting overhead pressing derivatives (2,3). Force-time data was recorded using a force platform (AMTI) interfaced with a laptop and data were collected in Qualisys Track Manager Software. Data were analysed using a customised Excel spreadsheet to obtain the kinetics and phase duration and displacement of the center of mass (COM). The mechanical power achieved by displacing system mass was calculated as the product of the force and velocity of the COM, as previously described elsewhere (4). Repeated measures ANOVAs with Bonferroni post-hoc corrections were performed to compare the peak and mean power outputs between exercises. Statical significance was set at $p<0.05$.
RESULTS: There were significant differences for the peak ($p=0.012$) and mean ($p=0.006$) power between the PP (2930.1 ± 778.7, 1816.7 ± 484.9 W), PJ (3139.1 ± 744.5, 1917.5 ± 483.5 W) and SJ (3265.35 ± 779.3, 2004.3 ± 478.7 W). Results from Bonferroni revealed that there were significant differences in the peak power between the PP and SJ ($p=0.013$, ES = 0.43). In contrast, there were no significant differences between the PP and PJ ($p=0.062$, ES=0.27) and between the PJ and SJ ($p=0.206$, ES=0.17). Similarly, there were significant differences in the mean power between the PP and SJ ($p=0.005$, ES = 0.39). In contrast, there were no significant differences between the PP and PJ ($p=0.111$, ES=0.21) and between the PJ and SJ ($p=0.068$, ES=0.18).
CONCLUSION: The exercise at which the peak and mean power outputs are optimized is the SJ, followed by the PJ and PP, although there were no significant differences between the PJ and SJ. Practitioners may consider implementing the SJ exercise to enhance the athletes ability to generate high power outputs.

## KINEMATICS AND KINETICS OF LEFT AND RIGHT LEGS DURING LANDING OF GRAND JETÉ PERFORMED BY PROFESSIONAL BALLET DANCERS

KUROMARU, A.

*TOKYO INSTITUTE OF TECHNOLOGY*

INTRODUCTION: Ballet dancers are required to use the same technique on both sides of the body, though humans have each characteristic movement as seen in dominant foot manner. It is supposed that there are characteristics of movement control unique to ballet dancers. Although a difference between left and right ground reaction forces was observed in ballet students' landing of a grand jeté, a basic ballet jump (1), there have been few kinematic and kinematic studies between left and right professional ballet dancers' ones. The purpose of this study was to compare kinematics and kinetics of those left and right grand jeté landings performed by professional ballet dancers.
METHODS: Fifteen female professional ballet dancers (age: 26.5±3.2 years, height: 160.5±3.8 cm, weight: 47.1±3.4 kg, their ballet experience: 22.1±3.4 years) were recruited to participate in this study. A questionnaire survey was circulated and replied before the experiment. Subjects were instructed to perform three times grand jeté plays for each leg at maximum effort, of which each highest jump in both legs was analyzed.
Using the data obtained in the experiment, we calculated the jump height and maximum ground reaction force (Max Fz), the angle of flexion and extension of the three lower limb joints at Max Fz, the angle of external and internal hip rotation, the moment of flexion and extension of the three lower limb joints at Max Fz and the max moment of extension of each joint to evaluate the performance of the grand jeté. The time required from IC (initial ground contact) to Max Fz and IC to maximum extension moment of each joint were individually calculated. Unpaired t-test was performed using the above-calculated data assuming equal variances with $\alpha = 0.05$ Variables of left and right legs were compared.
RESULTS: The questionnaire showed that all subjects usually used the right grand jeté, and 86% of them, which indicated that they were good at the right grand jeté. However, t-tests for each analyzed item showed no statistically significant differences in the angles and moments of the three lower limb joints at Max Fz or the max moment of each joint at their landing in the left and right grand jeté.
CONCLUSION: The results of this study have suggested that professional ballet dancers have more or less strong and weak points on their grand jeté plays depending on the dominant foot manner and also their total amount of practices. However, from viewpoints of kinematics and kinetics it was confirmed that the left and right grand jeté landings were coincident. This could be attributed to their daily training effect as professional ballet dancers of which enhancement may reduce bilateral difference.

## ACUTE EFFECTS OF DIFFERENT FULL SQUAT SET CONFIGURATIONS ON VERTICAL JUMP PERFORMANCE, VELOCITY LOSS AND SKIN TEMPERATURE

BAENA-RAYA, A., DÍEZ-FERNÁNDEZ, D.M., GARCÍA-RAMOS, A., MARTINEZ-TELLEZ, B., BOULLOSA, D., SORIANO-MALDONADO, A., RODRÍGUEZ-PÉREZ, M.A.

*UNIVERSITY OF ALMERÍA*

INTRODUCTION: The post-activation performance enhancement (PAPE) refers to an acute increase of maximal voluntary strength, power or speed following a conditioning activity (CA) (1). The set configuration and intensity directly determine the acute velocity loss (VL), metabolic, and hormonal (2). Therefore, implementing velocity-based training might help to monitor CA intensity and the incurred fatigue (3). Although most literature suggest an increased muscle temperature as the main mechanism underlying PAPE (4), no studies have measured skin temperature (Tsk) during PAPE protocols, which is a noninvasive method used as a surrogate of muscle temperature (5). Therefore, the aims of the current study were (I) to evaluate the acute effects of different full squat set configurations on countermovement jump height (CMJ), VL and Tsk, and (II) to determine whether the VL or the changes in Tsk incurred during the CA may modulate the change in CMJ height.
METHODS: Sixteen resistance-trained men randomly performed 4 squat protocols at maximal intended velocity with the 60% of the one repetition maximum (sets × repetitions [intra-set rest]): TR (2×6 [0-s]), CL2 (2×6 [30-s every 2 repetitions]), CL1 (1×12; [36-s between each repetition], and control (CO; no training). CMJ height was assessed before and 2, 4 and 8 minutes after the squat protocols. Tsk was continuously measured during the protocols.
RESULTS: Unexpectedly, a significant main effect of time ($F = 20.61$, $p<0.001$) was observed due to the comparable reduction of CMJ height after 8 min compared to baseline for the 4 protocols: TR (-3.4 ± 4.2%), CL2 (-5.3 ± 4.9%), CL1 (-5.4 ± 2.9%), and CO (-4.2 ± 3.6%). As expected, the VL was higher for the squat protocols with lower intra-set rest ($F = 20.54$, $p<0.001$: TR > CL2 > CL1) as well as the mean Tsk tended to decrease after the protocols. The VL and the change in Tsk were not associated with the change in CMJ height ($p>0.05$).
CONCLUSION: The four experimental protocols showed a comparable decrement in the CMJ height. CL sets configuration significantly mitigated the VL, while the mean Tsk tended to acutely decrease after all the protocols. The change in CMJ height was not modulated by the VL or the changes in Tsk, which seems not to provide further insights into the acute change in CMJ height. Relative loads of 60% 1RM performed at maximal intended velocity would not be recommended to promote PAPE during the final phase of the warm-up in this population.

### CP-SH01 Coaching and leadership

#### A CASE STUDY EXPLORING IF A BEHAVIOUR CHANGE INTERVENTION CAN INCREASE ADHERENCE TO ATHLETE MONITORING

NEUPERT, E.1, HOLDER, T.2, JOBSON, S.A.2

*<1> UNIVERSITY OF PORTSMOUTH; <2> UNIVERSITY OF WINCHESTER*

INTRODUCTION: Athlete monitoring is used to inform training programming, to optimise performance and to minimise the risk of athlete maladaptation. This is particularly important in elite sport where the high training loads and limited recovery periods increase the risk of negative performance and health outcomes. Poor athlete buy-in to monitoring has been recognised as a significant barrier to athlete monitoring system (AMS) implementation (1). However, the application of any systematic approach to combat poor buy-in to monitoring is notably absent from research. This study therefore aims to assess if a behavioural change intervention can remedy poor AMS adherence (2).
METHODS: The participants included three coaches (43.6 ± 10.0 years) and eight age-group national team athletes (20.1 ± 2.0 years) that had been using an AMS for one year. Initially, coaching staff attended a facilitated workshop where a behaviour change intervention was collectively planned. The intervention was then implemented and adherence to the AMS measured over 6 months. Subsequently, the participants attended one-to-one semi-structured interviews where they discussed their views on the AMS.
RESULTS: Seven target behaviours were identified in the workshop: 1) Increase athlete knowledge of monitoring value; 2) Increase coach's knowledge of monitoring value; 3) Conduct weekly case conferences which form part of athlete feedback; 4) Improve and increase feedback to athletes; 5) Upload and rate technical videos in AMS; 6) Put in place consequences for non-adherence; 7) Increase reminders to improve adherence. The main themes from the interviews were: Changes During the Intervention; AMS Attitudes; and Leadership. A decrease in adherence was observed during the intervention from a weekly average of 62% in the first week to 22% in the final week.
CONCLUSION: Despite the interventions, a decrease in adherence over the intervention period was demonstrated. This was likely caused by organisational changes within the sport where two out of the three coaching staff announced their resignations, and subsequently not all behaviour change interventions were implemented. This led to a reduced emphasis on completing the AMS and palpable frustration from both the coaching team and athletes. Despite this, the coaches reported improved athlete awareness in the purpose of monitoring. Overall, the intervention allowed practical behavioural targets to be discerned, but the time-consuming nature of its approach prevented it from being easily modified in the fast-paced setting of elite sport. Practitioners may instead want to consider a more agile approach to implementing behaviour change interventions, for example supporting key interactions such as the coach-athlete dyad.

#### ELITE TEAM SPORT ATHLETES' PERCEPTIONS AND EXPERIENCES OF DESTRUCTIVE COACH LEADERSHIP BEHAVIOR

SIGVARTSEN, K.K.1, SÆTHER, S.A.1, HAUGEN, T.2, ERIKSTAD, M.K.2, PETERS, D.M.3, HØIGAARD, R.2,1

*NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY <1>, UNIVERSITY OF AGDER <2>, UNIVERSITY OF WORCESTER <3>*

INTRODUCTION: Research on coach leadership in sport has traditionally been aimed at positive aspects of coach leadership styles and behavior. Ineffective coach leadership has primarily been linked to the absence of constructive leader behavior, often labeled in the concept of laissez-faire leadership resulting in unsatisfactory performance and losses for both athletes and teams. Less research has focused on identifying behaviors that the coaches shouldn't do; destructive behaviors that may undermine the immediate and long-term effect of their otherwise effective and constructive behaviors. The purpose of this study therefore was to explore elite team sport athletes' perceptions and experiences of destructive coach leadership behavior.
METHODS: Eight (4 females, 4 males, age range 20 to 37 yrs.) former and current World Class and international elite soccer and handball players participated in individual online semi structured interviews. Question examples from the interview guide included: "Can you describe coach behavior you have experienced as a player that you would label as 'destructive'?", "What effect did that type of behavior have on you?" "On other players? on the team?" The interviews were transcribed verbatim, pseudo-anonymized and analyzed using thematic analysis.
RESULTS: The athletes' experiences of destructive behavior were categorized in two overarching themes 'active' and 'passive' behaviors that then contained subcategories. Active behaviors were related to the actions a coach performs in a situation, and passive behaviors were ones where the coach omitted or failed to act in a situation where action was expected from or needed by the athletes. The active destructive behaviors consisted of five subcategories: Abusive & Aggressive behavior, Condescending behaviors, Negative Criticism, Autocratic Decisions, and Punishment behavior. Passive destructive behavior consisted of two categories Rejection and Ignoring. In addition, one subcategory was labeled as 'incompetent sport coaching behavior' that contained both active and passive behaviors, but this was not deemed to be intentionally destructive behavior.
CONCLUSION: This study parallels leadership studies in organizational contexts and confirms anecdotical stories that indicate that destructive coach leadership behavior is prevalent in sport. The sample in this study were elite athletes and it may well be that destructive leadership is more common and tolerated at this level than in sub-elite and recreational sports. However, this study highlights the importance to further investigate the "dark side" of leadership in sport and we recommend more research on destructive coach leadership behavior in other contexts such as individual sports, different sporting levels, and in different age groups.

#### COACHING AT CHAMPIONSHIP – NATIONAL ATHLETIC COACHES EXPERIENCES AND PRACTICE HOW TO HANDLE CHALLENGES CONCERNING GOAL SETTING STRATEGIES

AUGUSTSSON, C., WAGNSSON, S., HÖGMAN, J.

*DEPARTMENT OF EDUCATIONAL STUDIES*

Coaching at Championship – National Athletic coaches experiences and practice how to handle challenges concerning goal setting strategies

Background: A decisive factor in performance environments is the coachs ability to set different types of goals in collaboration with his/her athletes (i.e., outcome, performance and process goals).
This is especially important at major championships. Consequently, this study was conducted during the European Championships in Athletics among Swedish national team coaches (n=20).
Aim: To study how coaches experience and practice goal setting strategies at Championship
METHODS: Data was collected during the championship using a questionnaire with a mix of fixed and open-ended questions.
Results: The perceived pressure of participating at a championship is in itself very high. Therefore a majority of the coaches (60 %) used a process-oriented goal setting strategy, which according to the coaches provided a safer environment for the athletes compared to setting outcome goals.
“As a coach you have to know what kind of goal setting approach that suits every individual athlete…this athlete, as a I coach now, acts far more differently than previous athletes Ive had at any Championships before "
Most coaches set outcome goals when preparing for the championship, however in this study only a minor group of coaches (20 %) used outcome goals as a strategy during the Championship.
"We always work with outcome goals because thats what competition is all about,...."
However, as seen in our results, and in line with earlier research, coaches tend to focus more on process and performance compared to outcome goals when being at a championship.
Discussion/Conclusion: According to the coaches in our study, it is important to constantly be permissive and reflective, to consciously affirm the athlete no matter what happens. There are great improvements to be added by learning and reflecting on the experience of being at an international championship, rather than only appreciating the performance outcome.
Athletes are looking forward to compete and therefore they are also ready to work with outcome goals and performance goals. Hence, in our result coaches expressed that a sustainable development benefits from having process-oriented goals as “their main track”. Further the coaches emphasized the importance of working with a process-oriented goal setting in close collaboration and involvement with the athletes.

**SUSTAINABLE LEADERSHIP**

METTÄLÄ, M.

*FACULTY OF EDUCATION AND SOCIETY*

Introduction
There is a declining proportion of children and youth in Sweden who are involved in sport associations, but there are also difficulties for youngsters to participate as leaders in associations. And so, the work of engaging more young people as leaders must be intensified by generating new knowledge and skills about sustainable leadership-roles for youth.
Methods
From the ethnographic approach which enables studying the social world in its ‘natural state’ and involves observations, data will be collected by planning, developing, and implementing workshops where young leaders together with experienced leaders from sport-clubs and associations are invited to share their experiences. In parallel, conduct semi-structured interviews with the participants that will be documented and analysed. The results from the interviews and workshops will form the basis for an intervention with some selected associations where sustainable leadership-roles will be tried, studied, and analysed.
Results
Preliminary results show that young people tell us that they are rarely asked to lead in an association, some underline that they themselves cannot influence what happens during various activities. Furthermore, associations do not make use of their experiences and knowledge and have poor follow-ups after completed leadership trainings for youth. Hence, there is a need for collaboration between different actors in society such as the Academy, the municipality, sport associations and the private sector; a kind of relationship exchange where each experience can create new interactions based on interpretations of each others conceptual worlds, with the goal of generating new knowledge that is practically useful and theoretically interesting, with a common learning process as the core.
Discussion
A starting point for this interactive research project with the aim to create change is collaboration. This approach which usually is described as part of the action research family has the purpose to identify a problem and develop solutions through a set of processes that are initiated. Also, since this study involves collaboration with different groups, there is a need for new ways and approaches to communicate and report findings to be able to include all participants.

**COMMUNITIES AS POWERFUL AGENTS OF CHANGE: A STUDY ABOUT MEDIATIZATION AND KNOWLEDGE EXCHANGE IN EQUESTRIAN SPORT.**

BROMS, L.

*EDUCATION AND SOCIETY*

The field of sport has frequently been referred to as an example of how media has become powerful agents of change (Hepp, 2012; Schultz, 2004). However, equestrian sports and media seem to have a rather complex relationship and equestrianism is traditionally underrepresented in media in comparison to sports like men’s football and Ice hockey (Andersson & Radovic, 2011; Andersson, 2003; Dashper, 2017; Eriksson & Norblad, 2009). In parallel, Information and Communications Technologies (ICTs) are proven to be highly important assets when it comes to exchanging ideas, knowledge and information about horses and riding (Broms et el., 2021; Byström, 2015; Dashper, 2017). Previously, institutions such as the military, riding schools, educational institutions and the equestrian federation has been the main providers of knowledge in equestrian sports (Moore-Colyer & Simpson 2004; Hedenborg 2009; Thorell & Hedenborg 2015). However, several studies show that equestrians today, to some extent, use ICTs and more specifically social media to obtain and exchange information and knowledge (Bolwell et al.,16 2013; Byström, 2015; Hii et al., 2013; Lofgren et al., 2015). Professionals in the equine industry are worried about the issues surrounding knowledge exchange through social media. The lack of coverage in traditional media and the fre-

quent use of ICTs among the equestrian community questions the idea of media as powerful agents of change in (all) sports. Is it perhaps rather the lack of visibility in traditional media in combination with the possibilities offered through ICTs that are the drivers of change in equestrian sports? And what are the consequences of this? The aim of this study is to investigate in what way experts in equestrian sports (veterinarians, coaches and teachers) are affected by the increasing use of ICTs as platforms for knowledge and analyze what this means for the developments in the sport. The material includes nine interviews with equestrian professionals (three veterinarians, three coaches and three riding school-teachers) as well as netnographic observations and is analyzed with support from mediatization and affordance theory (cf. Nagny and Neff, 2019; Hepp, 2012). Results show that it is more appropriate to use the term communities as powerful agents of change rather than media as powerful agents of change in sports that are traditionally underrepresented in media. Further, this study highlights the importance of increased understanding of how audiences in sports use social media and what this means for the development in the specific sports context.

### THE CONFLICTS OF GREENER GRASS: THE REGULATION OF ARTIFICIAL TURF IN SWEDEN

DE BERNARDI, C., WALLER, J.H.

*MID SWEDEN UNIVERSITY*

Introduction
Artificial turf is a popular substitute for natural grass and is widely used for playgrounds, landscaping and sport surfaces. Artificial turf has increased in popularity over the past decade, with the development of surfaces designed specifically for soccer. The use of these surfaces has increased the availability of playing hours and allowed for matches and training to take place in climatic conditions where natural grass is not easy to upkeep. However, from a sustainability viewpoint, artificial turf has been increasingly criticized for being dangerous to both people and the environment. As these surfaces are used extensively, from regular youth team training to elite professional matches, the environmental and health priorities must be evaluated alongside the geographical requirements, the risk of injury, the regulation of the game itself and a more effective exploitation of playing surfaces. Research on the policy terrain surrounding artificial turf from the perspectives of different stakeholders combined with the perception of players is not well-developed, as the focus is usually on purely technical or medical aspects or on strictly environmental and health-related perspectives.
Method
The focus of this study is on the sustainability of artificial turf in relation to soccer and is based on semi-structured interviews with a number of different actors such as municipalities, companies and sports associations, a qualitative survey of soccer players, and the analysis of different policy documents and reports. The data has been analyzed with a thematic analysis using the software NVivo.
Results
This investigation uncovers the issues that are related to the procurement, use, maintenance, and disposal of artificial turf in Sweden. They shed light on the different constraints that the actors who work with artificial turf encounter when the policy terrain is so complex.
Conclusion
The data, as well as previous research suggests a tendency for soccer to take priority over other sport and outdoor activities. There is also an indication that information and knowledge about the technical attributes and materials used in artificial turf pitches has a great influence on the decisions taken by the actors. Despite the encountered constraints, the study participants mentioned a number of efforts to improve the sustainability of artificial turf throughout the different phases of its lifecycle, from acquisition to disposal. Some recommendations are made based on the results relating to information flow, knowledge about materials and better handling of several kinds of policies in order to support the efforts that are already are in place for municipalities and other actors working with artificial turf.

### RESEARCH ON THE DEVELOPMENT STRATEGY OF ACADEMIC EXCHANGE OF THE CHINESE SPORT SCIENCE SOCIETY

ZHI, Z., LIU, X., WANG, Y.

*CHINA INSTITUTE OF SPORT SCIENCE*

Introduction
This study uses SWOP-PEST and SWOT-AHP models to analyze the development of academic exchanges at home and abroad of the Chinese Society of Sports Sciences from the perspective of management, so as to achieve the purpose of exploring the optimal development strategy of academic exchanges of the Society. Under the global background of the COVID-19 pandemic, it provides a strategic reference for academic exchanges between sports academic organizations at home and abroad.
Methodology
This study mainly uses SWOT-PEST, SWOT-AHP, Delphi Method and mathematical statistics.
Results and discussions
The analysis of the AHP model shows that the size ranking of the total strength (absolute value) between the four groups of SWOT: Opportunity O Group (2.4019) > Advantage S Group (0.8849) > Disadvantages W Group (0.3953) > Challenge Group T (0.2757), which determines the development of academic exchanges of the Society. The exhibition strategy should be the main, and the WO strategy should also be taken into account.
SO strategy: Accelerate the establishment of the "four links" strategic system, that is, to realize policy communication between the society and the government, economic integration with social enterprises, communication with the hearts and minds of the people, and technical communication with sister associations.
WO strategy: seize opportunities to effectively promote the reform of "de-administration"; actively strive for opportunities for government purchase services and transfer of government functions; dynamically introduce and absorb diversified forms of communication; informatization construction and vocational training of the workforce go hand in hand.
Recommendations:
(1) Establish and improve a quality evaluation system for academic activities that conforms to its own characteristics;(2) Appropriately add the "academic gunpowder flavor" to the exchange activities in the form of pilot;(3) Establish a systematic results management platform for academic exchange activities.

## CP-AP02 Sport performance

### USE OF A STATISTICAL MODEL TO FOLLOW THE EVOLUTION OF THE PROBABILITY OF VICTORY OF PARA TABLE TENNIS MATCHES.

HAMRI, I., SCHIPMAN, J.

*INSEP*

INTRODUCTION: Para-table tennis is an opposition sport where the mind and self-confidence have a predominant role. The purpose of this study is to estimate the probability of winning a para-table tennis match and to calculate the evolution of this probability at the end of each set.
METHODS: We have collected all the para table tennis matches since 2016, i.e. 26 535 mens and womens confrontations of all impairment categories. For each match, we have the exact score, the international ranking of opponents, their impairment category and the results of previous confrontations. Five ordinal logistic regression models were used to estimate the probability of final result, before the start of the match, then after each set until the end.
RESULTS: Some indicators did not significantly enrich the prediction model such as the impairment category ($p = 0.13$), the tournament phase ($p = 0.42$). The main indicators retained are the international ranking of opponents ($p<0.01$) and the results of previous matches ($p<0.01$). Before the beginning of the match, based mainly on the rankings and previous confrontations, 81% of the results are correctly predicted, including 40% with the correct scores. After the first set, 83% correct predictions including 51% with correct scores. At the end of the 4th sets, the model has a success rate of 66% with great importance given to the result of the 4th set.
CONCLUSION: The models used have shown very good predictive performance and are statistically robust. The study brings real added value in the prediction when the opponents have a similar level. The results of this study can be used by the staff for mental preparation before a Para-table tennis match to study the different possible scenarios.
Key words : paralympics ; para table tennis ; logistic regression ; performance ; score

### TYPES AND SEVERITY OF PHYSICAL IMPAIRMENTS OF PARA-KARATE ATHLETES

AUGUSTOVICOVA, D., NEMCEK, D.

*COMENIUS UNIVERSITY*

INTRODUCTION: Para-karate is applying to be added to the Paralympic Games scheduled to be held in 2028. Research on the classification of para-athletes is common in other para martial arts sports [1,2], however, there is limited research on the classification of para-karate athletes. This study aimed to provide details on the impairments and disabilities of the para-karate players. The secondary objective was to investigate the relationship between the level of impairment and the athletes rankings.
METHODS: The data of 197 para-karate athletes (65 females and 132 males), who had been classified over the past six years (World Para Karate Championships 2012 Bremen, 2016 Linz, 2018 Madrid, 2021), were analysed. Descriptive information (counts and percentages) was calculated for each variable. Spearman rho correlation between the athletes standing in the WKF ranking and the extra score (level of impairment) was calculated.
RESULTS: The K20 class was the most popular, and 84 (43%) of the classified athletes belonged to this class (35% female / 65% male athletes), followed by the K10 sports class, 58 athletes (27%, 30% female / 70% male athletes), and K30 sport class, 55 athletes (30%, 35% female / 65% male athletes). In K30 sport class, an accident or a disease was the most frequent cause (73%) of impairment, and 27% of all impairments/disabilities occurred during 0–5 years of age. In K20 sport class, 44% of the athletes had Down syndrome. There was a weak but significant correlation ($r_s = 0.3$, $p = .00$) between the ranking and the level of disability / extra score.
CONCLUSION: Continued data collection that provides insights into the impairment profiles of para-karate athletes is needed to improve the current classification system to enhance safety and fairness in Para Karate competition.

### MATCH CHARACTERISTICS OF “RASPALL”, A MODALITY OF “PILOTA VALENCIANA”, A TRADITIONAL SPANISH HANDBALL SPORT

LARRÉ-CASAÑA, A., PALACIOS-NEVADO, D., GENE-MORALES, J., GENE-MORALES, A.

*PILOTA 3.0 2020 S.L.*

INTRODUCTION: Pilota Valenciana is a sport integrated by different modalities of handball. It is typically played in Spain, in the Valencian Community. Raspall is one of these modalities of Pilota Valenciana (see official regulations of the Pilota Valenciana Federation [1] for further information on the specific rules of this modality). To win a raspall match a player must sum five games, each of them composed of four points (15, 30, Val, and Joc). [1] Previous research analyzed certain parameters of this sport [2,3] and highlighted the need for further research on the specific structural features of this sport modality. [3] Therefore, the aim of this study was to present the main structural features of raspall.
METHODS: Ten elite raspall singles matches involving 12 different players were recorded by one researcher or extracted from television broadcasts. The games took place during the year 2019. The matches were analyzed by one researcher using Longomatch software in which all actions were recorded on an electronic sheet. A second researcher confirmed the validity of the data extracted. Raw data were transferred to an Excel database to be cured. The variables selected were grouped in duration, punctuation, rest time duration, and hits. IBM Statistical Package for Social Sciences was used to perform descriptive analyses. Values are presented as mean ± standard deviation [95% confidence interval].

RESULTS: A total of 68 games and 399 points were analyzed. The duration of playing and non-playing activities during elite raspall games follow an intermittent activity pattern. Means for the variables analyzed were 1) match duration: 3389.47 ± 1316.61 seconds, 95%CI [2447.63-4331.32]; 2) game duration: 418.37 ± 246.97 seconds, 95%CI [358.59-478.15]; 3) point duration: 35.52 ± 37.91, 95%CI [31.79-39.25]; 4) games per match: 6.80 ± 1.62 [5.64-7.96]; 5) points per match: 39.90 ± 13.24, 95%CI [30.43-49.37]; 6) points per game: 5.87 ± 2.23, 95%CI [5.33-6.41]; 7) rest time between games: 93.78 ± 25.81 seconds, 95%CI [86.93-100.63]; 8) rest time between points: 43.06 ± 19.18 seconds, 95%CI [40.99-45.14]; 9) hits per match: 460.50 ± 168.69, 95%CI [339.83-581.17]; 10) hits per game: 67.72 ± 39.61, 95%CI [58.13-77.31]; 11) hits per point: 11.54 ± 10.07, 95%CI [10.55-12.53].
CONCLUSION: This study presents the structural features of raspall. The findings presented can be of interest to coaches, athletes, and strength and conditioning specialists to further understand the sport and design training programs based on the specific structure of this sport modality. Future scientific evidence analyzing the specific characteristics of raspall is required.

### PERFORMANCE IN LONG JUMP: A QUESTION OF BIRTHDATE IN FEMALE ATHLETES?

JAVET, M., RUEEGER, E., BORN D.P., ROMANN, M.
*SWISS FEDERAL INSTITUTE OF SPORTS MAGGLINGEN SFISM*

INTRODUCTION: Relative age effects (RAEs) bias sport participation, talent development (TD) and selection (TID) programs in youth sport. Most of RAEs studies showed results in cross-sectional samples, longitudinal studies are sparse. This study adds knowledge by providing data showing longitudinal RAEs for female long jump athletes.
METHODS: Out of 161'852 competition's results of 16'168 athletes, 18'368 results of 4141 athletes were extracted in order to include at least 3 results per season and at least 3 seasons of participation. Athletes were included from U8 to U23 in the timespan between 2010 to the 2019. Athletes were separated by one year age groups (AG) and birth quarters (Q). Odds ratios (OR) with 95% confidence intervals (95%CI) were used to quantify RAEs and ANOVA (one-way and repeated measures) to compare performance differences.
RESULTS: Significant RAEs with large effect were found for U8 (OR=3.52 (95%CI 2.63, 4.72)) and U9 (OR=3.01 (95%CI 2.45, 3.69)). Medium effect was shown for U10 to U12 and small effect for U13 to U18. No significant RAEs were found for U19 to U23. Mean long jump performances for AG were significantly shorter for Q4 than Q1 for U8 to U16. Performance differences were ranging from 7.41% in U8 to 3.44% in U16 with a mean difference of 5.82 ± 1.89%. Q4 performances were equally to Q1 between U17 and U19 and higher from U20 to U23 (not significant). Regarding the whole pathway, Q4 athletes showed a relevant higher performance development of 13.8 % compared to Q1. The 100 best athletes for each AG, showed even higher RAEs, i.e. OR= 15.24 (95%CI 4.49, 51.7) at U10, however a similar performance evolution.
CONCLUSION: Female athletes of different birth quarters are differently affected by the consequences of RAEs on their sport participation and TD pathway. RAEs bias performance outcomes till the age of 16 and distort participation, TD and TID decisions. In other words, RAEs induce inappropriate learning environments, a waste of talent, waste of resources and drop-outs before athletes can realize their full potential. Future research should analyse RAEs in other sports using a longitudinal approach.

### DEVELOPMENT OF A BADMINTON RECEIVING SKILLS ANALYSIS SYSTEM -EXTRACTION OF THE POSSIBLE RESPONSE AREA BASED ON SHOT ATTRIBUTES, COURSE, AND SHOT COMBINATION-

TANAKA, S., AIHARA, S., TORIYA, S., TAKAZAWA, S., ISHIBE, K., IWATA, H.
*WASEDA UNIVERCITY*

INTRODUCTION: In sports training, it is important to set the level of difficulty according to the level of the players [1]. Therefore, a system that can change the level of difficulty according to the players level is needed.
We herein focused on the smash receive of badminton and developed a system to enable the receiver to practice receiving in virtual reality (VR) [2]. In this study, the system was redeveloped to visualize and analyze the area where a receiver can respond by individual players based on shot attributes, course, and shot combination.
METHODS: First, we developed a VR system for badminton receiving motion that can acquire variables necessary to estimate the receiving skills of each individual, such as the time it takes for the shuttle to fall, the time difference from one ball before, the coordinates of the falling point, and the left-right and front-back difference between the falling points from one ball before. Next, experiments using the VR system were conducted and the subjects' receiving data were acquired under various conditions of smashes. The subjects were an experienced badminton player and an inexperienced player. The number of balls that the experienced player received was 911 and the inexperienced player received was 800. Finally, a model was built to define and estimate the area where a receiver can respond. Using a random forest algorithm, we calculated the probability of a receiver being able to receive based on shot attributes, course, and shot combination in each of the 143 regions of the court and identified the possible response area for each individual.
RESULTS: Using the test data, we evaluated the expected calibration error (ECE) score. The ECE score was 0.065 for the experienced player and 0.082 for the inexperienced player. Both scores are sufficiently small showing that this model is effective in estimating player level.
We analyzed the effect of shot combination by classifying the shots launched from the drop time and drop point. The results showed that both inexperienced and experienced players had a lower return rate on the smash following a drop. However, there was no significant difference in the return rate for the drop following a smash. Thus, by focusing on the return rate, the possibility was shown to analyze the players ability to respond to the shots and their combinations.
CONCLUSION: This research enabled us to quantitatively evaluate the shot attributes, course, and shot combination that each player has difficulty receiving. In addition, by using our VR system, we can reproduce the poor shots and realize effective receiver training. In the future, we plan to verify the effectiveness of the training system based on the results of this research.

**MATCH CHARACTERISTICS OF "ESCALA I CORDA", A MODALITY OF "PILOTA VALENCIANA", A TRADITIONAL SPANISH HANDBALL SPORT**

PALACIOS-NEVADO, D., LARRÉ-CASAÑA, A., GENE-MORALES, J., GENE-MORALES, A.

*PILOTA 3.0 2020 S.L.*

INTRODUCTION: Escala i corda is the most practiced Pilota's Valenciana modality [1], which is a traditional handball sport played in Valencian Community, Spain (see official regulations [2] for further information on the specific rules). To win a escala i corda singles match a player must sum nine games, which in turn are each composed of four points (15, 30, Val, and Joc). [2] Previous research has described how to play [1] or analyzed certain parameters of team's modality [3,4] and highlighted the need for further research on the specific structural features of this sport modality. [4] Therefore, the aim of this study was to present the main structural features of escala i corda.
METHODS: 11 elite escala i corda singles matches involving 14 different players were recorded by one researcher or extracted from television broadcasts. The games took place during the year 2019. The matches were analyzed by one researcher using Longomatch software in which all actions were recorded on an electronic sheet. A second researcher confirmed the validity of the data extracted. Raw data were transferred to an Excel database to be cured. The variables selected were grouped in duration, punctuation, rest duration, and hits. IBM Statistical Package for Social Sciences was used to perform descriptive analyses. Values are presented as mean ± standard deviation [95% confidence interval].
RESULTS: A total of 159 games and 991 points were analyzed. The duration of playing and non-playing activities during elite raspall games follow an intermittent activity pattern. Means for the variables analyzed were 1) match duration: 4505.51 ± 1316.61 seconds, 95% CI [3891.67-5119.35]; 2) game duration: 235.803 ± 115.982 seconds, 95%CI [217.636-253.97]; 3) point duration: 12.11 ± 12.95, 95%CI [11.303-12.92]; 4) games per match: 14.36 ± 2.06 [12.98-15.75]; 5) points per match: 90.00 ± 13.01, 95%CI [81.26-98.74]; 6) points per game: 6.23 ± 2.29, 95%CI [5.87-6.59]; 7) rest between games: 82.12 ± 23.19 seconds, 95%CI [78.36-85.87]; 8) rest between points: 30.174 ± 15.37 seconds, 95%CI [29.14-31.21]; 9) hits per match: 419.82 ± 102.75, 95%CI [350.79-488.84]; 10) hits per game: 29.03 ± 14.54, 95%CI [26.75-31.30]; 11) hits per point: 4.66 ± 3.76, 95%CI [4.42-4.89].
CONCLUSION: This study presents the structural features of escala i corda. The findings presented can be of interest to coaches, athletes, and strength and conditioning specialists to further understand the sport and design training programs based on the specific structure of this sport modality. Future scientific evidence further analyzing the specific characteristics of escala i corda is guaranteed.

**DIFFERENCES IN REACTION TIMES BETWEEN OPEN SKILL AND CLOSED SKILL SPORTS USING THE BATAKPRO, A CROSS-SECTIONAL OBSERVATIONAL STUDY**

COOKE, L., BALDWIN, M., MURRAY, M., MURRAY-BYRNE, N., HURLEY, K., CROGNALE, D.

*UNIVERSITY COLLEGE DUBLIN*

INTRODUCTION: Reaction times are an important component of sport performance; however, some athletes need to be more reactive (tennis, soccer and other open skilled sports) than others (cycling, swimming and other closed skilled sports) due to the nature of the sports. To our knowledge, no study has investigated the difference in reaction times between open and closed skilled sports using a simple, reliable and quick test that can be used by all different athletes, regardless of their sporting background. The aim of the study was to investigate the difference in reaction time between open and closed-skilled sports and the possible impact of physical characteristics (height and wingspan).
METHODS: Thirty-four participants (Age = 22.6 ±4 years) from sports including rowing, swimming, team field sports (rugby, GAA, handball), and combat sports (boxing and Muay Thai) had their reaction time tested using four pre-set protocols on the Batak Pro (protocol numbers 1,5, 12 and 24), which varied in difficulty and complexity. Each participant had four attempts (one practice and three testing trials) for each protocol. The primary outcome measure was their score on the Batak (targets struck or time taken to complete the task). A whole group correlation analysis was performed to investigate whether height, wingspan, or ape index was correlated with Batak performance and this was done for each protocol.
RESULTS: Surprisingly, there was not a significant difference between open and closed skill athletes in all four protocols ($p>0.05$). The only physical characteristic that was positively correlated to Batak score was wingspan for protocol 1 only ($r = 0.395$).
CONCLUSION: The results indicate that there is no differences in reaction times between open and closed skill athletes. This may suggest a limitation in the capacity of athletes to improve their reaction times in a general sports training setting. Further research may be needed to investigate the effects of sport-specific reaction time training. These findings may also be attributed to the sensitivity and specificity of the Batak Pro. However, the reliability of the Batak was demonstrated as the scores were largely unaffected by physical characteristics. In conclusion, the Batak Pro should not be dismissed as a useful tool for assessing and training general reaction times within the athletic population.

**MEDICAL ATTENTION INJURY RATES IN US WOMEN RUGBY-7S**

LOPEZ JR, V.

*HOSPITAL FOR SPECIAL SURGERY*

INTRODUCTION: Lopez, V, Jr.1 2, Victoria, C.1 2 3, Ma, R.1 2 4, Weinstein, MG.1 3, Strong, JM. 1 5, Borthwick, KG.1 6, Borrego, JD. 1, Borrego, MA. 1, Allen, AA.1 2 7 8.

1: RRIPG- Hospital for Special Surgery (New York City, USA), 2: AUT/SPRINZ (Auckland, NZ), 3: NYU (NYC, USA), 4: Univ. Missouri-MOI (Columbia, MO, USA), 5: Univ. Southern California (LA, CA, USA), 6: Case Western Reserve Univ., School of Med. (Cleveland, OH, USA), 7: HSS (NYC, USA), 8: NBA, (NYC, NY)

There is a lack of injury data on women's rugby, and less on the Olympic format of Rugby-7s among the amateur playing population (Lopez et al., 2012; Ma et al., 2016). The aim was to determine medical attention (no time-loss) injury incidence in U.S. women's Rugby-7s.
METHODS: A prospective epidemiology study of U.S. women Rugby-7s (6,768 players; 564 teams), in multi-level USA Rugby and USA Sevens LLC tournaments (2010-2014). Incidence (per 1000 player-hour (ph)) and biomechanism of medical attention injuries were captured via the Rugby Injury Survey & Evaluation (RISE) Report methodology (Lopez et al., 2012), adhering to the rugby consensus statement (Fuller et al., 2007). Medical attention injuries were injuries with no absence from play.
RESULTS: Medical attention injury rate was found at 84.4/1000 ph (n=356). Amongst positions, injuries were found at similar rates (backs: 60%, 59.3/1000ph, n=143; forwards: 40%, 53.6/1000ph, n=97; RR=1.11; P=0.447). Most injuries were acute (95%) occurring during the tackle (67%). Most match injuries were from a shoulder tackle (70%) (backs 72%; forwards 62%; RR=1.32; P=0.113). Recurrent injuries occurred at 25%. Lower extremity ligament sprains (53%) were most common, among injury types, muscle/tendon injuries were most common overall at 41% (backs 41/1000ph; forwards 42/1000ph; P=0.998). Knee injuries occurred more frequently in forwards (23%) than backs (16%; P<0.213). Head/neck injury rates, were 22% of all injuries. The sub-acute head contusion rate, where players were physician-cleared to return to sport was 6% (3.5/1000ph).
CONCLUSION: Documentation of medical-attention incidents is recommended in the literature, as this is likely to capture a far greater number of ailments, than time loss injuries alone and will therefore, provide a more inclusive picture of the true burden of injury and illness in a community population as compared to only studies on elite women. A panoptic view of rugby-7s injury rates collected by international standards among community rugby, provides fundamental gender injury data, to guide injury prevention protocols by stakeholders to guide player welfare. Head/neck and upper extremity injury rates (both at around 21%) support an emphasis on tackling techniques for injury reduction. A program, including contact-based-awareness, for women newly introduced to this collision-sport, would nurture injury prevention. Furthermore, adherence on return to play protocols would decrease recurrent injury rates seen in this gender-specific cohort.

## THE EFFECTS OF SOCCER HEADING ON THE DEVELOPMENT OF COGNITIVE AND SENSORIMOTOR PERFORMANCE IN FEMALE SOCCER PLAYERS

KERN, J., GULDE, P., HERMSDÖRFER, J.

*TECHNICAL UNIVERSITY OF MUNICH*

INTRODUCTION: Within recent years, the proliferate concern about the consequences of sport-related head impacts has led to an increasing amount of research on soccer heading and its potentially adverse effects on brain function. While current evidence on the actual risk remains inconclusive, female players, despite an increased vulnerability (Rubin et al., 2018), are largely underrepresented in previous approaches. Consequently, our aim was to prospectively investigate a potential relationship between purposeful heading and changes in cognitive and sensorimotor performance in female soccer players.
METHODS: Before and after one soccer season, 22 semi-professional female players (22.0 ± 3.9 years) underwent a comprehensive examination consisting of questionnaires and an extensive test battery for the assessment of cognitive and sensorimotor performance. Throughout the season, matches were video-recorded and footage then analyzed to obtain players' individual number of performed headers. The association between individual heading exposure and cognitive or sensorimotor performance changes was assessed by means of multiple linear regression while controlling for the potential effects of previously sustained head injuries.
RESULTS: Analyses revealed a statistically significant regression model with four factors ($R2adj = 0.65$, $p < 0.01$). Greater heading exposure was linked to negative changes in fine motor performance as assessed by writing tasks ($p = 0.02$ and $p < 0.01$). Moreover, players with greater heading exposure showed negative alterations in postural control ($p < 0.01$) while exhibiting concomitant changes in working memory performance ($p = 0.03$). The number of previous head injuries did not affect the observed relationships.
CONCLUSION: In contrast to previous reports (e.g., Lipton et al., 2013), our findings suggest that a greater number of headers is associated with sensorimotor rather than cognitive performance changes. Moreover, the present results are the first to point towards a cumulative effect of soccer heading on both postural and fine motor control in female soccer players. These findings may serve as a basis for larger scale studies on the potentially persistent effects of repetitive soccer heading in both male and female athletes.

## THE EFFECT OF PUBERTAL STATUS ON POST-ACTIVATION POTENTIAL IN YOUNG SOCCER PLAYERS

ESTRELLA, R.3, FERRAZ, T.3, GRAVA DE SOUZA, J.3, OLIVEIRA SILVINO, V.2, SANTOS, M.A.2, PRADO, D.M.L.1,3

*1-UNIVERSITY OF SÃO PAULO, 2-FEDERAL UNIVERSITY OF PIAUÍ AND 3-JOAQUIM GRAVA INSTITUTE*

INTRODUCTION: Post-activation potential (PAP) is a phenomenon in which neuromuscular performance characteristics are enhanced after intense contractile stimulation. Previous studies have documented that muscle twitch force can increase through a preceding dynamic conditioning stimulus. However, there is little research regarding the effects of aerobic exercise on subsequent neuromuscular performance in young soccer players. This study examined the effect of pubertal status on PAP after maximal cardiorespiratory exercise test in young soccer players.
METHODS: A total of 48 males aged 10-18 years (13.8 ± 2.3 years) were divided into three groups: pre-pubescent (n= 13, 11.2 ± 1.5 years); pubescent (n=15, 13.1 ± 0.8 years); and post-pubescent (n=20, 15.9 ± 1.3 years). The pubertal stage was determined from secondary sex characteristics. Participants underwent a countermovement jump (CMJ) test before and after maximal cardiorespiratory exercise test (CPET) in order to measure vertical jump height. The jumps were performed on a contact mat (Elite Jump, S2 Sports, São Paulo, Brazil). The obtained flight time (t) was used to estimate the jump height (h) (i.e., $h = gt^2/8$), where "g" is the gravitational acceleration. The PAP was assessed after CPET at 5 minutes of the recovery by calculating the difference between pre- and post-exercise CMJ height. The CPET (Cor-

tex, Metalyzer IIIB, Leipzig, Germany) was performed on a treadmill using a ramp protocol to determine maximal oxygen consumption (VO2 max) and maximal aerobic speed (MAS). One-way ANOVA was used to verify differences between groups.
RESULTS: Results are presented as mean and standard error of the mean. Pre-pubescent participants presented significantly lower CMJ height compared to pubescent and post-pubescent participants (23.8 ± 2.5 vs 29.0 ± 3.7 vs 34.9 ± 5.2, respectively). Both pre-pubescent and pubescent participants had significant lower PPA (1.5 ± 1.7 and 2.2 ± 1.9, respectively) than post-pubescent volunteers. Pre-pubescent players had lower VO2 max values (48.7 ± 7.3) than the other groups. However, no significant differences were observed between pubescent and post-pubescent participants (53.2 ± 5.6 vs 53.9 ± 4.7, respectively). Regarding MAS, pre-pubescent participants presented significant lower values compared to pubescent and post-pubescent (12.4 ± 0.9 vs 14.2 ± 1.9 vs 16.2 ± 1.4, respectively).
CONCLUSION: In conclusion, our results demonstrated that the enhancement of the PAP after maximal cardiorespiratory exercise test is lower in both pre-pubescent and pubescent children. These findings suggest that PAP effect on CMJ performance is associated with greater twitch potentiation in post-pubescent soccer players.

**SUBJECT-ENVIRONMENT RELATIONSHIP AND RUNNING PERFORMANCE: A MULTILEVEL APPROACH**

THUANY, M., KNECHTLE, B., GOMES, T.N.

*UNIVERSITY OF PORTO*

INTRODUCTION: Previous studies showed that running was a low-cost practice that could lead to significant health benefits. However, little was known about which specific environmental characteristics could be associated with the performance of runners. In another way, a friendly environment can be related to the highest physical activity commitment, and these aspects can positively influence the running performance. The purpose of this study was to verify the influence of environmental factors on the running performance of Brazilian runners, based on a multilevel approach.
METHODS: We conducted a cross-sectional research project (2019 – 2020). A total of 1,151 runners from all Brazilian states were sampled (711 men and 440 women), aged 18 – 70 years. An online questionnaire was used for data collection (age, sex, body mass, body height, and training characteristics). Data regarding environmental characteristics were downloaded from the Brazilian Institute of Geography and Statistics, based on the Census 2010 – Urbanistic characteristics of household surroundings, which provided information about the presence of illumination, paving, curt, green, space, and sewer in Brazilian states. Running pace was considered the outcome measure, and two models (individual-level and environmental-level) were built. The multilevel regression model was computed in SuperMix software with a 95%confidence interval.
RESULTS: Athletes are from the five Brazilian regions (Southeast = 418; South = 143; Northeast = 411; North = 87; Midwest = 95). The largest number of athletes was from São Paulo (Southeast) and Sergipe (Northeast). Descriptive data for the artificial environment indicated that except for Amapá and Rondônia (both in the north region), Brazilian capital states indicated >90% of the illumination. The best index was presented in the states from the southeast and south for the pavement, sidewalk, curb, green space, and sewer. Approximately 3% of the total variance in runners' performance was attributed to the environmental differences between the states. Approximately 55% of the within-state variance was attributed to individual characteristics inserted in the model, while these variables explained 56% of the between-state variance. Individual characteristics (age, sex, body mass index, training volume, and frequency) were associated with running performance. Illumination (β = 2.07; p = 0.01) and sewer (β = 0.28; p = 0.01) were positively associated with running performance.
CONCLUSION: The variance of running performance for the state of residence is 3% which shows that training in a different state can influence runner's performance; that is, most of the performance variance is explained by the individual characteristics. Besides the individual characteristics (e.g., age, sex, BMI, volume, and training frequency), environmental characteristics are negatively related to running pace. This suggests that these indicators can influence the training commitment and performance.

**A COMPARATIVE STUDY ON THE INCIDENCE OF ELBOW JOINT PAIN IN ELEMENTARY SCHOOL BASEBALL PLAYERS 10 YEARS AGO AND AT PRESENT**

KOUNO, C.1, ONISHI, M.1, MATSUMURA, N.1, DOI, N.1, TAHU, Y.2, SHIMIZU, H.1, KAWABE, R.1, NAGAI-TANIMA, M.1, AOYAMA, T.1

*1 KYOTO UNIVERSITY, 2 KYOTO PREFECTURE SPORTS LITTLE LEAGUE BASEBALL ASSOCIATION*

INTRODUCTION: Baseball is one of the most popular sports in Japan. On the other hand, it is a problem that there is a high incidence of pitching disorders associated with baseball. In addition, the incidence of them with pain in the shoulder and elbow joint is estimated to be 20-40%. These disorders in youth have a significant impact on performance in adolescence and beyond, and prevention of them is said to be important. Many studies have been conducted in the United States mainly to investigate the actual conditions of pitching injuries and to identify risk factors and predictors of injuries. Our laboratory also conducted a survey on the occurrence of pitching disorders in elementary school students 10 years ago. At that time, awareness of the prevention of pitching injuries was not yet widespread, and as a result, there were many players with elbow joint pain. On the other hand, in recent years, rule revisions have been actively implemented from the viewpoint of injury prevention, such as the establishment of a daily/weekly pitch limit and a system for declaratory esteem. Given the official adaptation of the pitching restriction rule in high school baseball players for the first time in 2020, there may be an increased awareness of injury prevention. Therefore, the purpose of this study is to compare data from 10 years ago with the current data on the occurrence of disabilities in the elbow joint, and to examine what differences in the actual occurrence of disabilities occurred during the 10 years between the rule revisions.
METHODS: Paper questionnaires were distributed to baseball players in elementary school in Kyoto Prefecture to investigate the actual condition of disability. Questions included practice time and menus, pitching form, body part with pain, and time of onset of pain. The results were summarized in graphs and tables using descriptive statistics.
RESULTS: Data were collected from 791 baseball players. 235 players (29.7%) had pain in some part of the body, 79 players of them (10.0%) had pain in the elbow joint. In addition, elbow joint disorders accounted for 21% of all injury sites in elementary school students.
CONCLUSION: Data obtained 10 years ago showed that the percentage of elbow disorders occurring was 19.1%. Comparing this data with the percentage of elbow joint occurrence obtained this time (10.0%), it is clear that the percentage of players with elbow joint disorders has decreased significantly. Since the survey on disorders 10 years ago, rule revisions, including restrictions on the number of pitches in youth baseball, have been implemented, and shoulder and elbow examinations to check current physical conditions have been actively conducted. These factors suggest that the prevention of disabilities through rule revisions and the promotion of early detection and treatment of disabilities through medical examinations might have led to a decline in the incidence of elbow joint disabilities.

### RUNNING IN MINIMALIST SHOES: DOES IT PREVENT INJURIES?

URBACZKA, J., SKYPALA, J., ZAHRADNIK, D., ELAVSKY, S., HAMILL, J., SILVERNAIL, J., JANDACKA, D.

*UNIVERSITY OF OSTRAVA*

INTRODUCTION: The vast majority of runners sustain a running-related injury (RRI) every year [1]. Various studies report that specific lower extremity adaptations (e. g. stronger foot muscles), induced by wearing minimalist shoes (MS), could theoretically lower the risk of RRI [2, 3]. Additionally, wearing MS is associated with a non-rearfoot footstrike pattern which has been shown in a retrospective study as a factor reducing the RRI incidence [4]. On the other hand, various cross-sectional studies reported that MS could cause a higher injury risk by increasing the forefoot plantar pressure [5-7]. Therefore, the aim of this study was to compare the overall injury incidence in runners using MS and runners using cushioned running shoes (CRS) during a 31-week follow-up.
METHODS: The experimental group (ER) of 30 MS runners (22 males, 8 females) was obtained from a database of the Healthy Aging in Industrial Environment Study—Program 4 (4HAIE) (36.1±13.8 yrs, 1.8±0.09 m, 74.6±11.3 kg, 25.5±21.0 km, 20.8±18.8 %). The control group (CR) consisting of 30 CRS runners (22 males, 8 females) was paired to ER according to their sex, age, height, weight, weekly training volume, and footstrike pattern [8] (36.2±13.1 yrs, 1.8±0.08 m, 74.8±12.6 kg, 24.0±17.3 km, 20.3±18.2 %). The protocols for the data collection are described in detail in our previous publications [9, 10]. For this study, we used data from weekly injury self-report (injuries count per runner, injury incidence per group) via the mobile app during a 31-week period after baseline measurement. A Wilcoxon signed-rank test was used to compare the injury occurrence between groups. Multiple linear regression was used to determine the relationship between injury incidence and shoe type, gender, or training volume. The alpha level was set at $P<0.05$.
RESULTS: There were 7 (ER) and 10 (CR) injured runners, respectively. Results of the Wilcoxon signed-rank test revealed that there was no significant difference in injury incidence between groups (ER: 23.3 %, CR: 33.3%, P=0.18). According to multiple linear regression analysis, shoe type (r_partial =0.1, P=0.46), gender (r_partial=0.07, P=0.61), and training volume (r_partial=0.2, P=0.14) were not significant predictors of injury in our study group.
CONCLUSION: The results of our study show that there were no significant differences in the injury incidence in using MS or CRS during a 31-week follow-up. These findings contradict the results of retrospective and cross-sectional studies [4–7]. Future studies should consider incorporating more specific injury related variables (biomechanical risk factors, specific injury sites) to assess RRI incidence in runners using MS compared to runners using CRS.

### INFLUENCE OF KICK DIRECTION AND KICKING FOOT ON KICKING PRECISION.

SHIMOTASHIRO, Y., SHINYA, M.

*HIROSHIMA UNIVERSITY*

INTRODUCTION: In soccer, accurately kicking to where a player aims is critical to successful play. A previous research has shown that the precision of kicks is influenced by the height of the aiming position (Hunter et al., 2018). However, the paper was the only study that investigated the precision of kicks in a quantitative way: no study has tried to quantify whether aiming to left or right influences the kicking precision. In addition, soccer players are required to kick with either the dominant or non-dominant foot. It is expected that variability in the kicks with the dominant foot is less that that with the non-dominant foot, however, no quantitative study has been conducted. The purpose of this study was to determine the effects of kick direction and kicking foot on kicking precision.
METHODS: The participants were six right-footed people with at least six years of soccer experience. The participants kicked using an instep kick aiming at a circular target with a 33 cm diameter. The target was placed just inside the goal post, 1.6 m above the ground. The distance between the kicking place and the target was 11 m. The conditions were the direction of the kick (right/left) and the kicking foot (right/left). The same condition was repeated 20 times. The order of the 4 conditions was counterbalanced between the participants. We used three cameras for our measurements (120 fps). We measured the ball position using the 2D DLT method. We analyzed the area, the long axis length, and the short axis length of the 95% equal probability ellipses as indices of kicking precision.
RESULTS: The 95% equal probability ellipse area was 3.34-13.82 m2 (min-max) for the dominant foot and 4.54-18.55 m2 for the non-dominant foot. The short axis length of the 95% equal probability ellipse was 1.54-3.97 m for the dominant foot and 2.34-4.04 m for the non-dominant foot. The long axis length of the 95% equal probability ellipse was 0.66-1.55 m for the dominant foot and 0.66-1.56 m for the non-dominant foot.
CONCLUSION: Our analysis quantified the superiority of the dominant foot in kick precision. The results suggest that the precise kick in the dominant foot was attributed to the smaller short axis of the 95% equal probability ellipse comparing to the non-dominant foot.

Hunter, A. H., Angilletta, M. J., Pavlic, T., Lichtwark, G., & Wilson, R. S. (2018). Modeling the two-dimensional accuracy of soccer kicks. Journal of Biomechanics, 72, 159–166.

### DO BIOFLUID MARKERS PROVIDE AN OBJECTIVE MEASURE OF THE EFFECTS OF SPORT-RELATED REPETITIVE SUBCONCUSSIVE HEAD IMPACT?

LEMBER, L.M.1, NTIKAS, M.1, MONDELLO, S.2, WILSON, L.1, HUNTER, A.1,3, DI VIRGILIO, T.G.1, SANTORO, E.2, DONALDSON, D.I.4, IETSWAART, M.1

*UNIVERSITY OF STIRLING, SCOTLAND UK1; UNIVERSITY OF MESSINA, ITALY2; NOTTINGHAM TRENT UNIVERSITY, ENGLAND UK3; UNIVERSITY OF ST ANDREWS, SCOTLAND UK4; * JOINT FIRST-AUTHOR; # PRESENTING AUTHOR*

INTRODUCTION: Exposure to routine head impacts, named sport-related Repetitive Subconcussive Head Impacts (RSHI), is increasingly thought to be associated with adverse long-term outcomes. Assessment of harm to the brain due to RSHI remains a major challenge because the effects are subtle and subjective, leading to an unmet need for accurate measurement tools. One promising solution is the use of biofluid markers to aid diagnosis and injury characterisation and help in medical decision-making. In this scoping review we therefore systematically examine the extent, nature and quality of evidence from studies investigating the effects of RSHI on fluid biomarkers.
METHODS: The review was carried out adhering to the Preferred Reporting Items for Systematic reviews and Meta-Analyses extension for Scoping Reviews. Seven electronic databases were searched (including databases from the EBSCO platform, Scopus, and Cochrane Library) using descriptors for subconcussive head impacts, biomarkers and contact sports. Publications evaluating biofluid markers following RSHI

exposure were considered irrespective of publication date. Studies were assessed for bias and quality, and results were structured primarily by marker and study characteristics.
RESULTS: Sixty-two 'relevant' original research reports were identified. Most studies assessed the acute and semi-acute effects of RSHI, while approximately a third investigated chronic effects. Most investigated markers were tau, neurofilament light (NfL), and S100 calcium binding protein B (S100B), while neuron specific enolase (NSE), glial fibrillary acidic protein (GFAP) and brain-derived neurotrophic factor (BDNF) were also included in a meaningful number of studies. RSHI were most researched in American football, boxing and soccer. Many of the studies 1) employed an observational analytic design, with few using an experimental design, and 2) were found to have methodological and design problems, primarily due to failure to control for confounding variables such as the effects of exercise. Overall, NfL and NSE were associated most clearly with RSHI effects, but definitive conclusions are constrained by the heterogeneous and limited nature and quality of the evidence base.
CONCLUSION: The results of this scoping review indicate that biofluid markers might be used to objectively measure the effects of RSHI; however, at present evidence must be treated with caution given the variable quality of the research. We use the gaps and limitations identified within the existing literature to formulate guidelines and research priorities for future clinical studies, including focused examination of specific biomarkers, the use of controlled studies and replication of findings across multiple sports. Improving the quality of biomarker research is essential to advance the field and define clinical utility of biomarkers in this setting.

**REPEATEDLY HEADING A FOOTBALL DIMINISHES ATTENTION, REDUCES LEARNING AND IMPAIRS MEMORY: EVIDENCE FROM AN EXPERIMENTAL IMAGING STUDY.**

NTIKAS, M.1, WILSON, L.1, KOURTIS, D.1, DONALDSON, D.I.2, IETSWAART, M.1

*1. UNIVERSITY OF STIRLING, 2. UNIVERSITY OF ST ANDREWS*

INTRODUCTION: There is growing concern that heading in football (soccer) brings significant risks to brain health. A recent survey of medical records of ex-professional football players in Scotland found them more likely to have developed dementia and other neurological diseases compared to the general population and more likely to die with Alzheimer's disease and Parkinson's disease. Such retrospective post-morbidity data cannot, however, directly examine the immediate consequences of heading footballs. Using a pre-vs-post heading experimental approach we have previously demonstrated changes in brain health due to heading, including impaired memory function. Building on that, we hypothesised that the electrophysiological correlates of attention, memory and learning will also be diminished after heading.
METHODS: The current study extended our previous work by examining football players performing twenty headers in a controlled environment using a ball projecting machine, compared to a control condition involving kicking the ball. We replicated the finding that memory function (Paired Associate Learning on the automated CANTAB cognitive assessment battery) was impaired after heading the ball. We also conducted fine-grained assessment of the neural correlates of attention and learning, using 64 channel EEG (electroencephalography) to record brain activity while participants (N=20) were performing cognitive tasks associated with attention (Oddball), inhibition (Go/No-Go) and learning (Semantic Verbal Associations).
RESULTS: Neural data from the Oddball task revealed a reduction in the magnitude of the P300 effect after heading the ball, but not after kicking the ball, suggesting a reduction in attention. Importantly, the effect was selective, with no equivalent reduction in brain activity during the Go/No-Go task, suggesting that inhibition was unaffected. In addition, neural data from the Semantic Verbal Associations task revealed a reduction in the magnitude of the N400 effect after heading (but not kicking) reflecting a reduced ability to learn new words.
CONCLUSION: Taken together these findings demonstrate that repeatedly heading a football leads to changes in functioning in multiple aspects of cognition, including attention, learning and memory. These findings strengthen concerns about the long-term influences of heading on brain health, adding additional evidence that repeated heading also has immediate effects on brain function.

### CP-MH05 Intervention and effect of study programmes

**PHYSICAL ACTIVITY AND ERGONOMIC INTERVENTIONS FOR DIFFERENT NURSING SETTINGS AND ITS EFFECTS ON WORKING ABILITY: A SYSTEMATIC REVIEW**

HEUEL, L., OTTO, A.K., WOLLESEN, B.

*TECHNISCHE UNIVERSITAT BERLIN, UNIVERSITY OF HAMBURG*

INTRODUCTION: Nurse health in European countries is jeopardized by stress, lack of time, or shift work. However, given the increased need for nursing personnel due to demographic trends, retention of nurses work ability is essential. The aim of the current study was to systematically review physical activity intervention studies and associated effects on the work ability of nurses.
METHODS: The review was preregistered on PROSPERO International Prospective Register of Systematic Reviews (CRD42021239665). Following PRISMA guidelines, three electronic databases (CINAHL, MEDLINE, and PsycINFO) were searched. The search identified intervention studies within three settings (hospital, outpatient, and elderly care) by combining search terms such as "nurses", "physical activity", "musculoskeletal disease", and "stress" and related synonyms thereof. Quality assessment of studies was performed by applying 14 quality criteria of the "Standard quality assessment criteria for evaluating primary research papers from a variety of fields" from the Alberta Heritage Foundation.
RESULTS: N = 30 studies with moderate quality (M = 0.73) intervened predominantly in the hospital setting (n =24; outpatient care n = 2; elderly care n = 2; mixed settings n = 3). Content, total intervention time and outcome parameters varied strongly between studies. Short-term positive effects on work ability exhibited n = 25 studies. Merely n = 14 studies reported follow-up measurements. Programs comprised of ergonomic work behaviors (n = 12), strength and endurance training (n = 8), physiotherapy (n = 4), Back School training (n = 3), and Yoga (n = 2). Yoga and Back School training improved outcome parameters such as pain and stress perception, sleep quality, and mindfulness, while strength and endurance training was linked to increased exercise-specific self-efficacy. Ergonomic work behavior can be addressed via didactical and practical programs, as well as by the provision of assistive lifting equipment. Physiotherapy yields positive results on work ability by applying an individual approach to the complaints of nurses.

CONCLUSION: The current results indicate the efficacy of physical activity-based health promotion with regard to work ability of nurses. However, effects typically diminished with follow-up measurements. More long-term intervention studies are necessary to maintain positive effects. Furthermore, evidence in the settings of elderly and outpatient care is scarce. Therefore, high-quality, setting-specific intervention trials are necessary to research the efficacy of physical activity and ergonomic work behavior on work ability in different care settings.

### NECESSITIES AND DESIRES OF PERSONS WITH OCCUPATIONAL DISEASES FOR A SPORTCOACH

VREULS, R., WEBER, E., STOLZ, I., ANNEKEN, V.

*FIBS GGMBH*

Introduction
A sport-related lifestyle takes on a significant role in the context of preventive and rehabilitative dimensions. In this regard, one aim of the project „Inclusion through Sport- applying a sportcoach for advising, accompanying and mediating of persons with occupational diseases into sport and an active lifestyle, by the German Social Accident Insurance Institution for the health and welfare services (BGW), is about the collaboration of sportcoaches with persons with occupational diseases. The collaboration starts after the participants completed their medical rehabilitation and the sportcoaches accompany them into organized or self-organized sports programs via a one-to-one consulting process. Next to that, in this pilot study a preferred and suitable method for implementing a sportcoach will be investigated. For this reason, the evaluation of all involved parties is important, in particular the participants. Therefore, the necessities and desires of persons with occupational diseases for a sportcoach during the project period are depicted here.
Methods
Participants go through an 18 months intervention time within four measurement periods in total. The research project uses a mixed-methods study design and participants were included from five regions, which are set by the BGWs regional distribution, throughout Germany. At each measurement period, participants evaluate the collaboration with their sportcoach (e.g. satisfaction, progress, behaviour, skills, etc.) in a structured interview.
Results
A total of 49 participants were included in the study. Interviews were analysed using Mayring (2010) qualitative content analysis. First results show that there is a huge discrepancy among the participants' sporting activity at starting point, which led to various participants' goals and therefore to different desires and necessities. Furthermore, it could be shown that participants' necessities and desires for a sportcoach differ over time. Hence, at t1 most mentioned desire for a sportcoach was to get healthier long-term by using a customized sport program/ method designed by the sportcoach. During t2 and t3 analysis revealed that the participants' desire was to gain more in-depth information and advices about preventing from falling back into physical infirmity. However, the actual need for a sportcoach declined for most participants.
In addition, all participants indicated that they appraised the sportcoach's knowledge, persistence and his/her presence led to an increase in motivation to continue their sport program. In addition, all participants stated that good communication is eminent and a necessity for the process.
Discussion & Conclusion
Preliminary results have shown that the one to one sport coaching can be beneficial for a wide range of participants. Furthermore, the sportcoach's services has led to an increase in motivation, enthusiasm and self-confidence of persons with occupational diseases towards physical abilities.

### DEVELOPMENT OF A SYSTEM AIMED AT IMPROVING MOTIVATION FOR SQUAT TRAINING

INOUE, Y., TOMONARI, H., YASUTOME, S.

*OSAKA INSTITUTE OF TECHNOLOGY*

Introduction
In recent years, people have begun to exercise for their health. However, many people find it difficult to exercise continuously and often drop out of training before realizing the benefits of exercise. In this study, we considered that a more enjoyable and motivating training system would increase the enjoyment of exercise and lead to continued exercise. Therefore, we developed a system that makes people performs squats by presenting visual and auditory feedback. In addition, as a new approach, we attempted to use real-time recognition of the participants facial expression to evaluate the enjoyment of exercise.
Methods
In order to compare the effect of the contents on the participants, four types of contents were created using Unity: the first one displays only text (text condition), the second one counts the number of squats with an avatar squatting with one participant (avatar condition), the third one displays the avatars cheer while dancing, and at four avatars appear every two seconds (cheering condition), and the fourth one presents an avatar lying down and simply watching over the participant (watching condition). The participants were 16 healthy male university students. They were asked to experience four contents in one day. The measurement items were electrocardiogram, 6 types of facial expression recognition, a questionnaire at the end of each content, and a final questionnaire after the completion of all the contents.
Results
The heart rates were 101-105 beats per minute during the content experience, about 10 beats higher than that at rest. In the facial expression recognition, neutral facial expressions were shown about 60% of the squatting time, and happy expressions were expressed about 20%. Negative emotions (anger, fear, sadness, and surprise) were about 20%. The results of the final questionnaire showed that the avatar condition and the cheering condition were more effective enjoying exercise and increasing motivation. In the watching condition, many participants answered that their motivation did not improve much.
Discussion
The results of this study indicate that, for the purpose of exercise continuation, it is effective to have an avatar on the display that trains with the participants and cheers for the participants as a feedback display. Future prospects include increasing the number of movement patterns of the avatar and presenting instructions on effective squatting methods. We conclude that by conducting research with a wider range of participants, we can find a more effective feedback method that is appropriate for younger and elder people.

### ICT-ENABLED COOPERATIVE LEARNING IN PHYSICAL EDUCATION

RÉVÉSZ, L.

*ESZTERHÁZY KÁROLY CATHOLIC UNIVERSITY*

Introduction
There is an extensive international and national literature on the potential and impact of integrating ICT tools in education. However, the use of ICT in the physical education is not universal and its applicability is often questioned due to the nature of physical education lessons. In the present study, the authors investigated how ICT tools used in PE lessons determine student achievement and motivation.
Methods
A four-week intervention programme included the use of ICT devices and applications (smartphone, website, Runtastic, Facebook) by students in PE lessons. The research was carried out in two study groups and one control group. The participants were secondary school students (n=85), 21 boys (24.7%) and 64 girls (75.3%), with an average age of 16.6 years. During the research, the students participated in a 12 lesson project, where the Experimental 1 group took part in lessons supported by ICT tools, while the Experimental 2 group did not use ICT tools. During the study, the change in students performance was measured by a 20 m shuttle-run test (psychomotor endurance test), the change in perceived motivational climate was measured by the PMCSQ-2 questionnaire, while the change in motivation was measured by the SMS questionnaire.
Results
Results show that in the group where ICT tools were used, students performance improved significantly, students increased the distance they ran and the time they ran, students task orientation and intrinsic motivation increased. In the group not using ICT tools, performance also improved as a result of the intervention, although there was an increase in ego-orientation and an increase in amotivation at the end of the project.
Discussion
Based on our results, we can conclude that ICT tools have a place in the teaching of physical education, as they increase students performance and motivation. Pupils performed better when given the opportunity to use ICT tools, were more interested in physical education lessons and were motivated to implement the 12-hour intervention. Pupils who did not use ICT tools had lower interest and did not strive for high levels of performance.

### THE EFFECTIVENESS OF ATTENTIONAL STRATEGIES ON THROWING PERFORMANCE AND GAZE BEHAVIOR OF SELF-PACED TASKS UNDER FATIGUE AND NON-FATIGUE CONDITIONS

KISLEV-COHEN, R.1,3, ZIV, G.2, LIDOR, R.2,3

*1. HAIFA UNIVERSITY, 2. THE ACADEMIC COLLEGE AT WINGATE, 3. WINGATE INSTITUTE*

INTRODUCTION: It has been widely accepted that an external focus enhances motor performance and learning relative to an internal focus. While evidence exists, the available literature still lacks studies that incorporate physiological stress. Specifically, the relation between attentional focus, gaze behavior (Quiet Eye; QE) and performance under these conditions is lacking. Therefore, the purpose of this study was twofold: (a) to examine the effectiveness of attentional strategies on learning and performance of a closed, self-paced motor task under rested and fatigue conditions, and (b) to examine the effectiveness of these strategies on QE duration under both settings.
METHODS: Sixty-four male (n=31) and female (n=33) adults (age = 26.19 + 4.04) novice in dart-throwing skill participated in our study. They were randomly assigned to three attentional groups (Internal - I, External – E, and Control - C). The participants in all groups received technical throwing instructions. In addition, the I group received instructions to focus attention on their arm movements, while the E group received instructions to focus their attention on the bullseye and the dart.
The study was composed of two phases. In Phase 1, the dart-throwing skill was learnt and performed by the participants during acquisition, retention, and transfer sessions. On phase 2, the participants were randomly assigned to performed either upper or lower repeated sprint protocol and following the exertion, performed the motor task. Gaze behavior and performance were analyzed during all phases.
RESULTS: During acquisition and retention stages, the participants in both I and E groups performed better compared with the C group, reflecting in lower Absolute Error, Variable error and Target Misses. During the transfer phase, all groups were less proficient and only the I group displayed an improved performance compared with the C group. Longer QE was measured in the E group compared with the I (only in the acquisition phase) and C groups during all stages and conditions. In phase 2, the performance of the I and E groups was reduced, yet both were able to maintain longer QE duration compared with the C group. For example, the QE durations during the fatigue stage were for the E group (1347.12+547.06 msec), I group (1106.52+602.69 msec) and C group (741.93+390.44 msec).
CONCLUSION: The results of the current study suggest that providing attentional instructions to novice participants will improve their performance and lengthen their QE compare to not providing attentional instructions. Both attentional groups were able to maintain a longer QE under the fatigue conditions, while in the C group a reduction was apparent. Yet, this was not translated to improved performance under these conditions since reduced performance was apparent. In order to elucidate how the ability to lengthen the QE duration under strenuous conditions might benefit performance, additional research is needed using different populations and expertise levels.

### EFFECTS OF A PHYSICAL EXERCISE PROGRAM IN WORKERS WITH SEDENTARY OCCUPATIONS ON ANTHROPROMETRIC MEASURES, PHYSICAL CONDITION AND PRODUCTIVITY COSTS ACCORDING TO GENDER

JIMÉNEZ DÍAZ-BENITO, V., ZAFRA DÍAZ, S., SANTACRUZ LOZANO, J.A., CLEMENTE REMÓN, A.L., ESPADA MATEOS, M., MARTÍN RODRÍGUEZ, M., JIMÉNEZ-BEATTY, J.E., BARRIOPEDRO MORO, M.I.

*UNIVERSITY OF ALCALA FACULTY OF MEDICINE AND HEALTH SCIENCES: UNIVERSIDAD DE ALC*

Objective: To assess the effect of a supervised physical exercise intervention in the workplace on anthropometric measures, physical condition and productivity costs in physically inactive workers according to gender.
METHODS: A pre-experimental study was conducted in office workers with sedentary occupations. Recruited participants underwent a physical exercise intervention (n = 75; mean age 43 ± 8 years). An intragroup analysis was carried out according to the gender of the subjects on anthropometric measures, physical condition and productivity costs.

Results: After the intervention, the men presented a significant decrease in their weight (p = 0.001; ?2 = 0.24), and improvements in balance (p = 0.009; ?2 = 1.71) and flexibility in the back (p = 0.011; ?2 = 0.46). Women had a reduction in weight (p = 0.003; ?2 = 0.22), BMI (p = 0.004; ?2 = 0.26), as well as improvements in cardiac recovery (p = 0.018; ?2 = 0.18). They also showed a significant increase in their scores in pectoral and triceps strength (p = 0.006; ?2 = 0.24). No differences in productivity costs were observed according to gender after the intervention (p > 0.05).
Conclusions: The 20-week supervised aerobic and strength physical exercise program with 3 weekly alternate-day training sessions could be effective in improving physical fitness in men and women, although no improvements in productivity costs were observed.

### MUSCLE-TENDON UNIT MECHANICS AND SPORTS PERFORMANCE

ARNDT, T.

*THE SWEDISH SCHOOL OF SPORT AND HEALTH SCIENCES*

The stretch shortening cycle (SSC) of muscle-tendon units is generally understood to facilitate stored energy during eccentric loading leading to increased performance in subsequent concentric actions. It is accepted to provide performance enhancement of the human musculoskeletal system, as seen for example in performance diagnostic tests such as countermovement jumps. The exact mechanisms underlying such a performance enhancement are however still not clearly understood.
One proposed mechanism is associated with a stretch-induced increase in steady-state force, referred to as residual force enhancement (rFE). There are indications that rFE generated during lengthening affects force depression when an eccentric action is followed by a concentric contraction. It therefore appears that stretch-induced rFE contributes to increased force and work during SSC. Recent studies have shown that SSC occur on the sarcomere level and that the SSC effect
is dependent upon the stretch-shortening velocity. The complexity of muscular mechanisms underlying the SSC effect is therefore receiving considerable attention, whereas the role of the tendinous tissue is less explored. Recent data investigating the effect of SSC on the non-homogeneous displacement of collagenous tissue in the human Achilles tendon will be presented and related to running performance.

### SPORTS INJURY BIOMECHANICS: SUCCESS STORIES, CHALLENGES AND OPPORTUNITIES

BAYNE, H.

*UNIVERSITY OF PRETORIA*

Injuries occur when the load applied to the tissue exceeds its capacity to withstand that load. Research on the biomechanics of sports injuries therefore aims to understand the injury mechanism by describing situational and behavioural factors, whole body motion, and detailed joint- or tissue-level biomechanics of the inciting event. With regards to acute onset injuries (e.g., anterior cruciate ligament rupture and concussion), this approach has yielded a body of evidence that provides the
basis for interventions to reduce injury risk. Gradual onset injuries present additional challenges as the inciting events are more difficult to identify. Recent technological advances pose new opportunities for enhancing our knowledge of injury mechanisms and effective injury risk reduction by moving biomechanical analysis out of the lab and into the field and providing real-time data.
Building on primary prevention goals, biomechanics also underpins comprehensive return to sport assessments that aim to reduce reinjury risk as neuromuscular deficits may not be detected by traditional screening tests. This presentation will discuss the successful integration of biomechanical research and practice for injury risk reduction and return to sport management, and the challenges and opportunities for progress in this area.

### OPTIMISATION OF SPORTS TECHNIQUES: HOW MODELLING AND SIMULATION CAN BE OUR HOLY GRAIL

CAZZOLA, D.

*UNIVERSITY OF BATH*

The ability to predict athletes' performance or the outcome of a specific intervention is the holy grail for sport scientists and coaches interested in either performance enhancement or injury prevention. Predictive computer simulation and modelling approach can now be used to support decision making processes and explore 'what if ' scenarios, particularly given the advancements made with this type of approach (e.g. ease of model development, tractability of performing simulations, computational power, and algorithm efficiency). However, the creation of a valid 'model' for the athlete, the availability of unique experimental datasets to train or validate the model, and the implementation of a realistic simulation framework are key challenges that hinder the actual applicability of such approach. In this talk, we will (i) explore what are the research questions that could be answered using modelling and computer simulations, (ii) discuss the key requirement for model development, and (iii) identify the most appropriate methods and algorithms to run realistic simulations. Finally, we will briefly discuss how to enable simulations to be performed routinely and with relative ease to inform changes in the techniques of athletes and the coaching principles, as well as supporting sport governing bodies in their decision-making processes.

## CP-PN04 Cardiovascular physiology and regulation

### REPRODUCIBILITY OF DEVICE-MEASURED SEDENTARY TIME AND PHYSICAL ACTIVITY IN PATIENTS WITH ARRHYTHMOGENIC CARDIOMYOPATHY. DO THESE PATIENTS MEET THE 2020 WHO GUIDELINES?

RUIZ-GONZÁLEZ, D.1, HIDALGO-MIGUELES, J.2, RAMOS-MAQUEDA, J.3, JIMÉNEZ-JÁIMEZ, J.4, SORIANO-MALDONADO, A.1

*1 SPORT RESEARCH GROUP (CTS 1024), UNIVERSITY OF ALMERÍA. 2 PROFITH RESEARCH GROUP, UNIVERSITY OF GRANADA. 3 LOZANO BLESA CLINICAL UNIVERSITY HOSPITAL. 4 VIRGEN DE LAS NIEVES UNIVERSITY HOSPITAL.*

INTRODUCTION: Major organizations universally recommend regular physical activity for the general population. However, in patients with arrhythmogenic cardiomyopathy (ACM), exercise has shown to trigger and accelerate disease progression, and exercise participation is generally restricted. Therefore, individuals with ACM may be susceptible to engage in low physical activity levels. This study aimed to describe the physical activity patterns using raw acceleration data in patients with ACM and to examine the reproducibility of accelerometer-based measures over 4 consecutive weeks.
METHODS: A total of 71 (49.6 [SD=17.5] years) patients with ACM wore a wrist-worn Axivity AX3 accelerometer for 30 consecutive days, and the raw signal was processed using the R-package GGIR. For descriptive analysis of metrics related to sedentary behavior and physical activity, participants were block-matched on sex, age (<50 years, >=50 years) and BMI. The participants were classified as meeting the 2020 World Health Organization guidelines if they engaged in >=150 min/week of moderate to vigorous physical activity (MVPA) using the previously proposed thresholds for wrist accelerometers [1]. The reproducibility of each metric was determined based on Intraclass Correlation Coefficients (ICCs; 95% CI) that were calculated using linear-mixed models adjusted for age, BMI, and season.
RESULTS: In total, 59.2% of participants did not meet the physical activity guidelines. ACM patients spent 71.1% of awake time in sedentary behavior (SED) and only 2.5% of awake time in MVPA. No significant differences were found in physical activity related variables between sex and age groups. However, patients >=50 years (n= 33) spent longer periods of sedentary time in comparison to those <50 years (mean difference 38.9 min/d, 95% CI 5.8 to 72.2, p = <0.05), and participants with obesity (BMI >=30 kg/m², n= 10) accumulated longer periods of SED and less MVPA than those without obesity. The ICCs ranged from 0.65 for MVPA (95% CI=0.57, 0.72) to 0.91 for light-intensity physical activity (95% CI=0.89, 0.93).
CONCLUSION: More than half of the patients with ACM did not meet minimum physical activity guidelines. Accelerometer-based classifications of activity are moderately stable over time, with some within-subject variability observed. It is highly advisable to assess the extent to which sedentary time and device-measured physical activity of different intensities are associated to the arrhythmic risk and other health outcomes in this population. It might be advisable to establish personalized recommendations for physical activity, taking into account the clinical circumstances and identification of individual barriers with the ultimate purpose of optimizing the care of people with ACM.

### HEART RATE VARIABILITY: HOW OFTEN AND WHICH PROTOCOL SHOULD WE USE IN ATHLETES?

CROGNALE, D., HORNER, K., ACHESON, T.

*UNIVERSITY COLLEGE DUBLIN*

INTRODUCTION: Heart Rate Variability (HRV) is a non-invasive measure commonly used in clinical settings to evaluate cardiovascular health and autonomic nervous system (ANS) function. In athletes/athletic populations it provides insight into recovery status and readiness for training. The majority of research in HRV is conducted in clinical populations, with a lack of detailed guidelines for use in athletic populations especially in relation to optimal frequency of measurement and protocol selection.
We hypothesized that a protocol taking the average HRV result from 2 tests per week (4 tests in total) would be a reliable monitoring tool for athletic populations.
METHODS: This test-retest reliability study assessed 16 athletes (5 male, 11 female, average age 22 y.o.) from an array of sports (including endurance, team sport, and combat sports). Participants were tested for HRV on 4 occasions over a two week period using a 30-minute, 3-lead electrocardiogram (ECG) BIOPAC measurement System. All tests were performed by the same operator, in standardized laboratory conditions (comfortable seated position, room temperature and brightness) at the same time of the day and on the same days of the week. The resulting data was then analyzed for inter- and intra-week reliability, as well as for accuracy when using shorter time periods for measuring HRV.
RESULTS: The study conducted showed that the use of an average of two 30-minute HRV measures within a one-week period is a reliable method to assess HRV (ICC = 0.798, CV = 5.88 +/- 4.34%) in standardized test conditions . Inter-week results were more reliable than intra-week results. It was also shown that shorter HRV measurements are as reliable as the 30minute reference measure when using this protocol.
CONCLUSION: HRV can be a reliable tool for monitoring autonomic function in athletic populations if suitable protocols are followed and standardized testing conditions are respected. Shorter protocols such as the one used in this study can give reliable results, and will allow longitudinal HRV monitoring to become more accessible to athletes and practitioners.

### WELL-TRAINED INDIVIDUALS HAVE AN EXAGGERATED BLOOD PRESSURE RESPONSE DURING EXERCISE TESTING

EITZEN, I.1, HEIMARK, S.2, VIANELLO, I., BØTKER-RASMUSSEN, K.G.1, MAMEN, A., HOEL RINDAL, O.M.1, WALDUM-GREVBO, B.2, SANDBAKK, Ø., SEEBERG, T.M.2

*1 DEPARTMENT OF SMART SENSORS AND MICROSYSTEMS, SINTEF DIGITAL, OSLO, NORWAY. 2 DEPARTMENT OF NEPHROLOGY, OSLO UNIVERSITY HOSPITAL, OSLO, NORWAY.*

INTRODUCTION: Blood pressure (BP) measurement is included as a regular component of exercise stress testing, in order to evaluate the physiological status of the individual and detect subclinical cardiovascular disease (CVD). However, the number of studies assessing systolic BP response (SBPR) during high-intensity exercise in well-trained populations is limited, and there is currently no consensus on what is to

be defined as a normal BPR during exercise for athletes. In addition, continuous bio-signal measurements are increasingly investigated to overcome limitations of intermittent cuff-based BP measurements during exercise testing. Therefore, the primary aim of this study was to investigate the SBPR during a lactate threshold and maximal cycle ergometer test in a population of well-trained male cyclists. As a secondary aim, we investigated whether pulse arrival time (PAT) measured with a novel cuff-less device can be used as a continuous SBP surrogate during exercise testing in an athletic population.
METHODS: Eighteen well-trained male cyclists were included (32.4 ± 9.4 years; maximal oxygen uptake 63 ± 10 ml/min/kg). The participants performed a stepwise lactate threshold test with 5-minute stages, followed by a stepwise test to voluntary exhaustion with 1-min increments when cycling on an ergometer. BP was measured with a standard automated exercise BP cuff, whereas PAT was measured continuously with a non-invasive physiological measurements device (IsenseU). Metabolic consumption was measured continuously during both tests.
RESULTS: Our findings confirm an exaggerated SBPR in well-trained individuals compared to suggested normative cut-off values. At lactate threshold (281 ± 56 W) and maximal intensity test (403 ± 61 W), SBP increased from resting values of 136 ± 9 mmHg to maximal values of 219 ± 21 mmHg and 231 ± 18 mmHg, respectively. The results further demonstrated that, on an individual level, PAT has a strong association with SBP, with linear within-participant regression lines between PAT and SBP at a mean of r2 of 0.81 ± 17.
CONCLUSION: This study provides new data on the SBPR in well-trained populations. The findings demonstrate higher SBPR at peak exercise compared to most comparable studies, and strengthen the assumption that athletes have different cut-off values than less trained populations. In addition, the results support the potential for using PAT as a surrogate measurement for SBP on an individual level. This has not previously been assessed in an athletic population with corresponding exercise intensities. However, our study population was limited. Comparison of results with the few existing studies on SBPR during exercise involving athletes is furthermore challenging, due to differences in reported exercise testing methods and protocols, BP measurement methods and determinations of SBP at maximum or submaximum workloads. Future research is needed to clarify the clinical implications of the high BPR in well-trained individuals.

## THE EFFECTS OF DIFFERENT TYPES OF RESISTANCE EXERCISE FOR LOWER LIMBS ON PULSE WAVE VELOCITY AND BLOOD PRESSURE IN ADULTS

CHUN-WEI, W., WANG, C.K., WANG, S.C., HE, C.S.

*NATIONAL CHUNG CHENG UNIVERSITY*

INTRODUCTION: Both isometric resistance exercise (IM) and isotonic resistance exercise (IT) can improve muscle mass and strength. Moreover, resistance exercise is beneficial in regulating blood pressure and the marker of arterial stiffness (pulse wave velocity, PWV). However, the current study did not determine the different effects of blood pressure and PWV between IT and IM. Therefore, the purpose of this study was to investigate the alterations of PWV and blood pressure after lower limbs IT or IM in healthy adult males.
METHODS: 28 participants from university were randomly divided into IM group (n = 14) and IT group (n = 14). Participants were asked to perform two trials respectively: the loads of isometric resistance exercise was 75% maximum voluntary isometric contraction (MVIC), the loads of isotonic resistance exercise was 75% one repetition maximum (1RM). Blood pressure and finger-toe PWV (ftPWV) were measured at pre-exercise (Rest), 0 min (T0), 15 min (T15), 30 min (T30), 45 min (T45), 60 min (T60), and 24 hour (T24H) after exercise. Two-way analysis of variance (ANOVA) was used to assess the differences between variables.
RESULTS: IM and IT group had a greater significantly increased in ftPWV at T0 post-resistance exercise than Rest (5.13 ± 0.54 vs 5.64 ± 0.47 m/s ; 5.13 ± 0.41 vs 5.62 ± 0.48 m/s ). In addition, the IM group at T45 (4.63 ± 0.47 m/s) were significantly lower than the IT group at T45 (5.03 ± 0.49 m/s) and IM group at Rest (5.13 ± 0.54 m/s). IM group had a greater significantly decreased in SBP and mean arterial pressure (MAP) at T45 post-resistance exercise than Rest (118.71 ± 10.51 vs 110 ± 9.03 mmHg ; 84.93 ± 5.12 vs 77.9 ± 7.09 mmHg ), heart rate (HR) and systolic blood pressure (SBP) significantly increased at T0 in both groups for resistance exercise (75.14 ± 14.57 vs 101.71 ± 18.7 bpm ;118.71 ± 10.51 vs 131.64 ± 10.25 mmHg).
CONCLUSION: The study showed that the significant reduction of ftPWV, SBP, and MAP was found in healthy adults participating isometric resistance exercise for lower limbs. Post exercise hypotension (PEH) was induced, which decreased to the lowest point at 45 minutes after exercise and returned to the baseline at 60 min and 24 hours later. In addition, there was no significant change in adults undertaking isotonic resistance exercise.

## EFFECTS OF HYDROXYUREA ON SKELETAL MUSCLE MICROVASCULATURE OF MICE WITH SICKLE CELL DISEASE

RICCETTI, M.1, MICHEL, C.P.2, BENDAHAN, D.2, MESSONNIER, L.A.1

*1UNIVERSITÉ SAVOIE MONT BLANC LIBM, 2AIX-MARSEILLE UNIVERSITÉ CNRS CRMBM*

INTRODUCTION: Hydroxyurea (HU), also known as hydroxycarbamide has been commonly used as a therapeutic strategy in Sickle Cell Disease (SCD) since 19841. HU has been recognized as efficient in SCD patients with an acceptable toxicity2. From a clinical point of view, HU has been shown to reduce painful episodes, hospitalizations, blood transfusions, acute chest syndrome and mortality3,4. These beneficial roles of HU are mediated by the increase of fetal hemoglobin (HbF) production and the decrease of abnormal hemoglobin (HbS) levelin erythrocytes. HU can then reduce the polymerization-sickling cascade thereby causing a decrease in the number of circulating sickled red blood cells5. HU also induces physiological changes such as an increase in both number and size of erythrocytes. It can also decreases hemolysis6. HU is also known as a nitric oxide (NO) donor which can directly affect the microvascular function. Although microvasculature is known to be remodeled in SCD (capillary rarefaction and enlargement8), the corresponding effects of HU have been scarcely reported. Given that HU improves hemorheologic and hemodynamic functions in SCD patients, one can hypothesize that HU may be beneficial for skeletal muscle microvasculature.
METHODS: Gastrocnemius muscles of 11 HbSS mice and 12 HbSS HU-treated mice (Townes model) were used to perform histochemical analyses. Morphometric analyses of microvasculature were performed by staining the endothelial cells with CD31 antibody. Microvascular network analysis included Capillary Outer Diameter (COD), Perimeter (CP), Surface Area (CSA), and Density (CD, number of capillaries per mm2) as well as the capillaries to muscle fibers ratio for a given muscle area (C/F). ANOVA and Tukeys post-hoc tests were used to compare data of HbSS and HbSS HU-treated mice. Significance was accepted when p≤ 0.05.
RESULTS: HbSS HU-treated mice displayed significantly higher COD, CP and CSA. than control HbSS mice (p = .033, p = .013, and p = .005 respectively, Figure 1). On the other hand, CD and C/F did not differ between HbSS and HbSS HU-treated mice (Figure 2).
CONCLUSION: Given that HU is a NO donor on the one hand and that NO can induce hyperemia on the other hand, one can hypothesize that that the widening of capillaries might be related to hyperemia related to HU-treatment. As supporting evidences, Bosman et al 9

reported that hyperemia induced capillary distension/enlargement while Kano et al.10 observed a reduced capillary luminal diameter in response to a reduced blood flow

### ASSOCIATION BETWEEN CARDIORESPIRATORY FITNESS LEVEL AND VISCERAL ADIPOSE TISSUE IN MIDDLE-AGED MALE RUNNERS

DOSTAL, T., SINDLER, D., CIPRYAN, L.

*UNIVERSITY OF OSTRAVA*

INTRODUCTION: Cardiorespiratory fitness (CRF) level is defined as a component of physiological fitness related to the ability of the circulatory and respiratory system to supply oxygen during sustained physical activity. Low CRF level is independently associated with increase in all-cause mortality and cardiovascular diseases risk (Barry et al., 2014). Abdominal obesity, especially the increase of visceral adipose tissue (VAT), is closely associated with increased mortality related to cardiovascular disease (Fang et al., 2018). Regular physical activity or exercise is associated with higher level of cardiorespiratory fitness and lower amount of visceral adipose tissue compare to inactive individuals. We assume, there will be association between CRF level and VAT in middle-aged male runners.
METHODS: 128 male-runners, with age 36-45 was obtained from a database of the Healthy Aging in Industrial Environment Study— Program 4 (4HAIE). VAT values were obtained via dual-energy X-ray absorptiometry (DEXA) and CRF level values (VO2max) were obtained during graded exercise test (GXT). The association between CRF level variable (VO2max) and visceral adipose tissue (VAT) the correlation analysis was used. Due to deviation of data from normality (Shapiro-Wilk test) the non-parametric Spearmen´s rho (ρ) correlation was used, level of statistical significance was set at level p value ≤ 0.05 for all test.
RESULTS: The statistically significant moderate negative association was observed between parameter of VO2max and VAT (ρ = -.565, p = .001) with r2 = 32%.
CONCLUSION: Our hypothesis was confirmed. We found statistically significant moderate negative association between parameters of CRF level and visceral adipose tissue in healthy middle-aged runners. These results confirm that higher level of cardiorespiratory fitness is associate with lower amount of visceral adipose tissue which can be considered as protective factor against cardiovascular diseases in these specific group population.

### EFFECT OF EXERCISE INTENSITY AND EXERCISE DURATION ON SALIVARY IGA SECRETION RESPONSE TO ACUTE EXERCISE

UCHINO, T.1, UCHIDA, M.1, FUJIE, S.1, INOUE, K.1,2, ITO, R.1, IEMITSU, K.1, SHINOHARA, Y.1, IEMITSU, M.1

*1>RITSUMEIKAN UNIVERSITY, 2>RESEARCH FELLOW OF JAPAN SOCIETY FOR THE PROMOTION OF SCIENCE*

INTRODUCTION: Salivary immunoglobulin A (s-IgA) secretion is the predominant antibody in mucosal fluids and plays a role of prevention of viral replication and inhibition of upper respiratory infection. High-intensity and/or prolonged exercise, such as a marathon, transiently induces depression of oral immune system function through reduced s-IgA secretion, and this state is called an “open window” (Kakanis et al., 2010). However, it is unclear whether s-IgA decreases depending on exercise intensity and exercise duration, that is, the onset point of the “open window” remains unclear. Therefore, we aimed to investigate the changes in s-IgA secretion response to acute exercise at different exercise intensity and exercise duration.
METHODS: Nine healthy young males with no exercise habits participated in two studies. Before starting the studies, we measured maximal oxygen uptake (VO2max) during an incremental cycle ergometer exercise test. [Study1] Subjects randomly performed three conditions: cycle exercise for 30 min at a work rate equivalent to 35%VO2max, 55%VO2max, and 75%VO2max. [Study2] Subjects randomly performed three conditions: cycle exercise for 30 min, 60 min, and 90 min at exercise intensity of 55%VO2max. Saliva samples were collected at baseline, immediately after, and 60 min after each exercise in both Study 1 and 2. The s-IgA secretion rate was calculated from s-IgA concentration and saliva flow rate per minute. The s-IgA concentration was measured by enzyme-linked immunoassay.
RESULTS: [Study 1] No significant differences in change in s-IgA secretion rate over time were observed at either 35%VO2max, 55%VO2max and 75%VO2max exercise intensity. However, the change in s-IgA secretion rate immediately after exercise at 75%VO2max exercise intensity was significantly lower than that at 55%VO2max (P<0.05). [Study 2] The change in s-IgA secretion immediately after exercise for 60 min and for 90 min was significantly lower than that for 30 min (for 60min, P<0.05 and for 90 min, P<0.01). In addition, the change in s-IgA secretion rate at immediately after exercise for 90 min was significantly lower to compare with the baseline (P <0.05) and return to baseline at 60 min after exercise (P<0.01). No significant differences in change s-IgA secretion rate over time were observed for 30 min and 60 min exercise.
CONCLUSION: These results suggest that the transient decrease in s-IgA secretion to acute exercise may be depending on both exercise intensity and the s-IgA secretion to acute exercise may decrease at 75% VO2max exercise intensity for 30min or at 55% VO2max exercise intensity for 60-90 min.

### CP-AP03 Warm - up / Recovery

### DOES PROPRIOCEPTIVE TRAINING INTERVENTION IMPROVE BALANCE SCORES IN COLLEGIATE WOMEN’S BASKETBALL PLAYERS WITHIN SIX WEEKS?

SHIM, A., ELDRIDGE, A., CESAR, G., RYAN, K., FIAUD, V.

*COLLEGE OF SAINT MARY*

INTRODUCTION: Several attempts have been made through several studies to derive variables that can improve overall balance scores in various sport athletes over the past several years [1,2]. Balance is an even distribution of weight that upholds an individual in the upright position. Proprioception training has been identified as an intervention that improves stability scores which could result in decreased ankle

injuries among college athletes who rely on quick movements of the lower limbs. However, there is no current investigation if an intervention on an unstable surface could improve Center of Pressure and Limit of Stability scores in collegiate women basketball athletes?
METHODS: Nine female college student athletes from a Midwestern University volunteered for the study (age 22.66±.87, height 174.77±4.12 cm, mass 76.56±9.17 kg, body mass index 25.06±2.75). A one group experimental pre-posttest design was selected for this study. Center of pressure (CoP) measurements was taken with the eyes open stable surface (EOSS), eyes closed stable surface (ECSS), eyes open perturbed surface (EOPS), and eyes closed perturbed surface (ECPS) using a Bertec Computerized Posturography Plate. Limit of Stability (LoS) were also assessed on a perturbed surface in 4 different body planes: left sagittal (LoSL), right sagittal (LoSR), frontal (LoSF), and posterior (LoSP). A 6-week intervention consisting of 15-minute sessions of shooting a basketball barefoot on a 0.5-centimeter soft mat surface from the 3-point line, twice a week occurred for the participants. A posttest assessment following the exact steps of the pre-test on CoP and Los measurements were taken after the intervention. Dependent t-tests were analyzed through SPSS (version 26) of pre to post scores of CoP and LoS scores.
RESULTS: There was no statistical difference within subject group with CoP scores EOSS ($p = 0.087$), ECSS ($p = 0.40$), EOPS ($p = 0.09$), and ECPS ($p = 0.19$). LoS variables indicated no statistically significant results LoSF ($p = 0.267$), LoSP ($p = 0.124$), LoSL ($p = 0.70$), LoSR ($p = 0.390$). The findings of our study did not match with similar studies previously performed on athletes [2].
CONCLUSION: A six-week intervention process of balance and proprioceptive training on a soft surface gym mat was found to have no significant changes on CoP variables EOSS, ECSS, EOPS, ECPS, or LoS variables of LoSF, LoSB, LoSL, and LoSR scores in women basketball players. Future studies should use a larger population, add session frequencies, and safely increase instability requirements on the intervention process.

## THE ACUTE EFFECTS OF VIBRATION FOAM ROLLING AND STATIC STRETCHING OF THE HAMSTRING MUSCLES ON RANGE OF MOTION, MUSCLE SHEAR MODULUS AND PHYSICAL PERFORMANCE

REINER, M., BERNSTEINER, D., TILP, M., KONRAD, A.

*UNIVERSITY OF GRAZ*

INTRODUCTION: Static stretching (SS) and foam rolling are common tools used as a warm-up routine. Both can acutely increase the range of motion (ROM) of a joint to the same extend (1). Moreover, a recent meta-analysis reported significantly favourable effects of foam rolling on performance when compared to static stretching (2). Although not clearly understood, it is assumed that foam rolling with an additional vibration has a more pronounced effect in increasing ROM compared to static stretching (3). Therefore, the first goal of this study was to investigate vibration foam rolling (VFR) or SS of the hamstrings on the hip flexion ROM, counter movement jump (CMJ) performance and hamstring maximum voluntary isometric contraction (MVIC) torque. Moreover, to understand a potential mechanism the shear modulus of three hamstring muscles (semitendinosus (ST), semimembranosus (SM), and biceps femoris long head (BFlh)) was measured pre and post both interventions.
METHODS: Twenty-five healthy male volunteers (mean ± SD; 27.62±6.63 years; 83.72±11.75 kg; 184.36±7.68 cm) were asked to visit the laboratory on two separate days within 48 hours and were randomly assigned to either a SS or a VFR treatment. Both interventions were performed continuously for 2 min on the hamstring muscles on both legs. Before and after each treatment, the shear modulus of the hamstrings of the right leg were measured with shear wave elastography and the hip flexion ROM was assessed using a sit and reach test. Moreover, MVIC of the right leg flexors was measured with a dynamometer and CMJ was performed on a force plate. After testing for normal distribution, two-way repeated measures ANOVA and if applicable t-tests were performed.
RESULTS: Following SS and VFR, ROM increased significantly by 8.0%, and 9.2%, respectively. However, no difference between the modalities was observed. Following VFR, muscle shear modulus of ST (-6.7%) and SM (-6.5%) deceased while there was no change in the shear modulus of BFlh. SS lead to a decrease in the shear modulus of the ST (-6.7%) only. Moreover, MVIC peak torque significantly decreased following SS (-5.1%), whilst no significant change was observed following VFR (+0.6%). Furthermore, no significant changes and differences were found in CMJ height.
CONCLUSION: According to our study and recent meta-analyses (2,3) it can be recommended that VFR should be preferably used as a warm-up routine compared to SS when the goal is to increase ROM without a subsequent decrease in performance.

## THE ACUTE EFFECTS OF PROPRIOCEPTIVE NEUROMUSCULAR FACILITATION STRETCHING WITH POST-STRETCHING DYNAMIC ACTIVITIES ON TISSUE STIFFNESS AND JUMP PERFORMANCE ARE MUSCLE- AND TASK-SPECIFIC

PATERNOSTER, F.K.1, SEIBERL, W.3, TILP, M.2, HOLZER, D.1, KONRAD, A.1,2

*[1] TECHNICAL UNIVERSITY OF MUNICH, [2] GRAZ UNIVERSITY, [3] UNIVERSITY OF THE BUNDEWEHR MUNICH*

INTRODUCTION: Proprioceptive neuromuscular facilitation stretching (PNF) incorporates static stretching and isometric contractions in a cyclical pattern. To overcome detrimental effects on performance parameters after stretching, post-stretching activities (PSA) were suggested [1]. During most stretch intervention studies testing for performance, all task-related muscle groups were stretched during the same intervention. Hence, possible positive effects of the intervention for one muscle group (e.g. quadriceps) might be cancelled out by negative effects for another muscle group (e.g. triceps surae), resulting in a lack of performance change [2]. Therefore, the aim of this study was to test jump performance parameters while stretching two task-specific muscle groups (quadriceps vs triceps surae) on separate days using PNF in combination with PSA (PNF+PSA). To further gain insight into possible mechanisms involved, tissue stiffness was measured.
METHODS: On two separate days, sixteen participants performed either PNF+PSA on the quadriceps or the triceps surae (PNF+PSAquad, PNF+PSAtri) for 60s on both legs. Participants stretched the target muscle for 10s, followed by 5-s maximal contraction of the target muscle in stretching position. This procedure was repeated three times. A force plate was used to test the performance of Countermovement-Jumps (CMJ) and Drop-Jumps (DJ) pre and post intervention. A MyotonPro device was used to measure tissue stiffness.
RESULTS: For DJ, ANOVA showed no effect for contact time (CT), however significant time effects (pre-post) for reactive strength index (RSI) and jump height (JH) ($p<.05$). Paired t-tests tests showed a large decrease ($d>1.1$) for RSI and JH after PNF+PSAtri and a small-to-medium decrease for PNF+PSAquad ($d>.25$). For CMJ, ANOVA showed no interaction or time effects ($p>.05$) on the tested parameters. Following PNF+PSAquad, overall quadriceps stiffness decreased ($p<.05$), however patella tendon stiffness did not change. In contrast, Achilles tendon stiffness decreased following PNF+PSAtri ($p<.05$, $d=0.83$), whereas triceps surae stiffness was unchanged.

CONCLUSION: Results showed that an acute bout of PNF+PSA on either the quadriceps or the triceps surae muscles influenced performance in fast, reactive but not slow muscle contractions (i.e., CMJ). For fast contractions involving strong time restrictions, PNF+PSA might disturb the well-coordinated interaction of the involved muscles and the series elastic component resulting in a performance decrease. Because of the lower time pressure for CMJ, these effects might play a less dominant role in CMJ. In contrast to previous research [2], this is the first study showing acute negative performance effects despite using PSA. Consequently, more research in needed to clarify the influence of PSA after stretching in acute settings.

## INTRAMUSCULAR TEMPERATURE CHANGES IN THE QUADRICEPS FEMORIS MUSCLE AFTER POST-EXERCISE COLD-WATER IMMERSION (10°C FOR 10 MIN): A SYSTEMATIC REVIEW WITH META-ANALYSIS

FREITAG, L.1, CLIJSEN, R.1,2,3,4, DEFLORIN, C.1, TAUBE, W.5, TAEYMANS, J.3,4, HOHENAUER, E.1,2,4,5

*1 UNIVERSITY OF APPLIED SCIENCES AND ARTS OF SOUTHERN SWITZERLAND, LANDQUART, SWITZERLAND; 2 INTERNATIONAL UNIVERSITY OF APPLIED SCIENCES THIM, LANDQUART, SWITZERLAND; 3 UNIVERSITY OF APPLIED SCIENCES*

INTRODUCTION: Post-exercise cold-water immersion (CWI) is a widely accepted recovery strategy for maintaining physical performance output [1]. However, existing review articles about the effects of CWI commonly pool data frequently from heterogenous studies and thus, do rarely differentiate between exercised muscles, CWI-protocols (duration, temperature, etc.), forms of activating the muscles before CWI, and thickness of the subcutaneous adipose tissue [2, 3]. This systematic review therefore aimed to investigate the effects of one particular post-exercise CWI protocol (10°C for 10 min) on intramuscular temperature changes in the quadriceps femoris muscle while accounting for skinfold thickness.
METHODS: An electronic search was conducted on PubMed, LIVIVO, Cochrane Library, and PEDro databases. Pooled data on intramuscular temperature changes were plotted with respect to intramuscular depth to visualize the influence of skinfold thickness. Spearmans rho (rs) was used to assess a possible linear association between skinfold thickness and intramuscular temperature changes. A meta-analysis was performed to investigate the effect of CWI on pre-post intramuscular temperature for each measurement depth.
RESULTS: A total of six articles met the inclusion criteria. Maximum intramuscular temperature reduction was 6.40°C with skinfold thickness of 6.50 mm at a depth of 1 cm, 4.50°C with skinfold thickness of 11.00 mm at a depth of 2 cm, and only 1.61°C with skinfold thickness of 10.79 mm at a depth of 3 cm. However, no significant correlations between skinfold thickness and intramuscular temperature reductions were observed at a depth of 1 cm ($r_s = 0.0$), at 2 cm ($r_s = -0.8$) and at 3 cm ($r_s = -0.5$; all $p > 0.05$).
CONCLUSION: The CWI protocol resulted in significant temperature reductions in the muscle tissue layers at 1 cm ($d = -1.92$ [95% CI: −3.01 to −0.83]) and 2 cm ($d = -1.63$ [95% CI: −2.20 to −1.06]) but not at 3 cm ($p < 0.05$). Skinfold thickness and thus, subcutaneous adipose tissue, seems to influence temperature reductions in the muscle tissue only to a small degree. These findings might be useful for practitioners as they demonstrate different intramuscular temperature reductions after a specific post-exercise CWI protocol (10°C for 10 min) in the quadriceps femoris muscle.

## EFFECT OF DRY-COOLING AND COMPRESSION SOCKS RECOVERY ON BLOOD LACTATE CONCENTRATION AND SOME PHYSIOLOGICAL VARIABLES AFTER ANAEROBIC EXERCISE IN TRAINED ATHLETES

AL GHAZWANI, A., ALJALOUD, K.

*KING SAUD UNIVERSITY*

INTRODUCTION: The effect of combining two recovery methods such as dry-cooling recovery (DCR) and wearing compression socks (CS) on blood lactate concentration and some physiological variables following anaerobic exercise such as Wingate test (30 seconds) in well trained athletes are not fully understood especially in short term approach.
METHODS: Total of 44 male athletes (aged: mean= 28.8 ±6.14) randomly grouped in this experimental design study into two experimental groups and one control group. Following signing the consent, participants underwent two laboratory visits. The first visit was to evaluate anaerobic power using Wingate test (30sec.). In the second visit, participants completed Wingate test followed with one of the recovery methods, dry-cooling recovery (DCR), dry-cooling recovery with compression socks (DCR&CS), or passive recovery (PR). The DCR group was exposed to (-20℃ for 2m), where DCR&CS group was exposed to (-20℃ for 2m) with wearing compression socks grad . Blood lactate concentration, heart rate and blood pressure were measured after Wingate test (30 seconds) at minutes (15-20-25-30-45-60).
RESULTS: Data of the present study reported lower lactate concentration and HR in both examined recovery methods (DCR and DCR&CS) compared to the passive method. Moreover, the recovery method of DCR&CS reported the lowest values significantly in both blood lactate and HR compared to the passive recovery method. However, no significant difference was found between DCR recovery method compared to the DCR&CS recovery method.
CONCLUSION: One of the potential benefits of DCR and CS methods is to decrease body temperature and increasing the mechanical pressure of the blood vessels and to improve related-metabolic recovery. consequently, the blood flow increases and cleaning rate of the metabolic wastes (Versey, N. G. 2013). Lovell et al. (2011), concluded that wearing compression socks during recovery stage of 60 minutes may increase recovery speed and reduce blood lactic concentration after strenuous exercise but does not affect blood pH (Lovell et al., 2011). While recent study found that wearing compression socks did not lead to significant effect on recovery indicators in elite judo (Brown et al., 2021), the results of the present study may explain that the combination of the two recovery methods DCR and CS together cloud help to improve recovery more compared to one recovery method such as DCR or CS. We suggest that the external pressure of the CS combined with the reduction in temperature may accelerate the reduction of blood lactic concentration and heart rate in intense anaerobic exercise. Thus, where possible, using both recovery methods DCR and CS may help for short term recovery (60 min) in well trained athletes. Further researches are encouraged to understand the mechanism of the effect of two methods to accelerate the recovery in athletes.

### COLD AND HOT WATER RECOVERY IN ELITE YOUTH FOOTBALL PLAYERS: THERMAL ADAPTATIONS DURING A TEN-WEEK TRAINING PERIOD.

FOLKESSON, M., PERNIGONI, M., FROLOVA, A., MONTIEL-ROJAS, D., BRAZAITIS, M., EDHOLM, P.

*ÖREBRO UNIVERSITY & LITHUANIAN SPORTS UNIVERSITY*

INTRODUCTION: Considerable physical demands are associated with frequent training sessions and matches in elite football and require optimal strategies for recovery. For this purpose, many elite players use immersion in cold (CWI) and/or hot water (HWI) following training and matches. Although shown to enhance recovery parameters, these approaches are physically stressful for the players, involving sweating or shivering, as well as discomfort. At present, little is known about the effects of long-term exposure to post-exercise CWI and HWI. The aim of the current study was to assess thermal adaptations to post-exercise CWI and HWI in elite youth football players during an intervention-period of ten weeks.
METHODS: Twenty-five elite male football players (15-20 years old) were assigned randomly to undergo either CWI (10°C for 10 min), HWI (42°C for 20 min) or 6 min sham-laser treatment (placebo; PLA) immediately after training at least twice each week for ten weeks. To compare their thermal adaptation prior to the intervention and after five and ten weeks, each player rated his thermal sensation (TS: 1-9; cold-to-hot), thermal comfort (TC: 1-5, comfortable-to-uncomfortable) and sweating/shivering (SS: 1-7, sweating-to-neutral-to-shivering) during the initial and final minute of CWI, HWI or PLA.
RESULTS: After prolonged post-exercise usage, players felt less cold during the first (TS after 5 weeks = 2.8±1.0, after 10 weeks = 2.4±1.1, Pre-intervention = 1.1±0.4, $p<0.05$) and final minutes of CWI (corresponding values at 10 weeks and Pre-intervention of 3.8±0.7 vs. 2.6±0.5, $p<0.05$). In addition, players reported reduced shivering during the final minute in CWI (SS at 10 weeks : 4.4±0.5 vs. Pre-intervention: 5.7±0.5, $p<0.05$). Players subjected to post-exercise HWI reported feeling less comfortable during the final minutes after 5 and 10 weeks compared to pre-intervention (TC:4.1±1.1,4.0±0.6, vs2.4±1.2, $p<0.05$). Treatment with the PLA modality resulted in no significant changes in any of the parameters examined.
CONCLUSION: Exposure of elite youth soccer players to either CWI or HWI following training at least twice a week for 10 weeks resulted in significant changes in their experience of the treatment. More specifically, CWI reduced the sensation of feeling cold and attenuated shivering, while HWI augmented the sensation of discomfort.

### OPTIMIZATION OF 10 M SPRINT PERFORMANCE WITH A SLED STIMULUS IN CONTRAST SPRINT TRAINING

PAIZIS, C.1, FURCHERT, P.1, COMETTI, C.1, METHENITIS, S.2, BABAULT, N.1

*1 UNIVERSITY OF BURGUNDY, INSERM U1093, CENTRE DEXPERTISE DE LA PERFORMANCE, DIJON, FRANCE. 2 NATIONAL AND KAPODISTRIAN UNIVERSITY OF ATHENS*

INTRODUCTION: Resisted sled sprint training used to improve sprint performance (1). Some authors studied the adaptations after a training period with sled training but not the immediate effect in contrast training (2). The aim of the present study was to examine the effect of load (on percentage of body weight) on 10 m sprint with a sled stimulus in the performance of the following 10 m sprint without sled in the context of contrast sprint training.
METHODS: Twenty-one subjects (20.8±2.2 yrs), after 15 min warm up performed 4 sprint in 10 m alternately with 3 sprint in 10 m with sled resistance. Rest of 2 min realized after each sprint. Subject performed in randomized order four training sessions separated from 1 week [1] control condition only sprint [2] sled 25% [3] sled 50% [4] sled 75%.
RESULTS: Time in 10 meters sprint decrease during the 2nd sprint after a sprint with a sled stimulus at 50% of body weight ((-1.9% compared to the 1st sprint) $P<0.05$). The speed at the second step and the amplitude of stride between the 2nd and 3rd step, are greater on the last 3 sprints of the condition at 50% with a sled push stimulus at 50% of body weight ((+6% for speed and +3% for amplitude stride to compared to the 1st sprint) $P<0.05$). No significant changes were observed for any sprint time after the control session of sprint and 25% and 75% body mass sled pull.
CONCLUSION: Ten-meter sprint performance in contrast training between sled sprint and normal sprint is potentiated 1min following a sled push loaded with 50% body mass while it is not affected after a 25% and 75% body mass sled or normal sprint in control condition. The determining factor of speed imporving seems to be the amplitude stride. These results are of great importance for coaches seeking to potentiate sprint performance in speed session with the sled exercise.

### EFFECTS OF MENTAL FATIGUE ON REACTION TIME IN ATHLETES

MIGLIACCIO, G.M.1, ORGIANA, T.1, CAMICIOTTOLI, M.1, MATTEO, M.1, PADULO, J.2

*<1> SPORT SCIENCE ACADEMY, ROMA, ITALY - <2> DEPARTMENT OF BIOMEDICAL SCIENCES FOR HEALTH, UNIVERSITÀ DEGLI STUDI DI MILANO, MILAN, ITALY*

Aim
Mental fatigue (MF) has been defined as a psychobiological state caused by prolonged periods of demanding cognitive activity and characterized by subjective sensations that are felt with the semantic expression of "fatigue" or "lack of energy" (Boksem & Tops, 2008; Van Cutsem et al., 2017)). However, mental fatigue plays a role in endurance athletes (Meeusen et al., 2021), while the impact of mental fatigue in motor task as reaction time (RT) to visual stimuli remains largely unknown.
Materials and methods
For this aim, 45 athletes (age 29.18±3.25 y) took party in this study. MF were induced by a routine of 15 minutes of Stroop Task (PsyTool), with 600 tasks and 5 different colours choice. Heart rate (HR) was recorded with Cardio-Polar H7 in pre-Stroop-Test, during Stroop-Test (every 5'), post-Stroop-Test and 1', 3' and 5' after post Stroop-Test. While RT were evaluated in pre and post Stroop-Test with a Cognitive Fun software. The variables considered was HR (bpm), RT on Pre-Stroop-Test (RTPR), RT on Post-Stroop-Test (RTPO). Univariate ANOVA and Bonferroni Post-hoc was used to compare HR in-between conditions and t-test to compare the RT performance before/after Stroop-Test. The significance level was fixed at priori as $\alpha < 0.05$.
Results

Analysis of variance (ANOVA) for HR showed a Fischer value of 6.051 and η2= 0.101 with p<0.001; while the post-hoc showed a significant difference (p<0.05) during the Stroop-Test (HR were 36.58±5.40, 40.31±6.36 and 42.87±7.36 %HRMAX at the 1st 2nd 3rd point, respectively) compared to the other conditions. RTPR and RTPO was 310.29±38.34 and 334.12±38.79 ms, with p=0.0029, respectively.
Conclusion
The present findings suggest that the parasympathetic branch of the autonomous nervous system functioning as a relaxation system tends to be activated under increasing mental fatigue with a decreased performance (RT). Therefore, the athletes could use MF induced during the training to improve the time delay related to the motor task.
These data have numerous implications. In the first place it suggests how MF has a direct relationship to the RT and how its alteration can become a determining factor in sports performance. Secondly, it suggests that the detection of HR can be used as a verification marker of mental fatigue, in the absence of physical fatigue.

#### ASSOCIATIONS BETWEEN CARDIORESPIRATORY FITNESS, MUSCULAR FITNESS AND ENDOCANNABINOIDS SYSTEM IN ADULTS WITH DIAGNOSED DEPRESSION: SONRIE STUDY

RUIZ-MUÑOZ, M.1,2, ORTEGA-GÓMEZ, S.1,2, JIMÉNEZ-PAVÓN, D.1,2, ESPINOSA-NOGALES, M.M.3, VALMISA, E.3, ROSETY-RODRÍGUEZ, M.A.1,2, ESPAÑA-ROMERO, V.1,2

*1 MOVE-IT RESEARCH GROUP, UNIVERSITY OF CÁDIZ - 2 INIBICA RESEARCH UNIT, PUERTA DEL MAR UNIVERSITY HOSPITAL - 3 MENTAL HEALTH CLINICAL MANAGEMENT UNIT, PUERTO REAL UNIVERSITY HOSPITAL, CÁDIZ.*

INTRODUCTION: Physical fitness is considered one of the most powerful indicators of health status, as well as predictor of morbidity and all-causes mortality (1,2). Endocannabinoids system (ES) is a widespread neuromodulatory network which appear to be modulate by physical fitness and seems to be altered in patients diagnosed with depression (3). Our aim was to examine the association of physical fitness, in terms of cardiorespiratory fitness (CRF) and muscular fitness (MF), with ES in adults with mild or moderate depression.
METHODS: ES ligands (AEA and 2-AG) were assessed in 85 participants (14 male) aged 25-65 years diagnosed with mild or moderate depression). CRF was measured by the 6 minutes walking test and MF by handgrip test. Stepwise linear regression models were used to examine associations of CRF and MF with ES biomarkers, adjusting for age, sex, smoking habits, cancer and diabetes disease.
RESULTS: CRF and MS were inversely associated with 2-AG (b coefficient: -50.96 and 95% confidence interval (CI): -82.58 to -19.34; b: -0.92 and 95%CI: -3.29 to 1.45 for CRF and MS, respectively) and positive associated with AEA (b: -53.62 and 95%CI: -103.52 to -3.71 for CRF and b: 1.05 and 95%CI: -2.72 to 4.82 for MS; all P values <0.01) after controlling for potential confounders.
CONCLUSION: Physical fitness components in terms of CRF and MS are associated with ES ligands after controlling for potential confounders in depressive adults. These results should stimulate a debate on whether the metabolism of ES could be a way in which the benefits of high fitness levels are exerted. Moreover, higher fitness level may be an additional target for clinical management of ES deregulation in depressive disorders.

#### INFLUENCE OF CHRONOTYPE AND HABITUAL TRAINING TIME-OF-DAY ON RATING OF PERCEIVED EXERTION IN YOUNG ADULTS

TOMMASINI, E., BARFUCCI, L., CARELLA, A., COLOMBO, T., COMBI, G., CURNIS, V., MARINONI, G., PINCIROLI, S., GALVANI, C.

*UNIVERSITÀ CATTOLICA DEL SACRO CUORE*

INTRODUCTION: To date, there has been little agreement on circadian variation in sports performance. It seems that both chronotype and habitual training time-of-day (HTT) need to be considered when assessing diurnal variation in performance [1]. Therefore, the aim of this study was to evaluate if chronotype and HTT may influence the rating of perceived exertion (RPE) after two different intensity trials performed in three times of day.
METHODS: The chronotype of participants (N56: age 23.8±2.1 yrs, BMI 22.1±2.0 kg/m2, V'O2max 40.1±9.1 ml/kg/min) was assessed using the Morningness Eveningness Questionnaire (MEQ) [2] and their maximal oxygen uptake (V'O2max) was determined via direct gas analysis (Fitmate-Pro, Cosmed, Italy) on a cycle ergometer (LC6, Monark, Sweden) using a submaximal exercise-based protocol. Subjects' HTT was objectively evaluated using an activity monitor (Lifecorder Plus, Kenz, Japan) worn for one week. Participants performed two 6-minute bouts of exercise on cycle ergometer at 60% and 90% of V'O2max at 8.30am (morning trial, MT), at 1.00pm (afternoon trial, AT) and at 5.30pm (evening trial, ET) in a randomised order. Training sessions were interspersed by 48 hours. After each session, participants reported their RPE (CR10) [3].

RESULTS: Distributions of chronotype and HTT were 27% of Morning-types (M-type), 59% of Neither-types (N-type) and 14% of Evening-types (E-type) and 21% of subjects trained in the morning, 55% in the afternoon and 23% in the evening, respectively. When the RPE of all the subjects were examined as a whole, there was no difference between the MT, the AT and the ET (60% V'O2max MT: 3.0±1.5, AT: 2.9±1.4, ET: 2.8±1.5; 90% V'O2max MT: 7.3±2.4, AT: 7.1±2.4, ET: 7.0±2.3). No time-by-group interaction effect on RPE was observed when participants were grouped by chronotype (60% V'O2max p=0.2931; 90% V'O2max p=0.7653) or HTT (60% V'O2max p=0.9370; 90% V'O2max p=0.9862). However, M-type reported lower RPE scores post MT and E-type post ET both at moderate (60% V'O2max M-type_MT: 2.6±1.1, AT: 3.3±1.7, ET: 3.1±1.5; E-type_ MT: 3.3±2.0, AT: 2.7±0.9, ET: 2.6±1.8) and vigorous (90% V'O2max M-type_MT: 6.8±2.7, AT: 7.3±2.8, ET: 7.4±2.1; E-type_ MT: 7.4±2.2, AT: 7.0±1.9, ET: 6.4±2.5) exercise intensity. Interestingly, the same trend was not observed for RPE and HTT.
CONCLUSION: In contrast to previous study findings [1], neither chronotype nor HTT have significantly influenced diurnal variation in RPE. Nevertheless, the lowest RPE scores found post MT for M-type and post ET for E-type, regardless of their HTT, seem to suggest that only chronotype might influence RPE. Future research needs to confirm this hypothesis.

### ATHEROSCLEROTIC CARDIOVASCULAR RISK IN PARALYMPIC ATHLETES WITH A LOCOMOTOR IMPAIRMENT: BENEFICIAL EFFECTS OF HIGH AEROBIC FITNESS AND PRACTICED SPORT

BERNARDI, M.1, DI GIACINTO, B.2, SQUEO, M.R.2, PELUSO, I.3, CAVARRETTA, E.4, ROMANO, S.5, DELLA PORTA, S.1, VALENTINI, F.1, ADAMI, P.E.6, SCIARRA, T.7, SPATARO, A.2, PELLICCIA, A.2

*1:SAPIENZA UNIVERSITY ROME; 2:SPORT & HEALTH; 3:COUNCIL FOR AGRICULTURAL RESEARCH AND ECONOMICS ; 4:SAPIENZA UNIVERSITY ROME; 5: L'AQUILA UNIVERSITY; 6:WORLD ATHLETICS; 7:ARMY MEDICAL CENTER.*

INTRODUCTION: Atherosclerotic cardiovascular disease (ACVD), the leading cause of morbidity and mortality in individuals (I) with a locomotor impairment (LI), occurs at earlier ages in I-LI than in ambulatory individuals because I-LI, in particular those with a spinal cord injury (SCI), display a higher prevalence of ACVD risk factors (RF) mainly due to their increased sedentary habit. However even in Paralympic Athletes (PA) with a LI (PA-LI) the prevalence of ACVD-RF is very high. We tested the hypotheses that both a high oxygen uptake peak (VO2peak) and different types of practiced sport (skilled sport – SS; power sports – PS; intermittent, aerobic and anaerobic mixed metabolisms, sports – IS; endurance sports – ES) affect ACVD-RF prevalence, which is supposed to be low in PA-LI competing in ES and having high VO2peak.
METHODS: Data from a total of 118 male PA (62 PA-SCI and 56 PA with other health conidiations (HC) determining a LI – PA-OHC) were retrospectively evaluated. Thirty-six PA competed in SS, 20 in PS, 42 in IS and 20 in ES. They had been screened through anthropometric and blood pressure (BP) measurements and laboratory blood tests to estimate an ACVD-RF score summing 1 point for each of the following RF: central obesity –OB- (waist circumference ≥102 cm), hypertension –HT- (rest systolic BP ≥ 140 mm Hg and/or diastolic BP ≥ 90 mm Hg), dyslipidemia -DL- (total Cholesterol -TC ≥200 mg·dl-1 or LDL-C ≥130 mg·dl-1 or HDL-C <40mg·dl-1), impaired fasting glucose -IFG (glycemia≥100 mg·dl-1) and subtracting 1 point when serum HDL-C was higher than 60 mg·dl-1. All PA underwent to an incremental cardiopulmonary maximal exercise test to assess VO2peak.
RESULTS: Prevalence of HT, TC, LDL-C, low-HDL-C, IFG and OB were equal to 8.1% and 8.9%, 39.3% and 41.2%, 45.2% and 41.1%, 27.9% and 24.3%, 33.9% and 32.1%, 19.4% and 7.1% in PA-SCI and PA-OHC, respectively, being significantly different only the OB prevalence (p=0.046). Based on the ACVD-RF score, 3 ACVD-RF groups were formed: group 1 (RF≤0, N=43, 13 PA competing in ES, 15 in IS, 8 in PS and 7 in SS), group 2 (RF=1, N=43, 6 PA competing in ES, 16 in IS, 8 in PS and 13 in SS), group 3 (RF≥2, N=32, 1 PA competing in ES, 11 in IS, 4 in PS and 16 in SS). Grouping the PA depending on sports and ACVD-RF determined a significant difference ($\chi 2$), indeed 65% of PA competing in ES had no ACVD-RF while 30% and 5% were in Group 2 and group 3, respectively, while 6.3% of PA competing in SS were in group 1 and 50% in group 3. VO2peak equal to 36±8.3 ml/kg/min in PA of group 1 was significantly higher than the VO2peak of PA included in group 2, equal to 31±8.9, which was significantly higher than that of the PA of group 3 (25±7.5).
CONCLUSION: Prevalence of RF was similar in the 2 groups of HC, with the exception of OB which was more prevalent in PA-SCI. DL had a relevant and dangerous prevalence in PA regardless the HC. Competing in ES and having high levels of VO2peak seems to provide a protective effect against the risk of developing ACVD.

### MODERATE-INTENSITY AEROBIC EXERCISE UNDER HIGH FINE PARTICULATE MATTER CONCENTRATION ACUTELY AUGMENTS PULSE WAVE REFLECTION IN HEALTHY YOUNG MEN

SON, J., KIM, J., PARK, S., LEE, Y., HWANG, M.

*INCHEON NATIONAL UNIVERSITY*

INTRODUCTION: Fine particulate matter (PM2.5) influences arterial stiffness, an independent predictor for cardiovascular diseases. Regular aerobic exercise has been demonstrated to be an effective behavioral intervention to improve arterial stiffness. However, the effect of aerobic exercise on arterial stiffness under higher level of fine dust environment has not been completely understood. Therefore, the purpose of this study was to investigate the acute effects of moderate intensity aerobic exercise on various arterial stiffness measures in young adults at the two different PM2.5 conditions (high vs. low).
METHODS: Seven young men (23-27 years) were recruited for this study with a randomized crossover design. Participants performed 30 minutes of treadmill running at 70% of peak heart rate under both high PM2.5 (HPM) and low PM2.5 (LPM) conditions. Arterial stiffness indices were measured before and after the exercise intervention. To assess aortic stiffness, both carotid-femoral pulse wave velocity and augmentation index adjusted at 75 beats per minute of heart rate (AIx@75) were measured by SphygmoCor Xcel System. Carotid arterial stiffness was assessed by using the Aloka Prosound α7 ultrasound system and the FDA-approved Cardiovascular Suite software.
RESULTS: After acute moderate-intensity aerobic exercise under HPM, AIx@75 was significantly increased (P = 0.007). However, in response to the exercise, there were no significant changes in the other arterial stiffness measures under HPM and also no significant alterations in any arterial stiffness indices under LPM.
CONCLUSION: In conclusion, acute moderate-intensity aerobic exercise under HPM adversely influences on wave reflection, a measure of arterial stiffness.

**ACUTE AEROBIC EXERCISE UNDER HIGH FINE PARTICULATE MATTER CONCENTRATION NEGATIVELY MODULATES BRACHIAL ARTERY FLOW-MEDIATED DILATION RESPONSE TO ITS PHYSIOLOGICAL STIMULUS**

LEE, E., KIM, J., PARK, S., SON, J., HWANG, M.

*INCHEON NATIONAL UNIVERSITY*

INTRODUCTION: Fine particulate matter (PM2.5) is one of the air pollutants attracting global attention recently. High-level PM2.5 introduced into human body has a negative effect on vascular endothelial function by increasing both local and systemic oxidative stress and inflammation. Regular aerobic exercise plays a critical role in improving brachial artery flow-mediated dilation (FMD), a validated non-invasive measure of human vascular endothelial function. However, the effect of aerobic exercise under high PM2.5 concentration on vascular endothelial function has not been clearly elucidated. Thus, the purpose of this study was to investigate the effect of moderate intensity aerobic exercise under high PM2.5 level on brachial artery FMD in young adults.
METHODS: A randomized crossover research design allowed seven young men (25±1 yrs) to perform 30 minutes of treadmill running at 70% of peak heart rate under both high PM2.5 (HPM) and low PM2.5 (LPM) conditions (57±1 vs. 7±1 μg/m3, P=0.002, HPM vs. LPM). To assess participants' vascular endothelial function, we measured brachial artery FMD using Aloka Prosound α7 ultrasound system and FDA-approved Quipu Cardiovascular Suite analysis software.
RESULTS: Compared to pre-exercise measures, there were no significant changes in both absolute FMD (0.29±0.05 vs. 0.29±0.05 mm, P=0.5, pre vs. post) and relative FMD (8.05±1.41 vs. 7.80±1.50 %, P=0.338 pre vs. post) responses to the aerobic exercise in HPM condition. Interestingly, FMD adjusted for shear rate area under the curve (FMD to SRAUC) was significantly decreased after the aerobic exercise only in HPM condition (0.14±0.02 vs. 0.10±0.02 a.u., P=0.02, pre vs. post). In LPM, absolute and relative FMD, and FMD to SRAUC did not change after the aerobic exercise (P >0.201).
CONCLUSION: Moderate intensity aerobic exercise under HPM level may adversely influence on FMD response to its physiological stimulus even in healthy young adults.

**SYNERGISTIC EFFECT OF ACUTE SELF-PACED RUNNING AND SOCIAL CONNECTION ON CIRCULATING ENDOCANNABINOIDS LEVEL AND AFFECT: A RANDOMIZED AND COUNTERBALANCED CROSSOVER TRIAL**

TETSUYA, Y., ANDO, D., KOYAMA, K.

*YAMANASHI GAKUIN UNIVERSITY*

INTRODUCTION: The number of patients with psychiatric disorders such as depression is increasing, and these diseases are suggested to difficult to completely cure. Although exercise itself might work as a primary prevention of depression, it is unclear the situation where to be done is optimal. The aim of this study was to investigate the synergistic effects of exercise and social connection during exercise on blood endocannabinoid (eCB) level and affect.
METHODS: Twelve young males participated six 20-min experimental trials: resting alone (1R), paired resting (2R), paired resting with cooperative task (2Rtask), exercise alone (1E), paired exercise (2E), and paired exercise with cooperative task (2Etask). The exercise consisted of a 20-minute submaximal treadmill running at the intensity that the participants felt comfortable. 2R and 2E trials allowed the participants to verbal and nonverbal communication during each trial. In cooperative tasks (2Rtask and 2Etask) promoting active and deeper interaction between 2 participants, one monitored the others heart rate (HR) and instructed to maintain HR within target HR range (2Rtask, + 5 bpm of resting HR; 2Etask, ± 5 bpm of 50% HR reserve), and vice versa.
Before and immediately after experimental trial, plasma concentrations in eCB, namely anandamide (AEA) and 2-arachidonoylglycerol (2-AG) were measured, and affect state was also evaluated by the physical activity affect scale consisting of four subscales: positive affect, negative affect, fatigue, and tranquility.
RESULTS: The average running speed in 2Etask (7.8 ± 1.1 km/h) was significantly lower than those in 1E (9.1 ± 1.1 km/h, p = 0.02) and 2E (8.7 ± 0.9 km/h, p = 0.03). However, no significant differences were observed in the rating of perceived exertion between three exercise trials (1E, 2E, and 2Etask). Two-way analysis of variance for changes in plasma AEA and 2-AG concentrations revealed significant main effects of exercise ($p < 0.01$, $p < 0.001$, respectively), but not in the main effect of social connection. With respect to the difference in affect state before and after experimental trial, significant main effects of exercise were observed in "fatigue" ($p = 0.04$) and "tranquility" ($p < 0.001$).
CONCLUSION: Although the present study demonstrated that circulating eCB level was significantly increased by a 20-min moderate comfortable exercise intervention, there was no synergistic effect of exercise and social connection. However, communicative cooperative task during exercise might facilitate eCB secretion even if the intensity of the exercise is relatively low.

**SCALING PEAK OXYGEN CONSUMPTION IN FONTAN PATIENTS**

WADEY, C.1, BARKER, A.1, STUART, G.2, TRAN, D.3, CORDINA, R.3, WILLIAMS, C.1

*1 CHILDREN'S HEALTH & EXERCISE RESEARCH CENTRE, UNIVERSITY OF EXETER; 2 BRISTOL CONGENITAL HEART CENTRE, UNIVERSITY HOSPITALS BRISTOL; 3 HEART RESEARCH INSTITUTE, UNIVERSITY OF SYDNEY.*

INTRODUCTION: Peak oxygen consumption (peak V̇O2) is traditionally divided ('ratio-scaled') by body mass (BM) for clinical interpretation. Yet, it is unknown whether ratio-scaling to BM can produce a valid size-independent expression of peak V̇O2 in people with a Fontan Circulation. Furthermore, people with a Fontan circulation have deficits in lean mass and increased fat mass, and it is unexplored whether using measures of body composition may improve scaling validity. The objective was to assess the validity of scaling peak V̇O2 to BM and fat free mass (FFM), using ratio and allometric scaling.
METHODS: METHODS: Eighty-nine participants (age: 23.3 ± 6.7 y; 53% female) with a Fontan circulation had their cardiorespiratory fitness and body composition measured by cardiopulmonary exercise testing and dual-energy X-ray absorptiometry. Ratio and allometric (log-linear regression) scaling was performed and Pearson correlations assessed scaling validity.
RESULTS: Results: Peak V̇O2 relative to BM (mL·kg-1·min-1) was significantly negatively correlated to BM and fat mass in both males and females (BM males, r=-0.34, BM females, r=-0.4, P<0.05; Fat mass males r=-0.52, fat mass females r=-0.46, P<0.01). However, peak V̇O2 relative to FFM (mL·kg-1·min-1) was not correlated to FFM or fat mass in both sexes (r range 0.01 to 0.08, P>0.6). Allometrically expressed peak V̇O2 resulted in no significant correlation to any scaling denominator (R2=0.03).
CONCLUSION: Conclusion: The traditional and accepted method of ratio-scaling peak V̇O2 to BM is invalid as it fails to create a size-independent expression of peak V̇O2 in people with a Fontan circulation. However, ratio-scaling to FFM creates both a size and body com-

position independent expression of peak V̇O2 in people with a Fontan circulation. Allometric scaling techniques also produced size-independent expressions of peak V̇O2 regardless of the body size variable used.

### IBUPROFEN INTAKE BEFORE INTENSE ENDURANCE EXERCISE INCREASES INTESTINAL DAMAGE OF HEALTHY MALE ATHLETES IN THE AGE GROUP OF 18 - 40 YEARS: A RANDOMIZED, PLACEBO-CONTROLLED CROSSOVER STUDY

WESSNER, B., SCHUHMANN, M., MOSER, J., PEER, F., CSAPO, R., REIF, A., TRISKA, C.

*UNIVERSITY OF VIENNA*

INTRODUCTION: It is well known that strenuous endurance exercise increases intestinal permeability, a phenomenon known as leaky gut associated with gastrointestinal discomfort and compromised performance [1]. On the other hand, non-steroidal anti-inflammatory drugs such as ibuprofen (IBU) are widely consumed by athletes to relieve pain or to increase pain tolerance [2], whereby negative consequences on gastrointestinal integrity cannot be excluded. The aim of the current study was to determine the effect of oral IBU administration before exercise on markers of intestinal damage, inflammation and performance.
METHODS: Eleven male participants with a mean (±SD) age of 28.6 (±5.5) yrs and a rel VO2peak of 53.0 (±5.2) $ml \cdot min^{-1} \cdot kg^{-1}$ were randomly assigned to one of two treatment orders (placebo-IBU or IBU-placebo) with a wash-out period of at least 7 days. At both testing days, participants had to run for 45 min at 75% of their individual VO2peak on a treadmill followed by a 5% increase of running velocity every 2 min until exhaustion. One hour before the respective exercise, participants received either a placebo or IBU (400 mg), whereby participants and assessors were blinded to the treatments. To assess small intestinal injury and inflammation, intestinal fatty acid binding protein (I-FABP) levels and immune parameters were determined pre as well as 0, 1, 3, 24 h post exercise from venous blood. A two-factorial ANOVA was used to assess treatment and time effects as well as treatment×time interactions.
RESULTS: A significant treatment×time interaction was detected for I-FABP ($F(2.06, 20.59) = 3.83$, $p = 0.037$, partial $\eta^2 = 0.277$), whereby the exercise-induced increase in I-FABP levels were higher after IBU intake at 0 ($p = 0.005$) and 3 h ($p = 0.011$) post exercise. Leukocytes increased significantly over time ($F(2.04, 22.47) = 32.94$, $p < 0.005$, partial $\eta^2 = 0.750$) returning to baseline 24 h post exercise with no differences between treatments. Interestingly, IBU intake resulted in 1.5 (± 0.8) min longer time to exhaustion ($p=0.019$) with a lower rating of perceived exertion at 15, 30 and 45 min of running (all time points $p<0.05$).
CONCLUSION: As hypothesized, even a single low-dose dose of 400 mg IBU may have a negative effect on the human gastrointestinal barrier as measured by damage to the intestinal epithelium despite slightly increasing time -to- exhaustion, potentially through lowering perceived exertion. The extent to which chronic use, higher doses and the intensity, duration or type of activity might influence this effect must be clarified in further studies.

### THREE MONTHS OF NORDIC WALKING: EFFECTS ON ANTHROPOMETRIC, BODY COMPOSITION AND FUNCTIONAL PARAMETERS IN THE NONCLINICAL POPULATION

GRIGOLETTO, A., MAURO, M., TOSELLI, S.

*UNIVERSITY OF BOLOGNA*

INTRODUCTION: Nordic Walking (NW) is an outdoor physical activity performed with the use of specific poles, which is easily accessible. NW does not require expensive equipment, special skill or special facilities and it can be practiced by anyone. In addition, several research suggest that performing outdoor physical activity have additional benefits, such as restoration from stress and mental fatigue [1,2]. The effects of NW in the nonclinical population were little studied, because it usually proposed for elderly and clinical population. So, the aim of the present study was to examine the effects of three months of NW training in a group of middle-aged people, without chronic diseases, on anthropometric, body composition and functional parameters.
METHODS: A pre-test/post-test study design was conducted on seventy-seven participants: 56 women (72.7%), with a mean age of 55.53±9.73 years, and 21 men (27.3%), with a mean age of 60.51±8.15 years. Anthropometric measurements (height, weight, skinfolds and circumferences), body composition and with three physical tests (handgrip, 30" squat test and six minutes walking test) were assessed. The baseline measurements were carried out in February 2021, while the follow up in June 2021. The participants did two weekly NW training sessions of about 60 minutes each. A questionnaire was administered to evaluate the attitude and the feels after the training period. Paired Students' test was carried out to value the pre-post differences and the analysis of variance was performed to evaluate the answers to the questionnaire.
RESULTS: Men and women showed different results with respect to the proposed activity period: women presented a significant decrease in fat parameters, as skinfolds, calf area, fat mass and percentage of fat mass and hip circumference. In addition, the arm muscle area increased. Men showed a significant decrease only in the subscapular skinfold, in fat mass and percentage of fat mass. Both women and men presented a significant increase in lower body strength, and women also showed an increase in the six minutes walking test. The phase angle presented a significant increase in both sexes after the period of training. Finally, participants showed a decrease of anxiety and stress after the activity.
CONCLUSION: NW has several potential benefits for the nonclinical population. In fact, it influences the resistance, the lower body strength and body composition. The popularity of this sport is increasing, because it answers two human needs: the possibility to easily perform physical activity and the contact with the green space. For these reasons, it would be important encourage people of all ages to practise this sport.

## CP-PN05 Women/metabolism

### CHANGES IN ANDROGEN PROFILE OVER THE MENSTRUAL CYCLE IN PHYSICALLY ACTIVE WOMEN

SALMI, V.1, LÖFBERG, I.1, MIKKONEN, R.1, MCNULTY, K.2, HICKS, K.2, HACKNEY, A.C.3, KYRÖLÄINEN, H.1, LEHTI, M.1, IHALAINEN, J.K.1

*1 UNIVERSITY OF JYVÄSKYLÄ, JYVÄSKYLÄ, FINLAND; 2 NORTHUMBRIA UNIVERSITY, NEWCASTLE-UPON-TYNE, UK; 3 UNIVERSITY OF NORTH CAROLINA AT CHAPEL HILL, CHAPEL HILL, NORTH CAROLINA, USA*

INTRODUCTION: Eumenorrheic women experience fluctuating levels of female sex hormones during the menstrual cycle (MC). Regrettably, research regarding changes in androgen profiles over the MC in physically active women is limited. Therefore, we examined changes in androgen concentrations over four pre-determined MC phases of physically active women.
METHODS: Thirty-six healthy, trained (tier 2) [1], naturally menstruating women [2] (age 26±4 y, height 1.67±0.06 m, weight 64.7±7.1 kg, fat percentage 23.5±6.5%, and VO2max 44.9±5.5 ml·kg-1·min-1) participated in this study. Blood samples were collected at bleeding (days 2-4), mid-follicular (mid FOL, 7-11 days from the onset of bleeding), ovulation (OV, 1-2 days after positive ovulation test) and mid-luteal (mid LUT, 7 days after positive ovulation test). Ovulation was confirmed using daily urine tests (luteinizing hormone (LH)) completed by the participants. Estrogen (E2), progesterone (P4), total testosterone (tT), free testosterone (fT), sex hormone-binding globulin (SHBG), dehydroepiandrosterone (DHEA) and its sulphate (DHEA-S) were analyzed from serum. Statistical analyses were conducted using repeated measures ANOVA with Bonferroni as post-hoc.
RESULTS: Serum concentrations of E2 were significantly higher at mid FOL ($p<0.05$), OV ($p<0.001$) and mid LUT ($p<0.001$) compared to bleeding. Ovulation was detected in all included participants whereas serum concentrations of P4 were significantly higher at mid LUT ($p<0.001$) compared to bleeding. However, only 21 participants had serum P4 concentrations >16 nmol·l-1 at mid LUT [2]. Concentrations of tT were significantly higher at OV than at bleeding ($p<0.05$) and mid FOL ($p<0.05$). Concentrations of fT were highest at OV being significantly different from bleeding ($p<0.001$), mid FOL ($p<0.05$), and mid LUT concentrations ($p<0.01$). DHEA concentrations were significantly higher at OV than at bleeding ($p<0.05$) while DHEA-S and SHBG concentrations remained unchanged throughout the MC.
CONCLUSION: Serum concentrations of E2 and P4 mimicked hormonal fluctuation expected during the MC. Despite positive urinary ovulation tests, serum concentrations of P4 remained lower than anticipated in 42% of participants during mid LUT, suggesting that our timing for blood sampling was not optimal or luteal phase defect possibly existed [3]. Concentrations of tT, fT and DHEA appeared to be highest at ovulation. Endogenous hormonal milieu, including androgens in women, may have implications for training responses and adaptations. As such, investigating the concurrent changes in female sex hormones and androgens may improve our understanding of mechanisms behind training adaptations in women.

### EFFECTS OF MENSTRUAL CYCLE PHASE ON WORKLOAD, RECOVERY AND STRESS IN ELITE FEMALE FIELD HOCKEY PLAYERS: A PILOT STUDY.

KIRSCHBAUM, E.M., HEYDE, K., TAPPER, P.

*INSTITUTE FOR APPLIED TRAINING SCIENCE, LEIPZIG*

INTRODUCTION: The hormonal fluctuations during the phases of the menstrual cycle (MC) have an impact on female athletes' self-reported physical fitness and performance (1) and they also lead to changes in mood and fatigue (2). Female athletes perceive their worst state of fitness and performance during bleeding, the early follicular phase (EFP), while their perceived best state of fitness and performance is in the late follicular phase (LFP) (1). In contrast to that, the physiological ability to recover after exercise is better in the luteal phase (LP) compared to the EFP (3).
METHODS: In total eight female German national field hockey players (17.0 ± 1.8 years; 164.5 ± 7.7 cm; 54.3 ± 4.4 kg) were included in this pilot study. They were not using hormonal contraceptives and had a regular MC (26.9 ± 3.2 days cycle length; 3.8 ± 0.9 days bleeding length). The phases of the MC were determined with a menstrual bleeding calendar. Based on the self-reported menstrual bleeding days, the MC was divided by the calendar method into three phases: EFP, LFP and LP. To assess individuals' acute recovery and stress levels the psychometric Short Recovery and Stress Scale for Sport (SRSS) was filled-in every morning (4). To assess their daily physical workload the Acute: Chronic Workload Ratio (ACWR) was used (5). A one-way repeated measures ANOVA was used to detect differences in means within the MC phases ($p< 0.05$).
RESULTS: No significant changes in the SRSS states and the ACWR (EFP 1.0 ± 0.3; LFP 1.0 ± 0.3; LP 1.1 ± 0.1) across MC phases were observed ($p > 0.05$). However, athletes' states of physical (EFP 4.1 ± 1.0; LFP 4.2 ± 0.8; LP 4.3 ± 0.8), mental (EFP 4.1 ± 0.4; LFP 4.3 ± 0.8; LP 4.3 ± 0.6) , emotional (EFP 4.3 ± 0.7; LFP 4.6 ± 0.9; LP 4.4 ± 0.8) and overall recovery (EFP 4.0 ± 0.7; LFP 4.3 ± 0.6; LP 4.1 ± 0.8) tended to be higher in the LFP, while the states of physical (EFP 1.4 ± 0.7; LFP 1.3 ± 0.5; LP 1.5 ± 0.7), mental (EFP 1.8 ± 0.7; LFP 1.5 ± 1.1; LP 1.7 ± 0.9), emotional (EFP 1.5 ± 1.1; LFP 1.0 ± 0.6; LP 1.3 ± 0.6) and overall stress (EFP 1.8 ± 0.6; LFP 1.4 ± 0.5; LP 1.8 ± 0.7) tended to be lower in the LP.
CONCLUSION: There is no significant effect of MC phase on workload and the acute states of recovery and stress in elite female field hockey players. However, the athletes have a higher states of recovery and a lower states of stress in the LFP than in the EFP and the LP. Especially the emotional and overall states of recovery and stress tend to be more sensitive to MC phases.

### MARKERS OF IRON STATUS AND HEAVY MENSTRUAL BLEEDING IN TRAINED FEMALES – A PILOT STUDY

LÖFBERG, I., IHALAINEN, J., VALTONEN, M., KYRÖLÄINEN, H., MIKKONEN, R.

*UNIVERSITY OF JYVÄSKYLÄ*

INTRODUCTION: Trained females are prone to iron deficiency due to exercise-induced iron loss, menstrual bleeding, and insufficient dietary iron [1], where 24–47% of exercising women experience iron deficiency in the absence of anemia [2]. Regrettably, research regarding iron status and heavy menstrual bleeding (HMB) in trained eumenorrheic women and hormonal contraceptive users is limited. Therefore, the purpose of this study was to investigate changes in markers of iron metabolism (ferritin, hemoglobin, and hematocrit) and self-reported HMB over one menstrual or hormonal contraceptive cycle.
METHODS: Blood samples were collected from trained (tier 2 [3]) women in two groups including naturally menstruating (NM, n=16) women and women using combined monophasic hormonal contraceptives (HC, n=12). Characteristics for NM: age 26±4 y, height 167±6cm, weight 67.0±7.6kg, fat percentage 21.8±6.6%, VO2max 44.1±5.8 ml·kg-1·min-1 and HC: age 23±3 y, height 170±5cm, weight 61.0±4.3kg, fat percentage 19.2±3.2%, VO2max 44.1±4.8 ml·kg-1·min-1. Measurements were conducted in NM at bleeding (days 2-4), mid-follicular (mid FOL, 7-11 days from the onset of bleeding), ovulation (OV, 1-2 days after positive ovulation test) and mid-luteal (mid LUT, 7 days after positive ovulation test) and in HC at bleeding/placebo (days 22-28), the beginning (day 8) and middle of hormone taking (day 15), and the beginning of placebo (days 21-24). Analyses were performed using repeated measures ANOVA with Bonferroni post-hoc and independent samples t-tests.
RESULTS: Ferritin, hemoglobin, and hematocrit did not fluctuate significantly over the experimental period in either group. HMB was reported in 69% of NM and 59% of HC while 25% of NM and 27% of HC had mean ferritin (over 4 measurements) <30 µg·L-1 indicating iron deficiency. NM with HMB had lower average ferritin across their menstrual cycle ($p < 0.05$) than those not reporting HMB whereas HC users reporting HMB and not reporting HMB had similar ferritin levels.
CONCLUSION: Serum ferritin, hemoglobin, and hematocrit remained stable over one menstrual/hormonal contraceptive cycle. No statistically significant between-group differences were observed between any variables. Lower average ferritin was observed in NM participants reporting HMB than those not reporting HMB while no differences were observed between HC users. These findings may reflect the reported beneficial effects of hormonal contraceptive use on serum ferritin [4]. As the investigated variables did not fluctuate over one menstrual/hormonal contraceptive cycle, longer follow-up research may be needed to elucidate the relationships between iron status and HMB including the possible influence of hormonal contraceptive use.

### EFFECT OF IRON SUPPLEMENTATION ON EXERCISE PERFORMANCE OF WOMEN WITH IRON DEFICIENCY OR ANEMIA - A SYSTEMATIC REVIEW.

NAKAMOTO, F., ALMEIDA, K.M., GONÇALVES, L.C., QUARESMA, M.V.L.S.

*CENTRO UNIVERSITÁRIO SÃO CAMILO*

INTRODUCTION: Female athletes have athletic performance impaired by iron deficiency or anemia. It is important that appropriate iron supplementation be prescribed, to improve womens health and physical performance. The aim of this review was to determine the effect of iron supplementation on exercise performance of women with iron deficiency or anemia.
METHODS: Pubmed, Web of Science, LILACS, SciELO, and Scopus databases were searched using specific Medical Subject Headings terms for clinical studies that enrolled women in an iron supplementation intervention. Athletic performance was considered as the primary outcome. PROSPERO registration ID: CRD42021245452.
RESULTS: A total of 253 studies were identified. However only 26 studies met the eligibility criteria. Twenty-five studies were randomized, placebo-controlled trials (15 double-blind; 2 single-blind, including 1 crossover; 8 did not inform blinding, including 1 crossover). One study was a randomized noncontrolled by placebo trial (blinding not informed). A total of 1179 women were included in the studies (610 allocated to treatment groups and 538 to control groups; one study did not inform participants distribution), aged 9-55 years. Sixteen studies (61,5%) showed positive effects on performance (improved time to complete time trials or treadmill endurance time; increased number of steps climbed or strength exercise repetitions) or its predictors (higher VO2max/VO2peak; lower lactate concentration, submaximal VO2, heart rate), along with unchanged results or improvement without significant differences when compared to controls (submaximal VO2, VO2max/VO2peak, lactate concentration, energy expenditure, ventilatory threshold, heart rate, work rate, muscle fatigue, strength, time to exhaustion, time to complete time trial). Three studies (11,5%) reported only positive results (improved VO2max, running time). Seven studies (27%) reported only unchanged results or improvement without significant differences when compared to controls (Wingate test, speed test, and repeat sprints performances, time to exhaustion, VO2max, lactate concentration). Iron supplementation related to positive results (18 studies, 95%) was mainly characterized by oral ingestion of 50-1135 mg $FeSO_4$, for 2 weeks to 1 year. Thirteen studies (72%) supplemented 10-135 mg elemental iron/day for 6-8 weeks (total supplementation of 420-7560 mg elemental iron), and 16 (84%) involved women aged 17-25 years. Women with improved performance were sedentary/untrained (7 studies), physically active (5), well trained athletes (2), or elite athletes (2). Two studies did not inform participants' training status. Finally, they were anemic (2 studies), anemic or iron deficient (2), nonanemic iron deficient (11), and non-deficient, iron deficient or anemic (4).
CONCLUSION: Despite the great variety of study designs, most studies show physical performance improvement of iron deficient or anemic young women of different training status, following oral iron supplementation.

### LOWER SYMPTOMS OF DISORDERED EATING AND TRAINING BEHAVIOUR AND DEPRESSION IN NATIONAL TEAM GYMNASTS COMPARED TO HEALTHY CONTROLS.

MELIN, A.1, FORSBERG, N., EDLUND, K.2,3

*1. SPORTS SCIENCE, LINNAEUS UNIVERSITY, 2. KAROLINSKA INSTITUTET, 3. SOPHIAHEMMET UNIVERSITY*

INTRODUCTION: Compulsive Exercise (CE) is characterised by excessive and increasing training loads, abstinence without training and an inability to reduce exercise amounts. In females CE is often associated with disordered eating behaviour (DE). Potential harmful consequences are injuries, depression and impaired social relations. Studies comparing the prevalence of CE, DE and depression among aesthetic

athletes and healthy controls are scarce. We therefore aimed to investigate CE and DE among individual and team national team gymnasts and healthy controls.
METHODS: 94 gymnasts (52 females, 42 males) aged 19 ± 4 years were recruited from the Swedish national team (team gymnastics n=53 and individual disciplines n=41). Controls consisting of 159 non-elite athletes (79 females, 80 males) aged 18 ± 4 were recruited from Swedish high schools and universities. The participants filled out a questionnaire comprising of the Eating Disorder Inventory (EDI) including subscales Bulimia, Drive for Thinness (DT), Body Dissatisfaction (BD), the EDI total score, Compulsive Exercise test (CET), and Montgomery Åsberg Depression Rating Scale-Self (MADRS-S).
RESULTS: EDI total score (15.1 ± 13.8 vs. 21.4 ± 17.5, p=0.003), BD (8.3 ± 6.8 vs. 11.6 ± 8.5, p = 0.002), and Bulimia (2.0 ± 3.4 vs. 3.6 ± 5.1, p = 0.004) scores were lower among gymnasts than controls, as well as MADRS-S (8.7 ± 6.6 vs. 11.8 ± 8.7, p=0.007) and CET (25.1 ± 8.8 vs. 50.7 ± 17.7, p < 0.001) scores. No difference in DT score was observed between groups. Gymnasts were less likely to have high scores of total EDI [OR 0.33, 95% CI (0.13-0.84)] and CET [OR 0.033, 95% CI (0.017 - 0.067)], as well as to moderate or severe depression [OR 0.31, 95% CI (0.12 - 0.77)] than controls. Gymnasts from team disciplines were more likely to report high CET score [OR 4.12, 95% CI (1.09 – 15.59)] than gymnasts in individual disciplines, where 13 vs. 3 had high CET score. Among gymnasts, total CET score was positively associated with total EDI score (r=0.516, p<0.001), and MADRS-S (r=0.254, p=0.014).
CONCLUSION: CE was associated with EDI and MADRS-S scores, but in this group of healthy national team gymnasts, gymnasts had lower symptoms of DE, CE and depression compared with controls, while gymnasts competing in individual disciplines were less likely to suffer from CE than team gymnasts.

**LOW-LOAD RESISTANCE EXERCISE INDUCES SIMILAR RESPONSES ON HUNGER SENSATION, GUT HORMONES, AND LACTATE AS MODERATE-LOAD RESISTANCE EXERCISE IN YOUNG HEALTHY MEN**

LIU, H.W.
*NATIONAL TAIWAN NORMAL UNIVERSITY*

INTRODUCTION: Continuous aerobic exercise on the hunger sensation have been widely explored, nevertheless the influence of resistance exercise (RE) with different variables, including training loads, training volume, and inter-set rest, on appetite responses requires further investigation. The study aimed to determine the importance of training load in RE-induced appetite suppression; total training volume and inter-set rest were equalized.
METHODS: In total, 11 healthy young men (mean ± SD age 23 ± 2 years, body mass index 22 ± 2 kg/m2) were included. Participants completed three trials, including moderate-load RE (MOD; 4 sets of 8 repetitions at 85% 8RM), low-load RE (LOW; 4 sets of 15 repetitions at 45% 8RM) and a control (CON; no exercise), in a randomized, crossover design. Subjective appetite ratings, ghrelin, peptide YY (PYY), lactate, and the autonomic nervous system were evaluated pre-exercise and during post-exercise 1 hour.
RESULTS: Area under the curve (AUC) of hunger and predicted food consumption ratings, and ghrelin levels during the trial period were significantly lower in MOD and LOW (p < 0.05 vs. CON). AUC of PYY and lactate levels during the trial period were significantly higher in MOD and LOW (p < 0.05 vs. CON). No difference was observed between MOD and LOW (p > 0.05). Changes in lactate was negatively associated with AUC of ghrelin (r = -0.565, p = 0.001) and hunger ratings (r = -0.470, p = 0.006). Slower recovery of heart rate variability recovery was observed in MOD.
CONCLUSION: These findings suggest that MOD and LOW with equal training volume and inter-set rest induces similar responses on hunger suppression and orexigenic signals, except for slower recovery of autonomic modulation after MOD.

**EFFECT OF VO2MAX ON BASELINE SERUM LACTATE AND BETA-ENDORPHIN LEVELS IN MALE BODYBUILDERS USING ANABOLIC STEROIDS, NON-USERS AND NON-BODYBUILDERS**

JAVAID, S.
*POSTGRADUATE MEDICAL INSTITUTE*

INTRODUCTION: Volume oxygen maximum is the maximum rate of oxygen consumption during strenuous exercise and a measure of physical fitness. Lactate accumulation occurs when anaerobic metabolism predominates. Exercise of sufficient intensity stimulates Beta Endorphin release in the blood. There is a difference of opinion among researchers on the intensity of exercise needed to cause endorphin release and the role of lactate. The use of anabolic steroids is increasing globally, particularly among bodybuilders hypothesized to affect body systems.
METHODS: This cross-sectional study was conducted at the exercise physiology laboratory at the Postgraduate Medical Institute, Lahore, Pakistan. The study involved 30 healthy male subjects (20 to 30 years) recruited through convenience non-probability sampling. The study population included 3 groups: Group I (non-bodybuilders), Group II (bodybuilders not using anabolic steroids), and Group III (bodybuilders using anabolic steroids). All participants underwent a graded exercise test on cardiopulmonary exercise testing (CPET) equipment up till exhaustion for VO2max assessment. Blood sampling was done pre and post-exercise (80% of VO2max) to measure blood lactate and beta-endorphin levels. Data were analyzed by SPSS version 23. Paired t-test, ANOVA, and Pearson were applied. p-value <0.05 taken statistically significant.
RESULTS: Bodybuilders achieved a significantly higher VO2max as compared to non-bodybuilders (43.4 ± 4.2ml/min/kg, 35.4 ± 4.8 ; p <0.001) respectively. Anabolic steroids using bodybuilders showed a significantly lower VO2max compared to non-users (38 ± 3.1ml/min/kg, 43.4±4.2 ml/min/kg ; p = 0.016) respectively. No statistically significant difference was seen in the respiratory exchange ratio among groups both at rest (0.9 ± 0.1 , 0.8 ± 0.1, 0.83 ± 0.1 ; p = 0.148) and at max (1.2 ± 0.1 , 1.1 ± 0.1 , 1.1± 0.1 ; p = 0.097). Minute ventilation showed a non-significant difference between the three study groups( 98.6 ± 38.2 , 121.6 ± 18.2 , 109 ± 15.3 ; p = 0.103) . Blood lactate and beta-endorphin levels increased significantly in all the three study groups at an exercise intensity of 80% of VO2max (p <0.001). A non-significant difference in blood lactate levels was found between anabolic steroids using bodybuilders and non-users (3.75 ± 0.3 , 4.00 ± 0.6 ; p = 0.756). Beta-endorphin levels were found to be significantly lower in anabolic steroid users than in non-users (26.4±10.0 , 40.4±12.8 ; p = 0.029). There was a significant positive correlation found between blood lactate and beta-endorphin levels post-exercise, r (28) = 0.31, p = 0.05.
CONCLUSION: Exercise intensity of 80% of VO2max is sufficient for the significant increase in blood lactate and beta-endorphin levels in bodybuilders using anabolic steroids, non-users, and non-bodybuilders. Exogenous steroid intake blunts the release of exercise-induced beta-endorphins. Acidosis caused by lactate accumulation is likely to contribute to an increase in beta-endorphins.

### CP-BM03 Biomechanics of the knee

**ALTERATIONS IN LOWER-LEG FUNCTION AND BIOMECHANICS IN ATHLETES AND RUNNERS WITH ACHILLES TENDINOPATHY: A SYSTEMATIC REVIEW**

QUARMBY, A.1, MÖNNIG, J.1, MUGELE, H.2, HENSCHKE, J.1, KIM, M.H.1, CASSEL, M.1, ENGEL, T.1

*1. UNIVERSITY OF POTSDAM & 2. UNIVERSITY OF INNSBRUCK*

INTRODUCTION: Achilles tendinopathy (AT) is a persistent injury in athletes, especially for those engaged in repetitive stretch-shortening cycle activities such as running. Clinical risk factors are numerous, but it has been suggested that altered biomechanics might lead to or be associated with the development of AT. No systematic review has been conducted investigating these biomechanical alterations in specifically athletic populations. Therefore, the aim of this systematic review was to synthesise research comparing the lower-limb biomechanics of athletes with AT to asymptomatic controls.
METHODS: MEDLINE, Web of Science and Cochrane were searched in March 2021 for relevant studies investigating biomechanics and neuromuscular performance during gait activities and other motor tasks such as hopping, isolated strength tasks, and reflex responses. Inclusion criteria for studies were an AT diagnosis in at least one group, cross-sectional or prospective data, a minimum of one outcome comparing biomechanical data between an AT and healthy group, and athletic populations (e.g., run >20km / week). Studies were excluded if patients had Achilles tendon rupture/surgery, participants reported injuries other than AT, and when only within-subject data was available (e.g., no healthy control group). Search terms were based on four key areas: “Biomechanics”, “Movement Task”, “Pathology (Tendinopathy)” and “Anatomical Location (Achilles tendon)”. Effect sizes (Cohen’s d) with corresponding 95% confidence intervals were calculated for relevant outcomes.
RESULTS: The initial search yielded 4442 studies. After screening, twenty studies (775 total participants) were synthesised, reporting on a wide range of biomechanical outcomes. Females were generally under-represented and patients in the AT group were 3 years older on average. Biomechanical alterations were identified during running, hopping, jumping, strength tasks and reflex activity, with small to large effect sizes. Kinematics in AT patients appeared to be altered during stretch-shortening activities of the lower limb, indicating a pattern of “medial collapse” e.g., increased hip adduction/ ankle pronation. Muscular activity of the calf and hips was different between groups, whereby in two studies AT patients exhibited greater calf muscle EMG amplitudes despite lower plantar flexor strength. Overall, dynamic maximal strength of the plantar flexors, and isometric strength of the hips might be reduced in the AT group. One study indicated an up-regulated reflex activity with AT.
CONCLUSION: In summary, this systematic review reports on several biomechanical alterations in athletes with AT. These factors may form potential treatment targets, although this needs further research and clinical approaches should additionally take other contributing health factors into account. Based on the cross-sectional design of most studies, it is difficult to discern whether these factors are causative or consequential of AT.

**BIOMECHANICAL ANALYSIS OF THE PATTERNS OF FEMALE FUTSAL PLAYERS WITH AND WITHOUT KNEE PAIN, ACCORDING TO LATERALITY. CROSS-SECTIONAL STUDY.**

VICENTE-PINA, L.P.1, FERRÁNDEZ-LALIENA, L.1, SÁNCHEZ-RODRÍGUEZ, R.1, ORANTES-GONZÁLEZ, M.E.2, HEREDIA-JIMÉNEZ, J.M.3, LUCHA-LÓPEZ, M.O.1, TRICÁS-MORENO, J.M.1

*1. UNIVERSIDAD DE ZARAGOZA, 2.UNIVERSIDAD PABLO DE OLAVIDE , 3. UNIVERSIDAD DE GRANADA*

INTRODUCTION: The incidence of knee injuries, especially anterior cruciate ligament injuries, in womens soccerl is very high and higher than in mens soccer, being an injury with a long time off work and a high recurrence rate (1). The identification of risk factors is key to the design of specific prevention programmes. Futsal, by incorporating the ball, conditions the motor pattern in the dominant leg (PD) and non-dominant leg (PND) (2).
METHODS: A sample of 16 female futsal players (23,94 ± 5,03 years) was selected. They were divided into two groups: knee pain (DR) and no knee injury (SL) subdivided into PD and PND. A 3D capture system consisting of 12 infrared cameras (Qualisys A.B, Gotegorg, Sweden) was used. Visual3D software was then used to create an 8-segment biomechanical model for the calculation of biomechanical variables. A pressure platform system was used to detect the peak torque of the braking reaction force. Specific tests were performed. A contrast of variables according to laterality was performed classifying by groups, KP and NI using Students t-test and an analysis of the effect size using Cohens d. A 95% confidence level was established.
RESULTS: Eight KP players and eight NI players were analysed. The contrast by laterality did not reach significant results, although relevant differences appeared when analysing the effect size. Both KP and NI players had more knee valgus in PD (d=1.19 , d=0.73), with a higher mean valgus in KP players (-10.58 ± 5,64) than in NI players (-8.87 ± 8,45). In the hip, both groups presented different biomechanics. KP players tended towards internal rotation (IR) in PD versus external rotation (ER) in PND (d=0.77). The NI tend towards ER in both hips, being greater in PD than in PND (d=0.77).
CONCLUSION: In both groups, KP and NI, there could be differences between the biomechanical pattern of PD and PND, corroborating the difference of roles in futsal. But being different patterns, in KP players the PD tends towards joint injury, while in NI players it would be the PND that presents worse control, although without reaching risk positions.

**DIFFERENT STRATEGIES IN PERFORMING A CUTTING MANEUVER ARE ASSOCIATED WITH THE BIOMECHANICAL RISK FACTORS FOR ACL INJURY**

BLASCHOVA, D.1, JANDACKA, D.1, HAMILL, J.1,2

*1 DEPARTMENT OF HUMAN MOVEMENT STUDIES, UNIVERSITY OF OSTRAVA, OSTRAVA, CZECH REPUBLIC; 2 DEPARTMENT OF KINESIOLOGY, UNIVERSITY OF MASSACHUSETTS, AMHERST, USA*

INTRODUCTION: The number of females participating in sport and exercise is increasing (1). Many studies are focused on risk factors for anterior cruciate ligament (ACL) injury during cutting maneuver, particularly in female participants. ACL rupture is more common in females more than males (2). The findings of current studies (3; 4; 5; 6) in relation to ACL injury during cutting maneuvers are focused on the knee adduction moment, knee flexion, menstrual cycle, laxity, and muscle activation. The results of these studies could be significantly affected by different strategies used to perform the cutting maneuver. However, there are no controlled studies which compare or evaluate different types of cutting maneuvers in relation to possible risk factors for ACL injury. Therefore, the purpose of this study was to compare biomechanical risk factors for ACL injury (knee adduction moment) according to different strategies of cutting maneuver used by females to accomplish the cutting task.
METHODS: Ninety-four females (age 23.0±3.8 yrs; height 167.7±6.2 m; mass 61.1±11.3 kg) performed two tasks: 1) a straight run; and 2) an unanticipated cutting maneuver, fully described previously (7). Five trials of cutting maneuvers for each female were qualitatively evaluated. We assessed foot position from the mid-line perspective of the left foot before force platform and subsequent step of the right foot on force platform. From the first 30% of stance phase the maximum of knee internal adduction moment was identified and normalized to body weight and approach velocity.
RESULTS: We defined four types of cutting maneuver and the mean values with standard deviation for adduction moments: 1) left foot without cross-over and the right foot without cross-over, 14.1±8.0 Nm·s·kg-1·m-1; 2) left foot without cross-over and right foot with cross-over, 5.3±3.7 Nm·s·kg-1·m-1; 3) left foot with cross-over and right foot without cross-over, 14.4±7.9 Nm·s·kg-1·m-1; and 4) left foot with cross-over and right foot with cross-over, 9.5±6.2 Nm·s·kg-1·m-1. The higher values of internal knee adduction moment for the different types of cutting maneuver were related to cutting maneuver without crossover of right foot.
CONCLUSION: Our results suggest that the main risk factor for ACL injury (e.g. knee adduction moment) may be different with regard to type of cutting maneuver. Cutting maneuvers without a crossover of right foot may be associated with an increased biomechanical loading of the ACL compare to other strategies for accomplishing cutting tasks in females possibly placing these females at risk for ACL injury.

**ANTERIOR CRUCIATE LIGAMENT INJURY IN YOUTH – IDENTIFYING MODIFIABLE RISK FACTORS FOR EFFECTIVE RISK REDUCTION IN 6- TO 13-YEAR-OLDS**

HEERING, T., ROLLEY, T.L., LANDER, N., FOX, A., BARNETT, L.M., DUNCAN, M.J.

*COVENTRY UNIVERSITY, DEAKIN UNIVERSITY*

INTRODUCTION: An anterior cruciate ligament (ACL) injury impacts an individuals' life forever. Along the actual injury, subsequent concerns include long-term health risk and large public health care costs. Growing ACL injury incidence levels are reported in developed countries for 5- to 14-year-olds yet research on injury risk reduction is focused on populations aged over 13 years. For successful early intervention and injury risk reduction, it is crucial to understand which modifiable risk factors are associated with ACL injury in youth aged 6 to 13 years and how they are examined.
METHODS: A rigorous scoping review was performed in five databases in August 2021 and included articles which examined modifiable risk factors of primary ACL injury in children aged 6 to 13 years. Articles were grouped according to sex and/or maturational and age differences and parameters extracted on modifiable risk factors during different physical screening tasks
RESULTS: Thirty-five included articles focused on intrinsic risk factors (97%) e.g., knee landing biomechanics or muscle strength, in 12-13-year-olds (81%). Assessment varied from muscle strength (22%), jump-landing tasks (49%) and motion capture (31%) to force plates (24%). Out of over 60 variables, seven variables had robust evidence (> 2 articles on the same physical screening task (e.g., drop vertical jump (DVJ))). Injury risk relevant variables in youth were knee flexion angle with decreased angles for males, knee joint moments with no sex difference, knee valgus/varus angle with increased valgus in older more mature participants but no difference between sexes, take-off force and concentric hamstring strength indicated no difference for age or maturational stage.
CONCLUSION: Research on youth (< 12 years) ACL injuries is limited to a small range of variables and physical screening tasks with robust evidence (> 2 articles on same risk factors at the same physical screening task). Variables, e.g., knee flexion angle, associated with increased ACL injury risk in adolescents and adults show relevance in youth aged 6-13 years. In contrast to findings in adolescents, smaller knee flexion angle, associated with increase ACL loading, were observed in males and not females during DVJ in youth. Indicating that injury risk in youth might differ from that after the onset of puberty, emphasising the unique needs of that age group.
This scoping review highlights, for the first time, the lack of evidence in youth ACL research in variables associated with increasing risk in adolescents and adults (e.g., knee adductor moment) in a range of physical screening task. The DVJ was predominantly used but has been criticised for not representing the actual injury mechanism and using more dynamic tasks such as unanticipated side-cutting (e.g., change in direction) has been proposed. Future research needs to focus on youth risk factors in tasks that reflect the actual injury mechanism to be able to plan effective interventions according to the needs of youth.

### CHARACTERISTICS OF LOWER EXTREMITY MUSCLE ELECTROMECHANICAL DELAY DURING AMATEUR ATHLETES AFTER ACL RECONSTRUCTION

ZHE, W.1, JIAN, C.2, MAKAI, A., JAROMI, M.

*1 UNIVERSITY OF PÉCS, 2 WUHAN SPORT UNIVERSITY, CHINA*

INTRODUCTION: Anterior Cruciate Ligament (ACL) reconstruction (ACLR) is a more common treatment for athletes after an ACL rupture (1). It has been suggested that the impact on neuromuscular control function due to ACLR is one of the causes of secondary injury (2). Electromechanical delay (EMD) is an index that can reflect the neuromuscular control of the target muscle precisely (3). There do not have many studies on EMD of lower limb muscles after ACLR in amateur athletes. This study aimed to investigate the EMD performance of quadriceps, biceps, and gluteus medius after ACLR in amateur athletes.
METHODS: Ten amateur athletes who were 24.7±4.47 years old and suffered from ACLR after 15.34±3.2 months were selected. Muscle strengths were collected using Isomed-2000 in isometric mode on the affected and healthy lower limbs in knee extension, flexion, and hip abduction, respectively. The surface electromyography (EMG) of the target muscles (quadriceps, biceps, and gluteus medius) were collected separately using Yunwei surface EMG instrument. During the test, subjects closed their eyes and performed isometric contractions of the target muscles immediately after receiving the sound signal to complete. Paired sample t-test in SPSS 25.0 was used to analyze the data.
RESULTS: The EMD of quadriceps, biceps, and gluteus medius on the healthy side was 50.6±19.03ms, 54.8±14.67ms, 87.6±31.03ms; on the injured side was 53.0±19.70ms, 57.0±15.68ms, 114.8±38.06ms. Statistical results showed a statistically significant difference in EMD between the healthy and the affected side of the gluteus medius ($p=0.022$, $p<0.05$).
CONCLUSION: In amateur athletes after ACLR, there is a difference in neuromuscular function between the healthy side and the affected gluteus medius, which may be one of the causes of knee instability.

### ACL LAXITY AND ACHILLES STIFFNESS DURING THE EARLY FOLLICULAR AND MID-LUTEAL PHASES OF THE MENSTRUAL CYCLE

SQUIER, K.

*UBC: THE UNIVERSITY OF BRITISH COLUMBIA*

INTRODUCTION: Previous studies have reported that the risk of musculoskeletal injury in women participating in sports is heightened during particular phases of the menstrual cycle (1). A systematic review found that women experience a substantially higher rate of ACL injuries during the first half of the menstrual cycle compared to the premenstrual phase (2). However, a systematic review with meta-analysis that concluded that ACL ligament's laxity increased during days 10-14 and 15-28 of the menstrual cycle (3). Though, the authors pointed out some major methodological shortcomings in this area of research suggesting that pre-selected measurement times led to false assumptions about the timing of ovulation in all studies included. Despite discrepant findings and limitations in previous research, there is a scientific rationale to suspect that ovarian hormone levels have a physiological impact on the mechanical properties of ligament and tendinous connective tissues (4,5,6). The aim of the current study is to use precise menstrual cycle timing methodology to assess and compare measures of mean ACL laxity and Achilles tendon (AT) stiffness in the early follicular (EF) and mid-luteal (ML) phases of the menstrual cycle.
METHODS: Using a prospective study design, 28 women with normal ovulatory cycles (28.9±4.1 yrs; 24.3±5 BMI) completed EF (within 4-8 days of menstruation) and ML (within 7 days of quantitative basal temperature increase) phase appointments. 11 women with anovulatory cycles (30.3±4.3 yrs; 26.3±4.7 BMI) were included as a low-hormone comparison group. The investigator was blinded to the ovulation status of each participant. ACL laxity (mm) was assessed using a KT-1000 arthrometer (load of 15-, 20- and 30-lbs) and AT stiffness (N/mm) was assessed using a MyotonPro digital palpation device at EF and ML appointments. Outcomes for dominant and non-dominant sides were combined into composite variables. Paired t-tests were used to statistically test for variable differences between the two timepoints.
RESULTS: The ovulation group exhibited an increase in ACL laxity from EF to ML (15-lbs: 5.0±1.2mm vs. 5.5±1.5mm; 20-lbs: 6.1±1.4mm vs. 6.7±1.7mm; 30-lbs: 8.2±1.78mm vs. 8.8±2.1mm; all $p<0.05$). There were no differences in the anovulatory group's ACL laxity at any load. AT stiffness did not significantly change in both the ovulatory and anovulatory groups.
CONCLUSION: Similar to the previously cited meta-analysis, results showed an increase in ACL laxity from a low hormone time point (EF) to an elevated hormone timepoint (ML) in women that are normally ovulating. The lack of ACL laxity change shown in the anovulatory group provides further evidence of the hormonal effect on ligament tissue. There was no difference in AT stiffness over the cycle, suggesting that the tendon may not be as sensitive to short term hormone fluctuations as it is to chronic exposure (7).

### ACTIVE KNEE JOINT POSITION SENSE IN HEALTHY PARTICIPANTS: INFLUENCE OF LEG DOMINANCE, GENDER AND QUALITY CRITERIA

BUSCH, A., BAUR, H.

*UNIVERSITY OF POTSDAM*

INTRODUCTION: Integration and processing of sensory information is mandatory for goal directed movement. Sensorimotor performance of the knee can be measured with the active joint position sense (JPS) test. However, data on influences of leg dominance and gender as well as reliability measures is limited.
METHODS: 20 healthy participants (10 male, 10 females, age: 29±8 years; height: 165±39 cm; weight: 69±13 kg) performed in a test-retest design an active knee angle reproduction task in seated position with a target angle at 50° flexion (0° = full extension). Two sessions were executed separated by a 2-week interval. Angular performance assessed with an electrogoniometer, was recorded during 2 blocks of 3 minutes of continues reproduction cycles with self-selected movement velocity per leg and sessions. The order of legs was randomized. Relative and absolute angular errors were presented descriptively. Friedman-test for repeated measures was used to determine differences in absolute angular errors between leg dominance and gender ($\alpha = 0.05$). Intra- and inter-session reliability was assessed with the

Intraclass correlation coefficient (ICC(2,A), Bland-Altman analysis (bias and limits of agreement (LoA)) and minimal detectable change (MDC).
RESULTS: Median (interquartile range) relative and absolute angular error over all participants per session and block were -5.2° (8°) and 7.5° (4°), respectively. No significant differences in angular error in leg dominance (p = 0.11) and gender (p = 0.44) were found. All participants combined showed limited inter-session ICC (0.366), bias of 3° (LoA -10.2° to 16.4°) and MDC of 8.8° and reasonable intra-session ICC (0.738), bias of 2.1° (LoA -5.9° to 10.2°) and MDC of 5.6° reliability measures.
CONCLUSION: No significant differences in leg dominance and gender are in line with findings in the literature. Lower inter- and higher intra-session ICC values confirm previous findings and bias as well as minimal detectable changes must be considered when comparing to other studies. Due to the small sample size and inclusion of only healthy participants the findings need to be handled with caution when applied to another population.

### CP-MH07 Ageing and physical activity

#### RELATIONSHIPS OF PHYSICAL ACTIVITY AND SEDENTARY BEHAVIOURS WITH MARKERS OF OXIDATIVE STRESS IN THE OLDER POPULATION.

CORRAL-PÉREZ, J.1,2, GIL-GONZÁLEZ, C.1,2, CASALS, C.1,2, ATIENZA, M.3,4, CANTERO, J.L.3,4, JIMÉNEZ-PAVÓN, D.1,2,5, PONCE-GONZÁLEZ, J.G.1,2, CARBONELL-BAEZA, A.1,2

*1UNIVERSITY OF CADIZ, SPAIN. 2PUERTA DEL MAR UNIVERSITY HOSPITAL, SPAIN, 3PABLO DE OLAVIDE UNIVERSITY, SPAIN, 4CIBERNED, SPAIN, 5CIBERFES, SPAIN.*

INTRODUCTION: The scientific evidence has stated sex differences in oxidative stress markers such as homocysteine and total antioxidant capacity (TAC), establishing sex hormones as the possible mechanism. However, the evidence showed that these differences still occur in the older population which could imply that other lifestyle factors, such as physical activity (PA) or sedentary behaviours have a relevant role, due to increased susceptibility to oxidative stress associated with ageing. Therefore, the current aim was to compare the oxidative stress markers between sexes and their relationships with accelerometer-based PA and sedentary behaviours.
METHODS: Sixty-three participants (36 women, 68.84±3.02 years) from a randomised control trial (NCT03923712) were included in the analysis. The PA levels [light, moderate, vigorous, and moderate-to-vigorous(MV), min/day] and sedentary behaviours (min/day) were measured using hip-worn accelerometers for 7 consecutive days. Raw data from accelerometers were used with the open-source package GGIR for analysis and transformed to euclidean norm minus one with negative values rounded to zero. Three 24 h dietary recalls were obtained from each individual to evaluate the nutrient intake. Plasma TAC levels (µmol/L) were measured using the ferric reducing antioxidant power method with some modifications. Serum homocysteine levels (µmol/L) were obtained using standard enzymatic methods. We conducted multiple regression models, with homocysteine and TAC as dependent variables and PA and sedentary behaviours as predictors after controlling sex.
RESULTS: Men showed significantly higher levels of TAC (1063.31±158.22 vs 894.12±171.75 µmol/L, p<0.001) and homocysteine (15.18±2.91 vs 12.43±2.70 µmol/L, p<0.001) compared to women, which remained significant after adjusting for nutrient intake. No significant differences between sexes were found for any of the PA or sedentary behaviours variables. In the multiple regression models, only MVPA was positively associated with TAC (β=0.25, p=0.042) which remained significant after controlling for sex (β=0.24, p=0.033). No significant associations were found between homocysteine and PA and sedentary behaviours.
CONCLUSION: The findings of the present study showed that, in our sample, there are still sex differences in oxidative stress which are independent of PA levels or sedentary behaviours. Additionally, even though it is well established that daily PA is beneficial for ageing, this study suggests that only MVPA intensity may have a protective and beneficial effect, even though it can acutely increase oxidative markers, it is also able to induce an adaptive response increasing the antioxidant defence without chronically increasing oxidative markers among older adults, contributing to a better overall oxidative stress balance.

#### INHERITED MUSCLE STRENGTH PREDICTS FUNCTIONAL CAPACITY, COMMON DISEASES AND ALL- CAUSE MORTALITY

SILLANPÄÄ, E.1,2, HERRANEN, P.1, PALVIAINEN, T.2, WALLER, K.1, KUJALA, U.1, KAPRIO, J.1

*1 FACULTY OF SPORT AND HEALTH SCIENCES, UNIVERSITY OF JYVÄSKYLÄ, JYVÄSKYLÄ, FINLAND; 2 INSTITUTE FOR MOLECULAR MEDICINE FINLAND, HELSINKI, FINLAND*

INTRODUCTION: Muscle strength is a highly heritable trait and especially low grip strength, measured at any time during adulthood, predicts future adversities and mortality. We hypothesized that muscle strength genotype is an important predictor of future health and lifespan. To test this hypothesis, we validated a polygenic risk score for grip strength (PRS GRIP) and investigated how it associates with functional capacity, most common age-related diseases and all-cause mortality among the Finnish population.
METHODS: PRS GRIPs (based on Pan-UB biobank GWAS summary statistics, N=418,827) were calculated for the older Finnish twin cohort (FTC, N=8,823) and FinnGen Data Freeze 9(N=315,594). FTC partipants (born 1938-1957) were followed up from the time of DNA sampling until December 31, 2020. Death dates were obtained from the population register of Finland and Statistics Finland. A subsample of FTC (N=429) had undergone measurements for maximal isometric grip and knee extension strength and several functional tasks. FinnGen data included genotyped individuals (age 40-108 years, women 53%) with longitudinal health register data. Endpoints were based on ICD codes and included cardiovascular, metabolic and pulmonary diseases, cancers, dementia and depression as well as musculoskeletal and connective tissue disorders. Analysis was conducted with linear, logistic and cox regression models.
Results: In FTC subsample, PRS GRIP accounted 6.1% of the variation in the measured grip strength (β 14.2, SE 3.1, P<0.001), 5.4% of the variation in the knee extension strength (β 19.6, SE 4.7, P<0.001) and was systematically associated with measures of functional capacity. In FinnGen, a high PRS GRIP predicted a lower BMI ( β = −0.059 kg/m2 per one SD change in PRS GRIP, SE = 0.011, P = 1.3 x 10 -7 ). Higher PRS GRIP was also associated with

a lower risk for ischemic heart diseases, hypertension, and stroke (odds ratio [OR] range 0.95-0.96.), osteoporosis, rheumatoid arthritis and knee and polyarthrosis (OR 0.90-0.98), type 2 diabetes and obesity (both OR 0.94), asthma (OR 0.93) and COPD (OR 0.94). Participants with higher PRS GRIP had also lower risk for some dementia subcategories (OR 0.93-0.98) and depression (OR 0.95). In FTC, 35% of the men and 26% of the women died during the mean follow-up time of 16.3 years. A significant sex* PRSGRIP interaction was found (p=0.023). In men, mortality risk decreased when PRSGRIP increased (HR 0.93, 0.88-0.98), while no association were found in women (HR 1.01). In men, mortality HR for PRSGRIP remained similar (0.93) also after adjusting for adulthood physical activity and other lifestyle covariates. Conclusion:Inherited muscle strength may reflect an individual's intrinsic capacity to resist pathological changes in old age. Origins of significant sex interaction in mortality need to be studied further. Whether high genetic muscle strength also helps to recover from episodes of poor health remains to be investigated.

### METHODS: RESULTS: CONCLUSION: DIFFERENCES IN VASTUS LATERALIS MUSCLE THICKNESS AND MAXIMUM KNEE EXTENSION FORCE BETWEEN MASTER ATHLETES, NON-ATHLETES AND PATIENTS UNDERGOING MAJOR ABDOMINAL SURGERY

DURO-OCANA, P., BRYAN, A., KORHONEN, M.T., QURAISHI-AKHTAR, T., ZAMBOLIN, F., PARKER, M., MOORE, J., SIRIWARDENA, A.K., MCPHEE, J., DEGENS, H., BAGLEY, L.

*UNIVERSITY OF MANCHERTER METROPOLITAN, LITHUANIAN SPORTS UNIVERSITY, UNIVERSITY OF MANCHESTER, UNIVERSITY OF JYVÄSKYLÄ*

INTRODUCTION: An important cause of frailty in old age is sarcopenia, which is associated with poor prognosis in major abdominal surgery1. While muscle mass is important, there is increasing evidence that the force generating capacity is proportionally more reduced during ageing than muscle mass2. The aim of this study is to obtain a measure of muscle size (Vastus Lateralis (VL) thickness), muscle function (maximal voluntary force generating capacity (MVC)) and the ratio between MVC and VL thickness, providing a measure of 'muscle quality'. As a substantial component of the development of frailty is likely to be attributable to low levels of physical activity, we hypothesise that 1) muscle mass and function are lower in patients undergoing a major abdominal surgery compared to age-matched Master athletes (MAs) and non-MAs and 2) poor muscle function is predictive of poor surgical outcomes in patients undergoing major abdominal surgery.
METHODS: Major abdominal surgery patients (hepatobiliary, MASP) were recruited during a preoperative clinic at MFT (UK). Non-MAs were recruited from the general population of Manchester, presented without any co-morbidities, whilst sprint-trained MAs were recruited from members of Finnish Track and Field Organizations. Ultrasound images of the VL were processed (ImageJ v.1.80) to obtain VL thickness (in mm). A strap placed above the tibial malleolus and attached to a custom dynamometer recorded MVC (in N) during a maximal isometric knee extension while participants were sitting down on a chair with knee and hip at 90°. Surgical outcomes were length of stay in hospital (LOS) (in days) and readmission after surgery. Differences in VL thickness and MVC/VL thickness between groups was assessed with an ANCOVA with age as covariate to assess differences in the age-related decline. Bonferroni post-hoc test assessed differences between groups.
RESULTS: A total of 98 male participants were included (MASP: N=31, 73±6 yrs, non-MAs: N=20, 73±5 yrs and MAs: N=47, 71±6 yrs). The mean LOS was 6 days (range: 2-12 days) No significant differences were found in VL thickness between groups (p=0.099), however MVC/VL thickness was lower in MASP compared with MAs and non-MAs (p<0.01). VL thickness and MVC/VL thickness declined similarly with age between groups (p>0.05). In the patient group, no significant relationship was found between VL thickness or MVC/VL thickness with LOS, and no difference was found in VL thickness and MVC/VL thickness between readmitted and non-readmitted patients (p>0.05).
CONCLUSION: Muscle quality, but not muscle thickness, appears to be negatively affected in MASP when compared to age matched controls. Future work should explore the impact of muscle quality on long-term surgical outcomes (1-year and 3-year survival rate) as similarly to our previous work, we found no relationship between any muscle parameter and short-term surgical outcomes3. A limitation of this study is that only male was included.

### RISK OF FALLS AND PHYSICAL ACTIVITY BEHAVIOUR IN COMMUNITY-DWELLING OLDER ADULTS. A CROSS-SECTIONAL ANALYSIS

KANAVAKI, A., MICHALOPOULOU, M., AGGELOUSIS, N.

*DEMOCRITUS UNIVERSITY OF THRACE*

INTRODUCTION: Falls in older adults are a public health problem and physical activity (PA) is an important behavioural factor in falls prevention. Following the reopening of community centers post Covid-19 restrictions, the study aimed to compare physical activity (PA) and sedentary behaviour (SB) of older adults at different levels of fall risk (FR) and identify socio-cognitive PA determinants.
METHODS: This is baseline data from ASPIDA, an on-going, longitudinal study, with 96 current recruits from community centers for older adults in Municipality of Rodopi, Northern Greece. Measures included an adjusted version of John Hopkins Fall Risk Assessment Tool, the Geriatric Depression Scale, Falls Efficacy Scale-International, Multidimensional Outcome Expectations for Exercise Scale, Self-efficacy for Exercise Scale, administered during site-visits, and triaxial accelerometers (Actigraph GT3X, GT9X), hip-worn for a week.
RESULTS: Mean age was 73.6 years (SD=6.2), 77.7% women. The proportion of people at low, medium and high FR was 22%, 60% and 16% respectively, with 69% reporting no fall history in the last 12 months. On average participants wore the accelerometers for 6.4 days and spent 58.3 minutes (SD=28.9) in moderate-to-vigorous PA (MVPA), 126.2 minutes (SD=36) in light PA (LPA) and 9.9 hours (SD=2) in SB daily. The guidelines of 150 minutes of weekly MVPA were met by 91% of participants. 67% reported doing no exercise, whilst 13% reported doing ≥1hour/week. There was no effect of sex, BMI and depression on FR. There was a significant effect of MVPA [$F(2,34.35)=22.08$, $p<.001$, $\eta2= .15$], the proportion of time spent in SB [$F(2,30.39)=11.21$, $p<.001$, $\eta2= .12$] and fear of falls [$F(2,22.74)=10.60$, $p<.001$, $\eta2= .36$] on FR. Those at high FR spent significantly less time in MVPA, more time in SB and had greater fear of falls than those at medium and low FR groups. Participants' PA/exercise outcome expectations (OE) were overall positive [M=4.3 (SD=0.5) for physical OE, M=4.2 (SD=0.6) for self-evaluative, M=3.2 (SD=0.7) for social]; self-efficacy was average [M=5.33 (SD=1.9)]. Only self-evaluative outcome expectations were associated with MVPA [$r(73)= 0.26$, $p<.05$].
CONCLUSION: The majority of participants met MVPA, but not exercise guidelines. Those at high risk of falls had a distinct profile with regard to MVPA and SB. In terms of falls prevention, which is the overarching aim of the ASPIDA project, these preliminary findings have implications for behaviour change targets: (a) increase exercise time and (b) boost PA associations with well-being and self-efficacy for all, (c) tailor interventions for individuals at high FR, e.g. by focusing on SB reduction and addressing fear of falls and safety concerns.

**ASSOCIATION OF MUSCLE FUNCTION, PHYSICAL PERFORMANCE, AND CARDIORESPIRATORY FITNESS WITH MILD COGNITIVE IMPAIRMENT: THE TOLEDO STUDY FOR HEALTHY AGING IN MIDDLE AGE**

SÁNCHEZ-MARTÍN, C., LEAL-MARTÍN, J., GARCÍA-AGUIRRE, M., SOTO-PANIAGUA, H., BALTASAR-FERNANDEZ, I., MUÑOZ-MUÑOZ, M., GUTIÉRREZ-REGUERO, H., ALCAZAR, J., LOSA-REYNA, J., ALEGRE, L.M.

Garcia-Garcia, F.J., Ara, I.

INTRODUCTION: Mild cognitive impairment (MCI) has been conceptualized as an intermediate stage between normal cognitive aging and dementia, with an estimated prevalence between 3% and 19% in older adults (1). MCI has a high risk of progression to dementia with a rate of 10–15% every year (2). However, it is considered to be a reversible process, as one-third of patients with MCI remain in clinical stability or even return to normal (3). On the other hand, previous evidence has shown an association between MCI and physical activity and exercise (4). Therefore, it seems reasonable to identify muscle function, physical performance, and cardiorespiratory fitness markers whose relationship with MCI may improve its early detection and subsequent intervention. Hence, this study aimed to examine the association between MCI and several physical fitness components in middle-aged adults.

METHODS: The sample comprised 138 middle-aged adults (53.9±0.1 years; 58% female) from the Toledo Study for Healthy Aging in Middle Age (THSA-ma). MCI was assessed by the Montreal Cognitive Assessment (MoCA), classifying patients with a score below 26 points as having MCI (5). Relative muscle power (30-second sit-to-stand muscle power test), handgrip strength (Jamar Dynamometer), functional mobility (Timed Up and Go Test), maximal walking speed (30-meter walk test), aerobic capacity (estimated VO2max; 6-min walk test), and balance (Y-balance test) were assessed. Logistic regression analysis adjusted for age, sex and education level was conducted.

RESULTS: The prevalence of MCI was 17.4%. Functional mobility was the only physical fitness component significantly associated with MCI (β= 0.019; [95 % CI 0.001 to 0.583]; p = 0.023). Relative muscle power (β= 1.079 [95 %, CI 0.698 to 1.667]; p= 0.732), maximal walking speed (β= 1.285 [CI 0.358 to 4,612]; p= 0.701),handgrip strength (β= 0.999 [95 %, CI 0.994 to 1.005]; p= 0.910),balance (β= 0.995 [95 %, CI 0.983 to 1.007]; p= 0.710) and aerobic capacity (β= 0,954 [95 %, CI 0.859 to 1.060]; p= 0.381) showed no associations with MCI.

CONCLUSION: Our preliminary data suggest that functional mobility was found to be the only physical fitness components associated with MCI in middle-aged adults from the TSHA-ma. Therefore, functional mobility could be a potential indicator when seeking for early detection of MCI. Future studies should focus on this relationship in the middle-aged population as there are no previous studies that have evaluated this association.

INTRODUCTION: Mild cognitive impairment (MCI) represents an intermediate stage between healthy cognitive aging and dementia (1). Its prevalence is estimated around 15-20% in aged more than 60 years (2). Brain-derived neurotrophic factor (BDNF) is essential for neuronal growth and survival, acting as a modulator neurotransmitter and being involved in neuronal plasticity (3). Increases in BDNF might be mediated by a response to exercise at the brain level. However, whether having a high fitness status could be linked to greater BDNF levels in cognitively healthy and MCI older adults, is still not clear. Therefore, this study aimed to examine the associations of a set of physical fitness components (cardiorespiratory fitness, muscular strength, flexibility, and coordination-agility), and BDNF in older adults cognitively healthy and with MCI.

METHODS: This study included cross-sectional baseline data from the EFICCOM project (Clinical Trial registration: NCT03923712). A total of 77 older adults (range 65 to 75 years, 39 women) participated in the study. Physical fitness was assessed by i) VO2peak through modified Bruce test and 6-minute walking test (cardiorespiratory fitness), ii) handgrip strength, arm curl, and 30 seconds-chair stand tests (upper and lower-limb muscular strength), iii) back scratch and chair sit and reach tests (upper and lower-limb flexibility, respectively) and iv) 8-foot up and go test (coordination-agility). BDNF levels were assessed in serum blood samples through by the Enzyme-linked immunosorbent Assay kit of RayBio Human BDNF. Neuropsychological criteria (non-MCI, MCI, and possible MCI) were determined by a specialist using a battery of cognitive tests. Linear regressions analyses were applied after adjusting for basic confounders (i.e., age, sex, and apolipoprotein E).

RESULTS: All physical fitness components were directly associated with BDNF levels in MCI group, (all $p<0.05$) in the overall adjusted model. Interactions of age and sex have been identified. However, physical fitness and BDNF levels were not significantly associated in non-MCI and possible MCI groups.

CONCLUSION: Cardiorespiratory fitness, muscular strength, flexibility, and coordination-agility were related to BDNF levels in older adults with MCI, but not in those cognitively healthy. Further studies analyzing the interaction role of age and sex in these relationships are needed.

KEY WORDS: cardiorespiratory fitness, muscular strength, flexibility, coordination, BDNF, old people, aging.

### ASSOCIATIONS OF LEAN MASS WITH OSTEOPOROSIS AND OBESITY AND THE INTERMEDIATE ROLE OF SEDENTARY TIME AND PHYSICAL ACTIVITY IN OLDER POPULATION

RODRÍGUEZ-GÓMEZ, I.1,2, MAÑAS, A.1,2, ALEGRE, L.M.1,2, RODRÍGUEZ-MAÑAS, L.2,3, GARCÍA-GARCÍA, F.J.2,4, ARA, I.1,2
*1GENUD-TOLEDO RESEARCH GROUP, UNIVERSITY OF CASTILLA-LA MANCHA, SPAIN; 2CIBER OF FRAILTY AND HEALTHY AGING , SPAIN; 3HOSPITAL UNIVERSITARIO GETAFE, SPAIN; 4HOSPITAL VIRGEN DEL VALLE, SPAIN*

INTRODUCTION: Osteoporosis and obesity constitute an important public health concern due to their high incidence (1, 2). Body composition changes are essential in the development of both pathologies, with physical activity (PA) and sedentary time (ST) as crucial parameters to reduce their risk (3, 4). However, no studies have been found in relation to the intermediate role of these confounders. Thus, the aim of this study was to determine the associations of lean mass with osteoporosis and obesity, and how these associations are moderated by PA and ST in older people.
METHODS: In total, 192 participants (53% women) from the TSHA study were analyzed in this study over a 4-year period. Lean mass determined by dual X-ray absorptiometry was the “exposure of interest” as a continuous variable (reference group includes participants who were in the lowest tertile). Osteoporosis and obesity were the “outcomes” and accelerometer-derived PA (light and moderate-to-vigorous) and ST were the “intermediate variables”. Associations between lean mass and outcomes were investigated using Cox proportional hazards models, adjusted for potential confounders. Interaction terms investigated whether intermediate variables modified these associations.
RESULTS: Lean mass was associated with a lower risk of obesity (hazard ratio [HR]:0.96; 95% confidence interval [CI]:0.94–0.99). This association persisted when the sample was categorized by tertiles, showing a decreased risk in the subgroups of greater lean mass (HR:0.46; 95% CI:0.26-0.80). Associations of lean mass with osteoporosis and obesity were not modified by PA and ST. Nevertheless, the stratification into different categories depending on the potential modifier, showed that those with higher moderate-to-vigorous PA presented lower obesity risk compared with the less active older people (HR:0.96; 95% CI:0.93-0.99). No significant associations were observed between lean mass and osteoporosis with this method.
CONCLUSION: Lean mass was strongly associated with obesity, even after adjustment for confounders. Interventions to reduce obesity incidence should be focused on increasing lean mass, which could be more effective if older people spend more time in moderate-to-vigorous PA. Further research focusing on the characteristics of lean mass is needed to reduce the risk of osteoporosis.

### DEVELOPING A FIELD-TEST FOR FORCE-VELOCITY PROFILING IN OLDER ADULTS

BOCHICCHIO, G., FERRARI, L., BOTTARI, A., SCARTON, A., POGLIAGHI, S.
*UNIVERSITY OF VERONA*

INTRODUCTION: Muscle function is a marker of current and prospective health and mobility throughout life and in ageing. Force-velocity profiling (F-V) evaluates muscle function through the identification of maximum force (F0), velocity (V0) and power (P0). To assess this relationship, Isokinetic Dynamometry is the laboratory gold standard. However, the high cost, request of specialized personnel and the unphysiological contraction pattern that does not resemble that of real life, have triggered the search for more applicable alternatives. The 5 Sit to Stand Test (5STS) is a multi-joint, close chain and functional test widely used in clinical setting to assess muscle power of the lower limbs. In its original version the test does not permit the characterization of F-V. Therefore, the purpose of this study was to use a modified version of the 5STS (m5STS) to characterize muscle function in older adults. To this aim, we compared F0, V0 and P0 from m5STS and isokinetic knee extension (ISO).
METHODS: Forty-one older adults (20 females: 63,5±3,7 years) performed 5STS in four different load conditions (Bodyweight, +12.5%, +25% and +37.5% of Bodyweight) in random order. The position of a marker placed on the subject’s trochanter was monitored by Motion Capture (MOCAP) and, for each subject and trial, the mean concentric velocity (ascending phase of the movement) was extrapolated. In addition, each subjects performed isokinetic tests at 5 different velocities (60, 90, 150, 180 and 210 °/sec, in random order). Individual F-V relationships were built for both tests and F0 (corresponding to the null velocity), V0 (corresponding to null force) and P0 (corresponding to maximum power) were calculated. A correlation coefficient for the individual F-V relationships was calculated for both methods. Comparison between the above variables from m5STS test and ISO were evaluated by paired t-test and correlation.
RESULTS: Mean correlation coefficients from ISO (-0.97 ± 0.05) and m5STS test (-0.96 ± 0.06) showed strong within-individual relationships and were not different between methods. The group mean value of F0 (m5STS: 1952.29 ± 594.16 [N]; ISO= 310.92 ± 84.45 [N]), V0 (m5STS: 0.91 ± 0.22 [m*s-1]; ISO= 3.03 ± 0.42 [m*s-1]), P0 (m5STS: 431.83 ± 127.97 [W]; ISO= 233,64 ± 65,00 [W]) were significantly different ($p<0.001$) as is expected for bilateral vs single-limb exercises. Linear regression showed moderate correlation between F0m5STS and F0ISO (r= 0,55) and high correlation between P0 m5STS and P0ISO (r= 0,81).
CONCLUSION: The m5STS proposed in our study is a simple, submaximal, time- and cost-efficient test to evaluate lower limb muscle function in older adults of both sexes. The high correlation coefficients of both methods for individual F-V relationships and the strong correlation between values of P0, indicate a good ability of m5STS to correctly characterize muscle function, making it a promising tool for the large-scale assessment and monitoring muscle function in ageing.

**ESTIMATING MUSCLE POWER OF THE LOWER LIMBS THROUGH THE 5-SIT-TO-STAND TEST: A COMPARISON OF FIELD VS LABORATORY METHOD.**

FERRARI, L., BOCHICCHIO, G., BOTTARI, A., LUCERTINI, F., SCARTON, A., POGLIAGHI, S.

*UNIVERSITY OF URBINO*

INTRODUCTION: Muscle power (MP) of the lower limbs is a key determinant of current and prospective mobility and independent living in ageing. The 5-Sit-to-stand test (5STS) has been proposed as simple "field method" to estimate lower limbs MP from the body's vertical velocity (vertical displacement/mean concentric time) and force (body mass*g). It relies on the chronometric measure of the time to perform 5 consecutive standing movements and the following unverified assumptions: i) vertical displacement (Vdspl) = (50% stature – chair seat height); ii) mean concentric time (meanT) = 10% trial duration; iii) mean force (meanF) = (90% body mass (BM) * g). We aimed to verify the correspondence between assumed and measured variables and the accuracy of field estimates of MP (MPfield) vs a laboratory approach (MPlab) that uses a motion capture system (MOCAP) and a force plate (FP) to measure the Vdspl, meanT and meanF.
METHODS: 40 older adults (20 females, 66 ± 6 yrs) completed two trials of the 5STS test. For the field method, total trial duration was measured with a chronometer, chair seat height with measuring tape and MPfield was computed as per the above listed assumptions. For the laboratory method, the Vdspl of a marker placed on the trochanter was identified by MOCAP; the meanT was identified based on the speed trajectory of the same marker over time; concurrently meanF was monitored with a FP positioned under the subject's feet in the concentric phase. MPlab was calculated as the product of speed and force. The correspondence between field and lab methods for Vdspl, meanT, meanF and MP was evaluated by paired t-test.
RESULTS: The assumptions of start (i.e. chair seat height) and end points (i.e. 50% of stature) of the displacement used in the field method were both overestimated compared to the direct measures by ~ 0.10 m. However, the Vdspl was similar for both methods (0.33±0.06 vs 0.34±0.05 m, p=0.28). Lab measures yield significantly lower meanT (0.63±0.14 vs 0.91±0.23 s, equal to 7±1 vs 10% of sit to stand time, p<0.001) and lower meanF (594.90±113.12 vs 646.62±96.42 N, equal to 82±9 vs 90% BM, p<0.001) and higher meanV (0.53±0.11 vs 0.40±0.09m*s-1, p<0.001) vs field. Finally, MPfield (257.71±75.24 Watt) was significantly underestimated compared to MPlab (321.24±103.11 Watt, p<0.001).
CONCLUSION: The 5STS field test is a valuable tool to estimate muscle power thanks to its simplicity and low cost. However, the assumptions on which it is based appear inaccurate, yielding to a significant and large underestimation (-21±21%) of muscle power of the lower limbs compared to the gold standard laboratory measures in a population of older adults. The identification of accurate and, possibly, population-specific assumptions is necessary to grant a generalised applicability of this time and cost-effective method for the monitoring of muscle power of the lower limbs.

**THE ROLE OF DEFAULT NETWORK AND EXECUTIVE CONTROL NETWORK IN THE IMPROVEMENT OF COGNITIVE FUNCTION IN THE ELDERLY BY EXERCISE**

MA, J.1, LIU, R.2, HOU, L.2

*CHINA INSTITUTE OF SPORT SCIENCE*

INTRODUCTION: With the deepening of the aging population, age-related cognitive decline has become the focus of social concern. Exercise has been shown to improve cognitive function in the elderly, and play an important role in delaying the onset of cognitive impairment (1, 2), but the brain mechanism behind the improvement of behavior in the elderly is unclear. Therefore, this study intends to use the resting-state brain network analysis to explore the role of default network and executive control network in the improvement of cognitive function in the elderly by exercise.
METHODS: The 69 subjects enrolled in the BABRI database were divided into control group and exercise group according to exercise frequency. A series of behavioral tests include mini-mental state examination (MMSE), clock drawing test (CDT), symbol digit modalities test (SDMT), trail making test (TMT), verbal fluency test (VFT) and Boston naming test (BNT) were used to measure the general cognitive performance, visuospatial ability, attention, executive function and language functions, respectively. Combined with imaging technology based on GIFT software, the independent component analysis method (ICA) was used to analyze the default network and executive control network of the elderly in two groups. The correlation analysis was made between different brain regions and cognitive performance.
RESULTS: (1) The exercise group had better behavioral performance on cognitive tests such as MMSE, SDMT, TMT, VFT and BNT than control group (P<0.05), but there was no significant difference in CDT between two groups (P>0.05). (2) In the default network, the brain functional activity in the dorsolateral superior frontal gyrus, middle left superior frontal gyrus, superior frontal gyrus and right anterior cingulate gyrus of the exercise group was significantly stronger than that of the control group (P<0.05). (3) In the executive control network, the brain functional activity in the left inferior parietal lobe, lower cerebellum, left inferior temporal gyrus and inferior frontal gyrus of the exercise group was significantly stronger than that of the control group (P<0.05). (4) In the executive control network, the left inferior parietal lobe of the exercise group was significantly positively correlated with the MMSE score (r=0.301, P<0.05). (5) In the executive control network, the left inferior parietal lobe of the exercise group was significantly positively correlated with the attentional SDMT score (r=0.374, P<0.05).
CONCLUSION: Regular exercise can improve the cognitive, attention, executive, and language functions in the elderly. Exercise improves cognitive function may be related to enhanced functional activity in the frontal, anterior cingulate, and inferior parietal regions of the default network and executive control network after exercise.

### CP-PN06 Sleep/metabolism

#### INFLUENCE OF COMPETITIVE SCHEDULE ON SUBJECTIVE AND OBJECTIVE SLEEP DURATION IN PROFESSIONAL FEMALE SOCCER PLAYERS

KNOTT, S.M., ANDERSON, R., TARNOWSKI, C.A., BROWN, L.R., CARTER, J.M., MOSS, S.L., BRIGHT, N., RANDELL, R.K., ROLLO, I.

*PEPSICO*

INTRODUCTION: To support performance, recovery and physical and mental health athletes are advised to achieve approximately eight hours of sleep. During the competitive season it is important to understand how sleep varies to inform sleep and recovery recommendations. In professional female soccer players there is limited sleep data available. In addition, no studies have compared objective and subjective measures of sleep duration within a comprehensive competitive soccer schedule. This information is important as objective measures are expensive and often cost prohibitive to teams. Therefore, the aims of this study were to 1) determine the impact of competitive schedule on sleep duration, 2) compare objective and subjective measures of sleep duration in professional female soccer players.
METHODS: Sleep was measured over 44 ± 10 d in seven professional female soccer players (age: 29 ± 5 y) during a competitive season (Women's Super League, England). Sleep duration (h:min) was measured objectively using wrist-worn actigraphy (Biostrap EVO, USA) and subjectively by a daily questionnaire completed the following morning. Only night time sleeping was included in the data set. Competitive schedule was categorised as: Match Day (MD), Training Day (TD; pitch based, soccer skills, gym based), Recovery Day (RD; non-soccer specific training), and Off Day (OD). Data are shown as mean ± SD; a statistical level of significance was set at $P<0.05$.
RESULTS: Objectively, players slept longer on TD (8:49 ± 1:21 h:min) compared to RD (7:59 ± 1:33 h:min, $P<0.05$). No differences between other days were found. Objective measures of sleep duration were higher (8:25 ± 0:36 h:min) compared to subjective measures (8:03 ± 0:28 h:min, $P<0.01$). Five out of the seven players consistently under-estimated sleep duration. Objective sleep duration was greater than subjective sleep duration on TD and OD (0:36 and 0:35 h:min respectively, $P<0.01$), with no differences observed on MD or RD ($P>0.05$). Subjectively TD and RD had highest sleep duration (TD: 8:13 ± 1:03 and RD 8:14 ± 0:56 h:min), MD had lowest (7:29 ± 1:34 h:min, $P<0.01$), with no differences observed on OD (7:54 ± 0:52 h:min, $P>0.05$).
CONCLUSION: The results of the present study show that competitive schedule does have an impact on sleep duration in professional female soccer players, however results varied between objective and subjective sleep measures. Further investigation is warranted to fully understand the depth of the interaction between competitive schedule and sleep in this cohort. Furthermore, this study shows that professional female soccer players underestimate sleep duration. This underestimation is limited at approximately 4% (0:22 h:min). As such, subjective measures may be appropriate for use on a longitudinal basis, especially when objective measures are not accessible or affordable. However, to determine a full sleep profile over a competitive schedule objective measures are advisable.

#### TIME-DEPENDENT CORTICAL PLASTICITY DURING MODERATE-INTENSITY CONTINUOUS TRAINING VERSUS HIGH-INTENSITY INTERVAL TRAINING OVER AN 8-WEEK PERIOD IN RATS

HUGUES, N.

*INSTITUT DE NEUROBIOLOGIE DE LA MÉDITERRANÉE*

INTRODUCTION: Beyond its role in improving cardiovascular and muscular functions, chronic endurance exercise is now recognized to enhance brain health by promoting cerebral plasticity. Nevertheless, the cortical plasticity which is heavily involved in sensorimotor tasks remains understudy. Hence, its temporal pattern specifically induced by various endurance training regimens is still to be defined to better clarify its benefits in preventing neurological disorders. Among the most common endurance training regimens are the moderate-intensity continuous training (MICT) defined by an intensity below the speed associated to the lactate threshold (SLT) or approximately 50–70% of the maximal speed (Smax) and the high-intensity interval training (HIIT) characterized by repeated bouts of intense exercise above the SLT. Thus, the purpose of this study is to define the time-dependent effects of work-matched HIIT and MICT on cortical plasticity, endurance and sensorimotor performances over an 8-week training period in healthy rats.
METHODS: Adult healthy rats performed incremental exercise tests on treadmill and sensorimotor tests before and at 2, 4, and 8 weeks of training. At the same timepoints, cortical markers related to neurotrophic, angiogenic and metabolic activities were assessed.
RESULTS: Our results indicate an effectiveness of both training regimens in maintaining forepaw mechanical sensitivity at the end of the training period as well as in enhancing forelimb grip strength, SLT and Smax over these 8 weeks. HIIT induces superior endurance improvements than MICT as observed by significant enhancement of SLT and Smax at 2 and 8 weeks. Nonetheless, MICT promotes early increases in the expression of neurotrophic, angiogenic and metabolic markers while it tends to show less influence at 8 weeks. Indeed, both brain-derived neurotrophic factor (BDNF) and the Apelin receptor (APJ) remain elevated until the 4th week of training whereas vascular endothelial growth factor (VEGF) returned to baseline at this timepoint with MICT. Interestingly, HIIT early triggers the insulin-like growth factor-1 (IGF-1) and upregulates VEGF later on as well as other neurotrophic, metabolic and angiogenic markers at 2 and 8 weeks. HIIT appears to be effective in the early downregulation of the neuronal K-Cl cotransporter KCC2 which has been shown to increase the neuronal activity and the upregulation of neurotrophic factors. Although HIIT does not alter BDNF levels, this training regimen is effective in triggering BDNF receptors levels which are a major cascade of its actions.
CONCLUSION: Hence, by altering specific markers of neuroplasticity at different timepoints, HIIT and MICT appears to be effective in a time-dependent manner suggesting a complementary effect that might be useful in physical exercise guidelines for maintaining brain health.

**EFFECTS OF ONE NIGHT'S SLEEP RESTRICTIONS ON MAXIMAL STRENGTH, MUSCLE POWER, AND STRENGTH ENDURANCE IN RESISTANCE-TRAINED WOMEN**

KOMAREK, Z., LATOCHA, A., KRZYSZTOFIK, S., KRZYSZTOFIK, M., SPIESZNY, M., HOLDA, M., FILIP-STACHNIK, A.

*AKADEMIA WYCHOWANIA FIZYCZNEGO IM. JERZEGO KUKUCZKI W KATOWICACH*

INTRODUCTION: Although several studies analyzed the impact of sleep loss on resistance performance in trained individuals, to date, no investigation has been conducted on women. Therefore, the aim of this study was to explore the effects of sleep restrictions on maximal strength, muscle power, and strength endurance in resistance-trained women.
METHODS: Twelve resistance-trained women participated in a randomized, counterbalanced and crossover experiment. Each participant performed two identical experimental sessions in two sleep conditions a) with sleep restrictions (SR), where they experienced acute sleep restriction the night before the test session (i.e., 2 h of sleep restriction versus normal sleep) b) with the control condition (CON), where they followed their habitual sleep-wake routines. Testing procedures included in the following order: a) maximal strength bench press test, b) three sets of three repetitions of explosive bench press exercise at 50% of the load representing one-repetition maximum (1RM); (c) countermovement jump; d) muscle endurance test in the bench press exercise at 50% 1RM. Additionally, before the testing, participants completed subjective responses to a readiness-to-train questionnaire (RTT-Q) and reported the rate of perceived exertion (RPE; range 6 - 20) and pain on a visual analogue scale (VAS; range 0 - 10) immediately after the treatment.
RESULTS: Significant differences between CON and SR conditions were observed in peak (0.51 ± 0.13 vs 0.45 ± 0.14 m/s; p = 0.023) and mean (0.30 ± 0.12 vs 0.27 ± 0.11 m/s; p = 0.012) bar velocity during muscle endurance test, without significant differences in the maximal strength test (43.75 ± 6.07 vs 43.16 ± 7.18 kg; p = 0.492), peak (1.30 ± 0.19 vs 1.31 ± 0.21 m/s; p = 0.780) and mean (0.91 ± 0.13 vs 0.90 ± 0.12 m/s; p = 0.752) bar velocity during explosive bench press exercise, countermovement jump (29.15 ± 5.17 vs 29.51 ± 5.34 cm; p = 0.356), number of repetition (31.83 ± 9.08 vs 30.66 ± 7.74; p = 0.410) and time under tension during muscle endurance test (63.17 ± 23.10 vs 63.08 ± 20.38 s; p = 0 .637). Significant differences between CON and SR conditions were observed in the values of RPE (14.7 ± 2.4 vs 17.3 ± 1.7; p= 0.001), VAS pain scale (6.9 ± 1.5 vs 7.8 ± 0.7; p = 0.035) and in RTT-Q answers for questions "Do you feel physically strong today?" (3.7 ± 0.9 vs 2.8 ± 1.0; p = 0.014), "Do you feel mentally strong today?" (4.3 ± 0.9 vs 3.5 ± 1.4; p = 0.027) and "Rate your motivation to train today" (7.7 ± 1.4 vs 6.5 ± 2.4; p = 0.031).
CONCLUSION: The present study indicates that short-term sleep restriction only slightly affects upper-body resistance performance. However, performance responses to acute sleep restriction seem to be highly individual. Significant changes were observed in reports of RPE, pain and RTT-Q. These findings suggest that subjective measures are more sensitive to the effects of two hours of sleep restrictions in resistance-trained women.

**EFFECTS OF ACUTE WRIST TENDON VIBRATION ON SPINAL AND CORTICAL EXCITABILITY**

AMIEZ, N., MARTIN, A., GAVEAU, J., JULLIAND, S., PAPAXANTHIS, C., PAIZIS, C.

*UNIVERSITÉ BOURGOGNE FRANCHE-COMTÉ*

INTRODUCTION: The application of tendon vibration (TV) stimulates the primary and secondary endings of the muscle spindles [1]. The integration of sensory information by the brain can produce illusions of movement in the opposite direction to the vibrated tendon. Prolonged application (several minutes) can induce cortical and spinal changes in the vibrated (agonist) and non-vibrated (antagonist) muscles of the same joint [2, 3]. The aim of this study was to improve our understanding of the neurophysiological adaptations induced by 30 minutes of continuous VT on the wrist joint.
METHODS: TV was applied to the FCR muscle (Duration: 30, Format: continuous, Frequency: 80hz, Amplitude: 0.5mm). The subjects had their arms masked during TV to promote an extension illusion. Motor-evoked potentials (MEPs, 17 subjects), Cervico-medullary-evoked potentials (CMEPs, 15 subjects), and Hoffmann-reflexes (H, 15) of the flexor carpi radialis (FCR) and extensor carpi radialis (ECR) were measured in three different sessions. Four blocks of measurement were performed: before TV (PRE) and at 0 (P0), 30 (P30) and 60 (P60) after vibrations were stopped. All measurements were performed at rest with an intensity set before the PRE block. All the results were expressed in percentage of the maximal muscular response (MMAX) obtained at each moment for the two muscles. Ratios MEP/CMEP for the FCR and ECR muscle (15 subjects) were measured as well as H/CMEP for the FCR muscle (12 subjects).
RESULTS: MEPs remained unchanged ($p > 0,073$) while CMEPs decreased at P0 ($p < 0,001$) for both muscles. The H-reflex of the FCR largely decreased at P0 and P30 ($p < 0,001$). The MEP/CMEP ratio increased for both muscles at P0 ($p < 0,05$). The H/CMEP ratio decreased at P0 and P30 for the FCR muscle ($p < 0,001$).
CONCLUSION: The MEP/CMEP ratio demonstrates that a temporary increase in cortical excitability occurs for both vibrated (FCR) and non-vibrated (ECR) muscles. The increase in the MEP response is masked by a decrease in the excitability of spinal motoneurons. Decreased spinal excitability alone does not explain the decreased H reflex for the FCR muscle. Apart from the H-reflex of the FCR muscle, the effects of TV on spinal (CMEP) and cortical (MEP/CMEP) excitability appear to be transient for both muscles, with a return to normal within 30 minutes after cessation of vibrations.

**CAFFEINE SUPPLEMENTATION IS EFFECTIVE TO MODULATE THE TORQUE EVOKED BY WIDE-PULSE HIGH-FREQUENCY NEUROMUSCULAR ELECTRICAL STIMULATION.**

LANFRANCHI, C., POPESCO, T., BAUDRY, S., PLACE, N.

*UNIVERSITÉ DE LAUSANNE*

INTRODUCTION: Neuromuscular electrical stimulation (NMES) is widely used in rehabilitation but holds some limitations, such as discomfort and limited evoked torque. Wide-pulse high-frequency (WPHF) NMES has been proposed to evoke larger torque ('extra torque') levels at relatively low stimulation intensity because of reflexive motor unit recruitment. However, there is a large interindividual variability in extra torque during WPHF NMES (Neyroud et al., 2018). Persistent inward currents (PICs), known as synaptic input amplifier (Heckman et

al., 2008), have been proposed as a potential mechanism underlying extra torque (Collins et al., 2001); thus any intervention aiming at enhancing PIC strength should increase WPHF NMES evoked torque. As caffeine has been suggested to enhance PIC strength (Walton et al. 2002), the present study aims at testing the hypothesis that caffeine supplementation would increase WPHF NMES torque through increased PICs.
METHODS: Sixteen healthy participants (25±5 years) participated in this double-blinded, randomized, placebo-controlled study. WPHF NMES was applied over the triceps surae during 10 s (pulse duration: 1 ms, frequency: 100 Hz) at an intensity evoking 10% of maximal voluntary contraction torque. One train of stimulation was delivered before (Pre) and 1h after (Post) placebo/caffeine (6 mg/kg) ingestion. The torque produced during stimulations was quantified using several parameters: torque time integral (TTI, area under the torque curve) and extra TTI (change in TTI relative to the value obtained during the 1st second of the train). Surface electromyography (EMG) was used on the Soleus (SOL) to measure sustained EMG activity (the persisting EMG activity after the end of the tetanic train, expressed in % maximal EMG activity), an index of PIC strength. Paired t-tests or Wilcoxon signed-rank tests were performed to test for differences in absolute changes (from Pre to Post) between conditions. Values are presented as mean ± SD.
RESULTS: Extra TTI increased after caffeine ingestion (Control: - 9±36% vs. Caffeine: +15±45%, P=0.046) as did SOL sustained EMG activity (Control: - 3±6% vs. Caffeine: + 3±4%, P=0.022), while the change in TTI values (Control: - 12±64 N.m.s vs. Caffeine: + 69±140 N.m.s, P=0.058) was close to significance. In the Caffeine condition, there was a significant positive relationship between the change in TTI and the change in sustained EMG activity (Spearman correlation coefficient = 0.57, P=0.027).
CONCLUSION: The present study shows that acute caffeine supplementation is effective to modulate WPHF NMES evoked torque. The association with the change in sustained EMG activity suggests that PICs may be involved, although this remains to be validated. These findings may pave the way for future therapeutic strategies aiming at enhancing torque production during NMES.

## THE EFFECT OF BODY TEMPERATURE DURING CYCLING EXERCISE, HOT AND COLD WATER IMMERSION ON CELL-FREE DNA LEVELS IN YOUNG ADULTS

JUŠKEVICIUTE, E.1,2, NEUBERGER, E.W.I.1, EIMANTAS, N.2, KILIKEVICIENE, S.2, BRAZAITIS, M.2, SIMON, P.1

*1 JOHANNES GUTENBERG UNIVERSITY, MAINZ, GERMANY; 2 LITHUANIAN SPORTS UNIVERSITY, KAUNAS, LITHUANIA*

INTRODUCTION: As a versatile biomarker of pathophysiological conditions, cell-free DNA (cfDNA) is involved in immunomodulation, inflammation, and other biological processes (Kustanovich et al., 2019). Exercise markedly increases cfDNA values and is a promising marker for training load or overtraining (Breitbach et al., 2012); however, the underlying physiological and molecular mechanisms are still unknown.
METHODS: Here, we investigated the effect of body core temperature (Tc) on cfDNA release. To identify the relative contribution of Tc on cfDNA release, 15 young male participants completed an exercise trial (cycling at 60% VO2max until Tc reaches 39 deg), hot water (43-44 deg) immersion (until Tc reaches 39 deg), and cold water (10 deg) immersion for 1 hour. Blood samples for cfDNA analysis were taken every time the core temperature rose by 0,5 deg and returned to baseline during cycling and immersion in hot water. In cold water immersion, blood samples were collected every 15 minutes.
RESULTS: During cycling exercise, cfDNA levels increased steadily 5.98-fold from Pre (9.81 ± 4.36 ng/ml) to 39 deg (57.31 ± 31.82 ng/ml). Compared to Pre values, the cfDNA levels were significantly increased at each Tc and remained elevated until Tc returned to pre-exercise values ($p \leq 0.05$). In the passive heating trial, there were significant elevations of cfDNA concentrations measured at Tc 39 deg and 38,5 deg post compared to the baseline value. The values were increased by 1.85-fold and 1.95-fold, respectively (18.34 ±7.03 ng/ml, 19.34 ± 10.77 ng/ml). We found no significant changes in cfDNA concentration during and after cooling at each of the eleven-time points. The levels remained between a minimum of 9.18 ± 3.98 ng/ml and a maximum of 12.14 ± 11.49 ng/ml.
CONCLUSION: Our analysis reveals different responses of cfDNA depending on the changes in core temperature. Since neutrophils play a key role in the release of cfDNA under resting conditions (Moss et al., 2018), and during exercise (Neuberger et al., 2022), and increasing body temperature affects neutrophils homeostasis (Capitano et al., 2012), neutrophils might contribute to cfDNA increases during heating. However, since the fold changes are much higher during exercise (5.89-fold) compared to heating conditions (1.95-fold) a different activation of the cells is likely. Our observations indicate that the release of cfDNA is dependent on the duration of exercise and body temperature.

## GLUCOSE MONITORING DEVICES - A COMPARISON BETWEEN MEASURING IN INTERSTITIAL FLUID (CGM-SENSORS) AND CAPILLARY BLOOD AT REST AND DURING ENDURANCE EXERCISE

BAUHAUS, H., ERDOGAN, P., TUMA, C., BRAUN, H., THEVIS, M.

*GERMAN SPORTS UNIVERSITY OF COLOGNE, INSTITUTE OF BIOCHEMISTRY*

INTRODUCTION: Continuous glucose monitoring (CGM) has become popular as a supportive tool in diabetic therapy. As CGM devices measure glucose in a minimally invasive manner in the interstitial fluid (ISF) in a frequency of 1 min-1, there is growing interest in the application of CGM systems in professional sports and research of glucose kinetics (Holzer et al., 2022). In a diabetic population, a lag-time between capillary blood (CB) glucose and ISF glucose was shown (Zaharieva et al., 2019). Therefore, the study's aim was to compare glucose concentrations from CB samples and from CGM measurements in an athletic population.
METHODS: Ten healthy athletes (training volume of 10±3 h, 26±4 yrs, 67±11 kg) underwent four tests at rest (R), and two running tests at 65% (65) and 85% maximal heart rate (HRmax) (85) following a standardized CHO meal in the evening prior to test morning. Tests were conducted either in a fasted (FAST) or postprandial state after intake of 1 g glucose / kg bodyweight (GLC). Glucose concentration was measured by CGM device (Abott Libre Sense Glucose Biosensor for Sport, Abbott Laboratories, Chicago, IL, US) using Supersapiens' Software for crude data access (TT1 Products Inc., Atlanta, GA, US) and CB samples (EKF Biosen C-line, EKF diagnostics Holding, Cardiff, UK). Descriptive data was calculated using Excel 2016 (Microsoft Corp., Redmond, WA, US). Further statistical analysis was performed using SPSS 28 (IBM SPSS Statistics, Chicago, IL, USA).
RESULTS: Pairwise T-test and Wilcoxon-Test analysis reveal a significant difference between CB and ISF glucose concentration for five out of six conditions ($p<.05$). Aggregated mean average relative deviation (MARD) is lowest for R_FAST (7±2%; 11±2%) and highest for 65 and 85 (22±14%; 18±11%). Pairwise T-test shows a significant difference in peak glucose concentration (PEAK) between CB and ISF for both R_Glc conditions (183±21 mg/dL vs. 167±20 mg/dL; 180±23 mg/dL vs. 159±17 mg/dL) ($p<.05$). Wilcoxon-Test for time to peak (TTP) reveals a significant difference between one out of two R_Glc conditions (27±9 mg/dL vs. 38±8 mg/dL) and for 85 (72±5 mg/dL vs. 43±20 mg/dL) ($p<.05$).

CONCLUSION: The present study shows a delay in ISF compared to CB glucose concentration. Beyond that, results show a higher deviation under exercising conditions compared to resting conditions. Further data collection especially postprandially and during physical activity is needed to confirm current findings and to estimate chances of CGM devices' application in practice and research.

## RELATIONSHIP BETWEEN SUBMAXIMAL OXYGEN CONSUMPTION AND BONE MINERAL DENSITY DIFFERS BETWEEN TRI-ATHLETES AND MARATHONERS

OUTWIN, J.R., DAVIS, F., MELVIN, A.C., STUMP, O., REED, S., KOZLOFF, K.M., LEPLEY, A.S.
*UNIVERSITY OF MICHIGAN*

INTRODUCTION: Maintaining bone mineral density (BMD) is a crucial component of lifelong bone health and is particularly important for injury prevention in sport. Athletes participating in high impact sports have higher BMD compared to running athletes [1], underscoring the importance of mechanical loading in osteogenesis [2]. In contrast, cyclists and swimmers are at a greater risk for osteopenia due to low mechanical loading [3]. Currently, there is a dearth of information about BMD in triathletes, combining running, cycling and swimming. Given that aerobic fitness may influence the extent to which an athlete can generate osteogenic bone stress during training, the purpose of this study was to assess the relationship between submaximal and maximal oxygen uptake and BMD across endurance athletes involved in multiple activities vs. endurance running alone.
METHODS: Triathletes (TA; n = 14, age = 38.4 ± 13.5 yrs, 7M:7F), training for an Ironman or similar event, and high-level marathoners (HLM; n = 14, age = 44.2 ± 17.3 yrs, 7M:7F), as determined by recent achievement of a Boston Marathon qualifying time, volunteered for this IRB-approved study. Dual energy x-ray absorptiometry (DEXA; Lunar iDXA; GE Healthcare, Chicago, IL) assessed total body, spine (L1-L4), and femoral neck BMD, which were converted to T-scores accordingly. An incremental treadmill protocol using a metabolic cart (Quark CPET; COSMED, Rome, Italy) recorded submaximal oxygen consumption (VO2) at participants' self-reported half-marathon race pace (RP) and maximal VO2 (VO2max) at maximal exertion. Independent t-tests were used to assess group differences. Simple bivariate correlations were assessed between each BMD measure and both RP and VO2max for both groups. $\alpha$ was set $p \leq 0.05$.
RESULTS: There were no differences between groups in VO2max, RP, or BMD ($P > 0.05$). RP VO2 was higher in HLM (45.5±7.3ml/kg/min) vs. TA (39.25 ± 6.2; $p = 0.03$). There were significant positive and moderate relationships between RP VO2 and femoral neck BMD ($R2 = 0.29$, $p = 0.048$) and total BMD ($R2 = 0.32$, $p = 0.036$) in the HLM group. These relationships were insignificant in the TA group ($R2 = 0.03$, $p = 0.58$; $R2 = 0.003$, $p = 0.84$). Trending correlations ($p < 0.10$) were seen between VO2max and BMD (FN, LS and total) in HLM, but not in TA participants.
CONCLUSION: The results indicate that higher RP VO2 is related to greater BMD in HLM but not in TA. Since higher RP VO2 was strongly associated with greater speed at RP ($p < 0.0001$), this could facilitate increased accumulation of osteogenic bone stress during chronic training in HLM. Its possible that TA do not see the same changes in BMD with RP VO2 because of training regimen differences, but further investigation is needed. These findings provide a basis for future research to understand the complexities contributing to BMD in endurance athletes.

## DOES THE NUTRITIONAL VALUE OF THE PALEO DIET MEET THE RECOMMENDATION FOR PROFESSIONAL ATHLETES?

PIETA, A., MAZUR-KURACH, P., SZOT, M., FRACZEK, B.
*UNIVERSITY SCHOOL OF PHYSICAL EDUCATION IN KRAKOW*

INTRODUCTION: Paleolithic nutrition is based on the principles of evolutionary biology with a focus on the moderate carbohydrate options available to hunter–gatherers. The relatively small amount of carbohydrates in the Paleo diet is increasingly used by athletes with the aim of using fat during exercises and saving carbohydrate reserves. The purpose of the study was to evaluate the nutritional value of the isocaloric Paleo diet according to recommendations dedicated to professional athletes.
METHODS: The food rations were prepared for nine professional handball players considering the isocaloric model of the Paleo diet (PD) based on individual assumptions. The following energy share of macronutrients was adopted: 20-30% protein, 35-40% fat and 30-35% carbohydrates. A total of 504 daily food rations were created and then prepared by the catering company for 8 weeks for each athlete. The nutritional value of the Paleo diet applied by athletes was compared to the recommendations for ones according to various position stands.
RESULTS: In relation to the recommendation for athletes the Paleodiet distinguished by a higher content of protein (24,22%, but not in g/kg of body mass: 2,82g/kg), fats (40,52%; 2,06g/kg of body mass), saturated fatty acids (15,76%), cholesterol (1018,16mg), fiber (59,86 g/d) and lower amount of carbohydrates (35,13%; but sufficient in g/kg of body mass: 4,23g/kg), sucrose (13,09%), polyunsaturated fatty acids (5,44%). The PD is characterized by an adequate content of sodium and vitamins: K, B1 and higher (exceeding the RDA/AI) content of minerals: phosphorus, iron, magnesium, zinc, copper, potassium, manganese, selenium, and vitamins: A (higher than UL), E, C, niacin, vit. B2, B5, B6, B12, and folic acid but lower than RDA/AI amount of minerals: calcium, and vit. D.
CONCLUSION: The analysis of the content of macro- and micronutrients in the Paleodiet, considering the increased energy needs of athletes, allows it to be considered a diet with high nutritional value. The carbohydrate content is close to the lower limit of the recommendation, and the fat content is slightly higher than the upper limit of the recommendation. Recommendations for polish population have been implemented. The Paleodiet is characterized by a high content of vitamin D, which should be considered an exceptionally beneficial feature of the diet. The results allow to justify the use of the PD by athletes as an effective method of nutrition with a low risk of deficiencies in most nutrients. A properly composed PD can be considered as a strategy for athlete representatives of disciplines that do not require high availability of carbohydrates (e.g., team sports).

### CAFFEINE DOES NOT INCREASE PERSISTENT INWARD CURRENTS IN HUMAN TIBIALIS MUSCLE

MACKAY PHILLIPS, K., ORSSATTO, L.B.R., POLMAN, R., VAN DER POLS, J., TRAJANO, G.S.

*QUEENSLAND UNIVERSITY OF TECHNOLOGY*

INTRODUCTION: Neuromodulation is a fundamental part of normal motor command. Several neurotransmitters play a role in neuromodulation. Specifically, serotonin and noradrenaline facilitate persistent inward currents (PIC) in motoneurons. PIC amplify and prolong synaptic input allowing motor units to fire at higher frequencies, as observed during normal motor behaviour. Caffeine is a methylxanthine known to increase the release of noradrenaline, enhance the concentration of serotonin, and increase self-sustained firing in human motor neurones. Self-sustained firing is a characteristic of PIC activity. Thus, we aimed to evaluate if the consumption of caffeine could influence estimates of PIC (measured through the paired motor unit technique) in human tibialis anterior muscle.
METHODS: In a crossover, double-blind design, 6 participants were asked to visit the laboratory on two occasions. For each visit, participants performed isometric submaximal triangular contractions (20% of their maximum force) with their tibialis anterior muscle. Surface electromyography (EMG) was recorded from a 64-channel electrode matrix over the muscle. EMG signals were decomposed into single motor unit discharge events and then converted into instantaneous discharge rates. ?Fs were calculated for pairs of motor units using a fifth order polynomial fit. All testing measurements were performed before and 60 min after consuming 6 mg · kg-1 of either a placebo (PLA) or caffeine (CAFF).
RESULTS: No differences were observed for ?F between PLA and CAFF (p = 0.07; ?2 = 0.04). ?F pre-post supplement consumption was 4.62 (95%CI: 2.83 ? 6.40) to 4.22 pps (95%CI: 2.78 ? 5.65) for CAFF and 4.33 (95%CI: 2.98 ? 5.68) to 5.01 pps (95%CI: 3.71 ? 6.31) for PLA.
CONCLUSION: Our findings show that an acute dose of 6 mg · kg-1 of caffeine was unable to modify estimates of PICs amplitude of lower-threshold motoneurons from healthy humans tibialis muscle.

### IMPACT OF ACUTE HEAT EXPOSURE ON THE CRITICAL POWER CONCEPT AND TIME TO EXHAUSTION DURING A HIGH-INTENSITY INTERVAL TEST IN MEN AND WOMEN

BOURGOIS, G., KERCKHOVE, M., CAEN, K., COLOSIO, A., BOURGOIS, J., MUCCI, P., BOONE, J.

*GHENT UNIVERSITY*

INTRODUCTION: The effect of heat on interval exercise is, up to now, not well documented, in contrast to sprint and endurance exercise. The aim of this study was to investigate the impact of acute heat exposure on the determination of the Critical Power Concept parameters and the recovery kinetics during a high-intensity interval test (HIIT) in a physically active male and female population.
METHODS: Twelve men (V̇O2peak: 58.2 ± 5.2 ml.min-1.kg-1, age: 25.4 ± 3.3 years, height: 1.82 ± 0.05 m, body mass 74.3 ± 9.1 kg) and twelve women (V̇O2peak: 41.2 ± 5.3 ml.min-1.kg-1, age: 26.4 ± 3.4 years, height: 1.69 ± 0.05 m, body mass 61.9 ± 5.5 kg) performed three constant load tests between 2 and 15 min to establish critical power (CP) and the curvature constant (W'), both in 18°C (TEMP) and 36°C (HOT) with 40% relative humidity. Afterwards, three HIIT were executed., one in TEMP based on CP and W' determined in TEMP (HIIT-1) and two in HOT, of which one based on CP and W' determined in TEMP (HIIT-2) and one in HOT (HIIT-3), respectively. HIIT consists of three work bouts (WB) to exhaustion, separated by 5 min active recovery, respectively at the intensity equal to the individual theoretical time to exhaustion (TTE) in 4 min based on CP concept (P4) and 90 % of individual gas exchange threshold (90%GET).
RESULTS: CP was lower in HOT compared to TEMP in men (267 ± 29 vs. 249 ± 30 W; p < 0.001) and women (187 ± 30 vs. 176 ± 29 W; p < 0.001), while W' was higher in men (20.0 ± 3.1 vs. 22.7 ± 4.5 kJ; p = 0.026) and women (12.8 ± 1.6 vs. 14.3 ± 2.6 kJ; p = 0.032). P4 was slightly lower in men (350 ± 32 vs. 344 ± 32 W; p = 0.055) and women (240 ± 32 vs. 235 ± 35 W; p = 0.044). Predicted TTE at WB1 was only correctly estimated (i.e., 240 s) in HIIT-1 in men (235 ± 38 s; p = 0.651 ) and women (226 ± 32 s; p = 0.165). TTE was different in HIIT and WB, regardless of sex of the participants (p = 0.008).
CONCLUSION: This study showed that acute heat exposure affected the determination of CP and W', using multiple constant load tests, in an opposite direction. The hyperbolic relationship was skewed with acute heat exposure, as short trials (2-5 min) were less impacted, in contrast to long trials (12-15 min). It has been shown that the use CP concept during interval exercise in heat needs special attention. Even though CP and W' are determined in HOT, TTE in HIIT was still diminished compared to TEMP in both men and women.

### EFFECTS OF 5-WEEKS OF 30-S ALL-OUT SPRINT INTERVAL TRAINING ON CONSTANT SEVERE DOMAIN EFFORT PERFORMANCE, NEUROMUSCULAR FUNCTION AND GLYCOLYTIC RESPONSES.

DE POLI, R.A.B., MILIONI, F., DUTRA, Y.M., ANTUNES, B.M., ZAGATTO, A.M.

*SAO PAULO STATE UNIVERSITY JULIO DE MESQUITA FILHO - BAURU CAMPUS*

INTRODUCTION: All-out efforts performed during sprint interval training (SIT) require a high demand of neuromuscular system as well as glycolytic pathway [1-2] and it is expected that chronically an improvement in physiological parameters and performance. However, some studies have reported reduction on the time to exhaustion for an equalized exercise intensity (ie., 115%@iVO2max) [3]. Thus, the study aimed to investigate the effects of 5-weeks of SIT on glycolytic pathway, neuromuscular function and time to exhaustion in a severe-domain effort.
METHODS: In the baseline moment (A1), 14 healthy men underwent a cycling graded exercise test to determine the respiratory compensation point (RCP) and an until exhaustion effort test at severe-domain (150% of RCP). Neuromuscular assessment by twitch interpolation technique were performed before and immediately after the severe-domain effort. In addition, muscle biopsies of vastus lateralis were also performed to measure the glycogen content, content (Western Blotting) and activity of enzymes hexokinase II (HK), glycogen phosphorylase (Gphos), phosphofructokinase (PFK), and lactate dehydrogenase (LDH), and muscle tissue buffering capacity. After A1, the participants were randomized into training group (TG; n=8) and control group (CG; n=6). The TG performed 5-weeks of the SIT (4-6 all-out sprints of 30-s; workload:0,70 Nm·kg-1; rest:4-min) while control group remained out of regular training programs. After 5-weeks (A2), the same

measurements performed at A1 were repeated. A two-way ANOVA for repeated measurements were used to detect changes between moments and groups. Significant main effects were followed-up by SIDAK post-hoc. Significance was set at $p<0.05$.
RESULTS: There was no difference in time to exhaustion at 150% of RCP for any group or moments ($p=0,66$; $F=0,20$). No significant interaction was observed for any neuromuscular outcomes (i.e., peak force; force evoked by doublet high-frequency, low frequency, and single stimulus; voluntary activation; and m-wave amplitude, and root mean square of electromyography) ($p=0,19$; $F\geq0,14$). The pre-effort glycogen content increased significantly for TG from baseline to post training (+27,3%; $p=0,03$), however there is no difference for content when measured after exhaustion ($p\geq0,56$; $F\leq0,36$). The content of HK, GPhos and LDH increased for TG (+56,3%; +12,2%; +20,4% respectively; $p<0,05$). The enzymatic activity of HK, LDH and PFK during A2 pre-effort increased only for TG when compared pre-effort in A1 (+22,4%; +21,2%; +57,6%, respectively; $p\leq0,04$), however there is no significative difference in the delta percentage during exercise ($p>0,06$;$F>3,38$). In addition, there was no difference for delta percentage buffering capacity ($p=0,93$;$F=0,01$).
CONCLUSION: Although 5-weeks of SIT to improve the glycolytic enzymatic content and activity, the time to exhaustion at 150% of RCP did not improve, as well as the neuromuscular function.

**EARLY NEUROPLASTICITY INDUCED BY HIGH-INTENSITY INTERVAL TRAINING IN RATS WITH CEREBRAL ISCHEMIA**

LAURIN, J., HUGUES, N., PIN-BARRE, C.
*AIX-MARSEILLE UNIVERSITY*

INTRODUCTION: Among its multiple benefits, endurance-training regimens might promote cerebral plasticity, or neuroplasticity, after stroke while optimal exercise parameters, such as intensity and duration of sessions, remain to be defined. Cognitive and sensorimotor functions partially depend on cortical actions of neurotrophic factors. Indeed, the brain-derived neurotrophic factor (BDNF) and/or insulin-like growth factors (IGF-1) could promote neuronal survival by modulating the expression of anti-apoptotic factors and pro-apoptotic factors. The neurotrophic factors could also influence GABAergic activity by interacting with potassium-chloride-cotransporter 2 (KCC2), a neuronal chloride extruder, and sodium-potassium-chloride-cotransporter 1 (NKCC1), a chloride intruder. These two chloride cotransporters play a crucial role in synaptic transmission and functional recovery after stroke.
When individualized, the high-intensity interval training (HIIT) is a time-efficient and secure endurance training regimen during the critical period of stroke rehabilitation (i.e., first weeks in rodents and first months in human post-stroke). To improve the translational relevance of training protocols, we use common physiological parameters of exercise intensity in humans and rodents, such as the speed associated with lactate threshold (SLT) and maximal speed (Smax), to distinguish low- from high-intensities and individualize running speed, as recommended in clinics. However, the early influence of individualized HIIT on sensorimotor/cognitive disorders as well as on the neuroplasticity processes (neurotrophins, apoptosis and cation-chloride cotransporters) remains poorly investigated in rodents.
This study is thus designed to assess the effects of individualized HIIT over a 2-week training on neurotrophic factors, key markers of apoptosis and cation-chloride cotransporters in both cerebral cortices in rats with cerebral ischemia, along with cognitive/sensorimotor functions and endurance performance.
METHODS: Rats with a 2-h cerebral ischemia performed HIIT (long intervals; 4min) for 2 weeks. Incremental exercise tests and sensorimotor tests were performed at day 1, 8, and 15 (D1, D8, and D15) and cognitive tests at D15. Molecular analyses (Western blot and ELISA) were achieved in both ipsi- and contralesional cortices at D17.
RESULTS: HIIT early promote expression of cortical neuroplasticity markers in both ipsi- and contralesional cortices. HIIT induces gains in endurance performance in a time-dependent manner and slight improvements in mechanical forepaw sensitivity. However, no effect on cognitive functions was found.
CONCLUSION: HIIT alone is effective to stimulate neuroplasticity in both hemispheres and to improve endurance capacities, but when HIIT is alone, it remains insufficient to enhance cognitive and sensorimotor functions after stroke suggesting that combination between HIIT and other rehabilitation strategies should be investigated.

**MONITORING OF JUMPS WITH AN AD-HOC INERTIAL SYSTEM**

MORENO-PÉREZ, J.A.1, RUIZ-GARCÍA, I.1, NAVARRO-MARCHAL, I.2, PALMA, A.J.1, GÓMEZ-LÓPEZ, P.J.2, CARVAJAL, M.A.1
*1. ECSENS, DEPARTMENT OF ELECTRONICS AND COMPUTER TECHNOLOGY, IMUDS-UGR, CITIC-UGR, UNIVERSITY OF GRANADA, 2. SKI-INGLAB, IMUDS, DEPARTMENT OF PHYSICAL AND SPORT EDUCATION, UNIVERSITY OF GRANADA*

INTRODUCTION: The height and time that an athlete is able to jump can be a clear indicator of both their physical ability and the state of fatigue. An electronic system has been designed, based on Inertial sensors, where the data are collected and processed using an ad-hoc developed application running on a smartphone. The main motivation for this development has been to achieve a wearable system capable of monitoring jump performance accurately, achieving the highest possible portability while maintaining a low-cost design, which would represent a considerable improvement with respect to the methods currently used [1].
METHODS: In a preliminary system evaluation, three subjects of similar complexion participated in this study, being the technique performed the countermovement jump (CMJ). Data was collected with both a force platform as a gold standard (Kistler 9260AA6) and the inertial system simultaneously.
The developed system consists of an inertial measurement unit that includes a microcontrolled 3-axis accelerometer with a sampling frequency of 200 Hz and configured in the range of +-16g. It is connected to a smartphone through the low energy Bluetooth protocol thanks to the BM78 module. It also has a lithium-polymer battery of 450 mAh that provide an autonomy higher than 3 hours and an SD card that allows data storage. The total weight of the system is 47 g, which is almost unnoticeable to the athlete. For data processing, an algorithm has been developed to detect the most characteristic points of acceleration and obtain both the time the jump duration and the height reached, and has been implemented in a smartphone application.
RESULTS: A statistical analysis was carried out to verify the level of agreement of the data reported by the force platform and the system developed, both with the flight time and the jump height, being the results obtained satisfactory, as a good correlation of the data can be found (linear regression is 1,04x-0,01 and R2 factor 0,91 in the first case, and 1,1x-0,03 with R2 factor of 0,91 in the second one) and the high repeatability of the measurements has also been checked. If error percentages are calculated in absolute value, the average would be 1,53% and 3,63% respectively, which is a rather small value.
CONCLUSION: From this preliminary evaluation, it can be concluded that the proposed system presents promising capabilities. Work is currently conducting a validation trial with a larger number of more differentiated subjects, and the system is expected to be applied in field trials.

**INTRASESSION AND INTERSESSION RELIABILITY OF A LOW-COST JUMP TOOL**

PAGADUAN, J.

*PALACKÝ UNIVERSITY*

INTRODUCTION: The vertical jump is linked to lower body power, an essential physiological characteristic in many athletic skills. The 'gold standard' for measuring vertical jump employ costly equipment such as force platform or high-speed motion cameras. Portable, useful, and accessible low-cost equipment are currently available for practitioners. The purpose of this study was to investigate the intrasession and intersession reliability, and usefulness of a single-beam laser jump equipment for measurement of jump performance.
METHODS: Three experimentation sessions between 0600-0800 hrs, separated by 24 h, at the training facility were participated by seven male and five female world class poomsae athletes. Athletes executed a standardised warm-up, succeeded by three trials of hands-on-waist countermovement jump (CMJ). Rest interval in between trials is 60 s. Athletes were encouraged to jump and land at a specified area, ensuring similar contact of the foot between the laser during take-off and landing. Additional trial was carried out for an unsuccessful jump execution or any CMJ discrepancy of > 5 cm across trials. CMJ was acquired from a single-beam laser equipment connected to a mobile application (Jump Pro, Mobi Pro, Philippines), using the flight time equation. The average CMJ height of three trials was used for analysis. Relative reliability was established using intraclass correlation coefficient (ICC), interpreted as poor (< 0.5), good (0.7-0.9), and excellent (>0.9). Absolute reliability was identified through typical error as coefficient of variation (%CV), expressed as good if %CV < 5%. Comparison of smallest worthwhile change (SWC) (computed by 0.20 mutiplied by between-subject standard deviation) and typical error (TE) was used to establish usefulness, interpreted as marginal (TE > SWC), ok (TE = SWC), or good (TE < SWC). The reliability spreadsheet by Hopkins (2015) was used for calculating reliability and SWC.
RESULTS: Intrasession values are as follows: Day 1 (CMJ: 44.7 ± 1.40 cm; ICC = 0.96; %CV = 3.16); Day 2 (CMJ: 42.8 ± 0.78; ICC = 0.99; %CV = 1.80); and, Day 3 (CMJ: 42.9 ± 1.01 cm; ICC = 0.99; %CV = 2.38). Intersession values displayed ICC = 0.98, %CV = 3.57, TE = 1.21 cm, and SWC = 1.41 cm.
CONCLUSION: This study investigated the intrasession and intersession reliability of CMJ performance using a low-cost tool. Results revealed excellent relative reliability and good absolute reliability for CMJ across all sessions. CMJ intersession relative reliability was excellent, with good absolute reliability. The usefulness of low-cost jump tool was also deemed good. In conclusion, the low-cost jump tool is reliable and useful for measurement of intrasession and intersession countermovement jump performance.

### CP-MH08 Ageing and strength

**AGE-RELATED CHANGES IN THE SKELETAL MUSCLES OF THE EXTREMITIES OF THE MIDDLE-AGED AND ELDERLY**

JIANG, L., ZHANG, Y., PAN, X., GAO, Y.

*CHINA INSTITUTE OF SPORT SCIENCE*

INTRODUCTION: The goal of this study was to look into the characteristics of changes in limb muscle mass, strength, and quality in healthy middle-aged and older persons aged 40-69 years.
METHODS: The study included 900 healthy middle-aged and older adults aged 40 to 69 years. Questionnaires were used to gather basic information; The nylon tape ruler was used to determine body form, and the dual-energy X-ray absorptiometry scanner DXA was used to determine body composition. Researchers used an electronic grip strength meter and a motor function analyzer to test grip strength and squat strength. Skeletal muscle mass was calculated using the ratio of limb muscle mass (kg) to height squared (m2). For the calculation of muscle mass, the strength index of the corresponding limb such as grip strength or squat strength (kg) is used divided by the skeletal muscle mass of that limb (kg). When evaluating differences across groups, SPSS 11.0 was used, and multiple comparisons and ANOVA were used.
RESULTS: (1) In middle-aged and older adults, there was a gradual loss of limb muscle mass. (2) Men and women showed different incremental age-related changes in skeletal muscle mass, with men aged 60-69 years showing a degree of decline in skeletal muscle mass of the limbs compared to those aged 40-49 years ($P < 0.05$); however, the difference between men and women was not significant, and the rate of change in all parts of the muscle was lower than that of men. (3) The decrease in skeletal muscle mass in the right upper and lower limbs was slightly greater than in the left upper and lower limbs ($P < 0.05$). (4) Grip strength levels in the 60-69 age group were around 15% lower than in the 40-49 age group, but squat strength dropped by about 30%. (5) In the 60-69 age range, lower limb muscle quality fell by more than 20% in both men and women, but upper limb muscle mass declined by just 10% to 15%. The right limb had slightly more muscle mass than the left ($P < 0.05$), but there was no statistical difference between males and females.
CONCLUSION: (1) Skeletal muscle mass declines faster in men than in women as they age, but there are no gender differences in skeletal muscle quality. (2) Most peoples right limb has more skeletal muscle mass and muscle strength than their opposing side. (3) Skeletal muscle mass is higher in all lower limbs than in the upper limbs, but the rate of age-related skeletal muscle mass degradation may be higher in the lower limbs.

**IMPACT OF EXERCISE HABITS DURING MIDDLE AGE ON MUSCLE MASS AND AEROBIC CAPACITY AT OLD AGE**

EDHOLM, P., VEEN, J., KADI, F., NILSSON, A.

*SCHOOL OF HEALTH AND MEDICAL SCIENCES*

INTRODUCTION: The impact of regular exercise habits at middle-age on muscle mass and function at old age remains inconclusive. While regular exercise likely represents a primary source of health-enhancing PA, the physical demand of occupation needs to be considered. Additionally, PA level at old age should be taken into account in order to elucidate true associations between past exercise behaviors and muscle mass and function at old age. Therefore, the aim of the study was to examine the impact of regular exercise habits during middle age years on muscle mass and physical function at old age, while considering occupation and objectively assessed PA level at old age.
METHODS: Self-reported leisure-time physical activity (PA) during middle age years [35-65 years] and present accelerometer-derived PA level were assessed in a population of community-dwelling older women (65-70 years; n=117). Participants who accumulated at least 600 MET-min of PA per week during middle age years were classified as physically active. Skeletal muscle mass index (SMI), aerobic fitness and maximal isometric arm and leg strength were determined. Analyses of differences in muscle mass and physical function between physically active and inactive at middle age were adjusted by present PA, adiposity level, and the physical demand of former occupation (sedentary vs manual).
RESULTS: Participants accumulating at least 600 MET-min of exercise-related activities during middle-age years had higher aerobic fitness ($P<0.01$) and SMI ($P<0.05$) at old age compared to their less active peers. Notably, these beneficial impacts were driven by exercise habits during late middle-age period [50 to 65 years], and remained significant after further adjustment by the physical demand of former occupation and present PA behavior at old age. Finally, middle-age engagement in exercise-related activities had no influence on maximal arm and leg isometric strength at old age.
CONCLUSION: Our findings highlight the importance of engaging in regular PA of at least moderate intensity during middle age years in order to promote benefits at the level of muscle mass and aerobic fitness. This clearly supports the potential of PA in delaying aerobic capacity impairment and the occurrence of clinically manifest sarcopenia at old age.

**MULTIMODAL AGILITY TRAINING DOES NOT AFFECT HANDGRIP STRENGTH IN HEALTHY OLDER ADULTS**

LABOTT, B.K., DONATH, L.

*GERMAN SPORT UNIVERSITY*

INTRODUCTION: Handgrip strength is considered as an important vitality surrogate indicator for general fitness, cognitive status and frailty in older adults. A meta-analysis of our group revealed that handgrip however does not notably reflect adaptations from whole body resistance training. Compared to selective health-related strength, balance and endurance exercise for seniors that can sum up to more than 500 weekly minutes of exercise, multimodal exercise training approaches seem to be more functional and related to relevant tasks of daily activity (e.g., stop and go, change in direction, cutting and reactive and decision making demands). As rate of force development (RFD) of handgrip strength and maximum handgrip strength (Fmax) are related to mobility in the elderly, it is aimed to analyse the relation between handgrip strength (Fmax and RFD) and motor performance assessed via the agility challenge for the elderly (ACE). Finally, our RCT aims at analysing the effects of such a multimodal agility training approach on handgrip strength in healthy older adults.
METHODS: Healthy older adults (N=79, age 72.2±4.8 years, weight 77.4±15.1 kg, height 169±10 cm) were randomly assigned to either an intervention (IG, n=39) or control group (CG, n=40). IG took part in multimodal agility training (strength, coordination, start-stop movements and change of directions, dual task and decision making tasks) twice a week for one year. Total training volume was 90 sessions and adherence ranged between 56-91%. CG continued participating in their normal behavioural sportive and daily activities. Handgrip strength (Fmax and RFD) was assessed pre and post with a hand dynamometer in a stable standing position and was computed using the software IsoTest. Time to complete ACE parcourse was assessed in pre and post measurements.
RESULTS: Of the recruited participants n=51 completed pre and post measurement for handgrip strength. Repeated measurements ANOVA (IG vs. CG) x (pre vs. post) for maximum handgrip strength revealed no significant group x time interaction ($F(1,31.9734)=0.0002$, $p= .98$). Repeated measurements ANOVA for handgrip strength RFD revealed also no significant group x time interaction ($F(1,29.0061)=2.8617$, $p= .10$). For correlation analysis n=66 completed the measurements for handgrip strength and ACE. Spearman correlation for ACE and Fmax HGS ($r(64) = - .367$, $p = .005$) and for RFD ($r(64) = -.487$, $p < .001$) was found to be negative.
CONCLUSION: A one-year multimodal agility training does not affect handgrip strength in healthy older adults. This could be due to the non-specific exercises for handgrip strength, as already concluded in the meta-analysis of our group. Motor performance is weakly associated with Fmax and RFD handgrip strength in healthy older adults. Handgrip seems not specific and sensitive to a multimodal whole body training, nevertheless it could reveal more information when study participants suffer from diseases as frailty, cognitive impairment or are at a high risk for falling.

**PHYSIOLOGICAL AND PSYCHOLOGICAL RESPONSES TO A PROGRESSIVE ACUTE SESSION OF SLED-PUSH EXERCISE AMONG OLDER ADULTS: PRELIMINARY FINDINGS**

SEBASTIAO, E., BAUMANN, M., HERRING, M., HURD, M., ESTRADA, B., SALINAS, R., CRAVEN, E., HILL, C., CAMIC, C., CHOMENTOWSKI, P.

*NORTHERN ILLINIOS UNIVERSITY*

INTRODUCTION: Sled-pushing is a functional full-body compound exercise defined as weighted or resisted sprint training. This study aimed at reporting preliminary results of the acute effect of a motorized wheeled sled-push exercise among older adults on physiological and psychological parameters compared to a walking session.
METHODS: This preliminary analysis included 18 older adults (Mean±SD; age: 68.9±4.9 years; BMI: 25.9±4.3 kg/m2; 56% women) that were randomly allocated into either the sled-push (SLP; n = 9) or walking (WKG; n = 9) group. We assessed: heart rate (HR) using a HR monitor with chest strap, rate of perceived exertion (RPE) using the Omni scale, and enjoyment using the Physical Activity Enjoyment Scale (PACES). The exercise protocol involved participants pushing a motorized wheeled sled 6 times on a 30-meter course with 2-minute rest periods in between. The exercise of the SLP was based on normal average speed pushing the sled with the motor disconnected (i.e., no resistance). Normal average speed was then used to create three different exercise intensity/speed zones: subnormal (75 and 85%), normal (100%), and supranormal (125%); with the 100 and 125% speed being completed twice each and the average used for the analysis. Data were collected during all 2-minute rest periods. An online metronome connected via Bluetooth to a speaker was used to pace and monitor

speed. The WKG condition performed the same task but without the sled. Data were analyzed using Mixed-Factor ANOVAs and independent t test with significance level set at p <.05, with holm correction.
RESULTS: Mixed-factor ANOVA revealed no statistically significant speed by group interactions on HR (F = 2.874, p = .071, ηp2 = .152) or RPE (F = 0.954, p = .396, ηp2 = .056); but there was a main effect for speed/intensity on HR (F = 6.282, p = .005, ηp2 = .282) and RPE (F = 16.514, p = <.001, ηp2 = .508); and a main effect for group on HR (F = 17.237, p = <.001, ηp2 = .519) and RPE (F = 19.408, p = <.001, ηp2 = .548). HR for the SLP group was higher than the WLK group for all speeds (Subnormal: 109.6±15.1 vs 86.3±15.9 bpm; Normal: 115.2±27.3 vs 83.9±14.8 bpm; Supranormal: 131.3±20.1 vs 89.6±16.4 bpm). Similar pattern was observed for RPE (Subnormal: 4.8±1.7 vs 1.7±0.7; Normal: 6.0±2.2 vs 2.1±0.9; Supranormal: 6.7±2.9 vs 3.1±1.5). No significant difference was observed for enjoyment between the SLP (5.16±1.38) and WLK (5.07±1.06) group; t(16) = .167; p = .869, d = .073).
CONCLUSION: The acute sled-push session demonstrated an intensity driven modality that may have potential to elucidate positive adaptations in the cardiovascular system of older adults as indicated by a linear increase in HR and RPE as the intensity of the exercise was increased. Overall activity enjoyment was high (5 out of 8) and similar between both activities. This is a positive finding since enjoyment has been associated with exercise participation and adherence.

## COMPARISON BETWEEN 10 VS. 20% VELOCITY LOSS DURING VELOCITY-MONITORED RESISTANCE TRAINING ON STRENGTH, POWER, AND FUNCTIONAL CAPACITY IN OLDER ADULTS

MARQUES, D.L., NEIVA, H.P., MARINHO, D.A., MARQUES, M.C.

*UNIVERSITY OF BEIRA INTERIOR*

INTRODUCTION: Recent studies demonstrated the effectiveness of 10 and 20% velocity loss (VL) during velocity-monitored resistance training (VMRT) on the improvement of strength and functional capacity in older adults [1, 2]. Nevertheless, to our best knowledge, no study examined the differences between 10 vs. 20% VL in the same intervention on older adults strength, power, and functional capacity. Therefore, in this study, we compared the effects of 10 vs. 20% VL on strength, power, and functional capacity in older adults.
METHODS: Eighteen community-dwelling older adults (75.5±11.2 years; 28.1±5.0 BMI) were randomly assigned into two groups: VL of 10% (VL10, n=10) or 20% (VL20, n=8). The participants performed a 10-week VMRT program (two sessions per week) using the leg press and chest press at 40-65% of 1 repetition maximum (1RM). In all training sessions, each repetitions mean velocity was monitored using a linear velocity transducer. At pre-test, mid-test (week 5), and post-test, the maximum dynamic strength (1RM) and peak power (PP) were estimated through a progressive loading test in the leg press and chest press. In addition, the 10-m walking (T10) time, 5-repetition sit-to-stand (5STS) time, and 1-kg medicine ball throw (MBT) distance were assessed at pre and post-test.
RESULTS: We did not observe significant differences between groups on strength and power measures at pre, mid, and post-test. Both groups significantly improved the 1RM and PP leg press from pre to mid-test (VL10: 11±6.0 kg and 40.2±42.6 W; VL20: 8.9±4.0 kg and 32.8±19.1 W), but neither group significantly improved these outcomes from mid to post-test. In the 1RM and PP chest press, there were no significant improvements in both groups at any time point. Regarding the functional capacity outcomes, we did not observe significant differences between groups at pre and post-test. Both groups significantly improved the 5STS time (VL10: -1.3±0.9 s; VL20: -1.4±0.9 s), but only the VL20 significantly improved the T10 time (VL10: -0.2±0.4 s; VL20: -0.3±0.3 s). Finally, no group significantly improved the MBT distance after the intervention.
CONCLUSION: Our results showed that VL10 and VL20 produced similar lower-limb strength and power gains after five weeks of VMRT, which remained stable until the end of the intervention. In addition, both groups improved the 5STS time, while only the VL20 group improved the T10 time. These results suggest that VL10 and VL20 are equally effective in increasing lower-limb strength and power and the ability to rise from a chair, while VL20 might yield better results than VL10 to improve walking performance.

## PHYSICAL FUNCTION AND HEALTH-RELATED QUALITY OF LIFE IN OLDER MEN AFTER 10-WEEKS POWER TRAINING – ANY ASSOCIATIONS?

LOHNE-SEILER, H., LINDBERG, K., FOSSTVEIT, S.H., SIBAYAN, E.E., FJELLER, J.S., LØVOLD, S., KOLNES, T., VÅRVIK, F.T., HARALDSTAD, K., BERNTSEN, S., BJØRNSEN, T.

*UNIVERSITY OF AGDER*

INTRODUCTION: A meta-analysis by Hart and Buck1 support the promotion of resistance training in improving health-related quality of life (HRQL) in older adults. However, in a study by Katula et al.2 it was concluded that high velocity power training may positively influence multiple levels of quality of life more than traditional strength training. In a recent study Sunde et al.3 found that physical function and HRQL-physical were strongly linked, and interventions improving physical function might improve HRQL-physical. The objective of the present study was therefore to investigate the effect of 10-weeks power training on physical function and HRQL, in addition the association between these variables at baseline and with training-induced improvements in older men.
METHODS: Forty-nine elderly men (67.7±5.3yrs, 83.4±10.5kg, mean±SD) completed a 10-weeks biweekly power training intervention. Physical function was assessed as Leg-press power (Keiser Air300), Sit-to-stand power (MuscleLab force plate), Timed-up-and-go time, Stair-climbing-time (15 steps), and Grip strength. HRQL was assessed by the Short Form health survey questionnaire (SF-12). Paired sample T-test and Wilcoxon signed rank test were used to analyse changes from pre to post. A stepwise linear regression was used to examine associations between physical function and HRQL. Alpha level of 5% was chosen for statistical significance.
RESULTS: At baseline, grip strength was positively associated with both the physical (R2=0.14, p<0.01) and mental (R2=0.19, p<0.01) component of HRQL. After the training period, the participants increased physical function measured as Grip strength (2.0±2.5 kg [5.4%], p<0.001), Leg-press power (40.2±68.0 W [4.2%], p<0.001), Timed-up-and-go time (-0.7±0.20 sec [-1.6%], p<0.017), and Stair-climbing time (-0.2±0.3 sec [-5.2%], p<0.001), in addition to an increase in HRQL-physical (6.5 [median] [7.9%], p<0.01) and HRQL-mental (3.5 [median] [4.2%], p=0.04). Additionally, changes in Grip strength were positively associated with changes in HRQL-physical (R2=0.06, p=0.04).
CONCLUSION: The current study revealed significant improvements in physical function in older men after 10-weeks power training. These changes were accompanied by increase in physical and mental components of HRQL. Furthermore, Grip strength at baseline was positively associated with both components of HRQL. Whereas changes in Grip strength were positively associated with changes only in the physical component of HRQL. However, caution should be taken when interpreting these associations. Future studies should therefore investigate

the effect of power training including exercise and non-exercise groups to determine how physical function may affect HRQL in older adults.

**TO EXPLORE THE EVALUATION METHOD OF LOWER LIMB SKELETAL MUSCLE STRENGTH IN HEALTHY MIDDLE-AGED AND ELDERLY PEOPLE**

GAO, Y., ZHANG, Y., PAN, X., JIANG, L.

*CHINA INSTITUTE OF SPORT SCIENCE*

INTRODUCTION: This study aims to explore the evaluation indexes and measurement methods of skeletal muscle strength of lower limbs in healthy middle-aged and elderly people aged 40 to 69 years, so as to evaluate the muscle strength quality of lower limbs in healthy middle-aged and elderly people.
METHODS: The subject was divided into 6 groups according to the changing rules of strength quality (40-49, 50-59, 60-69 years) and gender. There were 150 people in each group, with a total of 900 people. Firstly, circumference and body fat were measured, then lower limb muscle strength was measured using three METHODS: muscle function analyser (MES), longitudinal jump meter and lower limb muscle strength meter.
RESULTS: (1)Through mathematical analysis, 5 male and 6 female indicators reflect the lower limb strength of the middle-aged and elderly. (2) Among the three methods, MES has a significant advantage in evaluating lower limb muscle strength.(3)Lower limb circumference and whole body circumference have greater influence on lower limb muscle strength, which is greater than waist and abdomen circumference, while female lower limb muscle strength is significantly lower than that of male (P<0.05). (4)The total muscle strength of the lower limbs was measured by MES and lower limb muscle strength measurement, respectively. The total muscle strength of normal circumference men was significantly greater than that of women on the total muscle strength, left and right muscle strength(p<0.05).(5)The correlation coefficient between MES, lower limb muscle strength meter and lower limb circumference were greater. The circumference*gender has a significant effect on the muscle strength of the lower extremities. The greater the circumference, the higher the muscle strength of the lower extremities in men. (6)there is no significant advantage in the relationship between the vertical jump height measured in the vertical jump meter and the body fat rate.
CONCLUSION: (1)The indexes reflect lower limb strength better and there is a positive correlation between lower limb muscle strength and circumference for all three tests, especially lower limb circumference. However, MES and the lower limb muscle strength meter reflects lower limb muscle strength better than the vertical jump height of the vertical jump meter.(2)There is a correlation between body fat percentage and lower limb muscle strength.(3)Lower limb muscle strength measured by the MES was the best fit to different circumferences and body fat percentage, the lower limb plyometric fit was not significantly different from the former, and the longitudinal hopper was the worst fit.

**INCREASES IN MUSCLE MASS, STRENGTH, AND PHYSICAL PERFORMANCE FOLLOWING RESISTANCE EXERCISE TRAINING DO NOT DIFFER BETWEEN OLDER AND ELDERLY ADULTS**

MARZUCA-NASSR, G.N.1, ALEGRÍA-MOLINA, A.1, SANMARTÍN-CALÍSTO, Y.1, ARTIGAS-ARIAS, M.1, HUARD, N.1, SAPUNAR, J.1, SALAZAR, L.A.1, VERDIJK, L.B.2, VAN LOON, L.J.C.2

*1 UNIVERSIDAD DE LA FRONTERA, CHILE. 2 MAASTRICHT UNIVERSITY MEDICAL CENTRE+, THE NETHERLANDS.*

INTRODUCTION: Aging is associated with the loss of muscle mass and strength. Resistance exercise training can be applied effectively to increase muscle mass, strength, and physical performance in older adults (65-75 y). However, it has been speculated that elderly people (>=85 y) are less responsive to the benefits of exercise training. This study compares the impact of prolonged resistance exercise training on muscle mass and function in older (65-75 y) versus elderly (>=85 y) men and women.
METHODS: We subjected 17 healthy, older (65-75 y) females and males (OLDER; n=13/4 (f/m); 68±2 y; 26.9±2.3 kg·m-2) and 12 healthy, elderly (>=85 y) females and males (ELDERLY; n=7/5 (f/m); 87±3 y; 26.0±3.6 kg·m-2) to 12 weeks of supervised whole-body resistance exercise training (3x/wk). Prior to, and after 6 and 12 weeks of training, quadriceps and L3 muscle cross sectional area (CSA; CT scan), lean body mass (DEXA scan), strength (1RM tests), physical performance (TUG and SPPB), quality of life (SF-36), and instrumental activities of daily living scale (IADL) were assessed. Pre- versus post-intervention data were analyzed using repeated-measures ANOVA with time as the within-subjects factor and age group as the between-subjects factor, using an alpha level of 0.05. Data are reported as means±SD, and n2 (partial eta squared) was used to estimate effect sizes.
RESULTS: Twelve weeks of resistance exercise training resulted in a 10±4 and 11±5 % increase in quadriceps CSA (from 46.5±10.7 to 51.1±12.1 and from 38.9±6.1 to 43.1±8.0 cm2, respectively; P<0.001; n2=0.67), a 2±3 and 2±3 % increase in whole-body lean mass (from 40.5±8.0 to 41.3±8.7 and from 37.7±5.0 to 38.3±5.2 kg, respectively; P=0.001; n2=0.22), and a 38±20 and 46±14 % increase in 1RM leg extension strength (from 53±25 to 71±31 and from 36±13 to 52±20 kg, respectively; P<0.001; n2=0.77) in the OLDER and ELDERLY groups, respectively. No differences in the response to exercise training were observed between groups (time x group, all P>0.60; all n2<=0.012). In accordance, physical performance on the SPPB and TUG improved (both P<0.01; n2>=0.22), with no differences in the exercise response between the OLDER and the ELDERLY groups (time x group, P>0.15; n2<=0.07).
CONCLUSION: Prolonged resistance exercise training increases muscle mass, strength, and physical performance in older adults, with no differences between older and elderly adults. The adaptive response to resistance exercise training is preserved in the oldest of old.

### PL-PS02 Interorgan cross-talk and network physiology of exercise: dynamic perspectives for understanding and optimizing kinesiology

#### NETWORK PHYSIOLOGY OF EXERCISE: BEYOND MOLECULAR AND OMICS APPROACHES

BALAGUÉ, N.

*INEFC BARCELONA*

During the last century, Exercise Physiology has been deeply influenced by reductionism and classical cybernetics. The reductionist research approach has produced a lot of information, but has provided a limited understanding of exercise-related phenomena. An inductive analytic mode of inquiry, reflected by the redundant expression "Effects of" has characterized the field which, inevitably, has evolved towards Molecular Biology, Genetics and OMICS technologies. Although such biology branches are subjected to dynamical approaches, recent specialities like Molecular Exercise Physiology keep focused on questionable non-dynamic group pooled statistical inferences.
Inspired by the new field of Network Physiology and Complex Systems Science, Network Physiology of Exercise emerges to transform the theoretical assumptions, the research program and the practical applications of Exercise Physiology. The cybernetic Control Theory is replaced by Dynamic Systems Theory, the centralized control of the Central Nervous System by a multilevel self-organization of body functions, and the static regulatory mechanisms by dynamic mechanisms with synergetic properties. The inductive analytical research, generalizing from group inter-individual inferences to intra-individual phenomena, is replaced by an inductive/deductive research based on intra-individual time series analysis techniques. Considering the organism as a multilevel complex network system, Network Physiology of Exercise goes beyond molecular and OMICS approaches, mostly focused on bottom-up inferences from molecular data to the physiology of the entire person. It centres the research efforts on investigating the nested dynamics of the vertical (among levels) and horizontal (e.g. among organs) physiological network interactions. The embededness of lower network levels in upper levels, the circular causality (bottom-up, top-down) among levels acting at different timescales, and the emergence of nonlinear network phenomena are some of its genuine expected contributions.
Network Physiology provides a wide range of data analysis techniques that have the potential to be utilized as novel evaluation tools to investigate dynamic interactions among physiological systems under exercise settings. These techniques can lead to the development of new network-based biomarkers (e.g., cardio-respiratory interactions, inter-muscular interactions and cortico-muscular interactions) able to identify how different key organ systems coordinate and synchronize as a network during exercise, and track how these network interactions change in response to different physiological states and exercise interventions. The use of such network-based biomarkers may open exciting horizons on exercise testing, improve the understanding of exercise-related phenomena and contribute to enrich Basic Physiology and diverse fields such as Sports Medicine, Sports Rehabilitation, Sport Science or Training Science.

#### MOLECULAR TRANSDUCERS OF PHYSICAL ACTIVITY CONSORTIUM (MOTRPAC): MAPPING THE DYNAMIC RESPONSES TO EXERCISE

TRAPPE, S.

*BALL STATE UNIVERSITY*

Exercise provides a robust physiological stimulus that evokes cross-talk among multiple tissues that when repeated regularly (i.e., training) improves physiological capacity, benefits numerous organ systems and decreases the risk for premature mortality. However, a gap remains in identifying the detailed molecular signals induced by exercise that benefit health and prevent disease. The Molecular Transducers of Physical Activity Consortium (MoTrPAC) was established to address this gap and generate a molecular map of exercise. Preclinical and clinical studies will examine the systemic effects of endurance and resistance exercise across a range of ages and fitness levels by molecular probing of multiple tissues before and after acute and chronic exercise. From this multi-omic and bioinformatic analysis, a molecular map of exercise will be established. Altogether, MoTrPAC will provide a public database that is expected to enhance our understanding of the health benefits of exercise and to provide insight into how activity mitigates disease.

**FEATURES OF INCLINED ADJUSTMENT OF ALPINE SITTING SKIS RELATIVE TO TURN WIDTH: COMPARISON WITH STANDING SKIS**

SUGAJIMA, Y., KATO, T., KOEDA, M.

*ASAHI UNIVERSITY*

INTRODUCTION: Ski turns require a force to point inside the turn (centripetal force), which allows the skier to tilt the body inside the turn. With standing skis (STA), the movement of various joints of the lower limbs plays an important role in the inclined operation. However, with skis operated from a seat (SIT), 1), 2) depending on the difference in tools and range of motion, the inclined operation during sit turns is considered different from STA. Evaluating this difference is meaningful in understanding the turn technique of skiing as universal skiing regardless of disability or not.

This study aimed to clarify the characteristics of SIT by comparing the inclined adjustment of SIT and STA for turn width using two-dimensional motion analysis and seat pressure distribution analysis, to evaluate the ski turn technique universally.

METHODS: Eight skilled male alpine skiers participated in this study; two sitting skiers and six standing skiers. Participants turned at four cones on the fall-line (FL) at intervals of 8 m and skied 3-5 trials with two different turn widths. The narrow turn (N) was assumed to be about 1.5 m from the cone, and the wide turn (W) was twice the width of N. Each trial was videotaped from the lower FL, and the second and third turns of each trial were analyzed. Then, the turn width (Wid), time (TT), speed (Spe), tempo (Tem), inward tilt angle (IA) at the maximum turn amplitude and inner outrigger extension angle (EA) were calculated. In SIT, the seat pressure distribution was measured using a seat pressure sheet, and the centre of the seat pressure (COP) was calculated. Each index was statistically compared between N and W, and between SIT and STA.

RESULTS: The following results were obtained;

(1) Wid was not different between SIT and STA in both N and W. SIT had longer TT than STA, and Spe and Tem were lower. In addition, IA was larger in SIT.

(2) There was a negative correlation between Wid and Spe in both SIT and STA. There was no correlation between Spe and IA in STA, but there was a relationship in SIT.

(3) In the seat pressure distribution of SIT, there was a high correlation between IA and COP in the left and right directions (COPx).

CONCLUSION: SIT had longer TT than STA and Spe and Tem were also lower at the same turn width. From these results, SIT showed that the IA was enlarged and turned by the incline, which appeared to be supported by the displacement of COPx. In STA, the fact that Spe did not correlate with IA is considered inherent in movement that not only tilts the upper body, but also involved in the inclined movement of various joints of the lower limbs.

**ACUTE EFFECT OF IMPROVED HIP RANGE OF MOTION ON MAXIMUM HIP ANGLE IN POLE VAULTING: A PILOT STUDY**

ENOKI, S., KURAMOCHI, R., NAKAYAMA, K., TAKIGAWA, H.

*CHUKYO UNIVERSITY*

INTRODUCTION: A previous study reported that the lower back was the most common location of injury among collegiate pole vaulters. In addition, low back pain occurrence was associated with low hip flexion and extension range of motion among collegiate pole-vaulters and decathletes. Thus, large maximum hip flexion and extension range of motion is considered effective low back pain prevention. Moreover, we found that there was a significant positive correlation between range of motion and the maximum joint angle during pole vault in hip extension. However, it is unclear whether the improvement in hip flexion and extension ROM changes their hip joint angle during vaulting. The purpose of this study was to clarify the acute effects of interventions in hip flexion and extension range of motion for pole vaulters on the maximum hip joint angle during pole vaulting.

METHODS: Seventeen male pole vaulters who underwent the same interventions for hip range of motion were included. We measured both active and passive hip flexion and hip extension ROM in participants lying on a bed and recorded video of pole vaulting motion at a rate of 240 fields/s pre and post interventions. The maximum hip joint angle during the pole vault from the touchdown of the last step of the run-up to the pole straightening was calculated from videos taken pre- and post-intervention and then compared. We used three types of self-massages to improve hip flexion and extension range of motion and active straight leg raise exercises. We completed the program in approximately 25 min on an experimental day and all interventions were monitored by the examiner.

RESULTS: No significant differences between pre- and post-intervention hip range of motion were observed. No significant improvement in maximum hip joint angles was observed post-intervention. The magnitude of change in active hip flexion range of motion and the maximum hip flexion angle during pole vaulting pre-and post-intervention was significantly correlated ($p=0.002$, $r=0.687$). No significant correlations in the changes of other joitnts were observed between the ROM and maximum joint angle.

CONCLUSION: The magnitude of change in maximum hip flexion angle on takeoff leg during the pole vaulting was not significantly correlated with the change in passive hip flexion range of motion, but there was a significant positive correlation with the change in active hip

flexion range of motion. In order to change the vaulting motion to prevent injuries or improve, active ROM may need to be changed instead of passive ROM, and coaches and athletic trainers should keep assessing and improving active ROM. However, it is difficult to consider that an active ROM is greater than the passive ROM, and it is deemed necessary to acquire a large passive ROM as a basis.

### ASSOCIATION BETWEEN ELASTOGRAPHY-ASSESSED MUSCLE MECHANICAL PROPERTIES AND HIGH-SPEED DYNAMIC PERFORMANCE

EMA, R.

*SHIZUOKA SANGYO UNIVERSITY*

INTRODUCTION: Clarifying the muscular factors that contribute to performance improvement can be beneficial for athletes and coaches. One study (1) found that the medial gastrocnemius shear wave modulus, an indicator of passive mechanical properties, was associated with the drop jump height. In contrast, the shear modulus of the rectus femoris was not significantly correlated with the countermovement jump (CMJ) height (2). Thus, the relationship between passive muscle mechanical properties and performance during stretch-shortening cycle (SSC) exercise remains unclear. Also, performance during explosive exercises involving only concentric muscle contractions can also be associated with passive muscle mechanical properties, but no consensus has been reached among previous studies. It is possible that the association between passive muscle mechanical properties and performance is clearer for exercises that have a time restriction for generating force. The present study examined the relationships between the resting muscle shear modulus and dynamic performance during the SSC and explosive exercises.

METHODS: We measured the jump height during three types of vertical jumps [squat jump (SJ), CMJ, and rebound jump (RJ)] and the multi-joint leg extension power at three velocities (low, moderate, and high) of 30 healthy women. Using ultrasound elastography, the resting shear modulus of the vastus lateralis was assessed in the sitting position as an index of passive muscle mechanical properties.

RESULTS: The shear modulus was positively correlated with RJ height and multi-joint leg extension power at moderate and high velocities ($r = 0.435–0.563$, $P < 0.05$). The magnitudes of correlations were interpreted to be moderate based on the proposal by Guilford (3). There was no significant correlation between the shear modulus and SJ height, CMJ height, and multi-joint leg extension power at low velocity. Contact time (i.e., the time under force exertion against the ground) during RJ (161 ± 19 ms) was 19% of that during CMJ (869 ± 171 ms).

CONCLUSION: These results suggest that passive muscle mechanical properties play an important role in high-speed SSC and dynamic explosive exercises, although the contribution to the performance would not be high.

### THE EFFECTS OF DIFFERENT BALL MASS ON THE INSTEP KICK MOTION OF ELEMENTARY SCHOOL CHILDREN IN SOCCER

TAGO, T.

*TOKUSHIMA BUNRI UNIVERSITY*

INTRODUCTION: This study was to establish guidelines for proper selection of soccer balls for elementary school students by conducting a kinematic analysis of the form displayed by students of a youth soccer team when kicking two types of balls with differences in mass—a size 4 ball and size 3 ball .

METHODS: Ten youth soccer team players aged 8-11 years, who all kicked using their right foot, were included in this study. On a youth soccer pitch, the participants were asked to perform an instep kick with full strength to hit a stationary soccer ball toward a target 8 m away. Two types of balls were used in the experiment—a size 4 ball weighing 360 g (hereafter, normal) and a size 3 ball weighing 300 g (hereafter, light). The unit vector from the right superior anterior iliac spine to the left superior anterior iliac spine was defined as the xpelvis, the unit vector from the midpoint of the left and right sacrum to the right superior anterior iliac spine as the spelvis, and the unit vector from the midpoint of the left and right sacrum to the left superior anterior iliac spine as the tpelvis. The unit vector zpelvis was determined from the cross-product of the spelvis and tpelvis, and the unit vector ypelvis was determined from the cross-product of the zpelvis and xpelvis. The pelvic coordinate system was defined as the coordinate system with xpelvis, ypelvis, and zpelvis as the axes. As a kinematic calculation item, the angle of fore and aft inclination of the fuselage was calculated. The angle from the midpoint of the left and right hip joints projected on the YZ-plane to the vector projected toward the Y-axis and the vector from the midpoint of the left and right hip joints to the upper edge of the sternum was used as the torso flexion angle of the torso body.

RESULTS: Based on the finding that the average light-to-normal rebound ratio value was 1.077, participants with light-to-normal ratios lower than the average were placed in the SG group and those with ratios larger than the average were placed in the WG group. In the SG and WG groups, the forward–backward tilt angle became smaller after the ball impact, and there was a tendency to lean forward, with the WG group leaning forward more than the SG group. In addition, a substantial forward-leaning was observed in the WG group Normal, indicating a considerable difference before and after the ball impact.

In the SG group, there was no difference between Normal and Light in the angle difference between the forward and backward tilt of the torso before and after the impact. In the WG group Normal, the forward tilt was large, and there was a considerable difference from that of the SG group.

CONCLUSION: In the WG group, the forward tilt of the torso after ball impact was greater in Normal. However, this was thought to be owing to the difference in the mass of the ball, which was reflected in the kicking form, and also suggested that the kicking motion was far from the original kicking form.

### SHORT-TERM INFLUENCE ANALYSIS OF DIFFERENT WEIGHTS' INSTEP WEIGHTS ON 50 METERS SPEED AND RUNNING TIME

ESQUIROL-CAUSSA, J., COS-MORERA, M.A., PALMADA-ANDREU, P., MÉNDEZ-OLAVIDE, M., PADULLÉS-RIU, J.M.

*ESCOLES UNIVERSITARIES GIMBERNAT I TOMAS CERDA*

INTRODUCTION: Instep wearable resistances at running trainings(1) change mechanical parameters modifying muscle activity(2), ground plantar support and run biomechanics; changes could reduce lower limb's impairment risk produced by abnormal stepping during the

race(3). Instep weights show positive effects on the race, due to the influence of the instep specific placement without decreasing inter-muscular coordination nor altering running technique(2)(4)(5).

Objective: to analyze if instep weights use during warm-up for 50-meter running series could significantly modify race times in sprinters and hurdlers and evaluate genders differences.

METHODS: 30 semi-professional sprinters ran 6 consecutive 50-meter series at maximum speed (15 minutes resting between series) with or without instep weights, randomized into three groups: no-weight, Ascending (50, 100, 150, 200g load cadence) or Descending (200, 150, 100, 50g load cadence). 1st and 6th series were run without weight. Weight devices: Power Instep(R). Total and partial times and speed were collected as well as gender and anthropometric variables. Variables were statistically analyzed and compared. This study was approved by Universitat Autònoma de Barcelona Research Ethics Committee (CEEAH-UAB, number 4987).

RESULTS: Instep weights were always safe and well tolerated. Total race time between 1st and 6th series increased in all groups. In women, all groups' race times were longer in the 6th than in the 1st race. Instead, men in Ascending group decreased their race time an average of 667ms (SD=19.03) in the 6th race compared to the 1st (p=0.48), while Descending and no-weight worsened their running time 490ms (SD=13.76).

CONCLUSION: Instep load was safe and well tolerated (50 to 200g). Improvements obtained in Ascending group men in the last series (without weight) were statistically non-significant due to the small sample size, but magnitudes observed could be considered important in some elite sports contexts: using increasing instep loads in men during 50-meter series at maximum speed in training or competition warm-ups could slightly increase final race speed a few hundredths of a second. Different muscle stimulation(2) and adjustments to positive biomechanical changes(2) during warm-up with ascending loads could slightly modify race parameters to a small but significant speed increase.

Conclusion: Instep weights are safe and well tolerated as a warm-up technique in short distance runners. Upward weight cadence instep load in men during warm-up could positively modify 50-meter race time in sprinters and hurdlers, but larger studies are needed; if confirmed these results could be important in a professional sports context where hundredths of a second separate success from failure.

## BIOMECHANICAL PREDICTORS OF THE PITCHING KINETIC CHAIN AND PERFORMANCE AMONG ADOLESCENT BASEBALL PITCHERS

HSIAO, H.W., LEE, H.J.

*NATIONAL TAIWAN NORMAL UNIVERSITY*

INTRODUCTION: The pitching mechanic consisted of kinetic chain for energy transferred from the striding foot to the throwing arm. Ground reaction forces (GRFs), pelvic and trunk pitching kinematics play an integral role in energy transfer from the lower to the upper extremities and influence sports performance. This study was aimed to distinguish the pitching motion pattern between different ball speeds in adolescent baseball pitchers. To analyze the variables associated with pitch velocity from their biomechanical factors in the kinetic chain, and its ability to predict pitching performance in teenage pitchers.

METHODS: A total of 30 male teenage players (age 14.1±0.6 years; height = 173.5±5.5 cm; weight = 65.8±12.4 kg) were right-handed overhand baseball pitchers. In this study, a motion analysis system with 6 cameras (Motion analysis crop, 250Hz) was used to calculate for evaluate the pitching kinematics. One force plate (Kistler, 2500Hz) collected GRFs from the stride leg and used a pocket radar to collect the ball speed. After warm-ups, pitchers threw 5 fastballs on a custom-made pitching mound, assessed for segment rotation angle, angular velocity, and sequence via motion capture to investigate their pitching motion pattern. Besides, they were divided into 3 groups according to the average ball speed that they performed in the pitching experiment: High speed (HS), Middle speed (MS), and Low speed (LS). A one-way ANOVA and Tukey post-hoc analysis compared the GRFs kinetic data and pitching kinematic data between groups. The Pearson correlation coefficient examined the variables relations between ball speed. Last, a stepwise multiple regression model determined the contribution of the overall variables that could predict the pitch velocity in teenagers.

RESULTS: Five biomechanical variables showed a significant difference between groups in our study. The knee flexion angles at maximal external rotation (p=.011) and ball release (BR) (p=.007) that HS, and MS were significantly smaller than LS. The vertical pitching GRFs at BR, HS and MS were significantly larger than LS (p=.015). The maximal shoulder-hip separation angle (p=.017) and time% between max pelvis and trunk rotation velocity (p=.024), HS was significantly higher than LS. Those 5 variables also showed a significant correlation between ball speed (p<.05). When all variables were entered into a stepwise multiple regression analysis, vertical pitching GRFs at BR and maximal shoulder-hip separation angle accounted for 45% of the variance in ball speed (p=.008).

CONCLUSION: Our study found that the GRFs and shoulder-hip separation angles would significantly influence the energy kinetic chain transmitted from the lower to the upper extremities and pitch velocity among adolescent players. We suggest teenage pitchers require adequate lower limb strength and appropriate pelvic and trunk control to adequately transfer energy from the kinetic chain, elevating their performance.

## THE INFLUENCE OF BACK SQUAT AND COUNTERMOVEMENT JUMP EXERCISES WITH AND WITHOUT ELASTIC BAND RESISTANCE ON SUBSEQUENT JUMP PERFORMANCE

MINA, M.A.1, BLAZEVICH, A.J.2, TSATALAS, T.3, GIAKAS, G.3, KOKKOTIS, C.4, SIDERIS, V.5, KARAMPINA, E.3, KAY, A.D.6

*1: UOD , 2: ECU , 3: UOT , 4: D.U.TH , 5: ASPETAR , 6: UON*

INTRODUCTION: Preconditioning the muscle by performing maximal or near maximal voluntary contractions using elastic bands (EB) in combination with free-weight resistance (FWR) can increase subsequent force production and performance. However, such improvements are often reported after limited or no warm-up (1) and the impact of different conditioning contractions at different loads requires further investigation. Therefore, the aim of the present study was to examine the acute effects of conditioning EB exercises (back squat and countermovement jump) following a comprehensive warm-up on subsequent countermovement jump (CMJ) height performance.

METHODS: Fifteen active men (age = 21.7 ± 1.1 y, height = 1.8 ± 0.1 m, mass = 77.6 ± 2.6 kg) volunteered for the study and completed four conditions (EB50%, EB85%, FWR50%, FWR85%) in a randomised order each separated by 48 h. During each trial, participants performed a comprehensive warm-up of 5 min cycling, 10 continuous unloaded squats, 5 continuous CMJs at ~70% of perceived maximum, followed by maximal jumps performed every 30 s until 3 jumps were within 3% of maximum jump height. Participants then performed 5 repetitions of either EB- or FWR-loaded CMJs at 50% 1-RM or 3 repetitions of either EB- or FWR-loaded back squat at 85% of 1-RM (35% of load generated from elastic resistance during EB). CMJs were then performed 30 s, 4 min, 8 min, and 12 min later.

RESULTS: No change in any variable was found after both FWR warm-up conditions ($p > 0.05$). Significant increases ($p < 0.05$) in CMJ height (4.6-8.0%) and peak power (3.1-5.1%) were observed in the EB50% condition at 30 s and 4 min; no changes were found at 8 min and 12 min. CMJ height (5.6-6.5%) and peak power (4.4-6.0%) were also significantly increased in the EB85% condition at 30 s, 4 min and 8 min; no changes were found at 12 min.

CONCLUSION: The lack effect of the free-weight conditioning contractions suggests that the comprehensive task-specific warm-up routine mitigated any further performance augmentation. However, the improved CMJ performance following the use of EB is indicative that specific alterations in force-time properties of warm-up exercises may further improve performance. The use of heavy squat lifts or loaded CMJs with elastic band resistance result in similar increases CMJ performance following a comprehensive warm-up, although the heavier loading resulted in a more prolonged improvement in performance indicative of an intensity-dependent effect.

### EFFECTS OF A SHORT STRETCHING PROTOCOL AND THE DENTAL OCCLUSION ON SPINE: A PILOT STUDY

PATTI, A., GIUSTINO, V., FIGLIOLI, F., BELMONTE, G., GENUA, D., MESSINA, G., THOMAS, E., BATTAGLIA, G., BELLAFIORE, M., PALMA, A., BIANCO, A.

*UNIVERSITY OF PALERMO*

INTRODUCTION: A good balance and postural control are fundamental for a good performance of both simple daily tasks and more complex movement patterns. The purposes of this study were threefold: a) to evaluate the effects of a short stretching protocol on the spine; b) to evaluate the effects of dental occlusion on the spine; c) to analyze the possible suggestions that may emerge from an instrumental perspective that can reproduce spine images on a monitor using an infrared camera (ToF cameras).

METHODS: Twenty-three subjects were enrolled for the study. They were analyzed using light detection and ranging technology (LiDAR) called Spine 3D (Sensormedica, Guidonia Montecelio, Rome, Italy): an innovative and non-invasive three-dimensional optoelectronic detection system that allows an accurate assessment of vertebrae alignment. We evaluated the sample to 1) baseline; 2) with different mandible positions using a wax bite between the teeth; 3) after a short stretching protocol. A paired t-test was used to determine differences. Pearsons correlation coefficient was used to evaluate the correlation between the parameters. Cohens d was used to measure effect size.

RESULTS: The Person analyses showed some correlations. Particularly interesting are the correlations between trunk inclination parameter vs sagittal imbalance parameter (R=0,97), and cervical lordosis parameter vs lumbar lordosis parameter (R=0,87). After the stretching protocol, our results showed a significant difference in the trunk imbalance parameter ($p<0,05$, -0,46). The dental occlusion showed a significant effect on the trunk inclination parameter ($p<0,05$, d=0,49) and on the sagittal imbalance parameter ($p<0,05$, d=0,48).

CONCLUSION: Our data show an influence of the stretching protocol limited to trunk imbalance. On the other hand, the influence of dental occlusion on trunk inclination and the sagittal imbalance parameters are particularly interesting. Considering these results, Spine 3D can objectively contribute to ameliorating spine-related skeletal muscle disorders without an invasive approach.

### CORRELATION BETWEEN SNPE (SELF NATURAL POSTURE EXERCISE) PERFORMANCE AND MUSCULOSKELETAL PAIN

LEE, H., YOON, J., LEE, D.T.

*KOOKMIN UNIVERSITY*

INTRODUCTION: This study aims to analyze the correlation between the SNPE (Self Natural Posture Exercise) motion performance and musculoskeletal pain region in patients with musculoskeletal pain at ages of 20s and 40s.

METHODS: The subjects were 77 adult women with chronic musculoskeletal pain for more than 3 months (32.8±6.6 yrs, 21.7±2.9 kg/m2). Movement performance was evaluated by taking front and side pictures during performing SNPE number 1 movement. In the frontal, the acromion and the anterior superior iliac spine were marked to measure the balance of the shoulder and pelvis. The angle formed by the line connecting the left and right points of the affected area and the horizontal line starting from the left point was measured. In the side, a reference point was marked on the tip of the big toe, and a reference line was created that passed the reference point perpendicular to the floor. The angle between the reference line and the line connecting from the reference point to the knee, chest, and chin, respectively, was measured. When the value of measurement was high, it was considered as a poor performance. In addition, in order to measure the position of the shoulder, a line passing through the chest perpendicular to the floor was created, and then the angle with the line from the chest to the acromion was measured. The lower each measurement value, the higher the performance was judged. Musculoskeletal pain was assessed by pressure pain threshold (PPT) using an algometer for upper trapezius (UT), lower trapezius (LT), erector spinae muscles (ES), gluteus (GT), gastrocnemius (GN), iliotibial tract (IT), pectoralis major (PM), and rectus femoris (RF). It was judged that the lower the measured value, the greater the pain. Using the measured values, the correlation between performance and pain in each area was confirmed.

RESULTS: The relationship between performance of shoulder balance and PPT in UT ($r=.329$, $p<.01$), LT ($r=.339$, $p<.01$), ES ($r=.388$, $p<.01$), GT ($r=.507$, $p<.01$), GN ($r=.267$, $p<.05$) was significant. A relationship between performance of pelvic balance and PPT in UT ($r=.242$, $p<.05$), GT ($r=.342$, $p<.01$), GN ($r=.237$, $p<.05$), PM ($r=.240$, $p<.05$), RF ($r=.231$, $p<.05$) was significant. A relationship between performance of chin position and PPT in LT ($r=.236$, $p<.05$), between performance of chest position and PPT in IT ($r=.242$, $p<.05$) and PM ($r=.286$, $p<.05$), and

between performance of shoulder position and PPT in UT (r=.344, p<.01), LT (r=.616, p<.01), ES (r=.646, p<.01), GT (r=.475, p<.01), GN (r=.392, p<.01), IT (r=.494, p<.01), PM (r=.350, p<.01), RF (r=.236, p<.05) was significant. A relationship between performance of knee position and PPT was not significant.

CONCLUSION: The results direct us to identify the musculoskeletal pain regions which is related to the SNPE number 1 movement. This can be used as a useful reference data to provide an effective exercise program during SNPE exercise instruction for the improvement of chronic musculoskeletal pain.

## THE RELATIONSHIP OF BACKSWING PHASE MOVEMENT SMOOTHNESS AND SWING PERFORMANCE IN COLLEGIATE GOLFERS

PENG, Y.C.1,2, TANG, W.T.2

*1:NCKU, 2:NTSU*

INTRODUCTION: Past studies have shown that the swing length and extent of torso rotation in the backswing phase do not affect a golfers clubhead speed (1). Golf swings can achieve more consistent clubhead speed with a short backswing with minimal rotation (2). The performance of the back swing seems to have a significant impact on golf performance. The analysis of sport biomechanics can offer insight into the quality of a movement as it is being executed through the jerk parameters (3). The quality of the movement will improve with maturity, resulting in a smoother movement (3). This study was aimed to investigate the correlation between backswing phase movement smoothness and swing performance.

METHODS: In this study, 30 Division I collegiate golfers were recruited as the study participants. All the participants in this study demonstrated their swings for analysis, performing 10 swings with the same 7-iron. A TrackMan Launch Monitor was used to collect the participants' swing performance parameters. In this study, log dimensionless jerk (LDLJ) was one of the parameters for assessing movement quality, and the formula was defined by positional changes and must include a time-dependent closed interval. The formula is as follows Balasubramanian et al., 2015 (4).

RESULTS: The trunk LDLJ values during the backswing demonstrated moderate correlations with ball parameters ball speed and smash factor and with club parameters club speed, attack angle, low point, swing plane, and face angle.

CONCLUSION: The LDLJ parameters in this study provide clear data and statistical results that verify that the quality of the upswing directly affects the swing performance parameters; therefore, this study further investigated the possible reasons for the upswing's effect on the swing fluency. This effect may be related to a golfer's physical limitations. The research of Gulgin (2014) into golfers' physical limitations and golf swing faults found that the three most likely swing faults caused by golfers' physical limitations are hip extensions, loss of posture, and slide. Golf swing faults occur in the pelvic and trunk movements; physical limitations may cause the golf swings to exhibit jerk movements in the pelvis and trunk during the upswing, which then affect the ball parameters and club parameters of the swing performance. However, how physical limitations affect the fluency of the golf swing requires further study.

## EFFECT OF BALL INCLUSION IN UNILATERAL JUMP TEST ON LOWER LIMB NEUROMUSCULAR ASYMMETRY IN BASKETBALL PLAYERS

GONZÁLEZ MILLÁN, S., FERNÁNDEZ-VALDÉS, B., ALBESA-ALBIOL, L., CAPARRÓS, T.

*SCHOOL OF HEALTH SCIENCES, TECNOCAMPUS, POMPEU FABRA, UNIVERSITY, MATARÓ, SPAIN//INSTITUTO NACIONAL DE EDUCACIÓN FÍSICA DE CATALUÑA , BARCELONA, SPAIN//GRUPO DE INVESTIGACIÓN GRCE,INEFC, SPAIN.*

INTRODUCTION: Vertical jump (VJ) is one of the most prevalent acts performed by basketball players (1). Many of these jumps are unilateral and these could lead basketballs players to develop asymmetric neuromuscular adaptations of the lower extremities (2).Traditional jump tests are too static, since players need to constantly adjust their actions in dynamic environments (3). This study aimed to compare the movement variability of basketball players while they performed unilateral drop jump (UDJ) with the same exercise while catching a ball (UDJB). Movement variability was measured using Sample entropy (SampEn).

METHODS: Twelve amateurs basketball players (n=12, 7 females, 5 males, mean ± SD: age 22.3 ± 2.3 years old, height 1.73 ± 0.11 m, weight 67.6 ± 11.3 kg) were tested for drop vertical jumps from a 30-cm high platform and landing on a single leg with (UDJB) or without (UDJ) catching a ball. The acceleration of basketball players was measured using an inertial measurement unit (WIMU, Realtrack Systems, Almeria, Spain). Data was analysed using paired t-test and inter-limb asymmetry (4).

RESULTS: There were significant differences (p = 0.045) between limbs in UDJ condition and 18.68 % of inter-limb asymmetry. However, with the inclusion of the ball, (UDJB) no difference was found (p = 0.477) and inter-limb asymmetry was reduced to a 6.77%.

CONCLUSION: Were found significant differences between legs in UDJ condition, with the movement variability being lower with the right leg. However, when introducing the ball, the coordination challenge of the task increases, specially for the right leg and the differences in movement variability between limbs disappear. In basketball, when shooting with one hand the support falls on the opposite leg, this probably makes the ball affect less on the left leg as all players were right-handed. Therefore, the introduction of the ball equalises the coordinative challenge of the unilateral jumping task between limbs, increasing the unpredictability of the task, more similar to what happens in dynamic environments such as basketball.

### TIME COURSE OF CHANGE IN MUSCLE ACTIVITY DURING A MAXIMAL INTERMITTENT SQUAT PROTOCOL PERFORMED ON AN INERTIAL MACHINE

ALARCÓN, A., TORRADO, P., MARINA, M.

*UNIVERSITAT DE BARCELONA*

INTRODUCTION: Exercise induced muscle damage (EIMD) appears when subjects exercise at a very high intensity, particularly if they are non-trained or non-familiarized with the proposed workouts (1). Albeit both concentric and eccentric exercises can induce muscle damage, it is recognized that EIMD is much more sensitive to eccentric contractions (2). Nowadays, inertial machinery proved its efficacy to improve muscle force and power thanks to its impact on morphological and neural factors (3). We aimed to study fatigue induced changes of muscle activity among knee extensors and flexors when performing 10x10 (ser x rep) dynamic squats (Sq10x) on an inertial machine.

METHODS: Thirty-three adults performed a Sq10x with an inertial load of 1270 Kg/cm2. Three submaximal repetitions were allowed to accelerate the inertial disc before each series The recovery time in between the 10 series was 3 min. Muscle activity was assessed with sEMG recording at 2000 Hz by analyzing the root mean square values (EMGRMS) in the vastus medialis (VM), vastus lateralis (VL), rectus femoris (RF), biceps femoris (BF) and semitendinosus (ST). Force and power were measured during the Sq10x. Before and after the Sq10x, maximal force of knee flexion and extension were measured isometrically in a seated position and knee flexed at 90º. EMGRMS was normalized with baseline maximal voluntary contraction. All signals were synchronized by an external analog-to-digital converter (Power 1401; -CED-). Offline analysis was done with the Spike2 Software. A multivariate analysis of variance was performed to study the changes of the RMS and dynamometric signals across the Sq10x. The series 1 and 2 (beginning) were compared with the series 9 and 10 (ending).

RESULTS: The force decrement of knee flexion and extension measured after Sq10x in comparison to baseline ($p \leq 0.001$) endured even after 10 min of recovery ($p \leq 0.001$). During the eccentric contractions EMGRMS of VL and VM decreased significantly ($p \leq 0.043$) at the ending of the Sq10x. Moreover, an interaction effect (ser x rep) confirmed a higher decrement of EMGRMS throughout the within series' repetitions from the beginning to the end of the Sq10x, in these two muscles ($p \leq 0.05$). EMGRMS of the BF increased significantly ($p \leq 0.048$) during the last two series of the Sq10x. No significant changes were observed across the Sq10x during the concentric contractions for all muscles, except for the VM ($p \leq 0.049$).

CONCLUSION: Whereas the VM (chiefly) and VL were confirmed as prime movers, getting into a fatigue state during the Sq10x, the BF could be considered as a synergist "rescuer" thanks to its increased EMGRMS. Moreover, if during the first two series the participants were able to maintain their level of activation across all the repetitions, the opposite was observed during the last two series.

## Coaching

### ADOPTION, IMPLEMENTATION AND MAINTENANCE FOLLOWING A YOUTH INJURY PREVENTION WORKSHOP IN GRASS-ROOT COACHES FROM 3 EUROPEAN COUNTRIES

DE STE CROIX, M., AYALA, F., LEHNERT, M., HUGHES, J.

*UNIVERSITY OF GLOUCESTERSHIRE*

INTRODUCTION: The purpose of this study was to explore the effectiveness of a workshop in terms of knowledge gain, attitude towards and confidence of grass-root coaches to deliver movement competency training to youth participants. Additionally, using the RE_AIM framework, adoption, implementation and maintenance was determined following the youth injury prevention workshop for grassroot coaches.

METHODS: Knowledge, attitude towards and confidence to deliver injury prevention was explored before and after a workshop in 238 grassroot coaches from three European countries (Spain, United Kingdom and Czech Republic). The pre-post workshop questionnaires were analysed using Wilcoxon signed-rank tests and the effect size was calculated using rank-biserial correlation [rB]. An online follow-up questionnaire (six month after the workshop) was completed by 61 coaches (27% follow-up) and examined adoption, implementation and maintenance of the youth injury prevention programme. Follow-up data was analysed using Bayesian binomial (dichotomous variables) and multinomial (categorial variables) tests.

RESULTS: Statistically significant ($p < 0.05$) and large ($rB > 0.5$) positive effects on knowledge gain, attitude and confidence towards injury prevention were found post the workshop. Follow up Bayesian analysis indicated extreme evidence (Bayesian factor > 100) for adoption of the programme (88.5%), weekly implementation (71.4%) and maintenance (83.9%).

CONCLUSION: A bespoke 2 hours workshop can increase knowledge and confidence of grassroot coaches to deliver youth injury prevention programmes. Importantly the workshop resulted in significant adoption, implementation and maintenance of the injury prevention programme. As such appropriately delivered injury prevention workshops should be included in national governing bodies coaching awards or as continuing professional development (CPD) events for those who coach youth sport.

### A PRACTICAL REPORT ON THE COACHING OF "ANY RUSSIAN WENDESWING WITH 360° TURN AND 3/3 TRAVEL(ROTH)" OF POMMEL HORSE OF IN ARTISTIC GYMNASTICS

KIYORA, I.

*INTERNATIONAL BUDO UNIVERSITY*

INTRODUCTION: Gymnastics involves a huge number of element, and coaches and gymnast need to be familiar with the structure and coaching methods of those elements. Arkaev (2004) points out the importance of knowledge of "how to teach", and shows specific practice stages training devices(Additional equipment) (p.381-389). It is extremely important to develop training devices for effectively learning the technique and to present the rationale for using it.

"Any Russian wendeswing with 360° turn and 3/3 travel (Roth)" in pommel horse is called "Roth", which is performed as an advantageous element by many top gymnasts today. The coaching method of how to master this element has not been scientifically clarified. The purpose of this study was to verify the effectiveness of the new coaching method developed to effectively master this element.

METHODS: The author has coached “Roth” for 10 gymnasts. The coaching process and the process of modifying the coaching method based on the experience are divided into two phases: 1) Showing the details and intent of coaching method development, 2) Accumulation of practical knowledge related to coaching gymnasts and utilization of the teaching method based on the experience. The process is shown below.

RESULTS: The coaching practice revealed a learning process by new practice method. In the process from the start of practice to the acquisition of technique, he was able to effectively acquire it by using the balance beam as an additional equipment. Specifically, he learned the techniques related to hand movement and weight transfer, which are important in the movement of the element, using the balance beam. When this practice was performed, it was found that if the weight was applied too much to the head or the lower leg during the turning motion, the body would fall. In next stage, he performed this element on the pommel horse without pommel(pommel removed). By succeeding in each of the above steps, it became rational to learn this technique.

CONCLUSION: In this study, we presented step-by-step based on coaching practice and analyzed the kinesthetic sensation of each step for the acquisition method of "Russian 360 ° turning movement (3/3)" in pommel horse. In this case, it was found that by incorporating another apparatus -balance beam- into the training, it was possible to effectively learn how to touch hands and how to move weight.

Through these, effective findings were obtained for the guidance of “the russian wendeswing movement”, which is important for the Roth of pommel horse movement.

## AN EXPLORATORY STUDY EXAMINING THE RELATIONSHIP BETWEEN SESSION RATE OF PERCEIVED EXERTION AND HEART RATE DURING JUDO SPECIFIC CONDITIONING IN FEMALE JUDOKA.

CLOAK, R., LANE, A.

*THE UNIVERSITY OF WOLVERHAMPTON*

INTRODUCTION: This study aimed to investigate the relationship between athlete rating of perceived exertion (session-RPE and heart rate training load using Edwards TL method) as methods of assessing internal training loads during judo specific conditioning. Assessment of the intensity and loading of training is useful to tailoring adaptive training programmes, and something particularly important in judo where the demands of weight making can mean restrictions in caloric intake to meet the demands of training.

METHODS: 6 female judo athletes (24.6 + 2.5 years; 161.3cm + 2.9 height; 61.5kg + 5.9 weight) performed 5 judo specific training sessions lasting 45-60 min. The internal training load was quantified through the session-RPE (CR 0–10) and the Edwards TL methods, as suggested elsewhere. All data were collected immediately following the session.

RESULTS: The Pearson’s linear correlation was used to verify the relationship between session-RPE and HR methods ($p < 0.05$). A significant positive correlation was found between session-RPE and HR method during Judo specific conditioning ($r = 0.77$; $p < 0.001$).

CONCLUSION: Results from session-RPE and HR suggest that training load monitoring using either method provides useful insights into the overall load of the session. However, we suggest exploring the use of mood monitoring also. Although the relationship is positive and significant only 59% of common variance was found suggesting 41% could be explained by other variables. Of possible candidates, we suggested mood could be useful to assess as it can provide a lens through which people use to interpret inner states, and therefore, a player who is tense might report higher RPE than when feeling calm for the same session. This provides coaches with the option to use session RPE for the planning and programming training load where access to other equipment is limited. Further evidence is needed on how other variables such as mood may influence such self report measures.

## ARE ICE HOCKEY PLAYERS BECOMING FASTER AND STRONGER? A NINE-YEAR TREND STUDY OF THE SWISS U18 MEN’S ICE HOCKEY NATIONAL TEAM

BIELMANN, C., ANDREY, P., FISCHER, K., STRÜBI, J., MAYSTRE, H., CASTELLA, L., HESS, N., TSCHOPP, M.

*SWISS FEDERAL INSTITUTE OF SPORT MAGGLINGEN*

INTRODUCTION: Physical performance, including speed, power, strength, and endurance are considered critical success factors in elite ice hockey. Several studies have shown overall improvements in these qualities among elite-male ice hockey players over the years 1979–2005 (e.g. Quinney et al., 2008). The last decade has received less attention to date. Anecdotal evidence suggests that today’s players are faster, stronger, and more agile than players were 10 years ago. However, there are no data confirming this claim so far. The aim of this study was therefore to examine physical and physiological changes among the Swiss U-18 men’s ice hockey national team over the years 2011–2019.

METHODS: The data used for this longitudinal trend study were collected as part of the annual off-season testing procedures. These include countermovement jump relative peak power output (CMJ_rel_peak_power), 30m-off-ice Sprint time (30m-Sprint), Yo-Yo intermittent recovery test level 1 (Yo-Yo-IR1), and anthropometric measures (body mass and body size). 306 athletes (17.0±0.3 years) were tested over 9 years. To quantify changes over time, test results were divided into 3 time periods: period 1: 2011–2013 (N = 99), period 2: 2014–2016 (N = 105), period 3: 2017–2019 (N = 102). One-way ANOVAs followed by Bonferroni post-hoc tests were performed to assess differences in the testings between the time periods. For all pairwise comparisons, effect sizes (Cohen’s d) were calculated.

RESULTS: One-way ANOVA revealed significant differences in CMJ_rel_peak_power, 30m-Sprint time, and Yo-Yo-IR1 between at least two time periods (all p’s <0.05). No differences between time periods were observed in anthropometric measures. Although not reaching significance level, post hoc tests revealed superior levels of CMJ_rel_peak_power (mean percentage difference %Mdiff = +3.2%, $p = 0.06$, $d = 0.33$) and 30m-sprint time (Mdiff = -0.7%, $p < 0.64$, $d = -0.21$) for time period 2014-2016 in comparison to 2011-2013. Significant differences were observed between time periods 2014-2016 and 2017-2019 for 30m-Sprint time (%Mdiff = -1.1%, $p < 0.05$, $d = -0.33$) and Yo-Yo-IR1 (%Mdiff = +12.7%, $p < 0.05$, $d = 0.64$) and between time period 2011-2013 and 2017-2019 for CMJ_rel_peak_power (%Mdiff = +4.8%, $p < 0.05$, $d = 0.48$), 30m-Sprint time (%Mdiff = -1.7%, $p < 0.05$, $d = -0.51$), and Yo-Yo-IR-1 (%Mdiff = +8.1%, $p < 0.05$, $d = 0.64$).

CONCLUSION: This study identified small to moderate positive development in physiological fitness parameters over time, while body mass and body size remained unchanged. From the observed trend in the data, we can infer that off-ice fitness test performance has increased over the last 9 years in our sample of youth elite male ice hockey players. In conclusion, our data support the common perception that ice hockey players are becoming faster and stronger. Moreover, today’s players possess more stamina than their predecessors.

### EXPLORING THE KEY ATTRIBUTES OF FORMER RACEHORSES CONSIDERED TO HAVE THE POTENTIAL FOR A SUCCESSFUL SECOND CAREER IN DRESSAGE

EVANS, S.J., KINNIBRUGH, A., PENHORWOOD, G.T.C., WILLIAMS, J.M.

*HARTPURY UNIVERSITY*

INTRODUCTION: Each year, approximately one quarter of the British racehorse population retire from racing and potentially start second careers. A key strategic aim of the British Horseracing Industry is to maximise racehorse welfare and quality of life following their retirement from racing. Despite this, few studies have evaluated what factors underpin successful second careers in former racehorses. Exploratory research has recognised dressage as the main discipline that horse owners compete their former racehorse in [1]. This study therefore aimed to explore what key attributes in former racehorses, owners associated with a successful second career in dressage.

METHODS: A 29-question online survey was shared to existing former racehorse owners through social media channels, including but not limited to, racehorse specific Facebook groups. The survey gathered demographic data on former racehorses including level and success attained in dressage, and asked owners to comment on personality and behavioural attributes that make former racehorses' suitable candidates for dressage, as well as to identify challenges of competing former racehorses in dressage. Data were exported to Microsoft Excel and analysed using frequency analysis and thematic analysis, using a grounded theory approach.

RESULTS: A total of 113 former racehorse owners completed the survey (Margin of Error: 9.16%). Respondents predominately competed their former racehorses at sub-elite level dressage, with horses on average achieving tests scores between 60-70%. Respondents selected dressage as their former racehorse's main discipline, as it was considered a solid foundation for all other second careers, and they felt it mentally and physically develops the horse, while being enjoyable for both horses and owners. Former racehorses' athleticism, "natural talent" and willingness to learn were key attributes which were identified as essential for competitive success in dressage. However, respondents recognised when competing a former racehorse, that patience was required throughout former racehorse re-education, and that individuals' "quirks" and dressage judges' perceived preference for a warmblood conformation could present challenges within this discipline.

CONCLUSION: Former racehorse athleticism, natural talent and willingness to learn were key attributes owners recognised enhanced potential for a successful second career in dressage. Applying these results across the industry to support former racehorse transition could help facilitate successful, long-term rehoming and second career success.

## Disabilities

### ASSESSMENT OF BODY COMPOSITION AND STRUCTURE OF ATHLETES WITH SPINAL CORD INJURY

ZWIERZCHOWSKA, A., ROSOLEK, B., GAWEL, E., ZEBROWSKA, A.

*THE JERZY KUKUCZKA ACADEMY PHYSICAL EDUCATION*

INTRODUCTION: Spinal Cord Injury (SCI) - paralegic and tetraplegic (CSCI) dysfunction frequently determines and generates other deficits and disorders. Spinal Cord Injury results in physiological changes that reduce whole-body metabolism, resulting in neurogenic obesity via adipose tissue accumulation. Adipose tissue has been implicated in the release of proinflammatory adipokines that lead to chronic and systemic inflammation. Some scientific researches suggests these adipokines contribute to the pathogenesis of metabolic diseases which often accompanies obesity. That is why it is important specifically to create compensatory processes among persons with spinal cord injury who have sedentary life. Sport and physical activity is widely accepted necessary component for healthy individual, especially for a person with spinal cord injury . The purpose of this study was to compare several body features and indexes regarding their changes in the aspect of age and time of injury. It was assumed that main factors which differentiate body structure and composition of the people who had spinal cord injury are sports activity, type of injury, time since injury and age.

METHODS: The study group consisted of 43 Caucasian males aged 25 - 40 years (34.6 ± 2.8 years), who had experienced spinal cord injury. Conducted research was divided into three groups: G1 - wehler rugby players (CSCI), G2 - handbike (CSI) and G3- control group URK - no sports (sedentary life). All subjects were measured for body height, waist and hip circumference, thigh, calf and shoulder, all indicated in centimeters. Body mass (BM) was expressed in kilograms (MENSOR Chair of EC type P3 150 K). Body fat content was measured with the use of Abdominal Fat Analyzer ViSCAN Tanita AB-140 utilizes BIA. In addition, during the research there was conducted thorough interview concerning sports activity and duration of injury.

RESULTS: BMI calculated according to the standards of the general population indicated that 85% of participants fell within the norm (BMI <25), while according to BAI standards it was only 48%. Both the Body Mass and BMI depended inversely proportional from the time since injury, so that, the longer time since the injury, the lower Body Mass and BMI were. Similar correlation was observed for limb circumference. Furthermore, research revealed significant statistical differences in the study group regarding the body structure and composition depending by the age they had experienced injury.

CONCLUSION: Our research indicates that age moderately influences some characteristic of body structure and composition of individuals with SCI, specifically CSCI. We find that the elder the individual is at the time of injury, the greater the impact it has on characteristic of body structure and composition. In our opinion, this is important for the preparation of intervention programs for people with SCI in the form of sports activity.

### PHYSICAL FITNESS AND BONE DENSITY IN ADOLESCENTS WITH DIFFERENT LEVEL OF VISUAL IMPAIRMENT

SZMODIS, M., CSÁNYI, T., KAJ, M., KIRÁLY, A., ALMÁSI, G., KÄLBLI, K.

*HUNGARIAN UNIVERSITY OF SPORTS SCIENCE, BUDAPEST*

INTRODUCTION: Lower habitual physical activity in children and adolescents with visual impairment (VI) have unfavourable effect on their general health such as physical fitness and bone quality. Our aim was to demonstrate the physical fitness and bone density in adolescents with VI and to analyze of the relationships between physical fitness tests, body structure and bone characteristics.

METHODS: Children and adolescents with different level of VI (N=38) provided anthropometric, physical fitness (field and laboratory treadmill tests) and bone data (DEXA).

Differences between genders and subgroups (low vision vs blindness) were tested with Student's t-tests. The relationships between variables were analyzed using Pearson linear correlation. Linear regression models were used to explain the variation in BMD and BMC.

RESULTS: Body height, weight, body mass index (BMI), absolute measured VO2peak of children with low vision were similar as that of children with blindness despite the fact that the blind adolescents were older than the participants with low vision. Estimated relativeVO2 was significantly lower in children with blindness (43.84±4.42 vs 35.08±5.23 ml/kg/min; p<0.001) than in children with low vision. Standing long jump was poorer in blind girls than in girls with low vision (156.00±15.9 vs 118.57±35.2 cm; p=0.0034). Blind boys had higher handgrip strength than blind girls (35.97±9.97 vs 24.24±4.74 kg; p=0.003) and children with low vision (boys: 24.63±5.01, girls: 22.56±4.78 kg; p=0.001).

Bone mineral density (BMD) and bone mineral content (BMC) did not differ in subgroups, however Z-score of total body BMD was significantly lower in children with blindness. Z-score-means in L1-L4 lumbal spinal region were similar in both low vision and blind participants, the values of them were negative. The general linear regression model revealed significant relations of BMD (r2=0.538; p=0.0001) and BMC (r2=0.698; p=0.048) with BMI and handgrip strength test.

CONCLUSION: Individuals with VI have generally lower physical fitness level and decreased bone health. Body mass index and handgrip strength were good predictors of bone mineral density and bone mineral content. Bone health could estimate with this simple fitness test and body parameter without the need for expensive DEXA measurements.

## IS THE VISUAL IMPAIRMENT ORIGIN A PERFORMANCE FACTOR? ANALYSIS OF INTERNATIONAL LEVEL PARA SWIMMERS AND PARA ATHLETES

LE TOQUIN, B.

*INSEP*

INTRODUCTION: The aim of this study was to investigate the effect of congenital and acquired visual impairments on the international performance of Para swimmers and Para track and field athletes

METHODS: We collected results from visually impaired Para athletes competing in Para swimming or Para athletic events at all IPC-labelled competitions between 2009 and 2019. The dataset contained 20689 events results. Impairment origin was collected from the International Paralympic Committee (IPC) website. We separated impairment origin into two groups to distinguish those with a congenital impairment from those with an acquired impairment. In visual impairment sport classes (11-12-13), the performance level and the age performance relationship were investigated according to the impairment origin

RESULTS: In classes 11 and 12, peak performance was achieved earlier by male and female swimmers with a congenital impairment compared with those who had an acquired impairment ($p < 0.05$). No differences were present in class 13 or in any class in Para athletics ($p > 0.05$).

CONCLUSION: A similar performance level was observed among the two sport disciplines for each class ($p > 0.05$). This study demonstrated that impairment origin can influence the performance pathway among visually impaired swimmers.

## RELATIONSHIP BETWEEN THE TRAINING LOAD AND SLEEP IN PARALYMPIC POWERLIFTING ATHLETES

MELLO, M.T.1,2, STIELER, E.1, SILVA, F.R.1, GRADE, I.1, ANDRADE, H.1, GUERREIRO, R.C.1, RESENDE, R., ANDRADE, A.G.1, GONÇALVES, D.A.1, SANTOS, M.D.1, SILVA, A.1,2

*1: SPORTS TRAINING CENTER AT THE FEDERAL UNIVERSITY OF MINAS GERAIS ; 2: BRAZILIAN PARALYMPIC COMMITTEE*

INTRODUCTION: Since high-performance athletes often experience high physical and psychological demands (1), achieving optimal recovery in the training process is important in improving physical and cognitive performance (2,3). This study aims to compare the sleep parameters during the days with and without training of Paralympic powerlifting athletes, and to analyze the relationship between the training load and sleep of the same day.

METHODS: Actigraphy was used to analyze the sleep parameters of 11 Paralympic powerlifting athletes for 14 days (7 days without and with training) while Ratings of Perceived Exertion (RPE) analysis was used to assess training load. In addition, the Horne and Östberg chronotype questionnaire and the Epworth sleepiness scale were applied.

RESULTS: Athletes show a morning and indifferent chronotype and low daytime sleepiness. Sleep onset latency (SOL) was lower (average 5.3 min faster), and total sleep time (TST) and sleep efficiency (SE) were higher (TST averaged 169 min and SE 7 % higher) on training days compared to non-training days. In addition, the TST of the night before the training days was positively correlated with the RPE of the following day, as well as the training volume was negatively correlated with the SE of the same day.

CONCLUSION: It is concluded that positive effects of Paralympic powerlifting training were observed in increasing TST, SE and decreasing SOL on training days. These results point to the positive effects of this type of training in improving the sleep of athletes with physical disabilities. In addition, a good nights sleep the day before training can favor a greater effort in training the next day. Therefore, it is recommended to guide athletes to sleep more before training with more intense loads.

### POST-OPERATIVE EXERCISE TRAINING IN PATIENTS WITH METASTATIC COLORECTAL CANCER – THE POET STUDY

YFANTI, C., THOMSEN, S.N., PEDERSEN, B.K., SIMONSEN, C.

*CAPITAL REGION OF DENMARK*

INTRODUCTION: Surgical treatment of liver metastases in colorectal cancer (CRC) patients has become a mainstay in the CRC treatment and has significantly improved survival rates (Xu et al., 2018). However, 50-75% of the patients experience a relapse in less than two years following metastatic tumor resection (De Jong et al., 2009).

CRC patients with liver metastasis, due to the high probability of relapse, undergo multiple rounds of surgery and adjuvant chemotherapy treatment which results in substantial physical deconditioning. Retrospective data indicate that physical activity increases progression-free survival rates in metastatic CRC (mCRC) patients (Meyerhardt et al., 2006). The objectives of this randomized controlled trial (RCT) are to investigate the effects of structured exercise training, applied in an early setting post-surgery and in a dose-response fashion, on:

Primary:

• Peak oxygen consumption (VO2peak)

Secondary:

• Recurrence-free survival (RFS), time-to-recurrence (TTR) and overall survival (OS)

• Overall physical fitness, inflammatory status and immune function.

• Patient reported outcomes.

METHODS: Sixty-six mCRC patients will be randomized 1:1:1 to either 1) 150 min/week of exercise (2 times /week), 2) 300 min/week of exercise (4 times/week) or 3) standard of care. Exercise training will start after discharge from surgery for resection of liver metastasis and will continue for 6 months. Training will consist of both aerobic and resistance exercise and will be partly center-based and partly home-based. The following assessments will be performed before the surgery and at 3, 6, 9, 12 months after initiation of exercise training: VO2peak, maximal strength, body composition, functional capacity, quality of life, fatigue. Blood samples will be collected at the same time points for assessment of immune function, inflammatory status and circulating tumor DNA as a marker of disease progression. CT scans performed every 3 months as standard of care will be used for detention of tumor recurrence.

RESULTS: NA

CONCLUSION: Six months of supervised, combined aerobic and resistance exercise training are expected to increase VO2peak in mCRC patients, improve physiological outcomes, inflammation status and immune function and delay tumor recurrence.

### EFFECT OF DIFFERENT TYPE OF TRAINING ON MUSCLE FUNCTION AND PHYSICAL CAPACITY IN CHRONIC HEMODIALYSIS PATIENTS

ROGOWSKI, L.1, KUSZTAL, M.2, BULINSKA, K.3, PAWLACZYK, W.3, STEFANSKA, M.3, ZEMBRON-LACNY, A.4, GOLEBIOWSKI, T.2, KRAJEWSKA, M.2, DZIUBEK, W.3

*1WITELON COLLEGIUM STATE UNIVERSITY IN LEGNICA; 2WROCLAW MEDICAL UNIVERSITY, 3WROCLAW UNIVERSITY OF HEALTH AND SPORT SCIENCES; 4UNIVERSITY OF ZIELONA GORA*

INTRODUCTION: Decreased exercise capacity due to muscle weakness and exercise intolerance reduces the ability to perform activities of daily living in patients with end-stage kidney disease. Data on exercise type in dialysis population and its muscle effects are scarce. We aimed to determine the impact of training type (strength, resistance and mixed) on cardiovascular performance, muscle function (strength-speed parameters for quadriceps (QUAD) for right (QUAD_R) and left leg (QUAD_L), electrophysiological function of quadriceps (QEMG) in patients on hemodialysis maintenance.

METHODS: Eighty six dialysis patients underwent claster randomisation and were assigned to an exercise intervention groups: A - controlled endurance training during haemodialysis using rotors, B - controlled force training (resistance) , C - Tai Chi training on non dialysis days. Intervention lasted 6 months, 3 times a week (A, B) and 2 times a week (C) for 60 minutes. The outcome measures were spiroergometry (VO2/VO2max), strength of the lower limbs (dynamometry) and electromyographic examination (superficial electromiography). Values at the baseline and 6 months later were compared.

RESULTS: 45 patients completed intervention period and were analysed. Mean age in group A was 64±12y (n-16), in B was 60,5±10y. (n-15) and in C  68,5±9y. (n-14). Patients did not differ markedly between groups in term of sex, BMI, dialysis vintage and comorbidities.

After 6 months of training, VO2 and VO2max increased significantly only in group B (resistance training) 12.7 % for VO2 and 12.9% for VO2max but not in A and C group. Regarding force torque of quadriceps (QUAD) in isometric conditions the highest peak values were measured in group B (resistance training), namely increase by 13.6% ($p=0.0004$) for QUAD_R and 14% ($p<0.0001$) for QUAD_L. In group A (endurance) were not significat changes in strenght observed (3.2% in QUAD_R and 3.7% in QUAD_L). In group C (Tai Chi group) strength has increased by 7% ($p<0.05$) for QUAD_R and 6.8% ($p<0.05$) for QUAD_L.

In terms of changes in electrophysiological function of right (QEMG_R) and left (QEMG_L) quadriceps , there were increases: for group A by 10.5% ($p<0.0001$) and 9.6% ($p<0.05$); B 9.7% ($p=0.0002$) and 20.1% ($p=0.0001$); for C by 4.5% and 6.2% for R and L, respectively.

In groups B and C significant increases in static force moments was associated with increases in electrophysiological action (%QEMG), but in group A increase in EMG activity did not correspond with rise in muscle force.

CONCLUSION: Differences in muscle strength and functions were observed after 6 months of various type of exercise intervention in dialysis patients. Resistance training during dialysis showed the largest improvement in cardiorespiratory function and isometric leg muscle strength.

## Health and Fitness

### THE OPTIMAL WAKE-UP TIME FOR PEAK PERFORMANCES IN THE MORNING

HONDA, A., KONDO, H., MATSUDA, T., OHNO, M.

*ASAHI UNIVERSITY*

INTRODUCTION: Sports performances display a circadian rhythm; many individuals perform better in the afternoon than in the morning. Therefore, for a morning match, it is very important to take the essential steps to improve performances. Therefore, the purpose of the present study was to verify the optimal wake-up time in the morning for peak performances.

METHODS: The participants were 14 male college baseball players (age=21.1±0.6 yr, height=176.2±6.4 cm, weight=76.4±6.8 kg) who came to the laboratory by 9:30 a.m. The performance test started at 10:00 a.m. and was conducted thrice, with the time elapsed after waking up being changed each time. These times were set as 1, 2.5 and 4 hours after waking up (1H, 2.5H, and 4H, respectively; the waking-up time was 9:00 a.m., 7:30 a.m., and 6:00 a.m., respectively). The sitting trunk flexion (STF), simple and choice reaction times (RT and CRT, respectively), grip strength (GS), back strength (BS), vertical jump height (VJ), and the time of the pro-agility test (PAT) were measured.

RESULTS: There were no significant differences in body temperature, heart rate and blood pressure at pre-exercise among three experiments. The BS at 1H was significantly higher than that at 4H ($p<0.05$), and the PAT at 1H was significantly slower than that at 4H ($p<0.05$). The other parameters did not change with the variation in the elapsed time. However, there were differences among parameters or individuals in the time when peak performance was observed. Six or seven participants showed peak value of muscle strength at 1H, while only two peaked at 4H. Eleven participants peaked at 4H in the PAT. Three participants peaked at 1H in VJ, while seven peaked at 2.5H. In other measurements, the peak time was evenly distributed. Additionally, a few participants showed peak performances at 1H in many parameters, while others at 2.5H or 4H, or evenly.

CONCLUSION: Our data shows that muscle strength can be exerted even shortly after waking up, but a certain period of time is required for agility. The participants underwent early morning baseball training (6:00 a.m.-8:30 a.m.) 1-2 times per week; they often slept until just before the start of training to maintain sleep time. They might have, therefore, shown good performance even at 1H, as they were accustomed to exercising immediately after waking up.

Though we could not indicate the optimal wake-up time for a match in the morning, it might be effective to set the wake-up time based on the individual patterns of peak performance.

### THE EFFECTIVENESS OF A 12-WEEK EXERCISE PROGRAM TO RELIEVE SYMPTOMS DURING MENOPAUSE

KNEFFEL, ZS., SZALAI, H.

*UNIVERSITY OF SPORTS SCIENCE*

INTRODUCTION: In menopause, women face a number of negative changes due to the reduced hormone secretion. A well-structured exercise program can delay these negative symptoms, and do a lot against osteoporosis, muscle loss, and obesity, but it also has a positive effect on mental health and general physical well-being. The aim of the study was examining the effectiveness of a 12-week exercise program specifically designed for this age group based on physiological and psychological measurements.

METHODS: In the first phase of the study (baseline data and first measurements) a total of 21 female participated, during the 12-week exercise program the dropout rate was less than 10%, so we included a total of 19 female to the evaluation, where the mean age was 52.5 ± 2.91 years. The training program was carried out between June-October 2021. Due to the COVID-19 pandemic the trainings were executed both face-to-face and online. Participants attended 2x1 hours of resistance training were per week and 1x1.5 hours endurance training (i.e. cycling, walking) per week. The resistance training was executed with various strength training tools as well as with participants' own weight. The fitness test contained a flexibility test (sit and reach), a 2-minute step test, and the handgrip measurement. The body composition was measured with a TANITA BC-545N bio-impedance scale. The Physical Self –Description (PSD) was measured with the short version of PSDQ (Marsh et al., 2010). The sympthoms of menopause were asked by a self-developed questionnarie. Descriptive statistics (means and standard deviations) calculated for each variable. The Student´s t-test (one sample) was used to calculate physical fitness level differences before and after the intervention, Wilcoxon test was used to analyze the PSDQ data and Spearman Rank Order Correlation was used to see connections in menopause symptoms, before and after the intervention.

RESULTS: Significant improvement was detected in all fitness tests (flexibility, handgrip and 2-minute step test). Although the mean body weight decreased, it did not reach the significance level of 69.19 ± 11.37 kg vs. 68.84 ± 11.21 kg; and BMI also showed a only decreasing trend (25.87 ± 4.32 vs. 25.58 ± 4.29). Mean values of bone mass, muscle mass, visceral fat, and body fat did not change significantly between the first and second measurements, but e.g. body fat% was reduced in 36% of participants. The self-description of the women changed significantly over the 12 weeks: more than half of the self-assessment questions showed significantly better median values at the second measurement.

CONCLUSION: Our results are in line with earlier findings indicates that postmenopausal women who engage in the comprehensive exercise program, benefit by maintaining a healthy body as well as a good mental health.

### PREFERENCE PATTERNS FOR EXERCISE/SPORTS ACCORDING TO NUMBER OF PEOPLE PARTICIPATING

HIDETOSHI, I.1, HIDEAKI, S.2, TOMOHITO, A.2, OSAMU, A.3, CHOI, T.4, HAN, N.4, HONG, Y.4, KOO, K.5, NAM, Y.6, SEO, Y.7

*1KYUSHU UNIVERSITY OF HEALTH AND WEALFARE, 2NIHON KEIZAI UNIVERSITY, 3FUKUOKA UNIVERSITY*

INTRODUCTION: When people attend university, exercise or sports involve many people in PE classes or club activities. However, after graduation, people decide on their own if they want to exercise or play sports. For instance, some people jog by themselves. Others do radio calisthenics together with many other people in a neighborhood park. However, jogging can be done also with two or more other people and radio calisthenics can be done alone at home. Thus, this study examined whether preference patterns for exercise/sports according to the number of people participating exist or not and, if they do exist, what those patterns are.

METHODS: Subjects were 1,333 Japanese aged from their teens to middle age. They were asked three questions about the degree to which they want to exercise or play sports 1) alone, 2) with a few other people, and 3) with many other people. Answers were obtained on a 4-point scale from 1: very much to 4: not at all. Quantification Theory Type Three (QTTT; factor analysis using binary data) was applied to the data and configurations showing mutual similarities of responses and person patterns were obtained. The patterns were studied from positional relationships in the configurations.

RESULTS: A two-dimensional plot obtained using QTTT was adopted because the accumulated ratio of eigenvalues up to two dimensions was 39.55%. The plot of the category weights of the alternatives of questionnaire items generated three clusters: 1) "Want to exercise or play sports very much;" 2) "Sometimes" or "Not so much;" and 3) "Never." That is to say, a fine classification by the number of people exercising or playing together with that originally assumed was not found, and they were categorized into those who actively wanted to play all kinds of sports, those who did not, and others with medium characteristics regardless of the number of people participating. Based on a two-dimensional plot of sample scores showing the similarities among individuals, the following seven clusters were found in which respondents gradually changed their preference from completely dislike to completely like: 1) three-dislike group (96, 7.2%); 2) two-dislike and one moderately-like group (55, 4.1%); 3) two-moderately-like and one-dislike group (115, 8.6%); 4) three-moderately-like group (402, 30.2%); 5) two-moderately-like and one-like group (256, 19.2%); 6) two-like and one-moderately-like group (173, 13.0%); and 7) three-like group (102, 7.7%). In addition, three additional clusters with extreme preference patterns were also found: 8) two-dislike and one-like group (29, 2.2%); 9) two-like and one-dislike group (37, 2.8%); and 10) all combinational pattern of like, dislike and moderately like (68, 5.1%).

CONCLUSION: There was no difference in sports preferences according to the number of people together with whom sports were played, and there was a tendency that those who liked/disliked sports liked/disliked all kinds of sports regardless of the number of people participating.

## 1-H NMR URINARY METABOLOMIC ANALYSIS IN ELDER SUBJECTS AFTER A HIP FRACTURE REDUCTION MAY PROVIDE VALUABLE INFOR-MATION FOR PATIENT CHARACTERIZATION. A PRELIMINARY INVESTIGATION.

DOUZI, W., BON, D., SUIKKANEN, S., SOUKKIO, P., BOILDIEU, N., NENONEN, A., HUPLI, M., KUKKONEN-HARJULA, K., DUGUÉ, B.

*UNIVERSITY OF POITIERS, LABORATORY MOVE–UR 20296, FACULTY OF SPORT SCIENCES*

INTRODUCTION: At the time of precision and personalized medicine, the importance of patient characterization to identify patient needs is crucial in order to provide the best available and cost-effective treatment. In this study, we used urine metabolomics to explore a possible characterization of elder patients who experienced hip fracture reduction and to explore the possibility of forecasting patient outcomes.

METHODS: Overnight urine specimens were collected in 33 elder patients after hip fracture reduction during their stay at the hos-pital. The specimens were analyzed with 1H NMR spectroscopy. We performed a metabolomics study regarding frailty evaluation and the results obtained at the Functional Independence Measure (FIM) and Short Physical Performance Battery (SPPB). We also investigated whether the categorization of the patients could predict their performance in FIM and SPPB one year later

RESULTS: The main metabolic variations concerned 10 identified metabolites: paracetamol derivatives (4 peaks: 2.15 ppm; 2.16 ppm; 7.13 ppm and 7.15 ppm); hippuric acid; acetate; acetone; dimethylamine; glycine; alanine; lactate; valine and TMAO. The urinary levels of these identified metabolites were significantly higher in frail persons (frailty score ≥ 3) with weak score of FIM and low score of SPPB compared to non-frail patients at baseline and after one year.

CONCLUSION: Our findings reveal that patients with increased levels of urine metabolites associated with metabolic, inflammatory, renal disorders presented clear signs of frailty, impaired physical capacity, and poor physical performance. Metabolomics could be a valuable tool to further characterize patients with frailty syndrome.

## 12 WEEKS OF WALTZ DANCE ON CARDIOVASCULAR RISK FACTORS AND BONE METABOLISM IN POSTMENOPAUSAL CHINESE WOMEN: A RANDOMIZED CONTROLLED TRIAL

XIAN, G.1, JIEDAN, L.2

*1 BEIJING SPORT UNIVERSITY, 2 THE SECOND FOREIGN LANGUAGE SCHOOL OF PINGSHAN DISTRICT*

INTRODUCTION: In postmenopause, estrogen withdrawal along with sedentary lifestyle could contribute to the increased risk of cardiovascular disease and fracture in women. The energy consumption recommended by the American College of Sports Medicine to improve female health has been exhibited for many years. In this study, we aimed to investigate the improvement effect of waltz dance which meets current energy consumption recommendations on cardiovascular risk factors and bone metabolism in postmenopausal women of 12 weeks.

METHODS: Twenty six community-dwelling sedentary postmenopausal women aged 45-65 years were recruited and randomly divided into the waltz dance group (WEG, n = 14, BMI: 25.57±2.47 kg/m2) and the control group (CG, n = 12, BMI: 24.47±2.92 kg/m2). WEG completed 12-week waltz dance exercise training, the dance sessions of approximately 105 minutes were performed 3 days a week. Body composition, maximal oxygen consumption, lipid profile, serum bone metabolic markers (osteocalcin), bone mineral density (BMD) and bone mineral content (BMC) were measured before and after the intervention.

RESULTS: During the intervention, the energy consumption of waltz dance was 1624kcal to 2000kcal each week. After 12 weeks of waltz dance, the body weight (-1.96±1.70%, $P<0.01$) and body fat percentage (-1.60±0.71%, $P<0.01$) in WEG were significantly reduced. The TG was significantly lower than before (1.23±0.72 mmol/L VS 1.61±0.86 mmol/L, $P<0.05$), and the HDL-C was significantly higher than before in WEG (1.53±0.40 mmol/L VS 1.08±0.36 mmol/L, $P<0.01$). Moreover, the VO2max in WEG was significantly improved (27.79±3.09 mL/kg•min VS 22.43±3.41 mL/kg•min, $P<0.05$). As expected, the intervention improved BMD (+1.2%, $P<0.05$) and BMC (+2.4%, $P<0.05$) in the WEG, but had no impact on serum osteocalcin (1.13±0.47 VS 1.09±0.43, $P>0.05$).

CONCLUSION: A 12-week waltz dance intervention is effective in reducing risk factors of cardiovascular disease and improving bone health in postmenopausal women. This suggests waltz dance could be adopted as an interesting exercise for women to improve health in senior community.

## PHYSICAL ACTIVITY, EATING AND SLEEPING HABITS IN BRAZILIAN ADULTS AT THE BEGINNING AND ONE YEAR AFTER THE PANDEMIC

BRITO, L.1,2, DE LIMA, V.2, MASCARENHAS, L.3, MOTA, J.4, LEITE, N.2,4

*COLÉGIO ESTADUAL DO PARANÁ, UNIVERSIDADE FEDERAL DO PARANÁ, UNIVERSIDADE ESTADUAL DO CENTRO-OESTE DO PARANÁ, UNIVERSIDADE DO PORTO*

INTRODUCTION: Social isolation is one of the strategies to prevent the contagion and transmission of the coronavirus (COVID-19), but the impacts of this new routine and lifestyle need to be understand. Therefore, the aim of this study was to analyze physical activity [1], sleep [2] and eating habits [3] of adults at the onset of the pandemic and one year after the COVID-19 pandemic.

METHODS: Cross-sectional study with 135 participants in first moment and 57 participants in second evaluation, divided by age group, comprising the sample. The group consisted of both sexes, enrolled in a physical activity program in a school community. An online questionnaire with 26 questions was applied about eating habits, sleep and physical activity, in addition to protective behaviors against COVID-19.

RESULTS: The distribution of participants the questionnaire by age groups were: 18-29 years (n=18; 9.3%), 30-40 years (n=37; 19.3%), 41-50 years (n=52; 27%), 50-60 years (n=53; 27.6%), 61-70 years (n=25; 13%). One year after the pandemic, 68.5% of the participants met the World Health Organization Physical Activity Recommendation, unlike the beginning of the pandemic, 52.7% did not meet the recommendation ($p<0.001$; $x2=6.89$). After a year of pandemic, participants became more active. At the beginning of the pandemic 78.1% occupied their time in more sedentary activities, such as watching television and spending a long time in front of the computer or cell phone and then 21.9% at the end of the first year ($p<0.01$; $x2= 5.61$). As for eating habits, 96.5% of the group responded that they took care of their diet after one year of the pandemic, at first only half (50.3%) of the participants did ($p<0.001$; $x2=37.99$). And, regarding the number of meals, 19.7% of the participants did not control the number of meals they had per day at the beginning of the pandemic and one year after this number went to 80.3% ($p<0.001$; $x2= 12.99$). In 68.7% of the participants declared that they slept an adequate number of hours, however 67.7% said that they slept poorly. There was no significant difference between onset and one year after the pandemic in terms of sleep habits.

CONCLUSION: One year after the start of the pandemic, most program participants were motivated by their physical activity and eating habits. Only the sleep habit did not improve, which can be concluded is that having more sleep is good for health, but it does not ensure quality, since the stress and frustration caused by the pandemic has overcome the possible positive effects of quarantine.

## HYBRID-TYPE, MULTICOMPONENT INTERVAL TRAINING IMPROVES CARDIORESPIRATORY FITNESS AND BODY COMPOSITION IN MIDDLE-AGED OVERWEIGHT AND OBESE ADULTS: A 1-YEAR DOSE-RESPONSE RANDOMISED CONTROLLED TRIAL

BATRAKOULIS, A., JAMURTAS, A., POULIOS, A., PAPANIKOLAOU, K., TSIMEAS, P., SYROU, N., DRAGANIDIS, D., GEORGAKOULI, K., DELI, C., FATOUROS, I.

*UNIVERSITY OF THESSALY*

INTRODUCTION: The rising prevalence of overweight and obesity is a major public health challenge negatively affecting more than one in two adults worldwide [1]. Regular exercise is a fundamental component of a comprehensive strategy for preventing, managing and treating obesity [2]. Particularly, a hybrid-type, multicomponent interval training programme (DoIT) has been reported as an effective exercise approach for improving a wide spectrum of musculoskeletal fitness indices [3]. This study examined the dose-response effects of a 1-year DoIT on cardiorespiratory fitness and various body composition parameters in previously inactive overweight and obese adults in a gym setting.

METHODS: Ninety-seven middle-aged (44.8 ± 5.2 years) overweight and obese individuals (31.2 ± 5.7 kg/m2) (66% female) were randomly assigned to the following groups: (i) no-intervention control (CON, n=29), (ii) DoIT performed once weekly (DoIT-1, n=24), (iii) DoIT performed twice weekly (DoIT-2, n=23) and (iv) DoIT performed thrice weekly (DoIT-3, n=21). DoIT was a time-efficient, intermittent-based, multicomponent exercise protocol using progressive loaded fundamental movement patterns with prescribed work-to-rest intervals (1:3 to 2:1) in a circuit format (2–3 rounds). Cardiorespiratory fitness (CRF), somatometric parameters [body mass (BM), waist circumference (WC), waist-to-hip ratio (WHR)] and body composition [body fat percentage (BF%), fat mass (FM), fat-free mass (FFM), trunk fat percentage (TF%)], resting metabolic rate (RMR), bone metabolism [whole-body and regional (femur) bone mineral density (BMD) and bone mineral content (BMC)] were assessed at baseline, 6 months and 12 months following intervention.

RESULTS: CON increased all somatometric (1.8%–2.2%, $p<0.001$) and body composition variables (0.5%–4.3%, $p<0.001$). In somatometric measures, all DoIT groups reduced BM (1.8%–5.2%), WC (3%–6.6%), WHR (1.1%–6.6%) at post training compared to baseline ($p<0.001$). In body composition, all DoIT groups reduced BF% (1.5%–4.5%), FM (5%–15%) and TF% (0.4%–1.8%) while increasing FFM (1%–2.4%), whole-body and femur BMD (0.4%–2.2%) as well as BMC (0.1%–1.8%) at post-training ($p<0.001$). All DoIT groups exhibited superior increases than CON in CRF (18%–23%, $p<0.001$).

CONCLUSION: These findings suggest that a multicomponent exercise approach incorporating bodyweight drills and resistance-based alternative modes performed under real-world conditions may improve cardiorespiratory fitness and several body composition indicators, but not widely in a dose-dependent manner in previously inactive, middle-aged overweight and obese adults. The results of this study will enable physicians and exercise professionals to follow more efficient exercise prescription guidelines for this popular and effective exercise modality.

### THE CHARACTERISTICS OF GENERAL MALAISE/INDEFINITE COMPLAINTS IN JAPANESE CHILDREN AS EXAMINED BY LATENT CLASS ANALYSIS

IKEDA, T.O.1, IKEDA, T.A.2, SAKAGUCHI, H.3, ANNOURA, T.3, AOYAGI, O.4, HONG, Y.5, HAN, N.5, CHOI, T.5, NAM, Y.6, KOO, K.7, SEO, Y.8

*1NISHI-KYUSHU UNIVERSITY, 2FUKUOKA PREFECTURAL UNIVERSITY, 3JAPAN UNIVERSITY OF ECONOMICS, 4FUKUOKA UNIVERSITY, 5JEJU NATIONAL UNIVERSITY, 6DUKSUNG WOMENS UNIVERSITY, 7CHANGWON NATIONAL UNIVERSITY, 8*

INTRODUCTION: We refer to subjective symptoms showing that physical conditions are something wrong despite that there is no disease causing it to be a general malaise/indefinite complaint (GMIC). It is said that GMIC consists of a feeling of tiredness, dizziness, headaches, palpitation, diarrhea, and others, and a disorder of the autonomic nervous system is involved. Since irregular menstruation, as well as psychological stress, a change in environment, and accumulation of fatigue, is thought to be associated with it, it is said that it is often seen in adult females. Even in advanced countries, it is caused by a deficiency of vitamins or essential nutrients or degraded physical fitness. Although it is often found in adults, it is appearing in children now and is considered to be similar to a life-related disease. However, its actual situation has not been made clear yet. Thus, this study examined the characteristics of GMIC in Japanese children using latent class analysis.

METHODS: 192 Japanese elementary school boys/girls aged 11 or 12 years in F-city were asked to answer a questionnaire survey about their GMIC, i.e., how often do they feel 1) Heavy head, 2) Sleepy, 3) Irritated, 4) Stomach aches, 5) Heavy and tired, 6) Intestinal disorders such as constipation and diarrhea, 7) Headaches, and 8) Lack of motivation, based on using the alternatives of a) Never, b) 1 or 2 days/week (ds/w), c) 3 or 4 ds/w, d) 5 or 6 ds/w, and e) every day. Latent class analysis was conducted using poLCA in R, which utilizes an EM algorithm. The optimal number of classes was obtained using AIC.

RESULTS: Since the AICs in 1 to 4 classes were 2417, 3184, 3113, and 3124, respectively, the 3-class solution was adopted of which the AIC was the minimum. The first class was interpreted as “Healthy children without any GMIC” because they answered with “No” for all questionnaire items, except that they answered with “1 or 2 ds/w” for “Sleepy” and “Stomach aches.” The results of the answers where they responded with “1 or 2 ds/w” for all items, except for answering with “No” for “Intestinal disorders,” allowed us to interpret the second class as the group with slightly GMIC. The third class answered with “every day” for “Heavy and tired,” “Heavy head,” “Irritated,” “Lack of motivation,” and “Sleepy” and “5 or 6 ds/w” for “Headaches,” and this class was thought to be a typical GMIC. However, this GMIC class responded with “No” or “1 or 2 ds/w” for “Stomach aches” and “Intestinal disorders.” That is, it is thought that typical GMIC in Japanese children is characterized not by disorders of the digestive organs, but by a shortage of active vitality or irritation. Again, the number of students included in each class was 42.2% in the “Healthy children group,” 47.9% in “Slightly-healthy children group,” and 10.35 in the “GMIC group.”

CONCLUSION: The rate of Japanese GMIC was approximately 10%, of which the main characteristics were not disorders of digestive organs, but a shortage of active vitality or irritation.

### EFFECTS OF CONCURRENT EXERCISE TRAINING ON PHYSICAL, PHYSIOLOGICAL AND PSYCHOPATHOLOGICAL PARAMETERS IN ADULTS WITH TREATMENT-RESISTANT DEPRESSION: TRACE-RMD STUDY

ETXANIZ-OSES, J., TOUS-ESPELOSÍN, M., PAVÓN, C., MALDONADO-MARTIN, S.

*UNIVERSITY OF THE BASQUE COUNTRY*

INTRODUCTION: Treatment-resistant depression (TRD) is defined as those who do not remit to major depressive disorder with pharmacological treatment. Concurrent exercise training (i.e. a combination of aerobic and resistance exercise in the same session) could be an efficient no-pharmacological treatment strategy for improving physical (cardiorespiratory fitness and body composition) and mental health (psychopathological variables). This study aimed to determine the effectiveness of a concurrent exercise program on physical, physiological, and psychopathological parameters in adults with TRD.

METHODS: Participants (n=13, 69.2% women, 57.3±13.7 yr old) with TRD undertook a supervised exercise program (concurrent training, 2 days/week). All variables were assessed pre-and post-intervention (12 weeks). A cardiopulmonary exercise test was performed to determine the cardiorespiratory fitness through the peak oxygen uptake (VO2peak). Waist circumference and body mass index determined the body composition. The depression symptoms and severity of the disease were assessed with the Montgomery Depression Rating Scale (MDRS) and Clinical Global Impression (CGI-G), respectively.

RESULTS: Following the intervention, there was not a significant (P>0.05) change decrease in body mass (Δ=-5.7%), body mass index (Δ=-0.7%), and waist circumference (Δ=5.4%). Likewise, cardiorespiratory fitness in, both, V̇O2peak (L·min-1, Δ=11.5%), V̇O2peak (mL·kg.1·min-1, Δ=12.3%), showed no significant (P>0.05) changes. However, in psychopathological variables, participants improved with lower values in both MDRS (Δ=-27.21%, P=0.02) and CGI-G (Δ=-25.32%, P=0.01).

CONCLUSION: The beneficial effects on psychopathological variables in patients with TRD after concurrent exercise should lead to consider exercise as a coadjuvant program in their treatment.

### TREATMENT WITH CONCURRENT EXERCISE IN PATIENTS WITH RESISTANT MAJOR DEPRESSION (TRACE-RMD): PHYSICAL, PHYSIOLOGICAL AND BIOCHEMICAL PRELIMINARY BASELINE OUTCOMES

TOUS-ESPELOSIN, M., ETXANIZ-OSES, J., IRIARTE, N., MALDONADO-MARTIN, S.

*UNIVERSITY OF THE BASQUE COUNTRY*

INTRODUCTION: Functional dysfunctions in people with resistant major depression (RMD) are frequent and severe, and their importance contrasts with the absence of drugs to alleviate these deficits. Associated risk factors are unhealthy lifestyle including sedentarism, social and economic factors, and the side effects of treatments. Exercise programs, which were initially developed as interventions aimed at improving physical health in early stages or mild symptomatology, have shown that they can also improve the symptoms of this disease in more advanced stages. Therefore, the aim of this study was to determine some key physical, physiological and biochemical markers of health status in adults with RMD.

METHODS: The current baseline study comprised a total of 15 participants (67% women, 57.7±13.8 yr old) enrolled in the TReAtment with Concurrent Exercise in patients with Resistant Major Depression study (TRACE-RMD). Body composition included body mass index (BMI), bioimpedance analysis, and waist circumference. Peak oxygen uptake (VO2peak) through the cardiopulmonary exercise test determined the cardiorespiratory fitness (CRF). After an overnight fast a blood sample was collected to determine the biochemical profile.

RESULTS: The studied population showed obesity according to BMI (30.0±4.8 kg·m-2), and taking into account the fat mass percentage (36.1±9.8%) and high metabolic risk considering the waist circumference (99.9±12.5 cm). Poor cardiorespiratory fitness (18.8±8.6 mL·kg-1·min-1) and 26.7% of patients were smokers. Regarding participants' biochemical profile high-density lipoprotein cholesterol (HDL-C) presented optimal values (>40 mg/dL). However, low-density lipoprotein cholesterol (125.93±44.0 mg/dL), cholesterol ratio (total cholesterol, TC/HDL-C=4.1±1.4), and C-reactive protein (5.34±5.9 mg/L) were, instead, upper to optimal values according to the Adult Treatment Panel III. There were normal TC (180.1±58.5 mg/dL), glucose (107.6±50.0 mg/dL) and hepatic enzymes (aspartate transaminase=19.1±4.1 U/L and alanine transaminase=22.92±10.9 U/L) values. According to Wildman Modified criteria, participants were classified as metabolically abnormal obese (i.e., obese and ≥2 cardiometabolic abnormalities).

CONCLUSION: Patients suffering from RMD present an unhealthy profile, with a low CRF, obesity, and high cardiometabolic risk. These results strongly suggest that targeting key behaviors such as improving CRF through exercise will contribute to getting a healthier population.

## A STUDY OF CARDIOVASCULAR RISK PREDICTION METHODS DURING EXERCISE IN PEOPLE AGED 45-55 AND 56-65 YEARS

SU, H.

*BEIJING SPORT UNIVERSITY*

INTRODUCTION: The purpose of this study was to investigate the factors associated with the occurrence of cardiovascular risk during exercise in people aged 45-55 years and 56-65 years, finally to construct a prediction formula for exercise risk in people aged 45-55 years and 56-65 years to provide some theoretical reference for the prevention of cardiovascular risk during exercise in adults of different ages.

METHODS: 206 subjects were divided into 45-55 years old group (group A, N=80) and 56-65 years old group (group B, N=126). The flow of this study was divided into the following 2 phases: basic test phase and exercise test phase. Basic test phase: This phase was conducted in the early morning, and subjects sat quietly for 10-20 min before the test, and physiological and biochemical indexes were measured, and breakfast was consumed uniformly after the basic test. The exercise test phase: Perform a GXT with power bicycle (60rpm, initial load of 25W, increasing 25W every 3 minutes). The changes in the ECG were monitored by a 12-lead ECG tester and the ST-segment depression values were recorded during the exercise. The cardiovascular risk during exercise was determined by the presence of an ECG ST-segment value of ≥0.1 for more than 1 minute. Finally, the indexes with higher correlation between the ECG ST-segment values during exercise in group A and group B were explored by Correlation Analysis, and the prediction formula of cardiovascular risk during exercise in different age groups was constructed by Bayesian discriminant analysis and multiple regression analysis.

RESULTS: 1. The incidence of cardiovascular risk was 55% for 45-55 years and 41.3% for 56-65 years.

2. The ECG ST-segment values during exercise were significantly correlated with CIMT, WHR and SBP in the 45-55 years old group, and prediction equations were constructed as shown below.

Y=-0.174X1-0.15X2-0.002X3+0.278; R=0.640, R2=0.360

Y: the ST-segment hypotension value during exercise, X1: CIMT; X2: WHR; X3: SBP

3. The ECG ST-segment values during exercise were significantly correlated with LDL, PA and PWV values in the 56-65 years old population, and prediction equations were constructed as shown below.

Y=-0.05X1+0.2*10-5 X2-0.54*10-4X3-0.022; R=0.556, R2=0.309

Y: the ST-segment hypotension value during exercise; X1: LDL; X2: PA; X3: the mean left- and right-side PWV values

CONCLUSION: 1. The degree of cardiovascular risk during exercise in people aged 45-55 years can be predicted by a cardiovascular risk prediction formula constructed from indicators responding to the degree of obesity, the degree of atherosclerosis and vascular elasticity.

2. The degree of cardiovascular risk during exercise in people aged 56-65 years can be predicted by a cardiovascular risk prediction formula constructed from indicators responding to the degree of lipid metabolism and vascular sclerosis and physical activity level.

## INTERMITTENT FASTING ON PROMOTING METABOLIC HEALTH: CURRENT STATUS, HOTSPOTS AND FUTURE PROSPECTS

YANBING, Z., XIAN, G.

*BEIJING SPORT UNIVERSITY*

INTRODUCTION: Intermittent fasting (IF), an eating pattern that cycles between periods of eating and fasting, has received considerable interest as strategies to ameliorate chronic diseases and promote metabolic health. It also has many potential long term health benefits. However, the specific mechanisms and strategies of IF for metabolic amelioration are still unclear. Therefore, a systematic review was conducted to focus on its effects on promoting metabolic health, involving global status, research hotspots and its future prospects.

METHODS: Cite Space software was used to visually analyze 703 publications in Web of Science core database from the period 2010-2022. Literature categories, research hotspots, the most prolific research by country and journal were analyzed separately.

RESULTS: Publication outputs increased smoothly year by year with a sharp rise from 142 to 251 in 2020 that reached the highest volume of all time. Approximately 73% of the research came from five countries: United States (36.42%), China (10.38%), Australia (9.82%), United Kingdom (8.96%) and Germany (7.40%). The most popular disciplines were Nutrition, sports science, endocrinology and metabolism, accompanied by multi-discipline intersections, showing a trend of diversification. Nine of the top ten most-published journals were medical that affiliated to United States with a large range of impact factor spans from 3.24 to 47.728. The first controlled feeding trial achieved the highest citation shown that IF contributes benefits independent of weight loss such as improvement of insulin sensitivity and oxidative stress. "Insulin resistance", "circadian clock", "childhood obesity", "time-restricted feeding", "glycogen", "oxidative stress" and "exercise" were demonstrated as major hotspots. "Body composition", one of the most widely used research outcomes, and "gene expression", one of the most common keywords of mechanism study, sustained both high frequency and centrality. Detected by the citation burst, the frequencies of the appearances of keywords "time-restricted feeding", "dysfunction" and "appetite" dramatically surged in the period between 2020 and 2022. TRF has been proved to substantially reduce the desire and capacity to eat at night, therefore help curb food intake and, in turn, facilitate weight loss and metabolic dysfunction.

CONCLUSION: The present study provides a further understanding of the trends in promotion of metabolic health by IF. Based on the aforementioned statement, the future research directions can be concluded as 1) personalized regimens for children, adolescents, women and the elderly; 2) to uncover promising targeted fasting therapeutic approaches for chronic diseases and cancer, and understanding the underlying mechanisms; 3) safety and dose-response relationship of different regimens in personalized populations.

### EFFECTS OF RECREATIONAL ACTIVITIES COMBINED WITH JAPANESE TRADITIONAL GAMES ON COGNITIVE FUNCTION IN ELDERLY PEOPLE

SUGIURA, H.1, ISHIDA, N.1, SAKAMOTO, K.1, MIRBOD, S.M.2

*<1> AICHI GAKUIN UNIVERSITY, <2> GIFU PHARMACEUTICAL UNIVERSITY*

INTRODUCTION: In Japan, the number of elderly people (aged 65 and older) with dementia is increasing. Because dementia is an incurable broad category of brain disease, early detection as well as early intervention regimens are imperative countermeasures. In addition, it would be wise to emphasize on dementia prevention at the age of 60 or less which would be beneficial even for high susceptibility individuals. In this study, we investigated the effects of recreational activities combined with Japanese traditional games (JTG) on cognitive function (focused on memory function) in elderly people.

METHODS: Forty subjects aged 65 to 85 years old were enrolled in the present survey. Twenty-five subjects performed recreational activities combined with JTG (JTG group). The control group consists of 15 individuals not being engaged in either recreational activities nor JTG (Co group). The subjects in the JTG group were asked to participate in 90-minute recreational activities combined with JTG. The intervention was set once every two weeks for one year (total participation=24). Before and after the one-year-long intervention, each group was assessed by cognitive evaluation tests including word memory test divided into short-term memory (STM) and long-term memory (LTM), kanji conversion symbol test (KCS), and animals' names recalling test (ANR).

RESULTS: The results demonstrated that the STM score, LTM score, KCS score, ANR score, and the total scores in the post-intervention of the JTG group was higher than those in their pre-intervention ($P<0.01$- $P< 0.001$), but not in the Co group. The STM score, LTM score and total scores of post-intervention in the JTG group was significantly higher ($P<0.05$ - $P<0.001$) than those in the Co group.

CONCLUSION: These results suggest that the intervention regimen used in this study is an effective method in improving the cognitive function of elderly individuals. Furthermore, we suggest that an intervention program, including recreational activities and JTG, could to some extent prevent cognitive decline in elderly people.

### ENERGY CONSUMPTION OF WALKING AND RUNNING AT DIFFERENT INTENSITIES IN THE ELDERLY

MENG MENG, C., XIAN, G.

*BEIJING SPORT UNIVERSITY*

INTRODUCTION: The improvement of physical activity level can effectively prevent and improve metabolic diseases and promote health in the elderly. However, it is not clear that how much energy is expended by different types of exercise for different populations. In this study, walking and running at low, medium and high exercise intensities were selected and energy consumption was measured to observe the energy consumption and post-exercise recovery.

METHODS: 15 male and female subjects aged 60-70 who met the inclusion criteria were recruited from the surrounding communities of Haidian District, Beijing. The subjects went to the lab to accomplish 3 different speeds of walking and running on a treadmill. During the 4.2km/h, 5.6km/h, 6.4km/h of walking and running, the participants wore a gas metabolism analyzer (Cortex3B-R2) and a Polar watch to measure energy expenditure and heart rate. Each speed lasted for 6 minutes, after each level of exercise the participants rested until the heart rate, oxygen uptake and respiratory quotient recover to the quiet level. Excessive post-exercise oxygen consumption (EPOC) was also tested in the rest period after each level of exercise. The differences between different intensities within groups were tested by one-way ANOVA, and the differences between groups were tested by independent samples T test. $P<0.05$ was considered statistically significant.

RESULTS: The energy consumption of walking and running in males and females were different under different intensities. There were no differences in energy consumption between men and women during exercise at 4.2km/h (4.94±1.44kcal/min VS 4.23±0.20kcal/min, $P>0.05$). There were significant differences in energy consumption between men and women during exercise under the intensity of 5.6km/h and 6.4km/h(5.6km/h:6.08±1.31kcal/min VS 5.10±1.24kcal/min; 6.4km/h:7.45±1.01kcal/min VS 6.09±0.25kcal/min, all $P<0.05$). There were no differences in EPOC between men and women under different intensities ($P>0.05$). The total energy consumption（exercise plus EPOC）of men is higher than that of women under three intensities. There were significant differences in total energy consumption between men and women at 6.4km/h (38.21±6.86kcal VS 32.51±6.80kcal, $P<0.05$), but there were no gender differences in total energy consumption at 4.2km/h and 5.6km/h (4.2km/h:23.49±9.13kcal VS 21.04±5.82kcal; 5.6km/h:30.93±7.63kcal VS 26.46±6.08kcal, all $P>0.05$).

CONCLUSION: For 60 to 70 elderly people, the exercise energy consumption and total energy consumption gradually elevate with the increase intensity of walking and running, but EPOC does not show the same increasement. Elderly male experience more energy expenditure than women both during walking and running.

Supported by National key R & D projects（2018YFC2000601）

### EFFECT OF AEROBIC EXERCISE COMBINED WITH HIGH PROTEIN DIET ON MYOCARDIAL HYPERTROPHY IN RATS

HIROYASU, M.

*KYORIN UNIVERSITY*

INTRODUCTION: It is known that aerobic exercise (AE) induces cardiac hypertrophy accompanied with an increase in left ventricular mass and cavity, and that high protein dietary intake (HPD) partly prevents myocardial weight loss associated with prolonged bed rest. However, the effects of the combination of AE and HPD on the myocardial remodeling are still unclear. The aim of this study was to examine the effect of the combination of AE and HPD on myocardial hypertrophy in rats.

METHODS: Twenty-four 10-week-old male Wistar rats were divided into four groups based on the presence of AE and HPG interventions; AE+HDP, AE only, HDP only, and no interventions. After a total of 8 weeks of exercise protocol, hearts were removed. Next, the samples were embedded in paraffin wax and the blocks were then serially cut into transverse 5-µm-thick sections and stained with hematoxylin and eosin for cardiac morphological analysis. Two-way analysis of variance was used to analyze the effects of AE and HPG, and the interaction between AE and HPG.

RESULTS: Cardiac cross-sectional area showed the main effect of AE ($F(1,23) = 20.76$, $p < 0.01$), the main effect of HPD ($F(1,23) = 8.75$, $p < 0.01$), the interaction effect of AE and HPD ($F(1,23) = 5.32$, $p < 0.05$). Left ventricular cavity area showed the main effect of AE ($F(1,23) = 128.30$, $p < 0.01$), the main effect of HPD ($F(1,23) = 131.38$, $p < 0.01$), and the interaction effect of AE and HPD ($F(1,23) = 37.33$, $p < 0.01$). Left ventricular wall cross-sectional area showed the main effect of AE ($F(1,23) = 13.42$, $p < 0.01$) and the interaction effect between AE and HPD ($F(1,23) = 12.64$, $p < 0.01$), but not the main effect of HPD ($F(1,23) = 0.04$ , $p = 0.85$). Left ventricular myocardial fiber cross-sectional area showed the main effect of AE ($F(1,23) = 137.96$, $p < 0.01$) and the main effect of HPD ($F(1,23) = 14.94$, $p < 0.01$), but not the

interaction effect between AE and HPD (F (1,23) =1.56, p=0.23), which was thus considered to be an additive effect. Left ventricular myocardial fiber short diameter showed the main effect of AE (F (1,23) =54.65, p < 0.01) and the main effect of HPD (F (1,23) =8.44, p < 0.01), but not the interaction effect between AE and HPD (F (1,23) =0.05, p=0.83), which was thus considered to be an additive effect.

CONCLUSION: The present morphological findings revealed that the combination of AE and HPD had the synergic or additive effects on eccentric myocardial hypertrophy with an increase in left ventricular cavity and wall thickness in rats. It is suggested that the combination of exercise and nutritional therapy is effective in promoting the physiological cardiac hypertrophy.

**CAN PHYSICAL FITNESS ATTENUATE THE IMPACT OF HIGHER BODY MASS INDEX AND ADIPOSITY ON INFLAMMATION IN WOMEN WITH SYSTEMIC LUPUS ERYTHEMATOSUS?**

SORIANO-MALDONADO, A., SOLA-RODRÍGUEZ, S., GAVILÁN-CARRERA, B., HERNÁNDEZ-MARTÍNEZ, A., MARTÍNEZ-ROSALES, E., VARGAS-HITOS, J.A.

*UNIVERSITY OF ALMERÍA*

INTRODUCTION: Higher body mass index and adiposity represent independent contributors to the systemic low-grade inflammatory state often observed in patients with systemic lupus erythematosus (SLE). This study assessed the role of physical fitness in the association of body mass index and adiposity with inflammatory markers in women with SLE.

METHODS: A total of 77 women with SLE were included in this cross-sectional study. Body mass index (kg/m2), waist-to-height ratio, and body fat percentage were obtained. Fasting blood samples were obtained and the concentration of relevant inflammatory markers (C-reactive protein, interleukin 6, and leptin) were assessed in serum. Cardiorespiratory fitness was estimated with the 6-minute walk test, range of motion with the back-scratch test, and muscular strength with handgrip dynamometry.

RESULTS: Cardiorespiratory fitness attenuated the association of body mass index and body fat percentage with interleukin 6 (all, P<0.05). Range of motion attenuated the association of body mass index with interleukin 6 (P<0.05) and the association of body fat percentage with C-reactive protein (P<0.05). These interactions indicated that higher fitness was associated with a lower increase in inflammation per unit increase of body mass index or adiposity. Muscular strength showed a non-significant trend to attenuate the association of body fat percentage with interleukin 6 (P=0.057) but potentiated the association of body fat percentage with leptin (P<0.05).

CONCLUSION: These findings suggest that higher levels of cardiorespiratory fitness and range of motion might attenuate the impact of higher body mass index and adiposity on inflammation in women with SLE. The role of muscular strength requires further investigation.

**KNOWLEDGE, ATTITUDES AND PERCEPTIONS OF TYPE 2 DIABETES MELLITUS AND THE ROLE OF EXERCISE INTERVENTIONS.**

SOOKAN, T.

*UNIVERSITY OF KWAZULU NATAL*

INTRODUCTION: Regular exercise has shown to have a positive effect on Type 2 Diabetes Mellitus (T2DM) but is underutilised in developing countries. Self-management of T2DM in South Africa (SA) is sub-optimal, with exercise reported to be the least employed modality of self-management. Health care professionals such as biokineticist can play a vital role in the treatment of T2DM by using exercise as a treatment modality. The aim of this study was to identify the knowledge, attitudes and perceptions (KAP) of T2DM and exercise interventions and to explore participants' awareness and acceptance of the role of biokineticists in the management of T2DM in KwaZulu Natal, South Africa.

METHODS: A quantitative, cross-sectional, purposive study design was used. Participants with T2DM who were receiving treatment from the Wentworth public hospital completed a validated questionnaire. Participants' knowledge was evaluated by true/false questions, and their attitudes and perceptions on a five-point Likert scale. Data was analysed using descriptive and inferential statistics ($p \leq 0.05$).

RESULTS: Reported adherence to prescribed diabetes medication by participants (n = 150) was high, at 96%. However, only 60% of participants reported exercising regularly; 47.3% followed a recommended diet for T2DM; and 32.7% took appropriate care of their feet. Responses given by the participants regarding their knowledge and perceptions indicated good insight into the role of exercise in the management of T2DM (94.7%). There was low awareness of the field of biokinetics, with 74% of participants admitting no knowledge of 'biokinetics'. However, after receiving information on the role of the biokineticist in T2DM, 92% of participants were willing to work with a biokineticist to manage their T2DM.

CONCLUSION: There was low reported adherence to exercise, diet and foot care among participants, despite good knowledge about, and attitudes to, the modalities of T2DM self-management. Majority of participants (92%) expressed a willingness to work with a qualified health care practitioner such as a biokineticist to manage their T2DM.

**EFFECTS OF SNPE ON PHYSICAL FITNESS, ISOMETRIC STRENGTH AND ROM OF THE LOWER EXTREMITY IN ADOLESCENT CHEERLEADING ATHLETES**

KONG, M.H.1, YUN, S.2

*1 UNIVERSITY OF ULSAN, 2 KOOKMIN UNIVERSITY*

INTRODUCTION: SNPE (Self Natural Posture Exercise) is an exercise mode that helps restore musculoskeletal function and relieve pain by using exercise tools and belts. The purpose of this study is to analyze the effect of SNPE training on physical strength, lower extremity muscle strength, and ROM in sports cheerleading athletes.

METHODS: A total of 22 participated; Exercise Group (EG: n=11, 15.9±2.0 yrs, 159.2±7.1 cm, 54.6±16.2 kg), and Non-Exercise Group (NEG: n=11, 15.9±2.5 yrs, 158.2±8.1 cm, 53.5±9.2 kg). EG underwent SNPE program consisting belt and tool exercises 60 min per session, 5 times a week, for 6 weeks. The exercise intensity was raised every 2 weeks by repetition and sets. Physical fitness (grip strength, back muscle strength, standing long jump, backward flexibility and sitting flexibility), isometric strength (knee- extension, and flexion, ankle- plantar and dorsi flexion, foot-inversion and eversion) and ROM (hip- external and internal rotation, ankle- plantar and dorsi flexion) of the lower were measured before and after SNPE training. Data analysis was performed using ANCOVA.

RESULTS: As the results of physical fitness, grip strength was increased in EG than NEG (23.8±0.6 vs 21.8±0.6 kg, p<0.05). The right (15.6±0.8 vs 11.8±0.8 N, p<0.01) and left (15.4±4.2 vs 11.5±3.2 N, p<0.05) knee flexion, right (23.0±1.0 vs 8.6±1.0 N) and left (22.2±1.3 vs 8.5±1.3 N) knee extensionp (p<0.001), right (11.1±0.7 vs 7.9±0.7 N, p<0.05) and left (10.7±0.7 vs 6.9±0.7 N, p<0.01) plantar flexion, right (11.7±0.7, vs 5.9±0.7 N, p<0.001) and left (11.3±1.1, vs 6.2±1.1 N, p<0.01) dorsi flexion, right (7.6±0.3, vs 4.8±0.3 N) and left (6.8±0.4, vs

3.8±0.4 N) inversion (p<0.001), and right (6.4±0.3, vs 4.2±0.3 N) and left (6.9±0.3 vs 3.8±0.3 N) eversion (p<0.001) in isometric strength of the lower extremity increased in EG than NEG. The right (29.4±2.1 vs 21.3±2.1 degree, p<0.05) and left (27.0±1.6 vs 20.2±1.6 degree, p<0.01) external rotation of hip joint, left internal rotation of hip joint (24.5±1.9 vs 17.7±1.9 degree, p<0.05), right (80.9±1.7 vs 70.0±1.7 degree, p<0.001) and left (78.8±1.3 vs 72.5±1.3 degree, p<0.01) plantar flexion, and right (11.6±0.8 vs 4.7±0.8 degree) and left (9.3±0.8, vs 3.6±0.8 degree) dorsi flexion (p<0.001) in ROM of the lower extremity increased in EG than NEG.

CONCLUSION: SNPE had a positive effect on lower extremity muscle strength and ROM. Program development will be required through continuous research.

### INTRADIALYTIC COGNITIVE AND AEROBIC EXERCISE TRAINING IN HEMODIALYSIS PATIENTS: STUDY PROTOCOL

BOGATAJ, S.

*UNIVERSITY MEDICAL CENTRE LJUBLJANA*

INTRODUCTION: Hemodialysis (HD) patients have lower cognitive functioning and reduced physical fitness compared to age-matched healthy individuals. These patients are less physically active and activate their mental functions to a lesser extent than the general population. Clinicians typically do not recognize the declining cognitive performance in these patients; therefore, cognitive impairment is greatly underestimated and not appropriately treated. Cognitive decline is widespread and progresses at a faster and greater rate than in the general population, so preventive and therapeutic interventions are urgently needed.

The primary aim of this research project is to investigate the effect of cognitive training combined with physical exercise on cognitive function, physical performance and frailty indicators in the HD population. Secondly, the project will test the feasibility of using the innovative cognitive platform to apply cognitive training to HD patients.

METHODS: We will conduct a randomized controlled intervention trial to examine the effects of a combined non-pharmacological intervention in the form of intradialytic physical exercise and intradialytic cognitive training on cognitive function, indicators of frailty, and physical performance measures in HD patients. The group of patients receiving the study intervention will be compared to the control group receiving standard HD care. The duration of the intervention will be 12 weeks. We will use sensitive instruments (cognitive domain tests) to assess cognitive functions. The primary outcome of the study at 12 weeks will be performance on the Alertness subtest of the computerized Test of Attentional Performance, which measures one domain of cognitive function, alertness. Secondary study outcomes are: Performance in other domains of cognitive function (executive function, psychomotor speed, information processing efficiency, working memory, attention), physical fitness (10 repetition sit-to-stand test, timed up and go test, handgrip strength test, spontaneous gait speed, Stork balance test), and assessment of frailty (Edmonton Frail Scale). Study outcomes will be assessed at baseline, immediately after the 12-week intervention, and six months after the end of the study without specific further intervention (retention effect assessment).

RESULTS: We hypothesize that the experimental group will achieve significant and clinically meaningful improvements in their cognitive and physical functions and reduce their frailty score compared to the control group.

CONCLUSION: Prevention and treatment of cognitive decline and dementia are one of the most important public health goals. If our hypothesis is confirmed, we would be able to offer an innovative, non-pharmacological, bimodal intervention that is cost-effective, safe, and easy to implement during the intradialytic period, with potential impact on patients important unmet needs and quality of life.

### EXPLORING THE FEASIBILITY AND USER EXPERIENCE OF AN AUGMENTED REALITY APP PRESCRIBING EXERCISE FOR CHILDREN AND YOUNG PEOPLE WITH CANCER

MARRIOTT, H., STRAUN, K., WINDSOR, S., WRIGHT, P., NEU, M., DREISMICKENBECKER, E., FABER, J.

*OXFORD BROOKES UNIVERSITY*

INTRODUCTION: This study is still ongoing and the following abstract has been composed to reflect the study protocol. Findings will be presented at the time of the conference. An updated abstract will be provided by the 29th of July 2022.

Children and young people with cancer face particular barriers when engaging with exercise, such as cancer and treatment-related side effects, psychosocial treatment burdens and lack of individualised provisions. In recent years, Coronavirus has further exacerbated these difficulties. Therefore, it is vital to explore new technologies as a way to enable remote, individualised exercise rehabilitation for young cancer patients. As part of the Europe-wide FORTEe trial, 16 institutions are exploring the use of exercise for enhancing physical and mental health among young cancer patients. The wider study includes a focus on using technology to support this effort. The present study aims to provide crucial evidence on feasibility and user experience of a novel exercise-focused smartphone augmented reality (AR) app to inform future technology development within paediatric oncology populations.

METHODS: Practical workshops and focus groups with n=65 children and young people aged 9-21 years will be conducted. The 30-minute workshop will encourage participants to engage with the smartphone app and complete a digitally prescribed low-moderate intensity exercise session consisting of bodyweight strength exercises. The subsequent focus group discussions will explore participant experiences, preferences, suggestions for improvement and impressions of potential long-term use.

RESULTS: The user-led and evidence-based development of the AR app is expected to allow participants to engage in meaningful exercise provisions and supportive encouragement via this novel technology. Due to the innovative nature of the AR app, study findings are expected to provide vital indications for further improvement.

CONCLUSION: The findings of this study will contribute to the future development of this technology to support exercise rehabilitation for young people with cancer. Evidence from this research plays an important role in enhancing clinical care pathways for patients, whilst allowing clinicians to explore novel interventions to support current practice.

### THE EFFECT OF UNIVERSITY FITNESS CLASS ON THE EXERCISE BEHAVIOUR: A PRE-POST STUDY

MUTO, R., YANAOKA, T., KUROSAKA, S.

*HIROSHIMA UNIVERSITY*

INTRODUCTION: Although accumulating physical activity is one of the important factors for health [1], Japanese university students have fewer physical activities in leisure hours compared with other countries [2]. One of the main reasons for few physical activities was a lack of equipment, facilities and knowledge [3]. The fitness class would be the opportunity to get knowledge in exercise and to begin exercise in Japanese university students. Therefore, the present study aimed to investigate the effect of university fitness classes on students' exercise behaviour.

METHODS: Eighteen university students (age, 19±1 years) have participated in the present pre-post study. Participants completed university fitness classes about once a week for five weeks. The fitness class consisted of 30-min lecture (e.g., diet and exercise) and 60-min fitness exercise (e.g., aerobic exercise, resistance training). Participants answered the Diagnostic Inventory of Health and Life Habit version 2 (DIHAL.2) [4] before the first class (pre) and after the final class (post). The DIHAL.2 can assess the physical, mental and social component summaries (PCS, MCS and SCS), exercise behaviour, exercise awareness, nutritional balance, regularity of eating, preference, rest, the regularity of sleep, sleep satisfaction and stress evasion.

RESULTS: The PCS ($t(18)=-3.019$, $p=0.008$), exercise behaviour ($t(18)=-6.262$, $p=0.000$), rest ($t(18)=-4.862$, $p=0.000$) and stress evasion ($t(18)=-2.310$, $p=0.034$) at the post were significantly improved compared with those at the pre. No significant differences were observed for the MCS, SCS, exercise awareness, nutritional balance, preference, regularity of eating, the regularity of sleep and sleep satisfaction.

CONCLUSION: The present study revealed that the university fitness class improved university students' exercise behaviour, which is consistent with some previous studies [5,6]. This may be due to 1) participants getting knowledge that there is fitness training needed no special equipment and facilities and 2) an increase in readiness for exercise. Indeed, the previous study has suggested that the fitness class in university positively affects students' transtheoretical model [7]. Moreover, the PCS and rest at the post were higher than those at the pre. These may result from the increase in university students' physical activities. Therefore, the university fitness class was a chance to improve the university students' exercise behaviour.

**EFFECT OF HABITUAL PHYSICAL ACTIVITY ON PHYSICAL FITNESS AGING AMONG COMMUNITY-LIVING MIDDLE-AGED AND OLDER JAPANESE: A 12-YEAR FOLLOW-UP STUDY**

KOZAKAI, R.1,2, NISHITA, Y.2, OTSUKA, R.2, ANDO, F.2, SHIMOKATA, H.2

*1 HOKUSHO UNIVERSITY; 2 NATIONAL CENTER FOR GERIATRICS AND GERONTOLOGY*

INTRODUCTION: Age-related decline in physical fitness is unavoidable even though physical fitness is the one of the most important factors in healthy aging. Physical activity has been considered to preserve physical fitness level. However, it is still unclear whether daily physical activity inhibits age-related decline in physical fitness across middle and late adulthood. The purpose of the present study was to estimate the effect of habitual physical activity (HPA) on physical fitness ageing in men and women through a 12-year longitudinal epidemiological study.

METHODS: Participants were randomly selected community-living men (n = 1,139) and women (n = 1,128) aged 40 to 79 years at baseline, who participated in the National Institute for Longevity Sciences- Longitudinal Study of Aging. They were repeatedly tested over a mean follow-up period of 9.8 years with a mean of 4.9 examinations. Grip strength, sit-and-reach and one-leg standing with eyes closed were examined for physical fitness. HPA at baseline was assessed by multiplying activity intensity rate (metabolic equivalents; Mets) with the total number of time (mins) spent on each activity during leisure time, at work and sleeping per day over the preceding year (Iwai et al., 2000). HPA was categorized in tertiles; highest, middle and lowest. The general linear mixed model was performed for analyses of repeated measures of physical fitness. The models were comprised of fixed effects of HPA (lowest=reference), baseline age, follow-up years, their interactions and covariates (height and weight). Significant probability levels were considered to be less than 0.05.

RESULTS: The main effect of HPA was significantly positive for grip strength in both men ($F=3.21$, $p=0.041$) and women ($F=3.20$, $p=0.041$), and for sit-and-reach only in men ($F=3.33$, $p=0.036$). The main effect of HPA for one-leg standing was also significant in men ($F=6.84$, $p=0.001$), but the effect was negative. The interaction terms, HPA×age×follow-up years were significant for grip strength in men ($F=3.48$, $p=0.031$) and sit-and-reach in women ($F=3.87$, $p=0.021$). Predicted trajectory substituting baseline age and HPA level indicated that the slopes in highest HPA were markedly less steep after 68 years of age for grip strength in men, and 59 years of age for sit-and-reach in women comparing to those in lowest HPA.

CONCLUSION: Twelve-year longitudinal data showed that habitual physical activity might affect the age-related decline in physical fitness over time, especially muscle strength in older men and flexibility in older women.

4. Dep. of Pediatrics, "Vittore Buzzi" Children's Hospital. 5. Ped. and Adolescent Unit, Dep. of Int. Med. and Therapeutics, Uni. of Pavia.INTRODUCTION: COVID-19 pandemic caused a negative change in daily habits, a decrease in physical activity and energy expenditure in
the worldwide population and especially in children. The regular practice of exercise promoted several benefits on fitness performance counteracting the adverse effects of obesity. During COVID-19 restrictions, online training showed the potential to reach a large number of subjects who live in different places counteracting sedentary behavior.
The aim of this study was to determine the functional results of an online supervised combined training adapted to children with obesity. The variation of physical fitness and self-perception was evaluated.

METHODS: 30 children (10 females) with obesity (11.50+1.83 years old) were enrolled in an online exercise training program, implemented three times a week for a 12-week period. The program consisted of a combination of aerobic and free body resistance exercises proposed by a trainer with a recreative approach including circuit games and fabulation. Each training session was developed through the ZOOM platform and lasted around 60 min. Six-minute walking test (6MWT), 5x10 meters run test and standing broad jumps (SBJ) evaluated respectively cardiorespiratory health, speed-agility and muscular strength. Perceived effort during training has been evaluated through the Children's Effort Rating Table (CERT).

RESULTS: Children, after the training period, increased their performance of the 6MWT (mean difference (MD) 53.6 meters; Effect size (d) = 1.064; p-value<.001), of the SBJ (MD=10 meters; d=.865; p-value<.001) and of the 5x10 meters run test (MD= -0.92 seconds; d=0.483; p-value=0.013). Perceived effort did not change before and after the training period (p-

value>.05) in 6MWT (MD=.033; d=.010) and in 5x10 meters run test (MD= .367; d=.155).

CONCLUSION: The online training program improved children with obesity performance keeping the perceived effort of the tests constant. Given the importance of improved physical fitness in children with obesity, further studies should focus on the assessment of the efficacy of an online training program evaluating other outcomes related to obesity.

INTRODUCTION: Breast cancer (BC) is the most common cancer in women worldwide responsible for 685.00 deaths in 2020, with approximately 10% developing metastases within 5 years of early diagnosis (1). Recently, epidemiological studies reported the benefits of a regular training program, mostly aerobic, in cancer prevention; the effects of adapted football training in BC survivors were also evidenced (2,3). The aim of this pilot was to investigate the effects of football training on BC cell migration in in-vitro system.

METHODS: 5 older (> 65 years) long-term football men trained for at least 15 years (VPG) and 5 active untrained subjects (CG) matched for age were recruited from P. Krustrup' s group; blood samples at rest (VPG and CG) and immediately after a football match (VPG) were collected. Human breast adenocarcinoma cells, MCF-7, were cultured to confluence in a medium (EMEM) containing 15% FBS. Cells were starved in 0.5% FBS for 24h, scratched to perform a wound healing assay, and cultured in 5% sera from VPG or CG or FBS (as control) for 72h, respectively; the wound closure percentage was calculated at 72h vs T0 in each group. Data are expressed as mean±SD from three independent experiments. Differences were considered statistically significant at $p < 0.05$. T-test was used for statistical analysis.

RESULTS: Long-term football training significantly reduced the migration of MCF-7 cells in wound healing assays (VPG vs FBS at 72h, $p<0.005$); a significant reduction in the wound closure percentage was also found in VPG compared to CG ($p<0.05$) cultured cells.

CONCLUSION: Our pilot study indicate that long-term football training reduces the migration of BC cells. Ongoing experiments will evaluate the effect of long-term football training on MCF-7 cell invasion and metastases.

## IMPROVING RESISTANCE TRAINING PRESCRIPTION THROUGH THE LOAD-VELOCITY RELATIONSHIP IN FEMALE BREAST CANCER SURVIVORS: THE CASE OF THE BENCH PRESS EXERCISE

DÍEZ-FERNÁNDEZ, D.M.1,2, BAENA-RAYA, A.1,2, ESTEBAN-SIMÓN, A.1,2, RODRÍGUEZ-ROSELL, D.3,4, SORIANO-MALDONADO, A.1,2, RODRÍGUEZ-PÉREZ, M.A.1,2

*UNIVERSITY OF ALMERÍA, ALMERÍA, SPAIN*

INTRODUCTION: Breast cancer is the cancer type with the highest incidence in women worldwide, with almost 2.1 million new patients diagnosed every year [1]. Muscular strength during treatment has been reported to be 12% to 16% lower in upper extremities compared to healthy individuals [2]. Resistance training is an effective method to increase muscular strength levels in breast cancer survivors [3]. Movement velocity allows to accurately quantify relative load to prescribe an effective resistance training program [4]. Due to a close relationship has been found between movement velocity and the relative load (%1RM) during a lower body exercise (bilateral leg-press) in breast cancer survivors [5], the aims of this study were to analyze the load-velocity relationship in an upper body exercise (bench press) in female breast cancer survivors and to examine what type of adjustment and velocity variable allows to predict with greater precision the velocities associated with each %1RM.

METHODS: Twenty-four breast cancer survivor's women (age: 50.2 ± 10.8 years, weight: 69.6 ± 15.2 kg, height: 160.51 ± 5.25 cm), as part of the EFICAN project [6], performed an incremental load test until 1RM in the bench press exercise. The mean propulsive velocity (MPV) and the peak velocity (PV), measured using a linear velocity transducer (T-Force System), were analyzed by lineal (LA) and polynomic (PA) regression models.

RESULTS: A very close relationship between MPV and relative load (%1RM) was observed ($R^2 = 0.954$; $p < 0.0001$; SEE = 0.068 m.s-1 by LA and $R^2 = 0.957$; $p < 0.0001$; SEE = 0.067 m.s-1 by PA). Similarly, a high correlation between %1RM and PV was observed ($R^2 = 0.908$; $p < 0.0001$; SEE = 0.141 m.s-1 by LA and $R^2 = 0.928$; $p < 0.0001$; SEE = 0.124 m.s-1 by PA). The MPV of 1RM was 0.15 ± 0.04 m·s-1, whereas the PV at 1RM was 0.38 ± 0.13 m.s-1

CONCLUSION: LA and PA allow to predict the velocities associated with each %1RM and the estimated 1RM with a great precision in bench press exercise in female breast cancer survivors. However, PA showed better accuracy. MPV was considered the most recommended velocity variable to prescribe the relative load during resistance training.

## INVESTIGATE OF POSSIBILITY TO PROMOTE RECOVERY OF MUSCLE HARDNESS AND DELATED ONSET MUSCLE SORENESS (DOMS) BY USING HIGH-CONCENTRATION ARTIFICIAL CO2-HOT SPRING WATER

YAMAMOTO, N.1, KASHIWAGI, Y.2, HIRANO, T.5, TAKENOYA, F.3, SHINTAKU, Y.4, WADA, T.5
*1 JAPANESE RED CROSS HOKKAIDO COLLEGE OF NURSING, 2 SENSYU UNIV., 3 HOSHI UNIV., 4 WAKAYAMA REHABILITATION PROFESSIONAL UNIV., 5 KOKUSHIKAN UNIV.*

INTRODUCTION: In our previous study, experiments in human subjects indicated that flexibility of the body was facilitated by bathing in artificial CO2–hot spring water [1]. Furthermore, near-infrared spectroscopy (NIRS) applied to the human subjects revealed that repeated immersion of the forearm into CO2-water augmented the local muscle O2 consumption and blood flow. These results suggest that a CO2-water bath may promote recovery from muscle fatigue. To inspect this hypothesis, we investigated whether the immersion of extremities including agonist muscles into artificially made CO2-water (CO2 ≥1000 ppm) influences recovery of muscle hardness and soreness in fatigue after resistance exercise.

METHODS: The healthy male college students (n=12) participated in this study (Age 19-26 yrs, height; 173.5±5.0 cm, weight; 64.9±6.9 kg). The subjects performed 100 times calf raise resistance exercises and immersed lower legs into tap-water or artificial CO2-water at 35 °C for 10 minutes after exercise. On exercise day, the hardness of the medial head of gastrocnemius dominant muscle was evaluated 3 times with indentation method, at 5 minutes before, immediately after and 10 minutes after the exercise. Simultaneously, muscle fatigue was assessed using a visual analogue scale (VAS). Perceived pain or soreness was determined using the Talag Scale [2]: (0) No Pain, (1) Dull Vague Ache, (2) Slight Persistent Pain, (3) More than Slight Pain, (4) Painful, (5) Very Painful, and (6) Unbearably Painful. Resistance exercise was performed only on the first day. Lower legs water immersions (tap-water or CO2-water) were performed every 24h for 5 consecutive days after the resistance exercise. Following the exercise day, muscle hardness and soreness were measured before and after lower legs water immersion once a day. Statistical evaluation of the data was done by repeated measures two-way ANOVA using Tukey test for post hoc multiple comparisons, where appropriate. Significance level was set at $p < 0.05$.

RESULTS: Muscle hardness peaked on the third day after the exercise. Muscle hardness on the third day was significantly smaller in CO2-water treatment group than in tap-water treatment group (tap vs. CO2 : 19.0±1.0 vs. 16.2±2.2 tone, $p<0.05$), and the difference between two groups disappeared after the peak day. Muscle soreness of the CO2-water treatment group was significantly smaller than that of the tap-water treatment group, which lasted only for 2 days after exercise, in comparison with 5 days in tap-water group.

CONCLUSION: These results imply that immersion into high concentration CO2-water after the exercise may contribute to rapid recovery from muscle fatigue. In this study, high concentration artificial CO2-hot spring bathing can contribute to the recovery from intense training in athletes, and there is a possibility of improving performance.

## ASSOCIATION BETWEEN STAGES OF CHANGE MODEL FOR PARTICIPATION IN PHYSICAL ACTIVITY, NEIGHBORHOOD WALKABLE ENVIRONMENTS, AND FRAILTY IN OLDER ADULTS

SON, H.1, THAPA, N.2, YANG, J.2, PARK, H.2, JANG, M.3, LEE, J.2, PARK, J.3, KIM, C.4, BAE, S.2, PARK, H.2
*1, 2.DONG-A UNIVERSITY, 3.PUSAN NATIONAL UNIVERSITY HOSPITAL, 4.DONGDUK WOMENS UNIVERSITY*

INTRODUCTION: Perceived and objectively-assessed aspects of the neighborhood physical environment have been postulated to be key contributors to regular engagement in active habitual physical activity in older adults. However, the association the neighborhood walkability and the participation in physical activity in frail older adults remains unclear. This study examined the associations between the stages of change model for participation in physical activity, frailty and neighborhood walkable environments in older adults.

METHODS: Participants were 126 older adults. Walkability was measured objectively using GIS. We also assessed participants' perceptions of neighborhood, street connectivity, safety (traffic, crime), etc. using a modified version of the Neighborhood Environment Walkability Scale—abbreviated (NEWS-A). Scale scores range from 1 to 4 (strongly disagree, somewhat disagree, somewhat agree, strongly agree). The readiness for physical activity stages of change scale was used to examine readiness to become and stay physically active with five stages: (1) precontemplation, (2) contemplation, (3) preparation, (4) action, and (5) maintenance. Frailty was assessed by an adapted version of the Fried Frailty Phenotype. Using logistic regression, we calculated the odds and 95 CI between physically active odds of any (compared with none) perceived and objectively-assessed neighborhood walkability, respectively.

RESULTS: The data were significantly described by linear regression models which showed that the perceived and objectively-measured environmental factor (access to recreational facilities, connectivity of streets, land use mix, traffic safety, presence of bicycle lane) associate with increasing participants of daily physical activity, theses tendency, however, was found to be higher in the elderly subjects with frailty. Multivariate-adjusted logistic regression analyses predicted that healthy and frail older adults who lived in poorer access to recreational facilities, street connectivity and traffic safety area were, respectively, 1.7-2.0, 1.7–2.2 and 2.2–3.5 times more likely to sustain physically active than those who live better environmental walkability.

CONCLUSION: The factors of the built environment appear to influence duration and frequency of the physical activity in general. In particular, access to recreational facilities, street connectivity and traffic safety was positively influenced physical activity participation in frail older. Therefore a better walkable neighbourhood appears to be a worthwhile investment as it encourages older adults who have frailty living on low walkability and/or income to walk for transportation and safe, and it seems crucial to identify aspects of the built environment that promote active behaviours, like physical activity, across a broad spectrum of older adults as a means to guide these decision makers.

### A POSSIBILITY TO IMPROVE THE PHYSICAL FATIGUE AFTER ARTIFICIAL HIGH CONCENTRATION CO2 HOT WATER IMMERSION IN ATHLETES

WADA, T.1, HYODO, H.1, HIRANO, T.1, KASHIWAGI, Y.2, SHINTAKU, Y.3, YAMAMOTO, N.4

*1 KOKUSHIKAN UNIVERSITY, 2 SENSHU UNIVERSITY, 3 WAKAYAMA PROFESSIONAL UNIVERSITY OF REHABILITATION, 4 JAPANESE RED CROSS HOKKAIDO COLLEGE OF NURSING*

INTRODUCTION: The bathing and sleep processes in physical recovery play an important role in athletes. One of the body recovery is the night sleep. The hot spring water containing high concentration carbon dioxide (CO2 ≥1000 ppm) has long been applied to the patients suffering from cardiovascular diseases in balneotherapy. The purpose of this study is to examine the physical recovery after artificial high concentration CO2-water immersion in athletes.

METHODS: Six healthy college competitive swimmers participated in this study. The subjects performed anaerobic exercise and immersed whole body into tap-water or artificial CO2-water at 38 degrees Celsius for 10 minutes immediately after the exercise. To measure the sleep-wake cycle, accelerometers (FS-760 and 770, ACOS, Japan) was used. The sleep-wake data were analyzed by circadian rhythm analysis software (SleepSign Act2, KISSEI COMTEC, Japan). Sleep variables included time in bed (TIB), sleep period time (SPT), total sleep time (TST), sleep efficiency (SE), and sleep latency (SL). Blood lactate concentration (BLa) was measured by means of Lactate analyzer (Lactate Pro2, LT-1730, Arkray, Japan).

RESULTS: BLa in recovery period was significantly lower in CO2-water immersion than that in tap-water immersion (20min after the exercise 2.4±0.8 vs 2.7±0.5 mmol/L $p<0.05$, 25min after the exercise 1.9±0.6 vs 2.6±0.8 mmol/L $p<0.05$, 30min after the exercise 1.8±0.4 vs 2.4±0.4 mmol/L $p<0.05$,). SL was significantly shorter in CO2-water immersion than that in tap-water immersion (7.8±2.3 min vs 16.5±3.8 min $p<0.05$). SE was significantly higher in CO2-water immersion than that in tap-water immersion (90.3±3.5% vs 83.2±4.6%, $p<0.05$). Therefore, these results suggest that as CO2-water immersion could raise body core temperature enough, this hyperthermia may cause a deep sleep.

CONCLUSION: Sleep after the CO2-water immersion seems to be significantly useful in the physical recovery from fatigue. The rapid decrease in BLa in the CO2-water immersion suggested efficient physical recovery after anaerobic exercise. Therefore, it was suggested that CO2-water immersion is effective for recovery.

### BLOOD PRESSURE RESPONSE TO ISOMETRIC EXERCISE WITH DIFFERENT INTENSITIES

VARJAN, M.1, GARCÍA-MATEO, P.2, SKALA, F.1, HAMAR, D.1

*1: FACULTY OF PHYSICAL EDUCATION AND SPORT, COMENIUS UNIVERSITY; BRATISLAVA, SLOVAKIA, 2: FACULTY OF EDUCATIONAL SCIENCES, UNIVERSITY OF ALMERÍA; ALMERÍA, SPAIN*

INTRODUCTION: Resistance exercise (RE) generates a prompt response of the human cardiovascular system. Because of its well-documented long-term benefits, RE has become recommended physical activity. As the cardiovascular system reacts to this type of exercise by immediate changes in blood pressure (BP), general population is usually restricted to lower intensities of 10 to 12 RM for given modalities. Despite of extensive research there are still debates whether blood pressure response depends more on absolute resistance or its value expressed in percent of maximum. Therefore, this study tried to elucidate BP response to isometric exercise is more closely correlated with absolute or relative load intensities.

METHODS: Twenty-five young healthy participants (age: 23.96 ± 2.95y; 11 males, 14 females) performed test of maximal isometric strength on a universal linear leg press (FiTRONiC Diagnostic and Training Systems LTD, Bratislava, Slovakia) at 90-degree. On a different day, they had to resist for 15 seconds to randomly assigned load of 20, 40, 60, 80 % of the maximum test value. Over each period, BP values were measured with a manual sphygmomanometer.

RESULTS: There was a significant difference in BP values between 20 % and 80 % of additional load for systolic BP (SBP) (131.8±10.1 mmHg vs. 166.7±12.7 mmHg; $t=2.011$, $p<0.001$), and for diastolic BP (DBP) (82.04±7.68 mmHg vs. 112.56±12.30 mmHg; $t=2.011$, $p<0.001$). Values of medial arterial pressure (MAP) and additional load correlations were nearly identical in absolute and relative expressions ($R=0.85$; $p<0.001$ vs. $R=0.85$; $p<0.001$, respectively). Similar trend was observed in SBP ($R=0.84$; $p<0.001$ vs. $R=0.84$; $p<0.001$) and for DBP ($R=0.83$; $p<0.001$ vs. $R=0.84$; $p<0.001$).

CONCLUSION: As expected there were strong correlations between BP (SBP, DBP, and MAP) and load intensity expressed. However, both correlations did not differ significantly.

### DEFINITION AND CONTEXT FACTORS OF NURSING HOME RESIDENTS' MOBILITY IN A HOLISTIC VIEW: A DELPHI STUDY

VOGEL, O., OTTO, A.K., WOLLESEN, B.

*HAMBURG UNIVERSITY*

INTRODUCTION: The importance of promoting mobility in nursing homes is underlined by a growing number of nursing home residents with a decreasing life space mobility. To include hitherto neglected confounding factors of mobility and create a holistic understanding, there is a need for expanding the definition of mobility. Research as well as care practices need to be based on a uniform understanding regarding the definition, context factors and valid assessments of mobility. The present study reports expert ratings from a Delphi study regarding these aspects of mobility.

METHODS: A total of 129 experts of different professional backgrounds (e.g., human movement sciences, medicine, nursing and geriatric science) were invited to a Delphi study via e-mail. Up to N=39 experts participated in each of the three rounds of online questionnaires. In the first round, open-ended questions collected possible definitions, context factors, and assessment tools, which were rated on Likert-scales (1-10) regarding their suitability in the second round. The last round presented a consensual definition as well as top rated context factors and assessment tools from the first two rounds for a final rating of agreement.

RESULTS: Experts agreed to the final version of the mobility definition with 8.9 ± 1.4 out of 10 points. The selected context factors for different categories (health status, cognition and emotion, social and leisure, environmental and residence-internal factors) met broad agreement with 8.4 ± 1.8 points to 8.9 ± 12 points (out of 10 points). The same applies to the top three assessment tools selected from previous rounds' results, which were agreed to with 7 or more points (out of 10) by 81.6 % to 100 % of all experts in the different categories.

CONCLUSION: The conducted Delphi survey confirms the above-stated need for an updated holistic understanding of mobility. As an interdisciplinary group of experts considers various context factors as relevant, this implies the necessity of a more comprehensive

definition regarding mobility. Hence, the present results might serve as a general basis for an updated interdisciplinary and holistic understanding of mobility.

**EXERCISE-MITIGATED, GENDER-BASED DIFFERENCES IN AGING RAT HEART**

BÖRZSEI, D.1, SZABÓ, R.1, PÁLSZABÓ, A.1, PRIKSZ, D.2, VARGA, CS.1,3, PÓSA, A.1

*1:UNIVERSITY OF SZEGED, 2:UNIVERSITY OF DEBRECEN 3: HR-PHARMA LTD.*

INTRODUCTION: Aging involves unfavorable progressive cardiovascular processes, therefore striving to maintain a physiological heart function is pivotal in old ages. The aim of our current study was to explore the voluntary exercise-evoked cardioprotective effects in aged male and female rats, from protein expression alterations to changes in heart performance.

METHODS: To determine the effects of a long-term voluntary exercise, we divided 20-month-old female and male Wistar rats to control and running groups. Control rats were placed into standard cages, whereas running animals were provided with a running wheel–equipped cage. This protocol was defined as a voluntary exercise model; animals were not forced to exercise but had free access to the wheel 24 h a day. After the 12-week-long experimental period, hearts were either removed for biochemical measurements or mounted into a Langendorff-perfusion system to detect infarct size. Using ELISA method, the following proteins were analyzed from heart: catechol-O-methyltransferase (Comt), endothelin-1 (Esm1), Purkinje cell protein-4 (Pcp4), and osteoglycin (Ogn).

RESULTS: Cardiac expression of Comt and Ogn was reduced as a result of exercise in aged males, whereas Pcp4 and Esm1 showed a marked overexpression. The key result of this study is that exercise enhanced the expression of the Pcp4 protein, a recently described regulator of calcium balance in cardiomyocytes, and suppressed Comt and Ogn protein expression, which has been associated with impaired cardiac function. In addition, as a result of exercise, a significant improvement was observed in the size of infarct elicited by left anterior descending coronary artery occlusion.

CONCLUSION: Our results clearly show that voluntary exercise has proved to be an effective therapeutic tool to improve cardiac function in aged rats with clearly visible sex differences. Exercise-moderated fundamental genetic alterations may have contributed to the functional adaptation of the heart.

**EFFECTS OF A SINGLE SESSION OF BRAIN YOGA ON BRAIN-DERIVED NEUROTROPHIC FACTOR AND COGNITIVE SHORT-TERM MEMORY**

KIM, H.

*KYUNGNAM UNIVERSITY*

INTRODUCTION: This study aimed to evaluate the effects of a cognitive enhancement brain yoga program on short-term memory and serum brain-derived neurotrophic factor (BDNF) levels according to the cognitive state in men aged 20–29 years.

METHODS: Thirty healthy volunteers aged 20–29 years were divided into four groups: brain yoga group, yoga group, combined exercise group, and control group. Seven people were assigned randomly per group. A single-session intervention was conducted over 50 min and consisted of three parts: warm-up, main exercise (brain yoga, yoga, combined exercise, or non-exercise), and cool-down. Serum BDNF levels were measured using enzyme-linked immunosorbent assay, and short-term memory was evaluated using the forward number span test before and after the intervention.

RESULTS: BDNF levels significantly increased within the brain yoga group after the intervention (from 28874.37±5185.57 to 34074.80±7321.12, p=.003), whereas there were no significant differences pre and post-intervention in the other groups. The inter-group comparison showed a significant interaction between the brain yoga group and the combined exercise group (p=.036) but no significant interaction between any of the other groups. Forward number span scores were significantly increased in the brain yoga group (from 9.43±9.83 to 23±7.92, p=.012) and the yoga group after the intervention (from 13.43±9.41 to 24.14±8.45, p=.011), whereas there were no significant changes after the intervention in any other groups.

CONCLUSION: Our findings showed that a single-session, 50-minute brain yoga exercise improved short-term memory and increased serum BDNF levels in healthy men aged 20–29 years and that yoga improved only short-term memory in healthy men of this age group.

**CARDIAC FUNCTION AND HEART RATE VARIABILITY DURING A MULTI-STAGE CYCLING EVENT: A CASE STUDY**

MENARD, V.1, BARRERO, A.1, LACHARD, T.3, ROBINAULT, L.5, LI, L.1, SCHNELL, F.2,3,4, CARRÉ, F.3,4, LE DOUAIRON LAHAYE, S.1

*1M2SLABORATORYUNIVERSITY OF RENNES 2/2CIC-CIT INSERM 1414/3DEPARTMENT OF SPORTS MEDICINE, UNIVERSITY HOSPITAL OF RENNES/4INSERM, LTSI-UMR1099/5LAMIH, UMR CNRS 8201*

INTRODUCTION: Due to high cardiac workload, prolonged intense exercise results in an exercise-induced cardiac fatigue (EICF) (1). This phenomenon is characterized by transient cardiac function alterations associated to an increase in the cardiac damage biomarkers after athletes performed this type of sport events whether isolated or repeated over several days (2). The EICF is generally assessed by conventional echocardiography and/or cardiac biomarkers, but these tools are expensive and require highly qualified bio-medical staff. The cardiovascular control by autonomous nervous system (ANS) can be assessed by heart rate variability (HRV) analysis. Due to strong relationship between ANS, HRV and cardiac function, we can consider the interest of the HRV analysis for determined EICF. The objective of the study was to describe the evolution of cardiac function and HRV parameters during a multi-stage cycling event and to determine their relationship.

METHODS: Using a case study approach, this investigation focused on one female athlete who performed the 21 stages of the Tour de France circuit 2018 without any spirit of competition of performance goal. Each morning, she underwent a rest transthoracic echocardiography and a RR recording (5 minutes supine, 5 minutes standing). Cardiac function was assessed by conventional echocardiography, tissue Doppler imaging and speckle tracking techniques. HRV analysis was performed in time and frequency domains. Descriptive analysis of cardiac function and HRV was first performed. Then, correlations between cardiac function and HRV parameters were tested (p<0,05, r=0,8).

RESULTS: Multiple's variations were observed on both diastolic and systolic function parameters (E/A, E/E' mean, LV global longitudinal strain, LVEF, S' mean) of left ventricle. There were also variations on the systolic function parameters of the right ventricle (TAPSE, FAC, RV

longitudinal strain). These variations were not considered as alterations or degradations of the heart function also known as EICF. During the 21 stages, multiple's variations were observed for the HRV parameters such as imbalance of HRV, increase of sympathetic tone and decrease of parasympathetic tone. No significant correlation was found between the HRV and the echocardiophy parameters.

CONCLUSION: Despite HRV imbalance, no evidence of a cardiac fatigue was observed all along the event. This repeated and prolonged endurance exercise seems insufficiently stressful to impair cardiac function, perhaps due to too moderate intensity.

## EFFECTS OF DIFFERENT TYPES OF EXERCISE ON CEREBRAL BLOOD FLOW AND EXECUTIVE FUNCTION IN YOUNG ADULTS

MIN, L., LIU, J., MA, X.

*TSINGHUA UNIVERSITY*

INTRODUCTION: Different types of exercise have recently received increasing attention in improving the cognitive and cerebrovascular function of the elderly. However, the cognitive benefits of HIIT and MICT in healthy young adults and their mechanisms have not been fully discussed. Some evidence shows the same effects also apply to a high-functioning population (e.g., young adults), yet whether high-intensity interval training (HIIT) and moderate-intensity continuous training (MICT) could improve the executive function (EF) and cerebral blood flow (CBF) is still unknown. Therefore, we hypothesized that both HIIT and MICT could be beneficial to EF compared to the control group in college students. Furthermore, the CBF was related to the improvement of EF.

METHODS: Eighty-two college students with irregular exercise habits were recruited from Tsinghua University to receive 12-weeks interventions three times a week. They were randomly divided into HIIT (10 minutes warm-up + [100% VO2max running for 1 minute + 50% VO2max fast walking for 1 minute] *10 times + 10 minutes cool down, 40 minutes totally, n=29), MICT (10 minutes warm-up + 70-75% VO2max running for 20 minutes +10 minutes cool down, 40 minutes totally, n=31) and control group (health education for 40 minutes, n=22). EF was tested by trail-making test (TMT), and CBF velocity (Transcranial Doppler, EMS-9WA) was tested before and after 12-week interventions. To avoid distractions, all the tests of participants were performed in the morning. We also controlled these participants' education level, birthplace (rural or city), age, and body mass index as covariates. A mixed-effect model was used to detect changes between the treatments as well as effect sizes expressed as t values. A p-value of 0.05 or less was considered significant.

RESULTS: The systolic and mean velocity of CBF (Vs and Vm) were negatively correlated with the total time of the TMT. Vs ($t = -2.60$, $p < 0.05$) was associated with the total time of TMT after controlling for other variances. Furthermore, MICT group improved significantly after 12 weeks intervention compared with the control group ($t = -2.01$, $p < 0.05$), and HIIT group has a significant edge effect compared with control group ($t = -1.99$, $p = 0.05$); Vm ($t = -2.29$, $p < 0.05$) associated with the total time of TMT after controlling for other variances. Furthermore, MICT group improved significantly after 12 weeks intervention compared with control group ($t = -2.04$, $p < 0.05$), and HIIT group has a significant edge effect compared with control group ($t = -1.95$, $p = 0.06$). The pulsatility index, resistance index (PI and RI) and ratio of systolic and diastolic CBF velocity (S/D) of these participants were significantly associated with the improved accuracy of TMT after interventions ($t = 2.14$, $p < 0.05$; $t = 2.16$, $p < 0.05$; $t = -2.13$, $p < 0.05$). However, there were no difference in these three groups.

CONCLUSION: As hypothesized, the 12-week of MICT and HIIT intervention, to some extent, could increase the EF of young adults, which associated with the improvement of the systolic and mean velocity of CBF. MICT was found to be better than HIIT in the improvement of EF in young adults. Future studies were needed to enlarge the sample size and duration of the intervention to confirm this conclusion.

## 8-WEEK RESISTANCE TRAINING MODULATES SOD1 AND PIRE1/IRE1 RATIO IN THE ELDERLY

ESTÉBANEZ, B., VISAVADIYA, N.P., DE PAZ, J.A., KHAMOUI, A.V., GONZÁLEZ-GALLEGO, J., CUEVAS, M.J., HUANG, C.J.

*UNIVERSITY OF LEÓN: UNIVERSIDAD DE LEON*

INTRODUCTION: Aging is been related to changes in redox balance, low-grade inflammation and a decreased endoplasmic reticulum (ER) unfolded protein response (UPR). Regular physical activity has been proposed as a successful intervention in the elderly, and resistance training has been shown to offset the inflammatory response, balance redox homeostasis and ameliorate the UPR. This work aimed to investigate the effects of a resistance exercise program on oxidative status, UPR and inflammation biomarkers in PBMCs of elderly subjects.

METHODS: Thirty healthy elderly subjects (22 trained; 8 controls) volunteered in an 8-week resistance training protocol. Basal data were also analyzed in a group of eleven young subjects. The expression of the anti-aging protein Klotho and oxidative stress markers (catalase, GSH, lipid peroxidation, NRF2, protein carbonyls, ROS, SOD1, and SOD2), and the activation UPR IRE1 arm and TLR4/TRAF6/pIRAK1 pathway, were evaluated prior to and following training.

RESULTS: No changes in HSP60 and Klotho levels, and TLR4/TRAF6/pIRAK1 pathway activation were found with training. Although most oxidative markers remained unchanged, a reduced SOD1 expression was found in the trained group compared to the controls. Moreover, an attenuation of the reduced pIRE1/IRE1 ratio induced by aging was observed.

CONCLUSION: Although SOD1 is considered as a major cytoplasmic antioxidant enzyme that metabolizes superoxide radicals to molecular oxygen and hydrogen peroxide, thus providing a defense against oxygen toxicity (Nojima et al., 2015), the H2O2/ROS-dependent reversible oxidation/reduction could drive to SOD1 oxidation leading to the formation of non-native disulfides that cause the formation of insoluble SOD1 multimers and aggregates, contributing to the cytotoxicity and resulting in ES stress and UPR activation (van Dam & Dansen, 2020). Moreover, during aging there is an inability to handle protein folding, accumulation, and aggregation due to a progressive failure of the chaperoning systems (Naidoo et al., 2014), as well as a decline in UPR components (Ogborn et al., 2014; Paz Gavilán et al., 2006). Therefore, the 8-week resistance training program could be able to reduce the aging-related SOD1 accumulation through an attempt of restoring the UPR response via IRE1 arm. These findings might partially support the modulating effect of resistance training on the oxidative balance through the endoplasmic reticulum stress alleviation in the elderly.

**THE USE OF OBJECTIVE ACTIMETRY TO ASSESS THE PHYSICAL ACTIVITY OF END STAGE RENAL DISEASE PATIENTS-PILOT STUDY**

DZIUBEK, W.1, ROGOWSKI, L.2, PAWLACZYK, W.3, BULINSKA, K.1, OSTROWSKA, B.1, STEFANSKA, M.1, GOLEBIOWSKI, T.4, KRAJEWSKA, M.4, KUSZTAL, M.4

*1UNIVERSITY OF HEALTH AND SPORT SCIENCES, WROCLAW, POLAND; 2WITELON COLLEGIUM STATE UNIVERSITY, LEGNICA, POLAND; 3LOWER SILESIAN ONCOLOGY CENTER, WROCLAW, POLAND; 4WROCLAW MEDICAL UNIVERSITY, POLAND*

INTRODUCTION: Patients with end-stage renal disease (ESRD) undergo replacement therapy such as hemodialysis spent about 400-900 hours of passive rest a year. The aim of the study was to assess the level of physical activity in patients with end stage renal disease using an accelerometer - actigraph.

METHODS: The study involved 59 people, divided into two groups. Group I - 25 patients on dialysis and Group II - control 34 healthy people. To assess the level of physical activity, the ActiGraph wGT3X-BT sensor was used, which allows for the objective registration of 24-hour daily physical activity and inactivity and sleep periods, including: total sleep time, intruded wakefulness, and sleep efficiency; automatic sleep detection (detection of awakenings); total energy expenditure expressed in kilocalories (kcal) and as metabolic equivalent (MET); the number of steps completed; the intensity level of physical exercise and the registration of the body position. On the basis of the information gathered by this device, it is possible to determine if the subject has sleep disturbances, additionally it is possible to determine the time spent in a sitting position and the caloric demand useful in choosing the right diet.

RESULTS: The results of the study indicate significant differences in the level of physical activity between patients undergoing dialysis and the control group. There are significant relationships between the age of the subjects and the level of their physical activity. Elderly patients are characterized by a lower average level of physical activity. Both groups also differentiate the time spent sitting, to the detriment of ESRD patients despite significantly younger patients on dialysis.

CONCLUSION: Dialysis patients should be encouraged by the medical staff to increase their physical activity. Monitoring of physical activity using objective devices should be carried out in this group of patients at least twice a year. In future research, we want to compare the result of the actigraph study to the subjective method of the IPAQ questionnaire.

**HIGH INTENSITY INTERVAL TRAINING IN PATIENTS WITH BREAST CANCER UNDERGOING CHEMOTHERAPY: PROTOCOL FOR A PARALLEL GROUP RANDOMISED CONTROLLED TRIAL**

CAMPA, M., KLAVINA, A., CESEIKO, R.

*LATVIAN ACADEMY OF SPORT EDUCATION*

INTRODUCTION: Neoadjuvant chemotherapy given to women with breast cancer (BC) is associated with cardiotoxicity, reduced cardiorespiratory fitness, fatigue, poor quality of life, fat gain, and muscle loss [1, 2]. In recent years, research on the suitability of high intensity interval training (HIIT) for BC survivors has emerged as well. Systematic reviews and meta-analyses of HIIT for cardiorespiratory fitness in cancer survivors and those undergoing chemotherapy have already shown HIIT to have some degree of effectiveness on improving physical fitness.[3].

This study aims to investigate the effects of individualised adapted aerobic exercise program (IAEP) on physical fitness and quality of life of patients with BC (age 35 to 65 years) during neoadjuvant therapy (NT). In addition, this study will determine association between multicomponent health risk factors and adherence in IAEP in patients with BC. It is hypothesized that IAPE improves physical fitness and quality of life, subsequently contributing outcomes of NT treatment.

METHODS: In the parallel group randomized controlled trial participants will be randomly allocated into IAPE group (n=40) and control group (n=40). All participants will complete EORTC QLQ-C30 and specific breast cancer module EORTC QLQ- 23 to determine the quality of life all six to eight cycles of NT. Daily living activities related physical fitness evaluation will consist of 6 MWT, 30 sec Sit to stand test and 5 reps Sit-to-Stand Test. Peak oxygen consumption (VO2peak) will be measured with Vyntus CPX gas analyser and The University of Northern Colorado Cancer Rehabilitation Institute (UNCCRI) treadmill protocol which has been chosen as most suitable for specific participants group considering wide age range and different previous physical activities experience and preparedness. 4x4 HIIT intervention program will be delivered to IAPE group.

RESULTS: Protocol for a parallel group single-blinded randomised controlled trial for 8-12 week intervention period has been successfully developed. Protocol includes detailed information of Timeline, overview of interventions and conducted tests, participants recruitment eligibility testing flow chart, intervention guidelines, data collection, management and quality control guidelines.

CONCLUSION: The study will address important aspects relative to including physical activity during NT for women with BC. This study is currently underway with funding support from the EEA and Norway Grants 2014-2021 financial Mechanisms project “Exploring the molecular mechanisms behind the effects of physical exercise on breast cancer prevention” (Nr. EEZ/BPP/VIAA/2021/2).

**INFLUENCE OF EXERCISE ON ENDOCRINE ADIPOKINES SECRETION – THE ROLE OF TISSUE CONTENT**

HUMINSKA-LISOWSKA, K.1, MIESZKOWSKI, J.1,2, BOJARCZUK, A.1, KOCHANOWICZ, A.1, MICHALOWSKA-SAWCZYN, M.1, NIESPODZINSKI, B.3, BRZEZINSKA, P.1, STANKIEWICZ, B.3, CIESZCZYK, P.1

*1-GDANSK UNIVERSITY OF PHYSICAL EDUCATION AND SPORT; 2-CHARLES UNIVERSITY, FACULTY OF PHYSICAL EDUCATION AND SPORT, PRAGUE, CZECH REPUBLIC; 3-INSTITUTE OF PHYSICAL EDUCATION, KAZIMIERZ WIELKI UNIVERS*

INTRODUCTION: Regular physical activity and training induce many systematic and organ adaptations, which contribute to the protection against many metabolic disorders, such as metabolic syndrome, obesity or type 2 diabetes. During physical activity, adipocytes release multiple adipokines that affect many organs and body systems. Observed changes are dependent on the type of physical activity and may induce inflammation. Thus, these changes may intensify the inflammatory process. We aimed to assess the changes in secretion activity of adipose tissue in association with intensive aerobic and anaerobic exercises in the context of the exercises induced inflammation process.

METHODS: Population of 48 volunteers (aged 21.78 ± 1.98) were assigned to one of the study groups: LBF low body fat (n=16); NBF, normal body fat (n=19); HBF high body fat (n=13); depending on body fat content (LBF<8%; NBF=8-15%; HBF>14%). Volunteers performed maximal aerobic (Bruce; BTT) and anaerobic (WAnT) tests. Before experimental testing, each individual completed a standardized warm-up on the cycloergometer (five min at 60 rpm, 1 W/kg). Each participant (for the WanT test) was required to pedal with maximum effort for a period of 30s against a fixed resistive load of 75 g/kg of total body mass according to Bar-Or [1]. The Bruce protocol was performed on a treadmill and composed of six stages, beginning at 1.7 mph at an inclination percentage of 10% degree [2]. Blood samples were collected at 4 time-

points: prior, 2-5 minutes after, 60 minutes after and 24h after each type of maximal physical activity. Selected parameters were measured and analyzed: Adiponectin, Follistatin like 1, Interleukin 6, Leptin, Oncostatin, Resistin, Adiponectin/Leptin Ratio. One-way variance recorded significantly higher results of body fat mass and percentage of body fat in HBF compared to LBF and NBF.

RESULTS: The analysis of variance showed a significant effect of 2xWAnT and BTT factor in all tested biochemical markers in addition to interleukin 6. Significant interactions of the body fat content in the case of the HBF group were noted for leptin and resistin (after 2xWAnT) and leptin (after BTT).

CONCLUSION: Our analysis presents different responses depending on the body fat content in different types of exercises. Among populations with high body fat (HBT), the endocrine activity of adipose tissue and the increase in circulating leptin and resistin is associated with leptin/resistin resistance developing in adipose tissue, but it does not affects the systematic inflammation process and does not correlate.

The project is financed by the National Science Centre, Poland (2018/29/N/NZ7/02800).

## MULTICOMPONENT SUPERVISED EXERCISE TRAINING DURING PREGNANCY IMPROVING MATERNAL PHYSICAL ACTIVITY, FITNESS, AND HEALTH: THE ACTIVE PREGNANCY PROJECT

SANTOS-ROCHA, R., SZUMILEWICZ, A.

*SPORT SCIENCES SCHOOL OF RIO MAIOR - POLYTECHNIC INSTITUTE OF SANTARÉM - PORTUGAL / GDANSK UNIVERSITY OF PHYSICAL EDUCATION AND SPORT - POLAND*

INTRODUCTION: Physical activity and exercise during pregnancy and postpartum seem to have important benefits, both during pregnancy and in postpartum recovery. The COVID-19 pandemic has accentuated the need for virtual interaction with populations considered to be at greater risk. It is pertinent to implement effective and safe exercise strategies and programs, adapted to the stages of pregnancy and postpartum, and to contribute to evidence-based knowledge about the impact of exercise on physical activity level, fitness, and health parameters.

The objective is to present the outline of the Active Pregnancy Project. The four aims are 1) To implement educational tools for women, exercise and health professionals, based on updated guidelines and evidence on the positive impact of exercise during pregnancy and in postpartum; 2) To build and implement friendly-use and effective virtual tools promoting exercise during pregnancy and in postpartum; 3) To assess the impact of various multicomponent exercise programs delivered in-person and online to improve maternal physical activity, fitness, and health parameters; 4) To assess the impact of exercise and healthy lifestyle on the prevention of common pregnancy and postpartum complaints and diseases.

METHODS: The project was approved by the ethics committee of the higher education institution. The main methods are: updating previous systematic reviews; validating the exercise program as a complex intervention in health; developing educational standards and training for the Pre/Post Natal Exercise Specialist; developing educational tools, such as webinars, workshops, guidelines, and a textbook* for women and professionals; developing the free access Active Pregnancy YouTube channel**; developing and implementing e-health software (app) for guidance and self-management of a healthy lifestyle of women; registering and implementing study protocols for multicenter (in-person and online) multicomponent randomized control trials, based on a customized supervised exercise programs lasting 12 weeks with two intervention groups.

RESULTS: Expected results are related to the publication of papers, various educational tools including a textbook*, a YouTube channel**, and the Active Pregnancy app.

CONCLUSION: The project is focused on the citizen engagement in health, wellbeing, and prevention of diseases, and shall enable women to become co-managers of their health and physical and mental wellbeing, including quality of life, health literacy, and lifestyle factors, with the help of new tools and evidence-based knowledge. The multidisciplinary team and approaches will boost research and knowledge in this field, as well as the role of exercise and health professionals in the health care process.

## INFLUENCE OF DIFFERENT TYPES OF EXERCISES AND HABITS ON BLOOD 2-ARACHIDONOYLGLYCEROL LEVEL.

YAMASHITA, T.1, KUME, K.1,2, ISHIBASHI, S.1,2, ARAKI, S.1,3, TOMIGA-TAKAE, R.1,3, TAGUCHI, N.1,3, ABE, U.2,4, OMAGARI, K.1,3, TOBINA, T.1,3

*1: UNIVERSITY OF NAGASAKI, 2: KWASSUI WOMEN'S UNIVERSITY*

INTRODUCTION: It is known that endogenous cannabinoids (eCBs), such as 2-arachidonoylglycerol (2-AG) and anandamide, is one of the mediators of euphoria and pain sensitivity. Our previous study identified that a single bout of moderate-intensity exercise increases blood eCB concentration. However, it is unclear whether exercise types and habits affect blood eCB levels. This study investigated whether differences in exercise types and habits affect the changes in blood 2-AG production.

METHODS: Twenty-five female subjects were recruited for this study. Six were national-level college football players (E: 20±1 years), 11 were experienced futsal players (A: 20±1 years) and the other 8 were beginners (B: 19±2 years). The Lactate threshold (LT) was measured using a cycle ergometer. They carried out a futsal match and cycle ergometer exercise for two equal periods of 20 minutes at LT intensity. During futsal playing, they wore heart rate monitors and regulated the exercise intensity. Blood samples were obtained before and after the exercise. Plasma samples were stored at -80℃ until the analysis. Because 2-AG is rapidly isomerized to 1-arachidonoylglycerol (1-AG), the concentrations of 2-AG and 1-AG were measured using LC-MS/MS (1). The sum of these values (2-AG + 1-AG) was used as the index of blood 2-AG level.

RESULTS: There was no difference in age, height, weight, and BMI between the groups. No significant differences in heart rate between the groups in Ergometer (Before 1st period: 68 (64-73) bpm, 81 (73-84) bpm, 82 (76-87) bpm, After 1st period: 130 (115-146) bpm, 127 (121-137) bpm, 133 (129-134) bpm, After 2nd period: 131 (120-149) bpm, 132 (124-141) bpm, 129 (127-133) bpm. (E, A and B, respectively, Data shown as median (quartile)), and in Futsal (Before 1st period: 59 (57-63) bpm, 82 (78-99) bpm, 74 (67-77) bpm, After 1st period: 139

(130-141) bpm, 144 (136-154) bpm, 136 (127-149) bpm, After 2nd period: 141 (126-145) bpm, 146 (140-158) bpm, 133 (126-152) bpm. (E, A and B, respectively)). After the ergometer exercise, 2-AG + 1-AG was significantly increased in all groups (E: 7.6 (7.3-8.8) ng/mL, and 11.0 (10.1-13.6) ng/mL, A: 1.6 (1.3-2.3) ng/mL, and 2.8 (2.1-2.9) ng/mL, B: 3.9 (3.5-4.7) ng/mL, and 5.8 (4.6-6.0) ng/mL). However, there were no significant differences after the futsal match in 2-AG + 1-AG (E: 5.7 (5.0-7.5) ng/mL, and 11.6 (8.9-14.1) ng/mL, A: 1.3 (1.0-2.0) ng/mL, and 1.5 (1.0-2.1) ng/mL, B: 3.8 (2.2-5.8) ng/mL, and 5.4 (3.6-6.6) ng/mL).

CONCLUSION: The result suggested that continuous moderate-intensity exercise increases blood eCB concentration. On the other hands, the exercise habits may not affect changes in eCB concentration.

## A STUDY ON THE ENERGY EXPENDITURE OF FITNESS QIGONG EXERCISE PROGRAMS IN THE CHINESE MIDDLE-AGED AND ELDERLY POPULATION

ZHANG, Y., PAN, X., GAO, Y., JIANG, L.

*CHINA INSTITUTE OF SPORT SCIENCE*

INTRODUCTION: This study uses the measurement of energy expenditure in the Baduanjin exercise program as a basis to explore the characteristics of energy metabolism in fitness qigong exercise and to further meet the needs of personalised fitness instruction for middle-aged and elderly people.

METHODS: Subjects: 892 healthy middle-aged and elderly people aged 40 and above, excluding those with heart disease, hyperlipidaemia, diabetes, anaemia, etc., including 94 men and 125 women aged 40-59, 266 men and 326 women aged 60-69, and 46 men and 35 women aged 70 and above. Each learnt and became proficient in the Fitness Qigong Baduanjin exercise program.

Experimental method: Experimental tests were carried out in age groups, with the main tests: height, weight, blood pressure and cardiopulmonary function. The subjects wore the CORTEX-3B exercise cardiorespiratory fitness tester and heart rate band, followed the fitness qigong music and completed the fitness qigong exercises. The experimental data were taken as the average values of the smoother phases of the process. Data indicators: METs, HR, RR, RQ, VCO2/VO2, VO2/HR, VO2/kg, etc.

Statistical methods: all data were smoothed (20s) and then statistically analysed using Spss10.0; t-test, Intra-classCorrelation Coeffieient ICC, etc.; significant level was $P<0.05$, very significant level was $P<0.01$. Multiple regressions were used to establish the energy expenditure of fitness qigong exercise programs in the middle-aged and elderly population formula.

RESULTS: 1. As age increases, exercise energy consumption tends to decrease in both men and women; the decreasing trend is greater between the ages of 60 and 69; the level of exercise energy consumption is always higher in men than in women.

2. The relationship between BMI indicators and exercise energy consumption, BMI and exercise energy consumption were significantly lower in men and women at the beginner level and in men ($p<0.01$); only in men at the proficient level was the correlation between BMI and exercise energy consumption significantly lower ($p<0.01$).

3. Age, gender, BMI and energy consumption were weakly correlated with heart rate, oxygen uptake/kg, respiratory exchange rate age, heart rate, oxygen uptake, metabolic equivalent, energy consumption, energy consumption/kg and gender, and oxygen uptake/kg, oxygen uptake, metabolic equivalent, energy consumption, energy consumption/kg were weakly correlated with BMI.

4. The best model of oxygen uptake, with fitness Qigong Baduanjin proficiency, gender and weight as the main predictor equations, is: Y=0.34*EXP(1.12*type)+0.018* weight-0.35 G1-0.41 G0 where: oxygen uptake (Y); type represents fitness Qigong Baduanjin exercise program proficiency, type=1,2,3. Weight represents body weight, in kg. When the gender is male, G1=1 and G0=0; when the gender is female, G1=0 and G0=1.

CONCLUSION: In this study, the relationship between age, gender, BMI and fitness qigong energy expenditure was mastered, and an energy expenditure formula for fitness qigong exercise programs in the middle-aged and elderly population was established.

## METABOLIC DIFFERENCES BETWEEN ADOLESCENT SOCCER PLAYERS WITH ADEQUATE BODY MASS INDEX AND THOSE WITH OVERWEIGHT/OBESITY

FRITZLER, W., RIVERA-CISNEROS, A.E., MURGUIA-CANOVAS, G., VARGAS-SANCHEZ, G., NORIEGA-MURO, I., LARA-MAYORGA, Y.

*CENTRO UNIVERSITARIO DEL FUTBOL Y CIENCIAS DEL DEPORTE*

INTRODUCTION: The practice of physical activity in its sports modality is desirable among the child and youth population. The objective of this study was to identify the differences in blood metabolic levels between male adolescents, who were engaged in regular soccer training, with adequate body mass and overweight.

METHODS: 74 male adolescents with normal weight and 72 with overweight according to their Body Mass Index (BMI) participated in the study. All the participants were members of the youth soccer training groups of the Professional Soccer Club Leon (Mexico). They were assigned to two groups: Group I (GI) with a BMI from 20 to 25 kg/m2 and Group II (GII) with a BMI > 25 kg/m2. In all cases, body height (BH), body mass (BM) and hip circumference (HC) were measured, and the following biomarkers in blood were analyzed: glucose (Gluc), total cholesterol (TC), triglycerides (TG) and high (HDL-C), low (LDL-C) and very low density (VLDL-C) lipoproteins.

RESULTS: In average, the participants of GI were 16.0 ± 2.5 years old, with BH of 164.1 ± 8.0 cm and HC of 78.1 ± 9.5 cm, while GII presented 16.0 ± 2.8 years, BH 163.1 ± 7.0 cm and HC of 84.1 ± 11.2 cm. The results of the other variables were as follows. Body mass: GI 58.9 ± 7.8 kg vs GII 75.7 ± 14.1 kg, BMI: GI 21.8 ± 1.8 vs GII 29.1 ± 4.1 kg/m2, Gluc levels: GI 4.70 ± 0.28 vs GII 4.97 ± 0.41 mmol/l, TG: GI 1.09 ± 0.39 vs GII 1.24 ± 0.38 mmol/l, and VLDL-C: GI 0.46 ± 0.10 vs GII 0.52 ± 0.2 mmol/l were higher in the overweight/obese group, evaluated by Student's t test for independent samples with $p < 0.05$. Only TC and HDL-C showed no significant differences with GI 3.9 ± 0.6 vs GII 3.7 ± 0.7 mmol/l and 1.69 ± 0.18 vs 1.65 ± 0.22 mmol/l, respectively.

CONCLUSION: The data are consistent with others reported in the literature and expected as an underlying metabolic condition in athletes from early stages of life in those who are overweighted or obese. It is considered necessary to include studies that assess the metabolic status of participants in different sport activities, particularly in adolescents with high weights (BMI > 25 kg/m2).

### EFFECTS OF SODA BEVERAGE ON ENDURANCE PERFORMANCE DURING EXERCISE

BALASEKARAN, G., AMIN, A.B., NG, Y.C.

*HUMAN BIOENERGETICS LABORATORY, PHYSICAL EDUCATION AND SPORTS SCIENCE, NATIONAL INSTITUTE OF EDUCATION, NANYANG TECHNOLOGICAL UNIVERSITY*

INTRODUCTION: Despite Coca-Cola being one of the most popular drinks in the world, very few studies in the past have tested the effects of Coca-Cola on athletes. Previous studies have only used Coca-Cola as a source of caffeine, but have not tested out the extensive effects of the beverage. The purpose of this study was to investigate the effects of a soda beverage (Coca-Cola) on heart rate (HR), blood lactate levels, rate of perceived exertion (RPE) as well as time to exhaustion.

METHODS: 10 athletes were recruited for the study (Weight: 62.4 ± 6.8 kg, Age: 21.8 ± 1.1 years). Each participant underwent 3 sessions, in a repeated measure design study. During each participant's first session, they went through a cycling VO2 max test. For the subsequent 2 sessions, they went through 2 different conditions; participants were given one serving of a placebo beverage for one session and one serving of a Coca-Cola beverage for the other session. During both sessions, participants went through a constant cycling activity at 60% VO2 max. HR was measured and blood was collected at 15 minute intervals until time of exhaustion. Participants' RPE was also collected at 5-minute intervals.

RESULTS: Differences in lactate levels between pre cycling to 30 min of cycling for both conditions (Placebo: 1.93 ± 1.98 mmol/L vs Coca-Cola: 1.68 ± 1.36 mmol/L, P = 0.73) and time to exhaustion (Placebo: 2154 ± 667.8 secs vs Coca-Cola: 2310 ± 548.6 secs, P = 0.10) were not significant between the two beverages ($p > 0.05$). Similarly results were non-significant between differences in resting HR and HR at 30 mins of exercise for the two conditions (Placebo: 88.44 ± 18.20 (beats per min (bpm)) vs Coca Cola: 90.7 ± 16.07 bpm, P = 0.402, ($p > 0.05$)). Differences in RPE between the 10th min and exhaustion for the both groups were significant (Placebo: 6 ± 1.7, Coca Cola: 6.7 ± 2.1, P = 0.045) ($p < 0.05$).

CONCLUSION: There were no significant differences in HR, lactate levels and time to exhaustion between the placebo and the Coco-Cola beverage. However, there were significant differences for RPE scores. Coco-Cola beverage may have a psychological effect in performance. Further research is needed to probe the causes.

### EFFECT OF AN ACUTE EXERCISE ON EEG AMONG OBESE WOMEN

WANG, H., WEN, H.

*TZU CHI UNIVERSITY*

INTRODUCTION: Obesity reduces brain volume and impairs neurocognitive function in the prefrontal region (1). Recent neurocognitive studies using event-related potential (ERP) confirm that the inhibitory control ability in obese women improved after a single bout moderate-intensity interval exercise (2). However, the resting brain wave-$\theta$ wave, which related to inhibitory control, still unknown after a single bout exercise among obese women. The purpose of this study was to explore the brain wave changes in obese women after a single bout of moderate-intensity aerobic combined with resistance exercise.

METHODS: Forty sedentary obese women (age 31.96 ± 7.00 year-old, BMI = 29.89 ± 3.37 kg/m2) were recruited for this study. All participants were randomly assigned to exercise group (EG) or control group (CG). The participant in EG received 30 min of single bout moderate-intensity aerobic combined with resistance exercise, which included 5 minutes warm-up, 30 minutes interval training at 55% of HR reserve (3), and 5 min cool down. Exercise intensity was monitored to ensure participants reaching their target HR zone. Participants in CG sit and rest for equal time to EG. All participants sit comfortable with eyes-closed recorded by electroencephalogram (EEG, eegoTM, Germany) before and after the intervention.

RESULTS: The results showed that the spectral power of Fp1 theta wave in prefrontal area was significantly increase in EG at post-test (10.55 ± 3.84, 12.41 ± 4.44, p= 0.022) while that in CG post-test significantly decrease (10.21 ± 3.62, 8.77 ± 2.90945, p= 0.043).

CONCLUSION: A single bout of moderate-intensity aerobic combined with resistance exercise may improve the inhibitory control ability in the prefrontal region among obese women.

Supported by Hualien Tzu Chi Medical Center (TCRD110-64).

### DOES DAILY PHYSICAL ACTIVITY AND AEROBIC CAPACITY ASSOCIATE WITH UPPER AND LOWER SKELETAL MUSCLE QUALITY IN YOUNG WOMEN?

ARAKI, S.1, HANAMURA, I.1, KUME, K.1,2, ISHIBASHI, S.1,2, TAGUCHI, N.1, YAMASHITA, T.1,3, TOBINA, T.1

*1: UNIVERSITY OF NAGASAKI*

INTRODUCTION: Strength exercise training is favorable for an increase of skeletal muscle mass and produces subsequential force. Absolute skeletal muscle strength and power are popular assessments for physical function. In addition, muscle quality (MQ), defined as exerted muscle strength per unit of skeletal muscle, is also an index of functional impairment.

A previous study reported that moderate aerobic exercise training improves MQ in older adults. A physically active lifestyle may associate with higher MQ independently skeletal muscle mass. Then, this study aimed to clarify the relationship between MQ and daily physical activity, body composition, and aerobic capacity in young women.

METHODS: Twenty-eight young women (21±2 years) were recruited for this study. The body mass, muscle, and fat mass were measured using bioelectrical impedance analysis (InBody720, InBody Japan). Maximal oxygen consumption (VO2max) was measured by the maximum cycle ergometer test. Additionally, to measure physical function and moderate-intensity exercise capacity based on the strenuous activity of daily living, the subjects carried 10kg weight for 300m. During the test, they wore a heart rate monitor to assess the physiological stress (ΔHR: Difference of Heart rate before and after the test).

Isokinetic biceps and knee extensor strength were measured. The thickness of the upper arm and femur was measured using an ultrasound imaging device. MQ was calculated for the upper arm (biceps strength(kg) / muscular thickness (mm) or mean arm skeletal muscle mass (kg)) and leg (knee extensor strength (kg) / muscular thickness (mm) or mean leg skeletal muscle mass (kg)), respectively.

The daily steps, light (1.8-2.9 METs), moderate (3.6-5.2 METs), and vigorous (above 6.1 METs) physical activity levels were measured using a uniaxial accelerometer (LifeCoder GS, Suzuken, Japan).

RESULTS: There were no correlations between daily steps, light, moderate, vigorous physical activity levels, and upper arm and leg MQ. VO2max is also not correlated with upper arm and leg MQ. A negative correlation was found between upper arm MQ (kg/mm) and ΔHR

(r=-0.396, p=0.037). However, their association was not found in absolute biceps, knee extensor strength, and ΔHR. Neither body mass nor skeletal muscle mass correlated with MQ and ΔHR.

CONCLUSION: This study identified that the daily physical activity levels are not strongly associated with MQ in young women. Interestingly, the upper arm MQ was negatively correlated with ΔHR during the moderate-intensity exercise capacity test, but not absolute biceps strength. The results of this study can not explain the phenomena, relative muscle strength may be favorable for physical function based on the strenuous activity of daily living such as carrying a heavy shopping bag.

**THE STABILITY OF ADHERENCE TO 24-H MOVEMENT BEHAVIOURS RECOMMENDATIONS IN MID-TO-LATE ADOLESCENCE: THE CRO- PALS STUDY**

MISIGOJ DURAKOVIC, M., KARUC, J., SORIC, M.

*FACULTY OF KINESIOLOGY UNIVERSITY OF ZAGREB*

INTRODUCTION: Physical activity, limited sedentary time and enough sleep are associated with health and contribute to lower risk for the chronic diseases development. Adolescence is an important period during which individual behaviour patterns establish including physical activity, sedentary and sleep behaviour. The aim of the study was to investigate the stability of adherence to 24-h movement behaviours recommendations (RCMD) in mid-to-late adolescence.

METHODS: This longitudinal study involved 618 adolescents (317 girls) in 1st grade of high school and followed them for 3 years. Adherence to 24-h movement guidelines was assessed according to the Canadian 24-Hour Movement Guidelines for Children and Youth (≥60 min per day of moderate-to-vigorous physical activity (PA), <2 h of daily leisure screen time, 8–10 h nightly sleep duration) in 2 time points: 1st grade of high school and again 3 years later. Daily PA was assessed via SHAPES questionnaire while sedentary (SB) and sleep behaviour (SLEEP) was self-reported with additional queries in separated questionnaire. Outcome measures included each of the 24-h movement behaviours measured during 4th grade, while predictor variables included parameters assessed during the 1st grade. A series of simple logistic regression analysis were employed to analyse the odds of adherence to individual and integral 24-h movement behaviours in 4th grade according to individual behaviours in 1st grade of high school. All analyses were done separately for boys and girls.

RESULTS: The prevalence of participants who met PA and SLEEP RCMD decreased during mid-to-late adolescence, while low prevalence (9%) of adolescents who met SB RCMD slightly increased (11%). Significant odds ratios (OR) were find for adherence to all components of 24-h movement behaviours RCMD, except to SLEEP RCMD in boys (PA RCMD: 3.4 [2.0, 5.9] in girls, 3.3 [1.8, 6.1]in boys; SB RCMD 6.1 [2.7, 14.1] in girls, 5.9 [1.9, 13.7] in boys ; SLEEP RCMD 2.1 [1.3, 3.5] in girls, 1.6 [0.9, 2.7] in boys. The odds of adherence to the 24-h movement behaviours RCMD in mid-to-late adolescence was slightly higher in girls than in boys. The highest odds of adherence to the 24-h behaviours RCMD were revealed for the SB RCMD adherence (OR 6.1 [2.7, 14.1] in girls; 5.9 [1.9, 13.7] in boys).

CONCLUSION: The significant stability of 24-h movement behaviours RCMD adherence during mid-to-late adolescence indicates the importance of early promotion of guidelines for physical activity and sleep, and particularly for sedentary behaviour.

**DETERMINATION OF ENERGY EXPENDITURE AND EXERCISE INTENSITY OF SNPE**

KIM, S., LEE, H., LEE, D.T., YOON, J., LEE, Y., JUNG, D., SON, S., LEE, J., HWANG, J.G., YUN, S., LEE, K., LEE, M.

*KOOKMIN UNIVERSITY*

INTRODUCTION: The purpose of this study was to examine energy expenditure (EE) and exercise intensity (EI) of SNPE (Self Natural Posture Exercise), which is relatively effective to release chronic musculoskeletal pain.

METHODS: A total of 39 women (20s-40s) who were certified SNPE instructor level 2 were participated. The volumes of Oxygen ($VO_2$) and heart rates (HR) were measured by K5 (CosMed, Italy) and Polar H10 (Finland) respectively, while performing eight SNPE basic moves (SNPE 1, 2, 3, 4, C, T, L, & SC-move). To determine the exercise intensity of SNPE moves, MET(metabolic equivalents) values of each moves were calculated based on measured $VO_2$. Descriptive and inferential statistical analysis were applied including mean, SD, ANOVA, post hoc Scheffe, and Pearson correlation ($\alpha$<.05).

RESULTS: SNPE #4 move (21.47±5.62 $VO_2$ ml/kg/min) was the highest EE and showed statistically significant difference from other 7 moves (p<.05) such as T-move (15.72±4.23), SNPE #1 (13.70±2.70), L-move (11.62±2.31), SNPE #3 (10.28±2.85), SC-move (8.48±2.51), SNPE #2 (6.52±1.52), & C-move (5.31±1.05). The EI of SNPE moves calculated based on the MET by employing the measured $VO_2$. SNPE #4 (6.14±1.60) was classified into the vigorous intensity, and T-move (4.49±1.21), #1 (3.91±0.77), and L-move (3.32±0.66) were moderate EI. The other moves was determined as low EI, which were SNPE #3 (2.94±0.81), SC-move (2.42±0.71), #2 (1.86±0.43), & C-move (1.51±0.30) in order. HR, nevertheless, showed the different order of intensity such as SNPE #1 (123.54±17.56), #4 (121.83±18.43), T-move (107.69±17.93), #3 (107.22±18.65), L-move (98.93±14.89), SC-move (90.25±12.06), #2 (79.30±13.55), & C-move (75.63±11.42), respectively. It was significantly different among SNPE #1, #4, and other 6 moves (p<.05).

CONCLUSION: SNPE moves showed a wide range of EE, EI, and HR. SNPE #4 was the hardest exercise among SNPE moves, which can be the vigorous physical activity. Therefore, SNPE can be employed to develop a physical activity program as well as releasing a musculoskeletal pain.

## History

**A PERIOD OF RAPID DEVELOPMENT FOR EQUESTRIANISM IN CHINA: FROM 2015 TO 2020**

JIAXIN, L., LÓPEZ ADÁN, E., DE LA RUBIA, A.

*UNIVERSIDAD POLITÉCNICA DE MADRID. FACULATAS DE CIENCIAS DE LA ACTIVIDAD FÍSICA Y DEL DEPORTE.*

27th Annual ECSS Congress Sevilla/Spain, August 30-September 2 2022

A period of rapid development for equestrianism in China: from 2015 to 2020

Universidad Politécnica de Madrid

INTRODUCTION: Chinas domestic horses established the foundations for commerce, communication, and state infrastructure along the old Silk Road in China [1] As trade patterns changed, the use of horses changed from trade to a sport and recreation. Chinas modern equestrian business has developed significantly over the previous decades, and the expansion between 2015 and 2020 is essential, as

China implements further policies to aid in the development of modern equestrianism. The equestrian sport can propel the horse industry forward, and the horse industry is a unique business in that it integrates primary, secondary and tertiary sectors, with plenty of space for growth. With the “dual circulation” strategy published, the service sector is largely non-tradable. [2] A countrys economic development and national income are positively correlated with its service sector. [3] Sports play a large role within this sector. Equestrian sports also positive changed with the general environment of sports development. This study assesses the development of equestrianism in China from four perspectives: the general sports economic environment; the development of equestrian activities; the economic industries driven by equestrian activities; and relevant equestrian policies. Problems in the current development of equestrian sports are pointed out and recommendations are made.

METHODS: Document analysis will be used to assess policy and documentation that relate to sport, as well as to look for congruence and corroboration. The terms we used to search included a wide range of sectors.

RESULTS: During 5 years, China government publish 6 policies to push the whole equestrian sport development. In equestrian market value has increased 52.1% in four years. The number of equestrian clubs increased 1800. Horse breeding structure was built and more young people join in equestrian.

CONCLUSION: The equestrian industrys rise is due to the sports environment and the increase in consumer demand for equestrian activities. Policy encouragement, combined with the rapid growth of Chinas income in recent years, has fueled Chinas continuous upgrading of its sports consumption, and the demand for middle- and high-end sports such as equestrian which was previously considered a niche sport, now is becoming popular. In the future, the equestrian sport in China will be popular and Localized.

## Mentoring/Coaching

### THE EFFECTS OF THE TWO-YEAR METHODOLOGICAL TRAINING PROGRAM (MIP-NPET) ON THE WORK EFFICIENCY OF BEGINNING PHYSICAL EDUCATION TEACHERS

EKLER, J.H., LAPPINTS, R., KOLTAI, M., NÉMETHNÉ TÓTH, O., SZIVÁK, J.

*EÖTVÖS LORÁND UNIVERSITY*

INTRODUCTION

In recent decades, there have been several methodological training programs (e.g. ASIP) worldwide to increase the effectiveness of PE teacher work. Effective training programs consist of short units in several elements with different content. Professional aids and samples have a positive effect, these are available in many forms of data during the entire duration of the intervention. In our poster, we present the results of our own methodological training program for beginner PE teachers, which shows the effectiveness of PE teachers work.

METHODS

The sample consisted of 10 physical education teachers (fm: 5; m: 5) participating in the two-year Methodological Intervention Program for Novice PE Teachers (MIP-NPET). At the beginning of the program, they completed their PE teacher training and began their PE teacher work in elementary schools. During the MIP-NPET program, they participated in four training days and ongoing professional consultations. Their feelings about teaching (4 times, at the beginning and end of the program years) as well as their experiences of training in the program (after the 4 training sessions) were reported in reflective diaries. These diaries related to teaching were analysed based on two aspects: organization (organization of student work, discipline) and self-efficacy (motivation, differentiation), training diaries were analysed based on theoretical knowledge and practical knowledge.

RESULTS

Adapting in their own groups of learners what was taught in the trainings reinforced the belief of the beginners that motivation is the key to effective physical education teacher work. By learning a lot of learner-centered exercises and tasks, they have gained tools that can be used not only for motivation, but also for differentiated lesson management. A deeper understanding of the modern theory of motivation, differentiation and evaluation also helped to apply the methods more effectively. Participants highlighted the possibility of joint, practical testing of the tasks and contemporary professional discussions about their individual application experiences as a priority. Thinking together with peers, learning from each other and exchanging experiences were the main strengths of the training program. Applying the learned cooperative games and tasks, they found that they can be adapted well to groups of learners of different ages and compositions, and thus can be good tools for differentiation, motivation and discipline.

DISCUSSION

The opinion of the participants showed that the training program fulfilled the expectations placed on it, helped to solve the problems of starting a teaching job and expanded the professional and methodological repertoire of the career starters as well. The program effectively included specific organizational, procedural, and cognitive elements to increase support for teacher autonomy and to help translate elements of modern methodology learned in teacher education into teacher practice.

## Molecular Biology and Biochemistry

### EFFECTS OF DIFFERENT EXERCISE ON PGC1A/FNDC5/IRISIN PATHWAY EXPRESSION IN SKELETON MUSCLES OF RATS

LI, P.F., FANG, G.L., YANG, X.Y., LI, L., YU, T., TIAN, Y.

*CHINA INSTITUTE OF SPORT SCIENCE*

INTRODUCTION: The relationship between exercise pattern and PGC1α/FNDC5/Irisin regulatory pathway is a hot topic in energy balance research. The purpose of this study was to investigate the effects of different exercise on the expression of PGC1α/FNDC5 in soleus and extensor digitorum longus muscles and serum Irisin concentration of Sprague-Dawley rats.

METHODS: This experiment has been approved by the ethics committee of the unit. Thirty rats were randomly divided into 3 groups, namely control(Con) group, climbing ladder exercise (Lad) group, and treadmill running exercise (Tre) group. Lad group took an 8-week and once-every-3-day program of resistance exercise using a model of improved climbing ladder with load. Tre group took an 8-week treadmill running of aerobic exercise. Body weight of rats was measured before and after training, and the soleus and extensor digitorum longus muscles were isolated at 48h after exercise. PGC1α/FNDC5 mRNA and protein expression in skeleton muscles were detected by quantitative PCR and Western Blot respectively. And serum Irisin concentration was observed by enzyme-linked immunosorbent assay.

RESULTS: After an 8-week training, body weight of rats from both exercise groups were significantly decreased compared with Con group, indicating that strength or aerobic training had a significant physiological effect on rats. Compared with Con group, there were a differential expression of PGC1α/FNDC5 in soleus and extensor digitorum longus muscle of rats from Lad group; but in Tre group, PGC1α/FNDC5 mRNA and protein expression in soleus muscle of rats were not significantly increased (P>0.05) and PGC1α/FNDC5 protein expression in digitorum longus muscle of rats were not significantly increased (P>0.05). There was no statistical difference in the serum concentration of Irisin among there groups.

CONCLUSION: 1)8-week climbing ladder exercise with load induces differential expression of PGC1α/FNDC5 in soleus and extensor digitorum longus muscles of rats, but don't influence the serum concentration of Irisin. It is suggested that there may be a complex balance effect and antagonist mechanism after a long-term resistance exercise. 2)8-week treadmill running exercise don't significantly influence PGC1α/FNDC5 protein expression in those muscles, which is slightly different from that reported in some literatures. 3)Resisteance or aerobic exercise have effect on PGC1α/FNDC5/Irisin pathway expression in skeleton muscles of rats in different ways, but resistance exercise may be the preferred training mode to induce the expression of PGC1α/FNDC5/Irisin pathway in skeleton muscles of rats.

### RELATIONSHIPS BETWEEN MAXIMAL OXYGEN UPTAKE AND DIVERSITY AND PHYLUM COMPONENTS OF GUT MICROBIOME

YUN, S., LEE, M., JUNG, A.R., LEE, Y., LEE, H., LEE, D.T.

*KOOKMIN UNIVERSITY*

INTRODUCTION: Maximum oxygen uptake (VO2max) is a major indicator of aerobic exercise capacity, and the gut microbiome is a major factor that can affect health and immunity. The purpose of this study is to determine whether aerobic exercise capacity affects the gut microbiome.

METHODS: A total of 32 men participated (28.6 ± 5.1 yrs, 175.5 ± 4.4 cm, 76.3 ± 10.5 kg, 24.7 ± 3.0 kg/m2). And their physical activity level, intestinal health status, disease prevalence, medical history, and eating disorder were assessed before inclusion in the study. The basal level of gut microbiome was examined by stools collected one morning after a 10-hour fasting, and their VO2max was measured. Pearsons correlation analysis was performed to analyze the relationships between VO2max and the diversity and the phylum of gut microbiome. In addition, according to their VO2max, they were divided into Low (LG: mean VO2max of 36.9 ± 4.3 ml/kg/min) and High Aerobic Capacity Groups (HG: 45.6 ± 5.0 ml/kg/min), Independent t-test was performed to determine the differences between groups.

RESULTS: As the results, there was no significant difference in the correlation between VO2max and the diversity index (Abundance, Shannon, OTUs) of the gut microbiome and the phylum (Actinobacteria, Bacteroidetes, Candidatus Saccharibacteria, Cyanobacteria/Chloroplast, Firmicutes, Fusobacteria, Lentisphaerae, Proteobacteria, Verrucomicrobia). Between groups, there were no significant differences in Abundance, Shannon, and OTUs (LG: 50676.7 ± 19013.5, 4.6 ± 0.5, 125.7 ± 26.6 score vs HG: 44208.8 ± 13528.25, 4.5 ± 0.5, 125.0 ± 17.8 score, respectively). In Phylum, Bacteroidetes were higher in HG (55.3 ± 13.8 %) than LG (43.4 ± 14.9 %) (t=-2.349, p=0.026). In contrast, Firmicutes were higher in LG (49.3 ± 13.2%) than HG (39.0 ± 12.6%) (t=2.252, p=0.032). There were no significant differences in Actinobacteria, Candidatus Saccharibacteria, Cyanobacteria/Chloroplast, Fusobacteria, Lentisphaerae, Proteobacteria, and Verrucomicrobia between groups (LG: 0.799 ± 2.212, 0.005 ± 0.008, 0.002 ± 0.003, 0.479 ± 1.099, 0.000 ± 0.002, 5.992 ± 4.799, 0.450 ± .0115 % vs HG: 0.192 ± 0.184, 0.002 ± 0.005, 0.0004 ± 0.001, 0.056 ± 0.106, 0.009 ± 0.036, 5.371 ± 5.387, 0.044 ± 0.165 %, respectively).

CONCLUSION: The results of this study were consistent with previous studies reporting the intestinal distribution of microbiome in healthy people as this study showed a higher aerobic capacity with high Bacteroidetes and low Firmicutes. It is necessary to analyze specific constituent factors later.

### MITOCHONDRIAL TRANSCRIPTION FACTOR A AND MYOGLOBIN GENES VARIATIONS ARE ASSOCIATED WITH ENDURANCE PERFORMANCE IN LITHUANIAN ELITE ATHLETES

GINEVICIENE, V., UTKUS, A.

*VILNIUS UNIVERSITY*

INTRODUCTION: Different genetic elements have a significant impact on the components of sporting characteristics (such as endurance, power, sprint, flexibility etc.). Studies show that proteins in muscle fibers such as myoglobin (encoded by the MB gene) and mitochondrial transcription factor A (encoded by the TFAM gene) are actively involved in aerobic exercise. Myoglobin providing oxygen to the working muscles and TFAM plays an important role in the maintenance of mitochondrial DNA integrity. Therefore, the aim of this case-control association study was to investigate and evaluate MB (rs7293, c.174G>A) and TFAM (rs1937, c.35G>C, p.Ser12Thr) gene variants on the physical performance in Lithuanian elite athletes.

METHODS: A total of 224 elite athletes and 255 non-athlete controls (healthy unrelated Lithuanian citizens) were genotyped for MB rs7293 and TFAM rs1937 variants by restriction fragment length polymorphism method. Statistical analysis was performed using Rv3.2.

RESULTS: Significant TFAM rs1937 polymorphism genotypes distribution were determined between the athletes and controls (GG/GC/CC: 68,3/26,8/4,9% vs 80,0/18,7/1,2%, p = 0.04). Additionally, differences in TFAM CC genotype and C allele frequencies were observed between the group of endurance athletes (CC:4,9%; C alelis 18,3 %) and sprint-power (CC: 0%; C alelis 7,1%; p<0.05). Analysis of the MB rs7293 polymorphism showed that the G allele (58.8%) is more common among male athletes compared to men in the control group (G allele 49.4%; p <0.03) and the MB GG genotype is more common in the endurance group (38.3%) compared to the sprint-power group (27%), team game athletes (12.7%) and control group (27.5%) (p <0.05).

CONCLUSION: Our findings provide support for an association between MB rs7293 and TFAM rs1937 and athletic status in endurance sports. The MB GG genotype and TFAM CC genotype are associated with endurance performance and determines aerobic capacity in Lithuanian elite athletes. It can be argued that the MB rs7293 and TFAM rs1937 genetic markers can be interpreted as overexposing factors for high scores in elite endurance sports. However, these genetic variants should be studied in a larger group of athletes, and the association needs to be confirmed in other populations around the world.

### THE CARDIAC EFFECTS OF NUTRITION AND VOLUNTARY PHYSICAL EXERCISE ON THE RAAS AND OXIDATIVE/INFLAMMATORY PARAMETERS IN SPONTANEOUSLY HYPERTENSIVE STROKE PRONE RATS

SZABÓ, R.1, BÖRZSEI, D.1, HOFFMANN, A.1,2, GESZTELYI, R.3, GÁLÓCZI, I.1, PÁLSZABÓ, P.1, VARGA, C.1,2, PÓSA, A.1

*1:UNIVERSITY OF SZEGED, 2:HR-PHARMA LTD., 3:UNIVERSITY OF DEBRECEN*

INTRODUCTION: Hypertension is considered as a disease of civilization, because its development and progression are closely linked to unhealthy lifestyle. The aim of our study was to assess the effect of physical exercise in the complex biochemical underlying mechanisms of hypertension.

METHODS: In our study, male Wistar and spontaneously hypertensive stroke prone (SHRSP) rats were used and randomized into groups based on the type of diet (standard chow: CTRL, high-triglyceride diet with 40% lard, fructose-enrich diet with 10% fructose content) and exercise (voluntary wheel-running exercise or lack of the exercise). After 12 weeks of experimental period, myeloperoxidase (MPO) enzyme activity, tumor necrosis factor alpha (TNF-α) concentration; levels of superoxide-dismutase (SOD) and glutathione (GSH); changes in the renin–angiotensine–aldosterone-system (RAAS) as well as expression of endothelial nitric oxide synthase (eNOS) were measured in the cardiac tissue of both Wistar and SHRSP rats.

RESULTS: Compared to the values of the Wistar animals, a significant increase was observed in the inflammatory parameters of SHRSP/CTRL group, which was further elevated as a result of HT and HF diet. A similar tendency was confirmed in the changes of RAAS/angiotensin II, which was accompanied by decreased levels of GSH and SOD as well as down-regulation of eNOS. However, the unfavorable effects of HT and HF diets were compensated with 12 weeks of physical exercise.

CONCLUSION: Our results verify that either HT or HF diet can modulate the RAAS via increasing the inflammatory processes and the oxidative stress. However, 12 weeks of voluntary wheel-running exercise – via the improvement of the oxidant/antioxidant balance – significantly decreased the angiotensin II-mediated endothelial damage.

### ANDROLOGICAL EFFECTS OF SPORT: MODERATE-INTENSITY SWIMMING PROTECTS AGAINST ISOPROTERENOL-INDUCED OXIDATIVE STRESS IN A RAT TESTIS

PÓSA, A.1, SZABÓ, R.1, BÖRZSEI, D.1, PÁLSZABÓ, A.1, PÁLSZABÓ, P.1, VARGA, CS.1,2

*1: UNIVERSITY OF SZEGED, 2: HR-PHARMA LTD.*

INTRODUCTION: Male infertility is closely linked to sedentary lifestyle; however, its underlying mechanisms are not fully elucidated. Our aim was to assess the protective effects of swimming exercise on the male reproductive system in isoproterenol-treated rats.

METHODS: 8-month-old male Wistar rats were divided into five groups as follows: (1) non-interventional controls (CTRL), (2) isoproterenol-treated (ISO), (3) pretreatment swimming training + ISO (PRE+ISO), (4) ISO + posttreatment swimming training (ISO+POST) (5) pretreatment swimming training + ISO + posttreatment swimming training (PRE+ISO+POST) groups. Testicular oxidative stress was induced by ISO injection (1.0 mg/kg). Rats in the pre-or posttraining groups were trained 5 days a week for 3 weeks individually, in a 20 cm × 20 cm pool filled with ~60 cm depth of water of 32–33 °C. At the end of the experimental period serum testosterone levels, sperms' hyaluronan binding and total glutathione (GSH) content, myeloperoxidase activity (MPO), tumor necrosis factor-alpha (TNF-alpha), and interleukin-6 (IL-6) concentrations in the testis and semen were measured.

RESULTS: Serum testosterone levels, sperms' hyaluronan binding, and GSH content were significantly reduced, while MPO, TNF-alpha, and IL-6 concentrations in the testis and semen were elevated after the ISO treatment compared to the CTRL group. Moderate-intensity swimming exercise effectively alleviated the negative effects of high oxidative stress.

CONCLUSION: Our results provide the first evidence that moderate-intensity swimming exercise confers sustained protection from isoproterenol-induced adverse effects on testicular inflammation. These findings give insight into the biochemical background of the beneficial effects of moderate swimming training, which may serve as an effective approach to improve male fertility.

### OVERREPRESENTATION OF T ALLELE OF MCT1 RS1049434 POLYMORPHISM IN THE GROUP OF POLISH ELITE SPORTSMEN.

CIESZCZYK, P., HUMINSKA-LISOWSKA, K., DZITKOWSKA-ZABIELSKA, M., LEONSKA-DUNIEC, A., BOJARCZUK, A.

*GDANSK UNIVERSITY OF PHYSICAL EDUCATION AND SPORT*

INTRODUCTION: Both the scientific and sporting communities agree that genetic factors contribute to athletic performance. The estimated percentage of the heredity of athletic status is 66%. Currently, around 155 genetic markers are linked to endurance and strength/power traits. Thus, we aimed to investigate whether selected MCT1 rs1049434, NRF-2 rs12594956, MYBPC3 rs1052373, HFE rs1799945 polymorphisms, which have been described as associated with elite sprint/power abilities, are associated with endurance capacity of the high-elite Polish athletes.

METHODS: 53 power and 48 strength high-elite Polish athletes- Olympic Championships medallists were included in a study. Additionally, the control group consisted of 41 healthy Polish individuals. WGS was performed using the following parameters: 150PE, 30x coverage, at least 90GB of data/sample. The following filters were applied per each group: mean GQ > 50, mean DP > 5, HWE p-value > 0.05.

RESULTS: 74 variants in the MCT1 gene, 47 variants in the MYBPC3, 158 variants in the NRF-2 (GABPB1), and 33 variants in the HFE passed all filters and underwent data analysis. We focused on MCT1, MYBPC3, NRF-2 and HFE polymorphisms . Out of all analyzed polymorphisms, only one did not meet HWE criteria - MCT1 rs1049434. This was due to an excess of T allele only in Polish elite athletes. No statistically significant between-group differences were found for any of analyzed polymorphisms.

CONCLUSION: Our study provides evidence of the overrepresentation of the T allele of MCT1 rs1049434 polymorphism in the group of Polish elite sportsmen, leading to a violation of the Hardy-Weinberg assumption. Small group size could lead to such results and therefore future research should include a higher number of participants.

### EFFECT OF LACTIC ACID TREATMENT ON BRAIN FUNCTION-RELATED VARIABLES IN CELL CULTURE AND RATS

KIM, K., AHN, N., LEE, G., KIM, Y.

*KEIMYUNG UNIVERSITY*

INTRODUCTION: As the association of lactate production (Schiffer et al., 2011) was suggested as an important mediator related to the increase in BDNF during exercise, the increase in lactate produced during exercise could act as an important mediator of brain function activation rather than a cause of fatigue. Does the increase in lactic acid produced during exercise act as an important mediator of brain function activation by hippocampal BDNF expression? In addition, there is a need to clearly identify the molecular biological mechanism involved.

METHODS: Expression of brain function-related factors including MCT2, GPR81, and BDNF after treatment with lactic acid and saline and silence treatment of MCT2 and GPR81 to β-amyloid-treated cells to induce brain function decline by applying the brain astrocyte culture method were analyzed by Western Blotting and RT-PCR. Additionally, by injecting lactic acid into the abdominal cavity of rats, the protein expression patterns of molecular variables related to brain function were analyzed.

RESULTS: Cell viability of C6 glioma cells was significantly slowed after β-amyloid treatment, but recovered after lactate treatment. After β-amyloid treatment, the protein expression levels of MCT2, GPR81, and BDNF were significantly decreased, and after lactate treatment, the protein expression levels of MCT2 and GPR81 were remarkably recovered. After treatment with β-amyloid and lactate, the expression levels of mRNA by item did not show any significant results. When MCT2 and GPR81 were silenced and then lactate was treated, the protein and mRNA expression levels of MCT2, GPR81, and BDNF were significantly recovered. In the hippocampus of rats treated with lactic acid, MCT2 and BDNF protein expression were relatively activated compared to rats treated with saline.

CONCLUSION: Lactate treatment significantly helps in the recovery of cell viability, and it is highly likely to have a positive effect on brain function activation as it helps to activate MCT2, GPR81, and BDNF protein and mRNA expression levels. ## Motor Learning and Motor control

### INFLUENCE OF AGEING ON FEED-FORWARD AND FEED-BACK CONTROL IN POSTURE STABILITY

EDAMATSU, C.1, TAKAHASHI, K.2, USUI, J.1, MIYAKAWA, T.3

*1. KURASHIKI UNIVERSITY OF SCIENCE AND THE ARTS, 2. TOKYO ARIAKE UNIVERSITY OF MEDICAL AND HEALTH SCIENCE, 3. KAWASAKI UNIVERSITY OF MEDICAL WELFARE*

INTRODUCTION: Few studies have examined the influence of aging on dynamically characteristic of posture sway. The purpose of this study was to investigate the influences of aging on feed-forward and feed-back control in posture stability.

METHODS: Twenty-one older subjects (69.2±5.6 years) and Six healthy young subjects (21.5±0.5 years) participated in this study. Stabilographic examinations were performed. The time-series data for the COP were acquired at 100 Hz with a 30-s sampling time. We calculated the directional change of COP trajectory by using Nagano method (Nagano et al. 2010). This method can analyze the dynamic characteristics of postural control.

RESULTS: The directional change of COP sway in the feed-forward phase of older subjects were significantly smaller than that of young subjects. This implies that the COP sway of young subjects displayed a random-like nature as one would expect from predictive postural control in the feed-forward phase. Meanwhile, the directional change of COP sway in the feed-back phase of older subjects were significantly larger than that of young subjects. This maybe because older subjects compensate the degradation of postural sway of feed-forward phase in feed-back phase.

CONCLUSION: It has become clear that dynamically characteristics of posture sway of older subjects were maintained movement at feed-forward phase and enlarged movement in the opposite direction at feed-back phase.

### ANTICIPATION AND SPLIT STEP EFFICIENCY IN EXPERT TENNIS PLAYERS (FEDERER VS DJOKOVIC, 2019 WIMBLEDON FINALS)

DIMIC, M., FURUYA, R.

*WASEDA UNIVERSITY, TOKAI UNIVERSITY*

INTRODUCTION: The efficiency of the split step is usually observed and taught from the aspect of force production. But without the acknowledgment of the hitter's stroke intention, split step is performed as a neutral preparatory vertical jump with the body weight equally distributed and without lateral preference. Due to the high spatiotemporal demands of the tennis game, expert tennis players tend to decide of the movement direction and intensity while still being above the ground (Uzu et al., 2009). The decision of how the body weight will be distributed at the time of the landing presents the crucial decision for the split step efficiency at the landing sequence (Melvill-Jones & Watt 1971; Lees 1981; McNitt-Gray 1993)

METHODS: We observed the split step performance of two expert players, Federer and Djokovic, at the Wimbledon finals match. The speed of play should be highest on grass (ODonoghue & Ingram, 2001) demanding the most efficient movement responses. Expert performance observed in situ should provide the most relevant information of the essential behavior needed for the performance to be successful (Ford et al., 2009). Guided by the Mecheri et al. (2019), we observed receiver's split step from the two phases, dependable on the hitters stroke movement: 1. Split-step take-off (air phase) when receiver's foot in contact with the court left the ground initiating the split-step; 2. Split step landing phase when the receiver's foot touched the ground and lateral step as the directional movement is initiated.

To create intensified lateral step (pivot), experts tend to supinate ankle joints (inwards) during the air phase enabling more explosive pronation (outwards) during the landing. By pivoting the leading foot towards the ball direction, players initiate rotations of the whole unit of the body (toe-knee-hip-shoulder) towards the impact zone (Vaverka et al., 2003). Obviously, if the receiver has intention of intensifying the lateral movement when landing, the decision of supination made at the pre-contact phase of the stroke should be based on the perception of the hitter's movement at the stroke set-up phase, or even before. Therefore, the SUP movement should be considered as crucial aspect of the anticipatory movement competency of the expert tennis players with decision of its execution made based on the observation and prediction

RESULTS: Our expectation was that the supination to pronation (SUP) sequence is the most frequent pattern in the anticipatory split step response. The sequence timely relates to the receiver's air phase (decision about the response) and hitter's pre-contact movement. Our data show that efficiency of the responsive decisions made at the air phase (accuracy of the SUP split step pattern) could be of highest importance for the outcome of expert's performance

CONCLUSION: Training split step from the decision-making perspective should improve movement competency of tennis players, speeding up the reaction time by observing the game context and its dynamics

## EFFECTS OF TONGUE POSITION ON POSTURE STABILITY: A PILOT STUDY

ORRÙ, S.1,2, CAPOLONGO, D.1, CAPOBIANCO, A.1, MARTONE, D.1,2, BUONO, P.1,2, MANCINI, A.1,2

*1 DIPARTIMENTO DI SCIENZE MOTORIE E DEL BENESSERE, UNIVERSITÀ DEGLI STUDI DI NAPOLI "PARTHENOPE, ITALY; 2 CEINGE BIOTECNOLOGIE AVANZATE S.C. A R.L., NAPLES, ITALY*

INTRODUCTION: Body posture has been shown to be affected by various factors, including vision, trigeminal afferents, head-neck position and proprioception. Jaw and neck regions share anatomical, biomechanical and neurological links; in addition, dental occlusion status contributes to the maintenance of postural balance. Here we investigated the effects of the tongue-mediated activation of trigeminal nerve endings, located at the Palatine Spot (PS), on postural parameters of healthy active adults.

METHODS: Seven active men (age 26.6 ± 3.6 yrs; height 176.9 ± 4.7 cm; weight 79.4 ± 9.0 kg; BMI 25.4 ± 2.9 kg/m2) and seven active women (age 26.0 ± 3.4 yrs; height 165.4 ± 9.7 cm; weight 58.3 ± 7.5 kg; BMI 21.3 ± 1.8 kg/m2) were recruited. Specific postural parameters were recorded using the DIERS Pedoscan platform: the sways of the Center of Pressure at the left and right foot (CPL and CPR) and the sways of the Center of Mass (CoM); sways were monitored on the antero-posterior (AP) and on the medial-lateral (ML) planes. Static and dynamic balance were evaluated with/without tongue positioned at the PS.

RESULTS: During the static balance test, when tongue was located at the palatine spot, men significantly reduced CoM sways at the ML plane ($p<0.05$); a similar behavior was observed when male and female data were grouped ($p<0.05$). Considering the dynamic balance, we observed a significant reduction of AP sways in the CoM of grouped men and women ($p<0.05$). Interestingly, within all considered groups (men, women, all), the AP sways of CPL and CPR were always significantly higher compared to ML ones, both during the static and the dynamic balance tests ($p<0.05$); nevertheless, when the tongue position was evaluated, no statistical significance was observed.

CONCLUSION: This pilot study confirms how the correct tongue position within the mouth is instrumental to get a better posture. In particular, the activation of the trigeminal nerve endings allows to reduce the ML sways of CoM in the static balance, whereas it reduces the AP sways of CoM in the dynamic evaluation.

## RELIABILITY OF THE COUNTERMOVEMENT VERTICAL JUMP PERFORMANCE AFTER VERBAL INSTRUCTIONS RELATED TO DOWNWARD MOVEMENT PHASE EXECUTION.

AÑÓN-HIDALGO, M.1, BUSQUETS, A.1, FERRER, B.1, SÁNCHEZ-SIXTO, A.2

*[1] INSTITUTO NACIONAL DE EDUCACIÓN FÍSICA DE CATALUÑA , UNIVERSITAT DE BARCELONA , BARCELONA, SPAIN [2] CENTRO DE ESTUDIOS UNIVERSITARIOS CARDENAL SPINOLA CEU, BORMUJOS, SPAIN.*

INTRODUCTION: The vertical countermovement jump (CMJ) performance is influenced by the execution of the downward movement phase (1). The instructions given to the athletes prior CMJ execution could influence the CMJ performance and the biomechanical variables obtained (2). However, the cues given could affect the consistency of the biomechanical variables of the CMJ. The present study evaluated the reliability of the biomechanical variables of the CMJ after different cues.

METHODS: Fifteen healthy adult participants habituated to performing CMJs (age: 21.4±2.95 years) performed 3 CMJ after the instruction "jump as high as possible" (CMJP), 3 CMJ after the instruction "jump as high as possible after descending slower" (CMJS) and 3 following the instruction "jump as high as possible after descending as fast as possible" (CMJF). The jumps were performed on a force platform (1000 Hz). Force data of each jump were used to calculate: time of downward movement phase (ECC_t), maximum velocity achieved in the downward movement phase (ECC_v), rate of force development in downward movement phase (ECC_RFD), estimated minimal center of gravity height (min_h), and take off velocity (TO_v). After checking normality and heterocedascity assumptions, reliability of the CMJs following each verbal instruction was assessed. Systematic error (ANOVA for repeated measurements), relative reliability (coefficient of variation, CV, and intra-class correlation, ICC), and absolute reliability (standard error of measurement, SEM, and minimum detectable change, MDC) were evaluated.

RESULTS: Only ECC_t in the CMJS showed differences between attempts (systematic error) where the descent time of the first attempt was longer than the second. The relative reliability of the downward movement phase variables (ECC_t, ECC, ECC_RFD) following the different instructions was low. CV between 6.51% and 28.58% and the ICC presented very dispersed values (ICC 95% CI lower and higher values were separated by up to 40%). The CMJF presented the lowest variability in these three variables. Also, the downward movement phase variables showed higher variability when looking at relative reliability, where the ECC_RFD had the highest SEM and MDC values in the CMJS and CMJP. On the other hand, the variables min_h and TO_v showed lower variability and greater consistency between attempts being CMJF the condition with the less reliability.

CONCLUSION: The CMJ following verbal instructions to modify the downward movement phase does not affect the repetitiveness of the test, which in general is usually moderate (3). CMJ following the instruction to descend as fast as possible seems to have the advantage of greater reliability in the downward movement phase execution but, in turn, it loses repeatability in the jump performance.

**EARLY DEVELOPMENT OF CHILDREN'S DROP-LANDING MOVEMENTS COORDINATION**

BUSQUETS, A.1, FERRER-URIS, B.1, FEDEROLF, P.2, ANGULO-BARROSO, R.1,3

*1 INSTITUT NACIONAL DEDUCACIÓ FÍSICA, BARCELONA, SPAIN 2 DEPARTMENT OF SPORT SCIENCE, UNIVERSITY OF INNSBRUCK, INNSBRUCK, AUSTRIA 3 KINESIOLOGY, CSUN, LOS ANGELES, USA*

INTRODUCTION: Drop-landing develops as a motor skill during childhood [1]. Knowing more about how children coordinate movements during landing will give us the opportunity to better equip individuals with proper technique and prevent potential injuries. Principal component analysis (PCA) can be used as a holistic approach to quantitatively describe movement coordination [2]. Our aim was to assess drop-landing movement coordination of young children related to predictable or unpredictable actions after landing.

METHODS: Forty-two children in four age-groups (G1=3-4.5 yrs, G2=4.5-6 yrs, G3= 6-7.5 yrs, and G4=7.5-9 yrs) were equipped with body landmark markers. They were asked to perform20 drop-landings on two force plates in four conditions. One where participants were aware of what to do after landing (participants had to remain stable and stationary); and three where participants did not know what do until they contacted the force plates and a light cue switched on (landing and remain stable and stationary, landing and run to the left, and landing and run to the right). PCAs were calculated for the pre-impact phase (300 ms before impact) and the absorption phase (650 ms after impact) on normalized and weighted markers coordinates and yielded the principal movement components (PPs). Waveform PCA analysis [3] was conducted for each PP. First and second Waveform-scores and their variability were submitted to repeated measures MANOVA (Age-group x Condition).

RESULTS: Only differences by age-group were found. During the beginning of the pre-impact phase, G1 abducted the legs with slight hip flexion while separating the arms and moved more the trunk-head-arms in the saggital plane than the other groups. In the middle of the phase, G1 decreased the amount of movements of the trunk-head-arms in the saggital plane and presented smaller use of knees extension while moving slightly up their arms. Also, G1 always presented higher variability than the other groups in this phase. During the absorption phase, G1 moved more the arms at the beginning of the phase while in the middle of the phase they increased the use of the hip-knee-ankle flexion-extension and the arm abduction-adduction. Also, G1 showed a trend to decrease the use of ankle flexion and CoM movement at the end of the phase. On the other hand, G2 mainly did not show differences with the other groups in the absorption phase.

CONCLUSION: The results suggest that (1) drop-landing movement coordination development could be related with age and it is not affected by the predictability of the action after landing at this young ages; (2) the youngest children have not acquired pre-impact movement coordination and they explored how to perform this part of the task showing larger variability; and (3) a transition to more consolidated and experienced coordination occurs between the ages of 4.5 to 6 years.

**SUCCESSFUL REHABILITATION THROUGH NEUROMUSCULAR STIMULATION-BASED TRAINING OF ASTASIA-ABASIA GAIT IN A LADY MIMICKING LEFT HEMISPHERIC SYNDROME STROKE**

OEY, N., TAN, Y.L.

*SINGHEALTH RESIDENCY*

INTRODUCTION: Psychogenic somatoform disorders may manifest as stroke mimics in the form of bizarre gait abnormalities. Here we describe the inpatient rehabilitation course of a patient who was admitted with initial concerns of recurrent falls, but whose stroke workup was entirely negative. She was severely disabled on admission, unable to walk independently, with examination revealing an astasia-abasia gait pattern mimicking unilateral monoparesis of the right lower limb. The patient underwent a period of successful neuromuscular conditioning incorporating manual, myofascial, and transcutaneous electrical stimulation which resulted in a dramatic increase of her gait speed from 0.01m/s to 0.5m/s, along with subsequent near-normalization of her gait pattern and return to independent living.

METHODS: During the course of a 4-week inpatient rehabilitation regime, a baseline measurement of gait speed, Berg Balance Score, Trunk Impairment Scale, and Timed Up and Go test was performed. Strength was quantified using the modified Research Council grading criteria before and after the rehabilitation programme. A combination of manual therapy, body weight-assisted gait training, and neuromuscular electrical stimulation using submaximal near-tetany amplitudes of 35-40mA was used on the patients iliopsoas, quadriceps, and tibialis anterior, in order to achieve a near-normal gait pattern. Gait speed was measured pre- and post-intervention.

RESULTS: A video recording of the patients gait pre- and post-intervention showed a clear improvement in the gait pattern, foot placement, and gait speed. Objective measures of balance and gait parameters including TUG (60secs to 25secs), BBS (18 to 30 points), TIS (5 to 15 points), and gait speed (0.01m/s to 0.5m/s) were obtained, indicating improved performance. Functional Independence Measure scores improved from 50 to 75.

CONCLUSION: The rehabilitation of patients with conversion disorder has been reported, but the utility of neuromuscular stimulation in cases of severe gait abnormalities has hitherto never been reported. Here we report a case of the successful use of NMES therapy in combination with physical therapy and gait retraining for a middle-aged woman with psychogenic functional gait disorder, and present a potential programme to be applied for patients with a similar condition.

## Neuromuscular Physiology

**HAMSTRING ACTIVITY DURING NORDIC HAMSTRING EXERCISES AND RAZOR CURLS ON FLAT AND SLOPED PLATFORM**

SOGA, T., HAKARIYA, N., SAITO, H., NAKAICHI, N., AKIYAMA, K., HIROSE, N.

*WASEDA UNIVERSITY*

INTRODUCTION: Hamstring strain injury (HSI) frequently occurs in the biceps femoris long head (BFlh) during high-speed running. Since the injury situation of HSI occurred in the late swing phase during high-speed running, hamstring exercise with high activity in the elongated position of the BFlh is recommended to HSI prevention. Although the conventional Nordic hamstring exercise (NHE) predominantly activates the semitendinosus muscle (ST), it has been reported that utilizing a sloped platform reduces the activity of the ST. Razor curl (RC) may also change their hamstring activity patterns due to different angles of the platform. Therefore, the purpose of this study was to investigate whether different angles of the platform would change the activity of the hamstring and the the BFlh length at peak BFlh

electromyography (EMG) activity during the RC. The purpose of this study was also to compare RC and NHE for those changes caused by different angles of the lower leg slope.

METHODS: This study adopted a crossover design. Twelve male volunteers (age 23.3 ± 2.5 y, height 169.9 ± 4.8 cm, weight 66.4 ± 7.3 kg, mean ± SD) participated in this study. Participants randomly performed following tasks: NHE with the platform angle set at 0° (NH), NHE with the platform set at 40° (N40), RC with the platform angle set at 0° (RC), and RC with the platform angle set at 40° (R40). The peak EMG activity of BFlh and ST during tasks was normalized by the value of peak EMG activity during maximum voluntary isometric contraction of prone leg curl with knee flexion angle set at 45°. To calculate the BFlh length at peak BFlh EMG, the EMG and kinematic analysis were synchronized using a trigger mechanism. The BFlh length was calculated by the flexion angles of hip and knee. Statistical analysis was performed using two-way ANOVA (within-factor: NH, N40, RC, and R40; between-factor: BFlh and ST). In addition, statistical analysis was also performed using one-way ANOVA (within-factor: NH, N40, RC, and R40). The significance level was set at $p < .05$.

RESULTS: The BFlh %MVIC was significantly higher for NH than RC ($p < .05$). In addition, the BFlh %MVIC was significantly higher for N40 than R40 ($p < .05$). The ST %MVIC was significantly higher for NH than N40 ($p < .05$), RC ($p < .05$), and R40 ($p < .05$). A significant difference between BFlh %MVIC and ST %MVIC was observed in NH ($p < .05$), and RC ($p < .05$).

The BFlh length at peak BFlh EMG of NH was significantly lower than those of N40 ($p < .05$), RC ($p < .05$), and R40 ($p < .05$). In addition, the BFlh length at peak BFlh EMG was significantly lower for N40 than RC ($p < .05$).

CONCLUSION: Although the RC is often prescribed a hamstring exercise which is specific to the late swing phase of high-speed running, it is recommended to utilize other exercises to compensate for the lower activity of hamstring for HSI prevention.

## EFFECT OF 10 DAYS OF UNILATERAL LOWER LIMB SUSPENSION ON NEUROMUSCULAR CONTROL

LEBESQUE, L., NARICI, M.V., MARTIN, A., SARTO, F., SCAGLIONI, G.

*UNIVERSITÉ BOURGOGNE FRANCHE-COMTÉ*

INTRODUCTION: Segmental limb reduction in mechanical loading may occur as a consequence of surgery, injury or illness, but also result from a reduced daily physical activity or a decreased gravitational input. An extensive literature shows that neuromuscular function is rapidly impaired by disuse in the first days of unloading (1), with muscle function-dependent specificities (2). Anti-gravity muscles, for instance, and knee extensors (KE) in particular, appear to be the most susceptible to unloading-related atrophy and contractility impairments (3). Regarding neural adaptations, despite an impaired muscle activity, the literature generally reports a preservation of the central neural drive and an enhancement of spinal excitability following the muscle inactivity period (1). However, because it is simpler and less binding for the subject to assess lower limb spinal excitability on the soleus, no data are available for KE. Thus, this investigation sought to identify the neural and muscular mechanisms involved in the loss of KE strength after 10 days of muscle unloading.

METHODS: Ten healthy volunteers (age: 22.9 ± 4.0 years old; body mass index: 22.9 ± 2.1 kg/m2) participated in this investigation. A testing session was conducted before (BLS1) and after (LS10) 10 days of unilateral lower limb suspension (ULLS). In each session, the KE function was assessed through the measure of cross-sectional area (CSA), maximal voluntary contraction (MVC), specific force (MVC/CSA) and maximal voluntary activation level (VAL). In addition, electrical stimulations were delivered over the femoral nerve to elicit maximal H-reflex (HMAX) and M-wave (MMAX) of the vastus medialis (VM) muscle at rest. We calculated the HMAX/MMAX ratio which is an index of spinal excitability. To assess nerve conduction velocity, the latencies of both HMAX and MMAX were also measured.

RESULTS: The MVC (-27.1 %, $p < 0.0001$), CSA (-4.4 %, $p = 0.007$), MVC/CSA (-23.7 %, $p = 0.0001$) and VAL (-5.5 %, $p = 0.013$) significantly decreased after the ULLS. Compared to BLS1, VM MMAX was unchanged at LS10 while HMAX/MMAX ratio increased by 33.1 %. The ULLS increased the VM MMAX latency whereas it did not modify the HMAX latency.

CONCLUSION: The protocol consisting of 10 days of ULLS resulted in a reduction in KE strength. The impairment in muscle performance is attributable to adaptations in both muscle structure and neural function. The decrease in voluntary activation is accompanied by an increase in spinal excitability. These observations suggest that presynaptic inhibition and/or post-activation depression of Ia afferents are reduced by disuse in KE, as already observed in PF. In addition, these findings imply that, contrary to most previous studies (1), unloading interferes with motor unit activation.

## DO STIFFNESS CHARACTERISTICS INFLUENCE CHANGE OF DIRECTION ABILITY IN BADMINTON PLAYERS?

ZHIHAI, W.1, MINGMING, Y.1, KAIYUAN, Q.1, XINYU, M.1, XIN, Y.1, JIAYU, Z.1, XIAOWEN, C.1, YU, C.1, ANQI, L.1, DAN, W.1

*SHANGHAI UNIVERSITY OF SPORT*

INTRODUCTION: Change of direction (COD) ability is a key predictor of athletic performance in badminton players [1], and stiffness may be one of the important factors affecting COD ability in badminton players [2-3]. The objective of this study was to investigate whether stiffness characteristics could influence the COD performance.

METHODS: A total of 15 badminton masters and first-class athletes (9 males: 19.8 ± 2.5 yr, 180.0 ± 7.0 cm, 71.0 ± 9.9 kg; 6 females: 20.2 ± 1.2 yr, 169.0 ± 7.0 cm, 60.0 ± 7.5 kg) were recruited in the study. A dynamic weight-bearing vest warm-up ((10% of body weight)) has been proved to improve COD ability. Prior to the warm-up (T0) , stiffness of soleus, gastrocnemius medialis (GM), and Achilles tendon (AT) for both sides were evaluated by MyotonPRO (MyotonPRO, Myoton AS, Tallinn, Estonia); vertical stiffness (Kvert) was measured by a force plate (Kistler Instruments, Winterthur, Switzerland) for both legs; COD ability was assessed by the badminton half-court agility test [6]. These variables were repeated measured at T0, 0-6 min following the warm-up (T1), 7-12 min following the warm-up (T2) and 13-18 min following the warm-up (T3). One-way repeated measures ANOVA and covariance analysis were used for data analysis.

RESULTS: There was a significant interaction effect in time for athletes COD ability at T1, T2 and T3 compared to T0 ($F=13.948$, $P<0.001$, $\eta 2p =0.499$). Bonferroni post hoc test showed that COD ability at T1 ($P =0.018$), T2 ($P=0.010$) and T3 ($P =0.004$) were significantly improved compared to it at T0. Right AT stiffness measured at T3 was significantly increased compared to those at T0 ($P=0.024$) and T1 ($P=0.039$). Compared to left soles stiffness at T1, it was significantly increased at T 2 ($P=0.047$). Right GM stiffness at T3 was significantly increased compared to it at T2 ($P=0.049$). The analysis of covariance discovered that right AT stiffness ($P=0.081$), left soleus stiffness ($P=0.531$) had an effect on COD ability improvement.

CONCLUSION: The increased stiffness of the right AT and left soleus muscle following a dynamic weight-bearing vest warm-up may be one of the mechanisms leading to the improved COD ability in badminton players.

## Nutrition

### EFFECTS OF DIFFERENT DOSES OF ANTIOXIDANTS(VITAMIN E) INTAKE ON EXERCISE INDUCED OXIDATIVE STRESS, ANTIOXIDATIVE CAPACITY AND CHRONIC INFLAMMATION

SUZUKI, R.

*KYORIN UNIVERSITY*

INTRODUCTION: Antioxidant enzymes are produced in a living body to defend against exercise induced oxidative stress. However excessive oxidative stress causes chronic inflammation. Therefore, it has been considered beneficial to supplement antioxidants from outside of the body to enhance protective function to the oxidative stress. On the other hand, since appropriate oxidative stress by exercise may generate improved carbohydrate metabolism and antioxidant enzymes production, excessive exogenous antioxidants may rather suppress beneficial effects of exercise. Indeed, several studies have shown disadvantageous effects of exogenous antioxidants during exercise intervention, while the others have not. The inconsistent findings may be due to the fact that each of the previous studies examined effects of a single dose of exogenous antioxidants on a single load of exercise. Therefore, it would be expected to conclude the debate by examining effects of several exogenous antioxidant doses on different loads of exercise intervention. The purpose of this study was to investigate effects of two levels of exercise stress and exogenous antioxidant doses on the exercise induced oxidative stress, antioxidant capacity and chronic inflammation.

METHODS: Wistar male rats were divided into two groups; sedentary (SED) and exercise (TR). The exercise was gradually increased from 4 weeks of low-intensity (90min/week) to 4 weeks of high-intensity (300min/week). The total duration was 8 weeks. TR was subdivided into low (70 mg/kg: TR+N), medium (350 mg/kg: TR+VE-M), and high (700 mg/kg: TR+VE-H) according to the amount of vitamin E (VE) intake. Oxidative stress (d-ROMs), antioxidative capacity (BAP) and chronic inflammation (hsCRP) were measured with blood sample before and after each of exercise loads using FREE Carrio DUO (WISMERLL) and ELISA. Antioxidant enzymes (SOD) were measured with leg muscles by Western blotting only after the whole exercise intervention.

RESULTS: d-ROMs increased as exercise intensity was augmented in all TR, and was higher in TR+N and TR＋VE-M than in SED after high-intensity exercise ($p<0.05$), while it was not different between SED and TR+VE-H. BAP increased in TR+VE-M and TR+VE-H after high-intensity exercise as compared with before ($p<0.05$). hsCRP increased in TR+N ($p<0.05$) and TR+VE-H ($p=0.055$) after high-intensity exercise as compared with before, but it did not increase in TR+VE-M. SOD was higher in the TR+N group in the soleus muscle.

CONCLUSION: The present results suggested that oxidative stress increased in an exercise loads dependent manner regardless of VE intake dose, and that a medium dose of VE with high-load exercise mostly reduced chronic inflammation, while a high dose of VE might exacerbate the inflammatory response. Taken together, these findings suggest the presence of the appropriate dose of exogenous antioxidants dependent on exercise loads.

### NEW ZEALAND BLACKCURRANT EXTRACT ENHANCES INTERMITTENT, HIGH-INTENSITY RUNNING CAPACITY, INDEPENDENT OF PREDICTED MUSCLE FIBRE TYPE

PERKINS, I.C., BLACKER, S.D., WILLEMS, M.E.T.

*UNIVERSITY OF CHICHESTER*

INTRODUCTION: New Zealand blackcurrant (NZBC) extract has been shown to enhance exercise performance, although inter-individual variations are common (1, 2). Many factors may contribute towards the inter-individual variation (3). Previous work suggested that NZBC extract may have muscle fibre type (FT) specific responses (4). The aim of this study was to examine the influence of predicted muscle (FT) distribution on the inter-individual response to NZBC extract on intermittent, high-intensity running capacity (IHIRC).

METHODS: Familiarised active males (n = 16, age: 23±3 yrs, height: 179±5 cm, mass: 79±11 kg, $\dot{V}O_2max$: 55.3±5 mL/kg/min, M ± SD) completed a fatiguing isometric protocol (FIP) to predict muscle FT distribution (5). Participants completed the Intermittent High-Intensity Treadmill based Running Capability test (Int. HIT-RC) (2) on four occasions; twice after 7 days NZBC extract (210 mg anthocyanin) & twice after placebo (PL) (double blind, randomised, cross-over design, wash-out ≥14 days). IHIRC was measured via total running distance (TRD) & high-intensity running distance (HIRD). Data from the two PL & two NZBC trials were pooled & paired-samples t-tests were used to compare differences between mean PL & mean NZBC IHIRC, with significance accepted at $p<.05$. Pearsons correlation coefficient was used to examine the relationship between change in IHIRC & FIP force decline. Participants were categorised into predominant type I (n=4) & type II (n=2) muscle fibre subgroups for individual analysis (5).

RESULTS: TRD was significantly greater following NZBC (4107±780m) compared to PL (3779±862m) ($p<.01$). HIRD increased by 8.4% after NZBC (2630±517m) compared to PL (2415±552m) ($p<.01$). There was no significant correlation between FIP force decline & IHIRC following NZBC ($p>.05$). In participants with predominant type I muscle fibres (n=4), HIRD increased by 10.9% following NZBC (2749±702m) compared to PL (2478±743m). Type II subgroup (n=2) showed a 4.6% decrement in TRD following NZBC (2761±237m) compared to PL (2878±13m).

CONCLUSION: Predicted muscle FT may have an influence on inter-individual responses to NZBC extract, with the type I subgroup showing greater improvements in IHIRIC, compared to type II subgroup. Previous work also suggested increased fatigue resistance in predominant type I muscle fibre subgroups (4).

No association was observed between FIP force decline & IHIRIC when analysing the full data set, suggesting other inter-individual differences, such as absorption, distribution, metabolism, & excretion (3) of blackcurrant anthocyanins may influence response to NZBC extract when muscle FT distribution is not clearly categorised in subgroups (Type I or Type II).

## REACTIVE DIVING AND SPRINTING PERFORMANCES IN SOCCER GOALKEEPERS IMPROVED BY CAFFEINE CONSUMPTION AND POST- ACTIVATION PERFORMANCE ENHANCEMENT

IMPEY, J.

*NELSON MANDELA UNIVERSITY*

INTRODUCTION: Goalkeepers are typically the last line of defence and perform a very specialised role in team sports such as hockey and soccer. The most decisive moments for goalkeepers in match-play are often dictated by the ability to make a save, which involves explosive actions such as dives and jumps.

METHODS: The purpose of this study was to assess the effect of caffeine and post-activation performance
enhancement (PAPE) on reactive sprinting and diving times in goalkeepers.

A total of twenty-five goalkeepers (soccer; n= 25) participated in the study (age: 21.68 * 2.21 years; height: 1.74 ‡0.05 m; weight: 74.30 € 11.71 kg; playing experience; 8.48 +: 4.05 years).Numerous tests which assessed simple and complex reaction/movement times for various treatments were completed.

RESULTS: Within-group differences were present for the treatments, showing that
reactive sprinting and diving times were
enhanced by 5.17 and 14.34%, respectively,
under caffeine consumption, and by 4.25
and 13.60%, respectively, under plyometric
conditions. Caffeine and plyometric trials
were not significantly different for sprinting
(MaN = 0.013s, p= 0,817) and diving
(MaN = 0,000 s, p= 0,999), respectively.

CONCLUSION: Firstly, neuromuscular perturbations in the form of caffeine consumption or plyometric drill implementation are effective in improving goalkeeper performance, and may likely be related to increased information processing speed and/or enhanced lower extremity force production capacities.

## EATING HABITS AND FOOD ATTITUDES OF CLIMBERS IN HIGH MOUNTAIN CONDITIONS

KARPECKA-GALKA, E., FRACZEK, B.

*UNIVERSITY SCHOOL OF PHYSICAL EDUCATION IN CRACOW*

INTRODUCTION: Due to the negative effects of weather and environmental conditions, mountain climbers are exposed to the risk of health deterioration and even loss of life. Proper preparation for the expedition, in particular taking care of factors influenced by climbers, including nutrition, may contribute to the prevention of nutritional deficiencies that affect the deterioration of the health and efficiency of the body. The aim of the study was to analyze the eating habits and food attitudes of Polish climbers in high mountain conditions.

METHODS: The study group consisted of 23 men and 4 women aged 23 to 49 years (average 34.1 ± 6.9 years), participating in summer alpine expeditions at an altitude of more than 5 thousand above sea level, lasting at least 3 weeks. The analysis of eating habits and attitudes was based on the authors questionnaire.

RESULTS: The majority of climbers (85.7%) declare that their habitual diet significantly differs from that in the high mountains. The most common choices in terms of consumed products in the mountains among the respondents include: bars (100%), freeze-dried dishes (86.75%), chocolate (71%), energy gels (39.3%), jelly beans (35.7%), salty snacks (32.1%) and dried meat (28.6%). Due to the high frequency and amount of carbohydrate snacks consumed, 75% of climbers declare that they are satiated with sweet taste, while 78.6% of respondents most often prefer sweet snacks in the mountains. The deficit groups of food products during the trip include: vegetables (92.9% of choices), fruit (82.1%), eggs (60.7%), milk and dairy products (57.1%), butter and cream (46.1%), fish (34.3%) and meat (35.7%). On the other hand, the following products are most often eaten by climbers: sugar and sweets (85.7%), nuts and seeds (67.9%), whole grain products (64.3%) and refined cereals (57.1%). As many as 50% of climbers report digestive discomfort (flatulence, abdominal pain, diarrhea) after consuming freeze-dried products. The most frequently consumed freeze-dried products during a trip by climbers include: lunch dishes, soups, porridges, porridge, desserts and fruit. Climbers usually take for an expedition: isotonic drinks (78.6%), tea (60.7%), water (53.6%), coffee (14.3%) or juices (10.7%). Majority of respondents (57.1%) believe that the amount of consumed fluids is not sufficient. The dietary supplements used by climbers include: protein and protein-carbohydrate supplements, caffeine, probiotics, omega-3 fatty acids, as well as some vitamins and minerals. After returning from the expedition, 73.3% of respondents noticed a decrease in body weight. Almost all climbers (92.9%) declare that the amount of food has an impact on the well-being in the mountains, and 96.4% emphasize that the quality of food is also very important.

CONCLUSION: There is a need to develop dietary and supplementation recommendations that serve as guidelines for climbers to improve their well-being and exercise capacity in severe alpine conditions.

**EFFECTS OF NEW ZEALAND BLACKCURRANT EXTRACT ON CLIMBING PERFORMANCE, MUSCLE OXYGENATION AND RECOVERY IN RECREATIONAL ROCK CLIMBERS.**

POTTER, J., PERKINS, I., WILLEMS, M.E.T.

*UNIVERSITY OF CHICHESTER*

INTRODUCTION: Anthocyanin-rich New Zealand blackcurrant (NZBC) extract enhanced climbing endurance with multiple efforts (1). Blackcurrant increased femoral arterial diameter during contraction (2) and improved forearm blood flow (3), thus could enhance O2 delivery. Off-loading of O2 in the flexor digitorum profundus (FDP) accounted for 24% of variance in climbing ability [4]. Enhancement of the O2 cascade at microvascular level may improve climbing performance and recovery. We examined the effect of NZBC extract on single climbing performance, physiological indices and O2 delivery at microvascular (FDP) level.

METHODS: 10 male recreational rock climbers (M±SD: age 22±3yrs, height 180 ± 5cm, mass 77±16kg: IRCRA grade; 12.8 ± 1.9) volunteered. Participants consumed capsulated NZBC extract (600 mg·day-1 CurraNZ™; containing 210 mg anthocyanins) or placebo (PL) for 7 days (double blind, randomised, cross-over design, wash-out ≥14 days). A continuous wave near infrared spectroscopy device (cw-NIRS) was placed over the FDP, sampling at 25 Hz to determine the Tissue Saturation Index % (TSI%). Following warm-up, participants climbed to exhaustion at a self-selected pace on a Treadwall (Brewer Ledge M6) at 90° with recording of physiological and performance parameters, followed by 10-minutes passive rest and 10-minutes active recovery. In the first 3-minutes, cw-NIRS recorded time to half recovery (TTHR) of TSI%. Other recovery measures included blood lactate (ear), heart rate and handgrip strength. Paired-samples t-tests were used with $P<0.05$ for significance.

RESULTS: No differences between trials were observed for climbing speed, distance, climb duration, peak VO2, change in heart rate, RPE at failure and TSI% minimum. During recovery, no differences were observed for heart rate (5min), handgrip strength and TSI%. Although not statistically significantly different, (high level of variability) TTHR of TSI% was 33% faster during recovery following NZBC (33.16 ± 26.40s), than PL (49.32 ± 26.40s) supported by a small effect size and low power ($t(9) = 1.582$, $p = .148$, $\eta 2p = .217$ Power = .293). A PPM correlation showed a negative relationship approaching significance between Peak VO2 and TTHR; the greater the oxygen consumption the quicker the time to half recovery, following NZBC extract ($r = -.554$, $p = .097$).

CONCLUSION: Seven days of NZBC extract did not improve muscle oxygenation during and following a single indoor climb to exhaustion. Faster TTHR of TSI% was observed with NZBC intake but the small effect size and power observed suggest further testing is needed. Faster TTHR of TSI% has been observed following NZBC extract in fatiguing isolated forearm task in slightly higher-grade climbers [5].

**EFFECTS OF A HIGH-CARBOHYDRATE DIET COMBINED WITH A HIGH-FAT DIET ON ENDURANCE PERFORMANCE.**

ISHIBASHI, S.1, YAMASHITA, T.1,2, ARAKI, A.1,3, TAGUCHI, N.1,3, TOMIGA-TAKAE, R.1,3, OMAGARI, K.1,3, TOBINA, T.1,3

*1:UNIVERSITY OF NAGASAKI*

INTRODUCTION: It is well known that a high carbohydrate diet improves endurance performance. Thus, the athletes increase carbohydrate ingestion for a few days before a competition, however, it also temporally increases blood glucose level and glycolysis. Whereas, a high-fat diet increases serum free fatty acid levels, and fat oxidation, and decreases glucose utilization for energy resources. On the day of competition, combining high-carbohydrate and fat meal may contribute preservation of glycogen, and enhances physical performance.

METHODS: Six subjects ( 3 males (30±9 years) and 3 females (26±5 years) were recruited for this study. The lactate threshold (LT) was measured using a cycle ergometer. Before 3 days of the test, a high carbohydrate meal (more than 7.5g/kg/day) was provided. A high-carbohydrate meal (C) was prepared with 360 kcal of 100% carbohydrate, and a high-fat meal (F) was prepared with 369 kcal of 63% fat. They carried out the Wingate test twice (First phase), and a cycle ergometer exercise for 60 minutes at LT intensity to consume muscle glycogen. After that, anaerobic performance was evaluated using the Wingate test (Second phase). Before 3 hours of the test, subjects ate C and C (C+C) or F and C (F+C) meal. Blood samples were obtained at rest, before and every 15-minutes during the LT intensity pedaling to measure blood glucose, serum triacylglycerol (TG), and lactate. At the same time, expired gas was collected to calculate energy expenditure.

RESULTS: There were no significant differences in peak and average power per body weight on the first and second phase Wingate test. Serum TG at rest was significantly higher in F+C (F+C: 155±37 mg/dL, C+C: 106±30 mg/dL, $p=0.037$, Data shown as mean ± standard deviation). During LT intensity exercise, energy expenditure and blood glucose levels were not significantly different, blood lactate at 45 minutes was lower in F+C than that of C+C (F+C: 3.5±1.6 mM, C+C: 4.6±1.5 mM, $p=0.045$）

CONCLUSION: Differences in pre-exercise diet did not affect anaerobic performance after vigorous and moderate intensity exercise. However, the higher resting serum TG in F+C and lower lactate at 45 minutes of LT exercise suggest that muscle glycogen utilization during exercise may have been more suppressed than in C+C. Consuming a high-fat diet before consuming a high-carbohydrate diet may allow the athlete to compete with some increased fat utilization.

**INFLAMMATION, RESISTANCE EXERCISE AND PROTEIN: DO THEY WORK TOWARDS A HEALTHIER LIFE?**

SILVA, L., SOARES, J., MARTINS, C., CORTINHAS, A., MONTEIRO, G., ABRANTES, C., MARTINS, M., BARROS, A., MOTA, M.

*UNIVERSIDADE DE TRÁS-OS-MONTES E ALTO DOURO*

INTRODUCTION: Inflammation is a natural part of aging process, which has been referred as inflammaging. Inflammaging has been associated with several health problems and limiting conditions (1). Knowing that resistance exercise plays an important role in improving quality of life in the elderly, through the capacity of preserving muscle mass, and that protein supplementation is also determinant to maintain lean body mass, we hypothesize that resistance exercise and/or protein supplementation, could provide benefits to the chronic inflammatory status of elderly people.

METHODS: To test our hypothesis, three main electronic databases were searched (PubMed, Scopus and Web of Science) until March 2022. Articles that included resistance exercise intervention, enteric protein

supplementation, or both, and inflammatory parameters (c-reactive protein, IL-6, IL-8 and TNF-Alpha) in adults older than 64 years, were included.

RESULTS: In the carried-out research, 6074 articles were obtained, then scrutinized. After evaluations three separated analyses were performed: one for resistance exercise (N=21), other for the elderly sample that only took protein supplementation (N=5), and the last analysis focused on articles that used both resistance exercise with protein supplementation (N=4). Using Comprehensive Meta-Analysis Software®, no significant value ($p \leq 0.,05$) between intervention and the decrease of inflammatory parameters was found for each analysis.

CONCLUSION: Contrary to what we hypothesized, it does not seem that resistance exercise, protein supplementation or both, can decrease the rising of inflammatory parameters in the elderly.

## HIGH CARBOHYDRATE DIET PARTIALLY PREVENTS DISUSE-INDUCED ATROPHY IN RAT SKELETAL MUSCLE

YOKOGAWA, A., KIDO, K., TANAKA, K., KAWANAKA, K.

*FUKUOKA UNIVERSITY*

INTRODUCTION: Muscle disuse promotes myopathy, leading to decreased daily physical activity and exercise capacity. Increasing protein intake is essential for maintaining or gaining muscle mass. However, it remains unclear whether carbohydrate intake contributes to muscle mass gain, although glucose itself was reported to stimulate muscle protein synthesis and reduce protein degradation (Hedden and Buse. Am J Physiol 1982, Saha et al. Diabetes 2010). Herein, we examined the potential of a high carbohydrate diet to prevent disuse-induced muscle atrophy.

METHODS: Twenty-four 10-week-old male Wistar rats were divided into two groups (n = 12 in each group); a low-carbohydrate diet (Low-CHO) group and a high-carbohydrate diet (High-CHO) group. In all the rats, the right leg sciatic nerve was severed on the first day of the experiment. The contralateral left leg was used as the control leg and subjected to the same surgery except for nerve transection. Following the denervation surgery, the Low-CHO and High-CHO groups were fed with a low and a high carbohydrate diet, respectively, for 7 days. The Low-CHO contained 20% carbohydrate, 60% fat, and 20% protein, while the High-CHO comprised 70% carbohydrate, 10% fat, and 20% protein. The energy intake in both groups was matched by pair-feeding. After 7 days of the dietary intervention, soleus, plantaris, and gastrocnemius muscles were harvested and weighed. All muscles were homogenized with ice-cold RIPA buffer containing protease and phosphatase inhibitors. The protein concentration of the muscle homogenates was quantified and the absolute muscle protein volume was calculated.

RESULTS: In both the Low-CHO and High-CHO diet groups, the muscle weights of the soleus, plantaris, and gastrocnemius muscles from the denervated lower limb were significantly lower than those from the contralateral lower limb. The relative change in soleus weights (denervated leg/contralateral leg) was not significantly different between the Low-CHO and the High-CHO groups. On the other hand, the relative change in plantaris and gastrocnemius weights were both significantly 6% higher in the High-CHO group than in the Low-CHO group. The absolute muscle protein volume in the denervated muscles was significantly lower than that in contralateral muscles. However, no difference in the relative change of the absolute muscle protein volume between the Low-CHO and the High-CHO was observed.

CONCLUSION: The high carbohydrate diet may partially prevent disuse-induced muscle atrophy in type II dominant muscles.

## EFFECT OF PYRUVATE SUPPLEMENTATION ON FOUR COAGULATION ITEMS AFTER ONE-TIME ACUTE EXHAUSTION EXERCISE IN RATS

FUHUA, Z., LIN, F., YANPING, Y., JUNQIANG, Q.

*BEIJING SPORT UNIVERSITY*

INTRODUCTION: Pyruvate has proven anti-inflammatory and antioxidative properties, but recently anticoagulant properties have been suggested. Additionally, acute strenuous exercise (100% individual anaerobic threshold) caused activated partial thromboplastin time decreased and induced platelet activation. Consequently, this study focused on the influence of pyruvate supplementation on four coagulation items after one-time acute exhaustion exercise in rats.

METHODS: 24 male Sprague-Dawley rats were used for this research. The rats were randomly divided into four groups: control group (C group, no exercise, n=6), pyruvate group (P group, no exercise, n=6), exercise group (E group, n=6), pyruvate and exercise group (PE group, n=6). The rats with P and PE group were gavaged with 616mg pyruvate per kilogram of body weight. the rats with C and E group were gavaged with 616mg maltodextrin per kilogram of body weight. All rats were gavaged with maltodextrin or pyruvate one hour prior to the familiarization run and exhaustive exercise The experiment design divided into two stages: familiarization stage and exercise stage. During the familiarization period, all rats of E and PE group were accustomed with treadmill running for 6 d. The protocol of familiarization stage was 10 min with a speed of 5m/min, and gradually increased treadmill speed with 5m/min per 3 min, until treadmill speed reached to 30m/min, subsequently, rats performed 3-5 sets high intensity interval exercise (HIIT). Each set of HIIT included 45m/min(110%VO2max) running and 10 m/min interval After the familiarization period, all rats of E and PE group were performed exhaustive exercise:13 sets HIIT. In the familiarization stage and exercise stage, treadmill was at 10° inclination all the time, in addition, treadmill was equipped with an electric stimulation grid at the rear. All rats were immediately euthanized by intraperitoneal injection of 10% pentobarbital sodium, Blood samples were collected from the abdominal aorta, blood samples were used to detected blood concretion four item. The values are expressed as the mean ± standard error of the mean (SEM). Data were analyzed by two-way analysis of variance (ANOVA) and least significant difference (LSD) in different groups

RESULTS: Blood concretion four item: PT(prothrombin time), Compared to C group, E group PT was significantly increased($p<0.01$), compared to E group, PE group PT was apparently decreased($p<0.001$); APTT(activated partial thromboplastin time), Compared to C group, E group APTT was notably increased($p<0.001$); compared to E group, PE group APTT was apparently decreased($p<0.001$); TT(thrombin time), Compared to C group, E group TT was significantly increased($p<0.001$), Compared to P group, PE group TT was significantly increased($p<0.001$), compared to E group, PE group TT was apparently increased($p<0.05$); FIB(fibrinogen), Compared to C group, E group FIB was significantly decreased($p<0.05$), Compared to P group, PE group FIB was significantly decreased($p<0.05$),compared to A group, P group FIB was apparently increased($p<0.05$)

CONCLUSION: Acute exhaustive exercise induced a significantly increase in TT, APTT, PT and lead to a notably decreased in FIB. Pyruvate supplementation restored TT, APTT, PT and FIB to normal range

### ACUTE SHORT-TERM INCREMENTAL EXERCISE DID NOT ALTER DETECTION THRESHOLD LEVELS OF SWEET TASTE IN FEMALE STUDENTS

KONRAD, M., HÖRMANN-WALLNER, M., WALLNER, D., MÜLLER, A., KAISER, J., PAIL, E.

*FH JOANNEUM*

INTRODUCTION: Oral taste perception is strongly influenced by buffer capacity of saliva during and after physical stress and the latter's modality. The aim of this study was to determine whether a short exercise bout influences sweet taste perception and detection in female students.

METHODS: 40 non-smoking recreationally physically trained and sensorily untrained female college students (age: 21.5±3.3, BMI: 21.4±2.2 kg/m2) were tested pre (T0) and post (T1) a maximal incremental cycle exercise test. After 3 minutes warm up at 20 Watts, workload was increased every minute by 15 Watt till exhaustion. Two identical threshold tests, using 9 solutions with saccharose concentrations ranging from 0 (=water) to 8 g/l in ascending order and one neutralizing rinsing solution administered between tastings were performed directly before (T0) and 3 min after the exercise bout (T1). Subjects were asked to document their subjective sensations in a taste-perception protocol. Protocols were compared in terms of distribution frequency and examined for significant differences ($p<0.05$).

RESULTS: 29 participants (72.5 %) identified the sweet taste at T0 and T1, 3 (7.5 %) of them did not identify at T1, another 3 didn't identify at T0, and 8 (20 %) never identified the sweet taste. The median detection threshold (DT) was at 2 g/l prior to and at 1.5 g/l after testing (n.s.). The perception threshold (PT) was the same before and after testing (3 g/l, n.s.). Furthermore, a positive correlation between DT T0 and T1 (0.413, $p<0.01$) and PT between T0 and T1 (0.701, $p<0.001$) was examined. No correlation was found between BMI or IPAQ Score and taste perception. However, a weak but non-significant correlation between BMI and IPAQ was detected ($r=0.307$, $p=0.054$). The subjects who identified the solutions correctly as sweet had a significant higher BMI (21.5 [3.9] kg/m², $p<0.0$) compared to those who were not able to identify (19.6 [1.5] kg/m², $p=0.038$).

CONCLUSION: This is the first study showing that a short incremental exercise bout does not influence the taste perception of young recreationally trained female students, as only 20 % of participants were unable to identify the sweet taste correctly. Future studies should focus on physical stress levels and include body composition as a higher IPAQ score positively correlated with the sweet taste identification.

### THE MODERATING EFFECT OF CARDIOVASCULAR FITNESS ON THE DETRIMENTAL INFLUENCE OF EXHAUSTIVE EXERCISE ON PROCESSING CAPACITY UNDERLYING COGNITIVE CONTROL

WANG, C.H., BAUMGARTNER, N., NAGY, C., FU, H.L., YANG, C.T., KAO, S.C.

*NATIONAL CHENG KUNG UNIVERSITY*

Introduction

Although cardiovascular fitness has been demonstrated to moderate the negative impact of exhaustive exercise on cognitive control, available evidence from research using traditional mean behavioral measures (e.g., accuracy, mean reaction time, etc.) remain somewhat controversial. Accordingly, the purpose of this study was to further address this issue by using a theory-driven diagnostic tool, the Systems Factorial Technology (SFT), which has the capacity to reveal the decisional mechanisms underlying cognitive processes.

Methods

Young adults aged 18 to 30 years with higher (n = 30; VO2max = 47.8 ± 5.6 ml/kg/min) and lower (n = 30; VO2max = 36.7 ± 3.9 ml/kg/min) levels of cardiovascular fitness were asked to execute a laboratory cognitive control task (i.e., the go/nogo version of redundant-target task) prior to and after a graded exercise until exhaustion (GXT). SFT was conducted to estimate the resilience capacity, which reflects the processing capacity underlying cognitive control.

Results

Following the GXT, both higher-fit and lower-fit groups showed quicker responses but decreased accuracy overall relative to the performance at the pretest. However, the analysis of SFT revealed that the resilience capacity decreased selectively for the lower-fit group, while such an effect was not found for the higher-fit group.

Discussion

The current findings suggest a maintenance of processing capacity associated with cognitive control in higher-fit individuals following the GXT, while a decrease in processing capacity in individuals with lower level of fitness. This study offers an alternative mechanistic explanation regarding the protective effect of cardiovascular fitness on cognitive control in response to a maximum physical stress.

### COUNTERMEASURES FOR THE DEVELOPMENT OF SPORTS FOR THE ELDERLY IN CHINA IN AN AGING SOCIETY

LIU, X.

*CHINA INSTITUTE OF SPORT SCIENCE*

Introduction

The aging process of Chinas population is getting worse and intensifying. At the end of 2020, Chinas elderly population aged 60 and above reached 264 million, accounting for 18.7% of the total population, and the elderly population aged 65 and above reached 191 million, accounting for 13.5% of the total population. China is already in a mild aging society and is heading towards a middle aging society development. Through the analysis of the current situation of physical exercise for the elderly in China in an aging society, we explore the problems arising in the physical exercise of the elderly in China, and put forward targeted countermeasures.

Methodology

This study mainly uses literature review, logical analysis and mathematical statistics.

Results and discussions

(1) Through multi-categorized logistic regression analysis, it is found that the main factors affecting the participation of the elderly in physical exercise include place of residence, age, education level, occupation, and health condition. (2) The proportion of the elderly in urban areas participating in physical exercise is 30% higher than that of the rural elderly. (3) With the increase of education, the proportion of the elderly participating in physical exercise has also gradually increased. (4) As the elderly (60 years old and above) get older, their participation rate in physical exercise gradually decreases. The proportion of elderly people aged 60-69 and 70-79 participating in physical exercise is 70.6% and 40.6% higher than that of elderly people aged 80 and above, respectively. (5) The proportion of healthy elderly people exercising is 14.2% higher than that of sick elderly people. (6) The elderly who work in government departments have the highest proportion of physical exercise.

Countermeasure: (1) Rationalize the allocation of public sports service resources, increase policy support for rural sports, strengthen the construction of sports infrastructure in rural areas, publicize rural sports culture, and expand the popularity of rural sports. (2) Improve sports security for the elderly. Do a good job in the prevention of sports injuries for the elderly and implement the policy guarantee system for sports insurance for the elderly. (3) Improve the training system of social sports instructors. Colleges and universities include social sports instructors in compulsory courses, cooperate with communities, hospitals, etc. to train practitioners with all-round development of practical theory; establish a regular assessment incentive system for employed social sports instructors, and standardize the team. (4) Enrich the content of sports activities for the elderly. The introduction of some novel sports with good effects for the elderly to choose from, that can also increase the innovation and promotion of traditional sports and enrich the lives of the elderly.

### ANALYSIS AND PREVENTION OF MUSCULOSKELETAL DISORDERS AMONG VOLUNTEER AND PROFESSIONAL FIREFIGHTERS IN THE TARN DEPARTMENT (FRANCE)

HUC, Q., JOFFROY, S., LAGOUTTE, N., GARNIER, S.

*UNIVERSITÉ PAUL SABATIER*

Introduction

Musculoskeletal disorders (MSDs) have been defined as the "disease of the century" for several years. This major health and safety issue leaves no one unexposed and affects firefighters in their daily emergency relief to people (ERMP) which accounts for approximately 44.5% of accidents (CNRACL, 2020), and also in their sports training, accounting for approximately 51% (CNRACL, 2020). ERMP represents more than 80% of the interventions against 12% for fires. Exposure to risk factors is therefore more important.

Method

This study aims to measure the exposure of firefighters to MSDs through a questionnaire in order to identify the various prevalence factors. The questionnaire was constructed according to two hypotheses: MSDs occur firstly in response to exposure to biomechanical risk factors and secondly in response to exposure to psychosocial risk factors. The questionnaire was therefore constructed on the basis of and adapted from the "Nordic" type questionnaire by Kuorinka et al. (1987) and the "Job Strain model" questionnaire by Karasek et al. (1979) to the world of firefighters. The study population (35 ± 4 yr) is composed of 41 professional firefighters (PFS) and 64 volunteer firefighters (VFS). The PFS have a compulsory daily physical activity (PA) (functional training, etc.) unlike the VFS who are not subject to this obligation and practice during their leisure time.

Results

89.5% of the firefighters say that they are aware of the risk whereas 10.5% are not. The study shows a vulnerability for the following areas: 71% of injuries are to the lower back against 28% for the neck, shoulder, knee and ankle-foot regions. 48% of the firefighters say they are affected by these injuries in their leisure activities. 49.5% reported an increased heart rate during intervention and 80% when the beep sounded during sleep and 38% felt anxious about the uncertainty of the intervention.

The results show there is no difference in risk awareness between the PFS and the VFS. The discomfort following an injury during usual activities is higher for professional firefighters than for volunteers ($p \leq 0.05$) whereas there is no significant difference between PFS and VFS in discomfort during leisure activities.

Discussion/Conclusion

The high frequency of ERMP has an impact on the occurrence of MSDs in firefighters. PA to prepare PFS for operational missions seem to have positive effects on MSDs on a daily basis because it prepares the body to biomechanical constraints and improves cardiorespiratory fitness.

All French firefighters are exposed daily to biomechanical and psychosocial factors which have a strong impact on their physical and mental health.

## Physical Education and Pedagogics

### PHILOSOPHICAL DISCUSSION ON TOPICS ABOUT SPORTS: PRACTICE IN A UNIVERSITY GENERAL EDUCATION CURRICULUM

MORITA, H.1, KODANI, K.2, KAWABATA, K.3

*1 OSAKA UNIVERSITY OF HEALTH AND SPORT SCIENCES, 2 TEZUKAYAMAGAKUIN UNIVERSITY, 3 KWANSEI GAKUIN UNIVERSITY*

INTRODUCTION: In Japan, the public education system was introduced by the Meiji government as part of a policy of increasing wealth and military power. As such, the Japanese public education was started under the strong influence of nationalistic purposes. To this day, quite a few education reforms have been made. However, in comparison with other countries, the Japanese education system still has the following three key problems: 1) rigid teaching style without flexibility, 2) a passive lecture style, and 3) too much weight put on rote learning. The Central Council for Education has pointed out two factors that the Japanese style of school education should materialize in the 2020s, which are (1) optimal individualized learning (individualized instruction and individualized learning) and (2) cooperative learning.

Method:

In universities, the problem-solving style of learning and active learning are currently being introduced. This study examines the practice of philosophical discussions on sports-oriented topics and the learning outcomes of learners in the case of seminar-style classes in a university general education curriculum.

Result and Discussion:

The subject of this study is the classes with the topic of fair play. We examined the relationship between fair play and pursuit for winning using a real example. In the first class, learners watched the video example (incident of the five consecutive intentional walks at the National High School Baseball Championship: NHSBC) and discussion on whether the play was justified or not. The result of the first vote (the walks are); Justified 20, Not justified 9. In the next class, after listening to the explanations of the points from the lecturer, the result of the second vote: Justified 17, Not justified 12. Five students changed their views. As for the reason for the change, among those who changed from justified to not justified (four students), two answered that it was because the educational benefit was more important than winning, while the others answered that the process was more important than the result and having good experiences was more important than winning. The reason chosen by the student who changed from not justified to justified was that it should be understood that sports are competition. The NHSBC has a huge impact on the future of the players because it affects the choice of who will be drafted by professional baseball teams.

CONCLUSION: Because the students were highly interested in sports and chose this course focusing on sports of their own free will, the discussions in the classes were active and lively. Nonetheless, there still were students who did not participate in the discussions. In addition, from the lecturer's perspective, too many students did not seem to be assertive enough. Students should discuss issues more frankly while respecting others. I hope that the cooperative style of learning will develop further in Japan from the level of compulsory education.

## EXAMINING THE PEDAGOGICAL IMPACT OF HEALTH EDUCATION IN HUNGARIAN SCHOOLS IN THE LIGHT OF THE SCHOOL HEALTH INDEX (SHI)

HORVÁTH, C., CSÁNYI, T., RÉVÉSZ, L.

*ESZTERHÁZY KÁROLY CATHOLIC UNIVERSITY*

INTRODUCTION: In Hungary, a model of institutional evaluation is emerging as a gap area in school health education, which evaluates school health education from the perspective of student needs and demands. Based on international literature, it is important to recognise and identify school-specific strengths and areas for improvement [1,2]. The aim of our research was to develop an institutional evaluation framework that could assess the pedagogical impact of health education through objective indicators.

METHODS: The framework's main benchmark is the School Health Index (SHI), what measures 5 domain, namely (1) the physical and (2) personal environment of the school, (3) health behaviour and (4) health literacy characteristics of the pupils, and (5) their subjective health status.

The SHI student questionnaire contains 128 closed questions. All domains were assessed with likert-scale based questionnaires, and all domain were categorised based on their scores. The indicators are defined in categories of excellent, adequate, needs improvement and needs increased improvement.

The sample consisted of 5 high schools in Northern Hungary, from which students (N=747) were selected by expert sampling.

RESULTS: The Physical and Personal Environment Indicators got the lowest average scores (59.4%; 50.1%-70.2%). The Personal Environment Indicator averages were (57.77%; 50.6-66.3%). The Health Behaviour Indicator were 70.6% on average (68.1%-72.2%). The Health Literacy Indicator got the highest average score (74.5%; 66.0%-82.5%). The Subjective Health Indicator got the lowest average score of 46.1% (40.8%-51.9%). The average score of iEGI were 61.9% (55.6%-66.9%).

CONCLUSION: The physical environment in 3 schools are categorised as „need improvement", also the personal environment in 4 schools, the health behaviour and health literacy indicators are categorised as „adequate" in all schools, and the subjective health indicator is categorised as „need improvement" in all schools. Four schools have an SHI in the adequate category.

For each of these schools, the area for „need improvement" is the personal and physical environment, which reflects the role of teachers, non-teaching staff, parents and external organisations and associations, as well as the condition and facilities of the infrastructure surrounding the pupils, from a health perspective.

Our framework can be used for evaluate and monitor of health education in the school sector.

## RESEARCH ON THE APPLICATION OF METAVERSE IN COLLEGE PHYSICAL EDUCATION

LI, F., CAO, Y.

*BEIJING SPORT UNIVERSITY*

INTRODUCTION: With features of immersing virtual world, ubiquitous access and decentralization, Metaverse will revolutionize college Physical Education which underpins sports' long term vitality. Due to limited resources, many sport activities cannot be developed in college. This paper aims to explore the practicability and scenarios of applying Metaverse in college Physical Education, and raise measures to tackle foreseeable difficulties.

METHODS: Literature review and logical analysis

RESULTS: There's broad space for Metaverse to benefit college Physical Education. With technologies of 5G, block chain, virtual reality, etc, "Physical Education-Metaverse" community could be established among college union members. First, college students could have free access to the community with digital headsets regardless of locations. They can create and decorate own avatars to socialize remotely with avatars of other users, exchanging ideas and working out together. Second, different scenarios can be created to suit various sports, like imitating mountain climbing or skiing background. In 3-D animated virtual world, students could enjoy outdoor recreations without environment limits, enhancing their enthusiasm of working out. Third, with intelligent monitoring sensors, targeted improvement on

fitness and physique can be achieved. College users could wear digital sensors to monitor not only motions but also physical change of bodies, so that reports with scientific advice could be formulated for targeted improvement.

CONCLUSION: To facilitate college Physical Education with Metaverse, measures are raised from two aspects, hardware and software. Hardware of Metaverse should be enhanced by deepening research in Virtual Reality, Augmented Reality, Block Chain, Digital Twin, etc. Colleges shall optimize Metaverse infrastructures with advanced wearable devices and 5G network. For software, first, "Physical Education-Metaverse" community should be promoted step by step. Metaverse-Sports Experience Areas can be first set up at campus, allowing students to feel the potential of Metaverse in person. Pilot colleges with rich resources will be selected for trail practice, and then successful experience could be spread to other places. Second, regulations on Metaverse in college Physical Education shall be strengthened to alleviate digital risks. As big data will be processed extensively while current provisions are almost blank, introducing strict regulations and supervision are vital to safeguard the data safety. Colleges should also protect students' privacy and prevent information form leaking out. Third, guidance ought to be provided to help students enhance self-discipline and balance virtual and real life. "Physical Education-Metaverse" community should have the fatigue systems that set reasonable time limit to avoid addiction. With measures above, Metaverse could upgrade college Physical Education with easier access to sports scenarios without physical limitations.

## MODIFYING PHYSICAL ACTIVITIES FOR MAXIMIZING LEARNING OPPORTUNITIES: PERSPECTIVES OF FINNISH PHYSICAL EDUCATORS AND SPECIAL EDUCATORS ON INCLUSIVE TEACHING STRATEGIES

MIHAJLOVIC, C., MEIER, S.

*UNIVERSITY OF VIENNA*

Introduction

Recent curricular reforms have aimed to make the Finnish education system more inclusive which requires the implementation of differentiated and individualised teaching practices within schools (Mihajlovic & Meier, 2022). In Finland, as it is internationally, efforts have been made to increase adaptive teaching strategies and collaborative practices between different professionals in the physical education (PE) context. So far, current research has revealed significant findings on how pupils with special educational needs (SEN) can be successfully included in integrated PE settings, focusing mainly on the perspectives of PE teachers (Hutzler et al., 2019). In comparison, little attention has been paid to the instructional strategies of different pedagogues involved in the PE classroom.

Methods

Drawing on the data from a multiple case study in a Finnish context, we explore how four PE teachers and four special education teachers attempted to work inclusively within PE. Document analysis of the current Finnish national curriculum and semi-structured interviews with special educators and PE teachers were used to extend the current understanding of pedagogical practices for dealing with diversity in PE. The interviews were content-analysed adopting a deductive-inductive approach utilizing the TREE/STEP model and the Inclusion Spectrum.

Results

Interested in the interplay between curriculum approaches and its reflections in inclusive teaching, the results of the present study illuminate how PE and special educators often showed willingness to modify the physical activities to meet the individual needs of all learners in PE which included the rules, equipment, and environmental modifications. Both teacher professions take individual responsibility for the teaching activities, but their traditional role as independent and autonomous professionals may also be an obstacle for collaboration.

Discussion

Overall, this paper contributes to a growing body of pedagogical research portraying the perspectives of different practitioners involved in the PE classroom. Future research should further examine the perspectives of different professionals as it may contribute to a more comprehensive perspective on diversity and inclusive teaching strategies. Paying greater attention to these issues holds strong potential to enrich the existing knowledge regarding a shared vision of inclusive teaching and could help other teachers justify their educational choices.

## DO VERBAL DISCUSSIONS IN PHYSICAL EDUCATION CLASSES INTERFERE WITH PHYSICAL ACTIVITY?

NAKAJIMA, T.1, KAWAMOTO, T.2, UMEMURA, T.3, ASANO, Y.4, HOJO, A.1, KONDO, Y.1, TAKAHASHI, M.5, TAKASE, J.1

*1 HOKKAIDO UNIVERSITY OF EDUCATION, 2 SAPPORO ELEMENTARY SCHOOL AFFILIATED TO HOKKAIDO UNIVERSITY OF EDUCATION, 3 HOKUSHO UNIVERSITY, 4 GRADUATE SCHOOL OF HOKKAIDO UNIVERSITY, 5 TOKAI UNIVERSITY*

Introduction

In recent years, verbal communication in physical education classes has become increasingly important. It is noted that through discussion activities, children can deepen the learning in physical education by sharing problems and solving issues (1). However, it has been pointed out that active discussion may prevent children from exercising (2). The purpose of this study was to examine the relationship between verbal communication and the amount of physical activity in elementary school physical education classes.

Methods

In this study, the survey was conducted in volleyball classes. The amount of physical activity and verbal communication were measured in physical education class of sixth-grade students (17 boys and 18 girls). Physical activity was measured in METs using an activity meter. The amount of verbal communication was analyzed and calculated using the Business Microscope (Hitachi, Ltd.) based on body vibration data from 3-axis accelerometers. Pearsons correlation coefficient was calculated for physical activity and verbal communication to verify the relationship.

Results

In volleyball classes, when children worked on individual tasks in their groups through discussions, there was no significant correlation between the amount of physical activity and verbal communication. However, when the children worked on the task as a group while

devising their game strategies, a significant correlation (r=.481, p=.007) was found between the amount of physical activity and the amount of verbal communication.

Discussion

Initially, discussions in physical education classes were regarded as a factor that decreased the amount of physical activity, but the results of this study verified that there was no such relationship. Rather, when the task was shared in a group, the amount of physical activity was higher for children who had more verbal communication. These findings suggest that the awareness of tasks is positively linked to physical activity in physical education classes. In situations where learning is conducted in physical education classes through group discussion and sharing of tasks, it is assumed that children who are unable to recognize the task and participate in the discussion are also unable to engage in physical activity. Therefore, it is necessary for teachers to understand the state of childrens discussion and engagement in physical activities, and to provide appropriate support for them.

### EFFECTIVENESS OF ADVENTURE EDUCATION ON HEALTH OUTCOMES RELATED TO PHYSICAL, PSYCHOLOGICAL, AND SOCIAL DEVELOPMENT IN CHILDREN: A SYSTEMATIC REVIEW

PENG, Z.

*HONG KONG BAPTIST UNIVERSITY*

Effectiveness of adventure education on health outcomes related to physical, psychological, and social development in children: A systematic review

Zhou Peng1, LAU Wing Chung, Patrick2

1 Department of Sport, Physical Education, and Health. Hong Kong Baptist University, Hong Kong, China

2 Department of Sport, Physical Education, and Health. Hong Kong Baptist University, Hong Kong, China

INTRODUCTION: Physical, psychological, and social development are essential throughout the developmental period of children. The positive effects of adventure education (AE) on physical, psychological, and social development are well-documented and previous systematic reviews have paid more attention to adults. However, due to age-related developmental limits, children encounter obstacles that are distinct from those faced by adults. whether adventure education can be beneficial to physical, psychological, and social developments in children remains to be addressed. Therefore, the objective of this systematic review was to investigate the impact of adventure education on children's (0-18 years old) physical, psychological, and social development.

METHODS: The review was reported based on Preferred Reporting Items for Systematic Review and Meta-Analysis (PRISMA 2015). Articles were retrieved in seven databases (EMBASE, PubMed, MEDLINE, Web of Science, SPORTDiscus, PsycInfo, Psychological database) from 2000 to 2021. Methodological quality was examined in accordance with Version 2 of the Cochrane risk-of-tool for randomized trials (RoB2).

RESULTS: Eighteen studies were screened. First of all, AE contributed to physical development in healthy and unhealthy children aged 9 to 16, moreover, positive changes in physical activity were sustainable for up to 18 months. Secondly, the investigation of psychological development (9-18-year-old health and unhealth children) showed that the changes in self-esteem, self-efficacy, and quality of life yielded inconsistent results. Finally, AE was conducive to the social development in 11-17-year-old healthy and unhealthy children and 3-7-year-old unhealthy children.

CONCLUSION: AE intervention is found effective to produce physical, psychological, and social benefits in children. The majority of studies focused on 9-18-year-old unhealthy and healthy children only one study involved 3-7-year-old unhealthy children. However, most of the studies in this field have weak methodological quality and thus, the present evidence should be considered with caution.

## Physiology

### MUSCLE OXIGENATION DURING DIFFERENT INTENSITY AND DURATION OF TIME TRAINING SESSIONS IN WORLD-CLASS KAYAK ROWERS

DADELIENE, R.1, NEKRIOŠIUS, R.2, DADELO, S.3

*VILNIUS UNIVERSITY 1, LITHUANIAN SPORTS UNIVERSITY 2, VILNIUS GEDIMINAS TECHNICAL UNIVERSITY 3*

INTRODUCTION: Aerobic metabolism processes in muscles play essential role in 1000 m. distance for kayak rowers' work. Interval training method is used as one of the means of training methods, applied for kayak rowers training. Therefore, the aim of the study was to explore an effect of different intensity and duration of time training workouts for world-class kayak rowers' (500 and 1000 m.) muscle oxygenation.

METHODS: Case study was carried out during preparatory cycle in 1919-2020. Two world-class kayak rowers participated in this study (K2). Muscle oxygenation was measured using MOXY Oxygen Monitor device while athletes worked on kayak ergometer DANSPRINT. Sensors were fixed on athletes' Quadriceps and Pectoralis Major Muscles.

After 30 warming up, there were two different interval-training sessions. The first – athletes repeated 6 min duration work 6 times, which was followed by 6 min sitting at rest. During 6 min workout athletes worked 60 s - 220 W (at anaerobic threshold limit) and 60 s – 60 W. The second session – athletes also repeated 6 min duration work 6 times, which was followed by 6 min sitting at rest. However, during 6 min workout athletes worked 10 s - 320 W (at critical intensity limit) and 30 s – 60 W.

RESULTS: Muscles deoxygenation processes were better visible in Quadriceps muscles than in Pectoralis Major Muscles. Oxygen consumption during 6 min session (60 s - 220 W and 60 s – 60 W) changed by more than during 6 min session (60 s - 320 W and 30 s – 60 W). However, amount of oxygen equally returned to baseline level during 6 min rest after different 6 min sessions. Heart rate during 6 min different intensity and duration of time training workout reached ventilation anaerobic threshold. During 60 s rest after 60 s - 220 W work HR decreased until 120-130 b/min, while during 30 s rest after 60 s - 320 W workout decrease significant more. Lactate concentration show little activity of glycolytic reactions and was without differences in both different training sessions (3.5-4.5 mml/l).

CONCLUSION: This study revealed that during different intensity and duration of time training workouts did not provoke different scale of muscle oxygenation in world-class kayak rowers'. Though during second training session athletes reached capacity that achieves through

competitions, glycolytic reactions was active without significant differences comparing to the first training session. We can assume that for enhancing aerobic metabolism is suitable to use workout at anaerobic threshold limit.

### RELATIONSHIP BETWEEN CHANGES IN RECTAL TEMPERATURE AND MICROBIOTA DURING TRANSIENT EXERCISE ON CHANGES IN THE EXTERNAL ENVIRONMENT

MATSUO, K., MURAKAMI, Y., YOSHIDA, N., WADA, T., NAKAMURA, R., FUJISAWA, S., ONODERA, S.

*KAWASAKI UNIVERSITY OF MEDICAL WELFARE., GRADUATE SCHOOL, KAWASAKI UNIVERSITY OF MEDICAL WELFARE.*

INTRODUCTION: Recently, it is important problem that global warming is progressing in the outdoor sports activity. From such a current situation, it is urgent to take appropriate measures for athletes in summer training or competitive race. In a heat condition, the necessity of taking physical condition management for athletes is emphasized by understanding the adaptation state of internal organs due to changes in the seasonal changes. There are considered that the gut microbiota is associated with physical condition, and it is also suggested that relevant to seasonal changes. The purpose of this study was to investigate, the relationship between changes in rectal temperature during exercise seasonal changes, and changes in gut microbiota and to obtain useful materials for the field.

METHODS: Nine healthy male adults (mean age, height, weight, % of Body fat, VO2max: 23.4 ± 3.0 years, 172.0 ± 6.5 cm, 73.6 ± 12.2 kg, 19.9 ± 6.9 %, 41.7 ± 5.9 ml/kg/min) participated 2 trials of aerobic exercise (Spring-Summer and Autumn-Winter). In Spring-Summer and Autumn-Winter sessions, participants performed 30-min aerobic exercise on a cycle-ergometer at intensity corresponding to 50% of VO2max. We examined whether the gut microbiota would change and whether the defecation status would improve in Spring-Summer and Autumn-Winter sessions. Gut microbiota on two times of stool samples in spring and autumn were classified by next-generation sequencing. In addition, we investigated the Bristol stool scale questionnaire was used to evaluate the form of fecal into seven types with the aim of obtaining basic material useful for the field.

RESULTS: Changes in rectal temperature increased immediately after-exercise compared to baseline, in addition, it was suggested higher than Autumn-Winter compared to Spring-Summer. Interestingly, it was shown that the subjects with high rectal temperatures immediately after-exercise may have low levels of Bacteroidetes phylum. In addition, it was shown that subjects on highly % of body fat that significantly higher rectal temperature immediately after-exercise ($p < 0.05$). On the Bristol scale, there were 3 out of 9 subjects in good condition in "Type 4" in "Autumn-Winter".

CONCLUSION: These results suggested that it was possible there may be gut microbiota associated with physical adaptability such as temperature sensitivity. Revealing the association between exercise and the gut environment can substantially contribute to health promotions. In the future, the gut microbiome data may be available for individual exercise prescriptions. This work was supported by JSPS KAKENHI (17H02147) and Grant for Wesco Scientific Promotion Foundation.

### DIFFERENCE BETWEEN FIT VS. UNFIT IN CEREBRAL AUTOREGULATION TO SEVERE ORTHOSTATIC STRESS

HIRASAWA, A., HIRABUKI, K., HATA, N., SUDA, T., SANO, Y., SUZUKI, R., FUKUIE, M., UECHI, T., MATSUDA, T., SUGAWARA, J., SHIBATA, S.

*KYORIN UNIVERSITY, TOKYO, JAPAN, UNIVERSITY OF TSUKUBA, IBARAKI, JAPAN, NATIONAL INSTITUTE OF ADVANCED INDUSTRIAL SCIENCE AND TECHNOLOGY, IBARAKI, JAPAN*

INTRODUCTION: It has been known that gravitational stress acutely increases arterial cardiac baroreflex sensitivity (Iwasaki, 1998). Our previous study reported that severe orthostatic stress with lower body negative pressure (LBNP) acutely enhanced the arterial-cardiac baroreflex sensitivity in sedentary individuals, while the severe orthostatic stress suppressed it in fit individuals (Suzuki, 2021). However, it is still unclear whether the severe orthostatic stress would affect cerebral dynamic cerebral autoregulation especially with regard to different physical fitness level. The purpose of the present study was to test our hypothesis that the severe orthostatic stress would acutely enhance the dynamic cerebral autoregulation in sedentary individuals, but not in fit individuals.

METHODS: Eight male endurance athletes (Fit; 24±10 years old, VO2max 61±3ml/kg/min) and 9 male non-athletes (UnFit; 24±4 years old, VO2max 36±7 ml/kg/min) were recruited. They underwent severe orthostatic stress test using graded maximal LBNP. The graded maximal LBNP consisted of -15 mmHg, -30 mmHg and -40 mmHg LBNP for 5 minutes each, then incremented by -10 mmHg every 3 minutes until pre-syncope. Beat-to-beta mean arterial blood pressure (MAP; Finometer), middle cerebral artery blood flow mean velocity (MCAvmean; transcranial Doppler), and end-tidal CO2 (EtCO2; Capnometer) were measured for 5 minutes before and after the graded LBNP test in the supine position with spontaneous respiration. In offline analysis, 5 minutes data of beat-to-beat changes in MAP and MCAvmean were used for transfer function analysis (TFA) to estimate dynamic cerebral autoregulation (dCA).

RESULTS: EtCO2 decreased in both groups after the maximal LBNP($P=0.001$). In Fit, MAP and MCAvmean increased after the maximal LBNP. The low-frequency (0.07-0.2 Hz, LF) gain of TFA was lower after the maximal LBNP as compared with before ($P=0.014$). However, the change in LF gain did not differ between Fit and UnFit ($P=0.483$).

CONCLUSION: The present findings suggest that dCA was improved after the acute severe orthostatic stress by the maximal LBNP, which was not different in fitness levels.

### EFFECT OF SAUNA BATHING ON SENSORY FUNCTION AND PERFORMANCE OF TASKS

IIDA, T.

*SHUJITSU UNIVERSITY*

INTRODUCTION: It is necessary to use a simple parameter about the health of the spectator in order that early detection of heat stroke during watching sports. Exercise under hot environment lower neural activity about cognitive process and salty taste sensitivity. These reports suggest that the sensory response may change with body temperature. The sauna is an environment where can elevation of body temperature and profuse sweat in a short time. Therefore, this study aims to clarify the influence of sauna bathing on sensory function and performance of task.

METHODS: Ten healthy young men (age: 22 ± 1 years, weight: 57.4 ± 6.2 kg, height: 173.5 ± 3.6cm, BMI: 19.1 ± 2.1) volunteered as subjects for this study. Subjects sit and rest for 20 minutes in a sauna (atomospheric temperatures: 47.5 ± 3.1 ° C, relative humidity: 62.2 ± 19.8%, WBGT (Wet-Bulb Glove Temperature): 43.4 ± 0.8 ° C). The measurements were body weight, pulse rate, thermal sensation, thirsty sensation, fatigue, sensory function and performance of tasks. Sensory function was measured using perceptual function test at the finger-tip, back of the hand, forearm and neck. This test was to measure the number of times subjects perceived, when they got pressure

stimulation 5 times on each point. The performance of tasks test was to measure the number of characters that subjects typed as much the specified English word as possible in 30 seconds using a smartphone.

RESULTS: The body weight after the sauna were significantly lower than the one before the sauna ($P < 0.05$), and the amount of body weight reduction was 0.32±0.09kg. Furthermore, pulse rate, thermal sensation, thirsty sensation and fatigue was significantly higher than that before the sauna. These results shows that sauna used in this study influenced physiological response like a heat stroke.

Regarding sensory function, no significant differences were observed in the finger-tip between before and after sauna bathing. On the other hand, the number of times perceived in back of the hand, forearm and neck point were significantly lower than before sauna bathing. However, no significant differences were found on performance of typing character task.

CONCLUSION: It was clarified that there are areas where the sensory function of the skin is reduced by heat stress. Among them, it was suggested that the part with low density of tactile points easily affected by heat stress. On the other hand, it was clarified that the performance of task had little influence at the hot environment and the measurement method of this study.

Therefore, we concluded that the use of cutaneous sensory stimulation may lead to early detection of heat stroke at sports spectators. We hope that results of this research will lead to the basic data of "a simple screening test for heat stroke using sensory reactions".

## EFFECTS OF BLOOD FLOW RESTRICTION AND RESISTANCE EXERCISE ON CARDIOVASCULAR RESPONSE AND MUSCLE MECHANICAL PROPERTIES DURING THERMAL STRESS

LEE, Y., SON, S., LEE, H., YUN, S., JUNG, A.R., LEE, D.T.

*KOOKMIN UNIV.*

INTRODUCTION: The purpose of this study was to evaluate the effect of blood flow restriction and resistance exercise on cardiovascular response and muscle mechanical properties under heat and cold stimulation.

METHODS: Seven healthy male subjects (26.4 ± 1.7 yrs, 174.5 ± 2.0 cm, 72.7 ± 6.8 kg, 23.8 ± 1.7 kg/m2, 16.5 ± 3.1 %body fat) participated in 6 testings in combination of 3 environmental conditions at low (LT; 10.7 ± 0.7 ℃, 23.6 ± 3.2 % relative humidity (RH)), room (RT; 25.4 ± 0.6 ℃, 36.0 ± 10.8 % RH) and high temperature (HT; 39.5 ± 1.5 ℃, 50.6 ± 2.8% RH) during either blood flow restriction (BFR) or not (NBFR). For exercise, Preacher Curl-Dumbbell was performed 3 sets, 30 repetitions in a set for 1 min followed by 1 min resting. After the exercise 15 minutes of recovery time was given. The exercise intensity in NBFR was 50% of 1 repetition maximum (RM), and that in BFR was 30% of 1RM while arm blood flow was restricted at a pressure of 200 mmHg. During the testings, blood flow (BF), blood pressure (BP), oxygen saturation (SpO2), and muscle mechanic properties (stiffness; SF, and frequency; FQ) were measured. For statistical analysis, two-way repeated-measures ANOVA was performed, when an interaction effect was found, a one-way analysis of variance was used to perform post-hoc verification.

RESULTS: When the 1-minute interval recovery period of BF was analyzed, there was an increase in HT. SpO2 was higher in LT at 5 and 15 minutes of recovery. SF was high in LT from immediately after 2 sets of an exercise to 15 minutes after recovery. FQ was high at RT from immediately after 3 sets of an exercise to 15 minutes after recovery. During blood flow restriction, systolic blood pressure immediately after exercise showed high in NBFR. The interaction effect was found in FQ after exercise ($F=7.909$, $P=.006$) and after 5 minutes of recovery ($F=22.729$, $P=.003$). After exercise, RT+NBFR (14.4 ± 1.0 Hz) showed statistical significance compared to RT+BFR (12.5 ± 1.2 Hz, $P<.008$), HT+BFR (12.1 ± 0.9 Hz, $P<.001$) and HT+NBFR (12.7 ± 1.5 Hz, $P<.020$). HT+BFR showed a statistical difference from LT+NBFR (1.36 ± 1.5 Hz, $P<.025$). Five minutes after recovery, HT+BFR (11.2 ± 0.6 Hz) showed statistical differences compared to RT+BFR (12.9 ± 0.9 Hz, $P<.018$) and RT+NBFR (13.1 ± 1.3 Hz, $P<.010$).

CONCLUSION: There was no difference in BF, BP, SpO2, and SF when blood flow restriction and resistance exercise was performed under environmental stress. An interaction was found in FQ, which was positively correlated with the level of muscle contraction. This means that when performing resistance exercise while restricting blood flow, the contractility of muscles can be affected depending on environmental conditions.

## EFFECTS OF INTERMITTENT, CONTINUOUS AND MIXED RUNNING EXERCISE ON FEMORAL BONE QUALITY PARAMETERS IN RATS

WAZZANI, R., BOURZAC, C., PALLU, S., ELHAFCI, H., AHMAIDI, S., PORTIER, H., JAFFRE, C.

*UNIVERSITÉ DE PICARDIE JULES VERNE: UNIVERSITE DE PICARDIE JULES VERNE*

INTRODUCTION: It is now well established that physical exercise is an effective preventive means to reduce and treat certain chronic diseases, particularly musculoskeletal disorders. At the bone level, running exercise is well known for its positive effect on the different parameters of bone quality. However, there is no consensus regarding the effects of different running exercise modalities studied in the literature.

Thus, the objective of this study was to compare, for the first time, the effects of three treadmill exercise modalities: intermittent, continuous, and mixed exercise on bone quality parameters in rats.

METHODS: Thirty-nine male Wistar rats (5 weeks old) were randomly divided in 4 groups: sedentary control (SED; n=10), intermittent exercise group (IE; n=10), continuous exercise group (CE; n=10) and mixed exercise group (ME; n=9). Exercise groups rats were exercised 5 days/week, for 8 consecutive weeks. Femoral micro-architectural parameters were assessed by micro-CT, femoral bone remodeling parameters (osteocyte apoptosis and osteoclast resorption) and bone histomorphometry were assessed by histological analysis.

RESULTS: Femoral trabecular thickness was increased in the mixed exercise group compared to the other exercise groups ($p<0.0001$). the cortical thickness, the osteocyte lacunae occupancy rate, the number of apoptotic osteocyte lacunae and the osteoclastic resorption surface were not significantly different between the groups. Statistical differences are occasionally noted depending on the anatomical region treated of the femur.

CONCLUSION: These results suggest that, the adaptive bone responses differ according to the exercise modality performed and that mixed exercise seems to have more effect on bone trabecular microarchitecture.

### CHANGES IN SKIN ADVANCED GLYCATION END-PRODUCTS VALUES OF UNIVERSITY STUDENTS IN FITNESS & SPORTS CLASSES

NAKAJIMA, S.1, KOIZUMI, K.2

*1 KYORITSU WOMEN'S JUNIOR COLLEGE,TOKYO,JAPAN; 2 JAPAN WOMAN'S COLLEGE OF PHYSICAL EDUCATION,TOKYO,JAPAN*

INTRODUCTION: Advanced glycation end-products (AGEs) are harmful compounds formed through an excess of protein and sugar in the human body. Excessive accumulation of AGEs has been reported to accelerate the aging process and contribute to diseases such as arteriosclerosis and diabetes. In addition, the accumulated amount of skin advanced glycation end-products (AGEs) is likely to be affected by lifestyle-related habits, including diet and exercise. Therefore, we measured AGEs in the Fitness & Sports class, which is a part of general education subjects at the university. Lectures on exercise and sports activity practices and meals were given during the first and second half of the period. Changes in the AGEs value were recorded. Accordingly, we decided to examine whether AGEs measurement can be employed as an indicator to measure health.

METHODS: Participants included 51 healthy female students who were enrolled in Tokyo universities. Classes of 100 minutes per week lasting 14 weeks from April to July 2021 were conducted. The survey, which was conducted during the second and 14th week, targeted the practical content of two classes: Walking & Fitness (Class A) and Badminton, Soft Volleyball (Class B). In addition, regular body composition measurements, including body weight and fat percentage, were conducted along with lectures on diet when needed. The participants learned the effects of exercise and diet on the body during the classes. A diagnostic tool called the TruAge scanner was used to measure AGE levels by measuring the amount of AGEs accumulated on the skin.

RESULTS: The value of the April AGEs for female college students in the Fitness & Sports class decreased by −5.82% compared with that of the July AGEs. While the decrease in Class A was −5.64%, the decrease in Class B was −4.80%. Although there was no significant difference between the two classes, the AGE value of Class A, which comprised mainly of aerobics, decreased further in the second measurement.

CONCLUSION: Even if the students had attended only Fitness & Exercise once a week, it had a positive effect on reducing the skin AGEs level for students who did not exercise daily. Furthermore, their awareness of exercise and dietary intake had a positive effect on the students.

### IMPACT OF 14 DAYS OF A MICROGRAVITY ANALOG AND AN EXERCISE COUNTERMEASURE ON LOWER LIMB STRENGTH AND ELECTROMYOGRAPHIC ACTIVITY

ST-MARTIN, P., LAGACÉ, J.C., RUEL, M., LÉONARD, G., LAMBERT-CORDILLAC, K., RIESCO, E., MCPHEE, J.S., DIONNE, I.J.

*UNIVERSITÉ DE SHERBROOKE*

INTRODUCTION: The microgravity context that astronauts experience leads to a significant decrease in the load applied to the body and results in muscular underuse. During prolonged exposure to microgravity, a considerable loss of muscular strength is observed, especially in the lower limbs. This loss is a major threat to the autonomy of astronauts and could be a survival matter in an emergency context. While muscular atrophy is the most evoked mechanism, the loss of strength precedes and exceeds the rate of atrophy which suggests the contribution of other mechanisms. Among them, the deterioration of the neuromuscular junction could explain the latency between atrophy and loss of strength, but the literature is scarce on the potential mechanisms involved in strength and muscle loss during microgravity. Objectives: The first objective was to verify how two weeks of head-down bed rest (HDBR) – the most widely used microgravity analog – influences lower limbs' strength and neuromuscular activity. As these deteriorations are usually secondary to muscle underuse, the second objective was to verify if an exercise program can prevent the deterioration of strength and neuromuscular activity.

METHODS: Maximal voluntary contraction strength (MVC) of the quadriceps will be measured in 24 participants (aged 55-65; 50% women) with isometric knee extension on a dynamometer (Biodex, System 3). Participants will then perform a contraction at 25% of MVC during which surface and intramuscular EMG signals will be recorded. In addition, the amplitude and area of the compound muscle action potential will be determined by stimulating the femoral nerve. These tests will allow the estimation of motor units number, their size, and the stability of the neuromotor junction. Participants will then be exposed to 14 days of HDBR after which all tests will be repeated. During HDBR, half of participants will be engaged in one hour of training per day comprising muscular and cardiovascular exercises, while the other half will be subjected to passive mobilization by a physical therapist. Following a 7-day recovery period, participants will return to their daily activities and follow-ups will be conducted 4 weeks and 4 months after leaving the facility to verify if any changes persist.

RESULTS: Data collection is ongoing but preliminary results suggest that one hour of daily exercise is not sufficient to mediate the loss of muscle strength induced by 14 days of HDBR. An ambulatory period of 4 weeks following HDBR does not appear to be sufficient to restore strength and neuromotor junction, whereas 4 months do. Neuromotor activity is under analysis and the complete results will be presented at ECSS 2022.

CONCLUSION: The benefits of this project are very relevant for the space sector and the medical field, especially in the context of older adults who are bedridden for long periods.

### EFFECTS OF ELECTRICAL STIMULATIONS AT DIFFERENT FREQUENCIES ON THE STRUCTURE OF TIBIAL ARTICULAR CARTILAGE IN HINDLIMB-SUSPENDED RATS

ZENG, X.

*TOYO UNIVERSITY*

INTRODUCTION: [Background] Osteoarthritis (OA) is a disease in which articular cartilage is reduced due to aging, loss of muscle volume, obesity, etc. and causes pain. OA progresses over time and is divided into three stages (early, middle, and late).It is thought that it is important for OA to early treat of OA is important for the reason why a repair of the degenerative knee joint is difficult.Currently, exercise and electrical stimulation are also used as therapies for the early treatment of OA.However, it has also been reported that exercise therapy increases pain levels due to the excessive load on the joints of the elderly.Therefore, Recently, a treatment method using a vector potential (VP) has been developed and is drawing attention.We have already found and reported that the articular cartilage thickness is maintained in rats in which the articular cartilage degeneration is caused by hindlimb suspension, by a new electrical stimulation method using vector potential. However, the effect is due to the electrical stimulation at a specific frequency, and it has not been clarified how the difference in frequency has an effect on the maintenance of articular cartilage.[Purpose]

This study aimed to morphologically investigate the effect of electrical stimulations of different frequency on the structural changes of tibial articular cartilage that was caused by mechanical unloading in rats.

METHODS: Twenty male rats (wistar strain, 7-week-old) were used as materials and they were divided into HS, VP and CO. Moreover, VP was subdivided, by frequency, into VP2（2KHz）、VP20（20KHz）and VP200（200KHz).CO was normally bred in the cage for 3 weeks. Tails of HS, VP2, VP20 and VP200 were suspended in cages for 3 weeks.The electrical stimulation was accomplished under anesthesia using a VP generator (Sumida Denki Co., Ltd.). The conditions of electrical stimulation of VP were AC, 67mV, 0.13mA, 2㎑, 20㎑, and 200㎑, and were set to 30 minutes /day, 5 days /week.

After the experimental period, the tibia in each group was excised and was analyzed histologically.

RESULTS: Thick trabecular bones were densely present in CO, but they were thin in HS, as observing those bones of the epiphyseal cancellous bone.

The trabecula bones gradually increased from VP2KHz to VP200, and the trabecular bone in VP20 and VP200 was thick and dense, and they were near that in CO.

As regards the articular cartilage, tidemark in HS elevated significantly than CO. On the other hand, the same change wasn't recognized in VP and the thickness of an uncalcified layer was maintained.

CONCLUSION: [Discussion] The tidemark elevated and the thickness of the calcified layer of the articular cartilage increased.However, in the VP the thickness of the unmineralized layer of the articular cartilage was maintained. It seems that the maintenance of the thickness of the uncalcified layer in VP is related to the suppression of the elevation of tidemark. [Conclusions]It was suggested that the decrease in articular cartilage thickness caused by redu

**VOLUNTARY EXERCISE ENHANCES OVA-SPECIFIC IGE ANTIBODY PRODUCTION BY OVA EPICUTANEOUS EXPOSURE IN MICE.**

SHIIBA, D.

*KURASHIKI UNIVERSITY OF SCIENCE AND THE ARTS*

INTRODUCTION: The number of patients with food allergies continues to rise, especially among infants. Recently, it has been reported that allergen hypersensitivity, the cause of food allergy, may be induced by dermal exposure to allergens. Although it is well known that exercise affects immune function, the effect of exercise on dermal exposure to allergens remains unclear. Therefore, the present study examined the effect of voluntary exercise on the acquisition of allergen hypersensitivity induced by allergen transdermal exposure.

METHODS: Six-week-old male BALB/c mice were divided into sedentary and exercise groups and reared individually for the experiment. Mice in the exercise group were placed on a running wheel in the rearing cage and exercised until the end of the experimental period, and the number of counts of wheel running and body weight during this period were measured. Two weeks after the start of exercise, mice including those in the sedentary group were exposed to OVA percutaneously. Briefly, the backs of mice shaved with clippers were coated with 4% SDS solution and 300μg OVA was added. Three weeks after final epicutaneous exposure with OVA, blood samples were taken and the concentration of OVA-specific IgE in serum was measured by ELISA. All experiments were performed with the approval of the Animal Experimentation Committee of the Kurashiki University of Science and the Arts.

RESULTS: In this study, body weight was significantly lower in the exercise group than in the sedentary group until epicutaneous exposure with OVA ($p<0.05$), but this difference disappeared during the second week of transdermal OVA administration, and no significant difference was observed between the two groups thereafter. In contrast, the OVA-specific IgE concentration in blood was significantly higher in the exercise group than in the sedentary group ($p<0.01$).

CONCLUSION: Our study suggests that voluntary exercise during the OVA epicutaneous exposure may enhance the response to OVA and increase the production of OVA-specific IgE antibodies. These findings might suggest that exercise may increase allergen hypersensitivity due to dermal exposure under certain conditions.

**EXERCISE-INDUCED CARDIAC ADAPTIONS IN RHEUMATOID ARTHRITIS DURING INTERLEUKIN-6 VS. TUMOR NECROSIS FACTOR ANTIBODY THERAPY: PROTOCOL FOR A RANDOMISED CONTROLLED TRIAL**

JØNCK, S., ADAMSEN, M., RASMUSSEN, I., ELINGSGAARD, H., PEDERSEN, B.K., BERG, R.M., CHRISTENSEN, R.H.

*COPENHAGEN UNIVERSITY HOSPITAL, RIGSHOSPITALET*

INTRODUCTION: Rheumatoid arthritis (RA) is a chronic autoimmune disease characterized by a systemic inflammation which is believed to mediate a 2-3 fold increased cardiovascular risk in patients with RA independent of conventional risk factors. The worldwide prevalence is estimated to 1%. The pro-inflammatory cascade is largely driven by the cytokine tumor necrosis factor (TNF) and interleukin-6 (IL-6) by a variety of cells. The inflammatory state is thought to play a key role for the increased cardiovascular risk. Consequently, disease-modifying therapy targeting TNF or its downstream cytokine IL-6, may attenuate the risk of cardiovascular disease.

IL-6 is a pleiotropic cytokine that is released from exercising skeletal muscle, acting as a myokine. In contrast to the TNF-mediated overexpression of IL-6 in the pro-inflammatory response, the exercise-induced release of IL-6 is stimulated by TNF-independent mechanisms, suppresses the production of TNF, and regulates both cardiac and metabolic adaptations to exercise training. As the effects of exercise may mitigate the overall cardiovascular risks in RA patients, knowledge of IL-6 and its role in exercise-induced adaptions is called for. Here, we introduce a novel RCT study that compare the two most frequent type of biological treatments, TNF inhibition and IL-6 blockade, and their effect on exercise adaptions in RA patients.

METHODS: RA patients treated with IL-6 blockade or TNF inhibitors are included in a 12-week randomized investigator-blinded high intensity interval training study (n=80). Patients are stratified for medical treatment and sex and allocated 1:1 to the exercise or control (no exercise) group. Patients will be encouraged not to change eating or physical activity habits during the study. Baseline and followup analysis are identical and include: cardiac MRI, abdominal MRI, transthoracic echochardiography, oral glucose tolerance test, questionnaries, and VO2max test.

RESULTS: The primary outcome is the difference in changes of the left ventricular mass (g) assessed by state-of-the-art methodology; cardiac magnetic resonance scan. Secondy outcomes include difference in changes of visceral mass (g), cardiac structural and functional changes and RA disease specific outcomes.

CONCLUSION: We hypothesize that IL-6 signaling regulates exercise-induced cardiac and metabolic adaptions and therefore pharmacological blockage of IL-6, but not pharmalogical inhibition of TNF, impairs exercise-induced adaptions, namely structural changes in cardiac ventricular mass and changes in viseral fat mass.

As biological treatments in RA patients are ever evolving, novel RCT studies that explore their potential limitating effects on exercise is called for.

### EFFECT OF FATIGUE GENERATED BY EFFORT ON REACTION TIME.

JASTRZEBSKA, A., BAKONSKA-PACON, E.

*WROCLAW UNIVERSITY OF HEALTH AND SPORT SCIEMCES*

INTRODUCTION: The simple reaction time (SRT), the minimal time needed to respond to stimuli is a physiological response toward a neutral sense stimulus. The aim of the presented study was to estimate the changes in simple reaction time (RT) in fatigue conditions induced by two efforts of a different nature.

METHODS: Twenty participants performed an incremental test (INC) to volitional exhaust for fitness level and VO2max estimation. The 40-min effort (LE) with the intensity of 80% VO2max was performed for fatigue elicitation. Respiratory parameters were measured breath-by-breath (K4b2, Cosmed, Italy). Participants performed a simple RT task before (pre-test) and follows the 5 min of recovery (post-test) for incremental and 40-min effort. Visual: red, orange, green light, and auditory: one sound, stimuli were given in random order. The mean value of reaction time was calculated excluding the first and last values and separately for each type of stimuli (3 colors and a sound). Blood was collected for estimation of lactate concentration (Dr Lange Küvettentest, LKM 140, Germany) and venous blood was collected to determine the concentration of selected neurotransmitters (ELISA Test Demeditec Diagnostics GmbH Germany).

RESULTS: VO2max in the incremental test was 53.79 ± 4.52 ml/kg/min. Lactate concentrations in the blood reach 9.25 ± 2.77 and 4.25 ± 1,2 [mmol] for INC and LE respectively. The concentration of neurotransmitters: Adrenaline, Noradrenaline and Dopamine in plasma, and Serotonin in serum increased significantly as a result of both efforts ($p<0.05$). Independently on effort performed, the direction of alteration in reaction time was the same and showed a decrease. There were no differences in RT in pre-test measurement while the significant effect of conducted efforts on simple RT was noted (INC, P=0.04; LE, P=0.003 respectively). Significant decrease in RT for red and orange light after INC (P=0.05 and P=0.003) and LE (P=0.02, P=0.04), and sound stimuli after LE (P=0.03) effort were noted.

CONCLUSION: We expected a return to the rest or longer reaction time after the efforts made. Five minutes after the tests, reaction times were still shorter than at rest. Interestingly, the most noticeable reduction in reaction time was noted for red and orange stimuli, but not for green. The increase of neurotransmitters in plasma and serum indicates the development of fatigue, although not translated into a decline of SRT directly after the efforts. It may be that 5 min after the effort the excitation of the nervous system enables a faster reaction and biochemical changes caused by exercise precede fatigue, which is manifested in the function of the nervous system.

Research granted by MNiSW nr 0022/RS4/2016/54

### DO THE EFFECTS OF DEVELOPMENTAL TRAINING IN SKELETAL MUSCLE PERSIST INTO OLD AGE?

NISHIZAWA, T.

*SIGAKKAN JUNIOR UNIVERSITY*

INTRODUCTION: It is known that exercise is effective in preventing muscle weakness that occurs during aging. On the other hand, it is not clear how training during the developmental period affects muscle function decline in the subsequent old age. We reported that the training conducted during the developmental period suppressed the regression change of the neuromuscular junction in the subsequent old age and maintained the fatigue tolerance of the muscle. Therefore, we examined the sustainability of the effect of developmental training on skeletal muscle endurance in old age from the viewpoint of oxidative metabolic capacity in the muscle.

METHODS: Fischer344 strain female rats were experimental animals. The Experimental muscles were PLA and EDL. Rats were divided: the group developmental training(T), the group subjected to normal rearing until 66 weeks of age(AC), after developmental training (DT), and the group retraining from 54 weeks of age after developmental training (RT). Developmental training consisted of intermittent running on a treadmill for animals. Training from old age consisted of running using forced exercise wheels (co. MELQUEST). ATPase and SDH staining were used to examine changes in muscle fiber type composition ratio and oxidative metabolism. Tissue images were observed with a light microscope and analyzed with ImageJ software. SDH activity is indicated by optical density (OD / min).＜RESULT＞ In AC group, Type I occupancy rate, the area occupancy rate (%area) by muscle fiber type increased significantly in PLA, and the number ratio (%no) by muscle fiber type increased significantly in EDL. Significantly higher values were shown in the DT and RT group. There was no difference in OD showing SDH activity.

RESULTS: The SDH activity, which is an index of muscle endurance, did not show any effect. In the muscle fiber type composition ratio, %area of EDL and the %no of PLA showed high values for Type I in the AC group. Aging-related slowing was observed. At a young age, type transfer is unlikely to occur between Type I and Type II. However, it has been reported that in old age, regressive changes in the neuromuscular junction and denervation cause transition between Type I and Type II. De-training and Re-training were not different from those in the young group. It is suggested that the age-related changes due to training were suppressed. Muscle fibers that are identified as IIb-FOG or Type IId are fast type but have high oxidative ability. Therefore, the increase in IIb-FOG may be that increased the muscle endurance of the training group.

CONCLUSION: From the results of this study, it can be expected that developmental training suppresses changes in histological characteristics associated with aging. In particular, it inhibits the transition to slow muscle fiber type. It is suggested that the training effect during the development period can be maintained for a long period of time.

### EFFECT OF GLUCOSE DELIVERY ON ADIPOGENESIS OF HUMAN MSCS EXPOSED TO A COMBINED MECHANICAL AND HYPOXIC STIMULUS

PULIDO, V., CAMACHO-CARDENOSA, A., TORRECILLAS-BAENA, B., CASADO-DÍAZ, A., GÁLVEZ-MORENO, M.A., CAMACHO-CARDENOSA, M.

*INSTITUTO MAIMÓNIDES DE INVESTIGACIÓN BIOMÉDICA DE CÓRDOBA*

INTRODUCTION: Effect of hypoxia on substrate use could be relevant to know the nutritional requirements for exposed hypoxia population. Since the oxygen requirement of ATP synthesis is greater during fatty acid oxidation than glucose oxidation, a switch in substrate preference away from fatty acids represents a possible mechanism of adaptation to hypoxia (Braun 2008). There is strong evidence that in hypoxia the transcription of genes related to membrane transport of glucose (GLUT-4) and glycolysis (Semenza 2003), density of lactate transporters and lactate dehydrogenase (McClelland and Brooks 2002) are up-regulated. HIF pathway also increases the expression of pyruvate dehydrogenase kinase 1 (PDK1) contributing to the suppression of oxidative metabolism (Murray et al. 2018).

However, when the hypoxic stimulus is combined with elevated basal metabolism (mechanical stimulus, as consequences of exercise), the energy deficit can obscure the effects of ‘‘true’’ hypoxia suggests that it is a more potent metabolic stimulus (Braun 2008). On the other

hand, the caloric restriction at altitude dampens the rise in blood glucose availability normally experienced at increased elevations (Barnholt et al. 2006). Lower blood glucose concentrations contribute to a shift in substrate selection from carbohydrate to alternate fuel sources such as fat or ketones to support energy needs. However, a reduction in lipid dependence at altitude has been noted when the subjects develop controlled diet in altitude (Roberts et al. 1996).

Taken together, these data could provide key insights that inform practical recommendations for nutrition at altitude (Braun 2008). There is a lack of knowledge in the scientific literature about predominant metabolic pathways when combining a mechanical and hypoxic stimulus with increased or decreased energy intake. Moreover, the physiological mechanisms are not described. Thus, the aim of this study is to know how the combination of agitation and intermittent hypoxia during adipogenesis, with a greater or lesser supply of nutrients, could influence on the capacity of these cells to generate fat vesicles.

METHODS: Cultures of human mesenchymal stem-cells of bone marrow were induced to adipocytes and exposed 4 days per week to agitation and hypoxia (1 or 2 hours per days). The culture medium was changed twice a week for part of the cultures and three times a week for the other part. Expression of adipogenic genes as well as fat vesicle formation were studied

RESULTS: In adipocyte where the culture medium was changed 2 days a week, subjected to hypoxia and agitation (both 1d/4w and 2h-4d/w), lower levels of fat vesicles were observed compared to the control group. However, the amount of fat was higher when the culture medium was changed 3 days per week.

CONCLUSION: Hypoxia training combined with a controlled diet may improve body composition through loss of fat mass.

**EFFECT OF TRAINING PHASE ON 8OHDG WITH MENSTRUAL CYCLE IN FEMALE ATHLETES**

MOMMA, R., SHIMIZU, K.

*JAPAN INSTITUTE OF SPORT SCIENCE*

INTRODUCTION: The Menstrual cycle influences change physical and psychological condition and performance in female athletes.

Previous studies have reported that increased stress and anxiety during the luteal and menstrual phases, as well as decreased agility performance, endurance performance, intermittent endurance performance.

8-hydroxy-2-deoxy-guanosine (8OHdG) excreted into the urine is a marker of oxidative stress, and it has been reported to be associated with fatigue, psychological stress, and exercise. It has also been reported that 8OHdG changes with the menstrual cycle. However, it is unclear how the training phase (competitive phase, preparation phase, transition phase) influences 8OHdG with the menstrual cycle in female athletes.

Thus, the purpose of this study was to investigate the effect of training phase on the 8OHdG with menstrual cycle in female athletes.

METHODS: 17 female competitive collegiate athletes participated in this study. We conducted the measurements during competitive phase and preparation phase of menstrual phase, follicular phase and luteal phase. Subjects were taken their urine on the day of measurement. First morning urine sample was collected. The 8OHdG concentration was measured using enzyme-linked immunosorbent assay.

RESULTS: The urinary 8OHdG concentration was significantly higher during competitive phase than during preparation phase ($P<0.05$). However, the urinary 8OHdG concentration did not show significant change with menstrual cycle. 2-way ANOVA was used to determine the effect of training phase on the urinary 8OHdG changes with menstrual cycle, and no interaction was found, but there was a main effect of training phase ($p<0.05$).

CONCLUSION: The results of this study showed that the urinary 8OHdG level with training phase but not with menstrual cycle. There was also no effect of training phase on the 8OHdG with menstrual cycle in female athletes.

**HEAT STRESS AMPLIFIES METABOLOMIC PERTURBATIONS INDUCED BY EXERCISE**

BENNETT, S., OWENS, D., PHELAN, M., GUIBERT, E., TIOLLIER, E., MORALES-ARTACHO, A., LALIRE, P., MORTON, J., BROCHERIE, F., LOUIS, J.

*LIVERPOOL JOHN MOORES UNIVERSITY*

INTRODUCTION: During endurance exercise, environmental heat stress induces greater carbohydrate (CHO) oxidation and is characterised by increased respiratory exchange ratio, relative hyperglycaemia and accelerated muscle glycogenolytic rate (Febbraio, 2001). Using untargeted metabolomics, we aimed to characterise the effect of environmental heat stress during exercise on the human serum metabolome.

METHODS: Twenty-three trained male triathletes ($VO_2peak$ = 64.8 ± 9.2 mL·kg·min-1, 332 ± 45 W) completed fixed duration (30 min) maximal exercise tests in Hot (35°C) and Temperate (Temp) (21°C) conditions. Power output (PO), heart rate (HR), core body temperature (Trec) and Rating of perceived exertion (RPE) were recorded throughout. Venous blood samples collected immediately pre- and post-exercise were assessed by untargeted 1H-NMR metabolomics in accordance with best practice set out by the metabolomics standards initiative (Sumner et al. 2007). Data were analysed via uni- (P values corrected for multiple tests by FDR) and multi-variate analyses to identify differences between conditions.

RESULTS: Mean PO was higher in Temp (231 ± 36 W) vs. Hot (223 ± 31 W) ($P < 0.001$). Mean HR (Temp = 162 ± 10 beats·min-1, Hot = 167 ± 9 beats·min-1, $P < 0.001$), peak Trec, ΔTrec ($P < 0.001$) and peak RPE ($P = 0.005$) were higher in Hot vs. Temp. Metabolite abundance (Δabundance) was analysed from pre- to post-exercise with Principal Component Analysis revealing distinct clustering per condition and partial least squares discriminant analysis accentuating variance between conditions. Ten metabolites critically important for distinction between conditions were identified. Six metabolites saw greater increase (2-Hydroxyvaleric Acid, Acetate, Alanine, Glucarate, Glucose, Lactate) in Hot than Temp ($P < 0.05$). Leucine and Lysine decreased in both conditions but to a greater extent in Temp ($P < 0.05$). Citrate ($P = 0.04$) was greater in Temp whilst Creatinine decreased in Hot only ($P > 0.05$).

CONCLUSION: Environmental heat stress poses a serious threat to endurance exercise capacity reducing workload and increasing physiological strain. Consistent with current literature, we have shown increased lactate accumulation and relative hyperglycaemia in response to exercise in hot conditions. Increased glycolytic metabolites in Hot with a concomitant increase in citrate in Temp indicates greater contribution of glycolytic CHO metabolism under heat stress. Furthermore, we have highlighted additional important metabolites including essential amino acids which increased during exercise in temperate conditions, highlighting environmental variation in protein metabolism.

### CHANGES IN CENTRAL ARTERIAL STIFFNESS AFTER THE FIRST VERSUS SECOND BOUT OF ECCENTRIC EXERCISE OF THE ELBOW FLEXORS

HASHIMOTO, Y.1, ESAKI, K.1, HATA, U.1, NOSAKA, K.2, OKAMOTO, T.1

*1. NIPPON SPORTS SCIENCE UNIVERSITY, 2. EDITH COWAN UNIVERSITY*

INTRODUCTION: Resistance exercise training increases muscle volume and function. Eccentric resistance exercise (ECC) is effective for muscle hypertrophy and strength gain and improves metabolic function, but unaccustomed ECC induces muscle damage. Muscle damage is a factor for the delayed increase in central arterial stiffness, which is an independent risk factor for cardiovascular disease (1). However, the relationship between the magnitude of muscle damage and the change in arterial stiffness is not clear. The magnitude of ECC-induced muscle damage is significantly reduced after the second bout of the same exercise, which is termed as the "repeated bout effect" (RBE) (2). Therefore, the present study compared between the first and second bouts of ECC for changes in arterial stiffness to test the hypothesis that arterial stiffness would increase greater after the first than the second ECC bout.

METHODS: Eleven healthy, untrained young men (22.6±1.8 y) who were normotensive (< 140/90 mmHg) and non-obese were recruited. They performed two bouts of ECC of the elbow flexors consisting of 6 sets of 10 eccentric contractions for each arm using a dumbbell set at 80% of one-repetition maximum strength separated by 2 weeks. Carotid-femoral pulse wave velocity (cfPWV), an index of central arterial stiffness, and some indirect markers of muscle damage such as maximal voluntary isometric contraction torque (MVC), muscle soreness, serum creatine kinase (CK) activity and high sensitivity C-reactive protein concentration (hsCRP) were measured before and 1, 24, 48, 72 hours after the exercise. Changes in these variables were compared between bouts by two-way repeated measures ANOVA (MVC, cfPWV), and Kruskal-Wallis and Mann–Whitney U test (muscle soreness, CK and hsCRP).

RESULTS: Decreases in MVC were greater ($P<0.05$) after the first (e.g., 24 h post-exercise: -59.0±12.0%) than the second bout (-20.0±10.6%). Muscle soreness developed greater after the first (peak: 25.9±32.9 mm in a 100-mm scale) than the second bout (6.8±8.8 mm). CK activity increased larger ($P<0.05$) after the first (peak: 26,341±24,809 IU/L) than the second bout (206±87 IU/L), but hsCRP concentration did not change significantly after both bouts. A significant ($P<0.05$) increase in cfPWV from the baseline (789.8±105.6 cm/s) was observed at 48 h after the first bout (824.1±103.9 cm/s), but no significant changes were evident after the second bout. The magnitude of increase in cfPWV was not correlated with the magnitude of changes in any of the muscle damage markers (r=-0.01–0.71).

CONCLUSION: The smaller changes in the muscle damage markers after the second than the first bout indicate typical RBF. The RBE was also evident for cfPWV, which increased 4.5±4.4% at 48 h after the first bout but unchanged after the second bout. These suggest that central arterial stiffness increases when muscle damage is induced by ECC.

## Physiotherapy

### RUMBA DANCE COMBINED WITH BREATHING TRAINING AS AN EXERCISE INTERVENTION ON IMPROVING STRESS URINARY INCONTINENCE IN POSTMENOPAUSAL WOMEN

YUTING, T., XIAN, G.

*BEIJING SPORT UNIVERSITY*

INTRODUCTION: Stress Urinary Incontinence (SUI) refers to involuntary leakage from the urethra, synchronous with exertion/effort, sneezing or coughing, which is common among postmenopausal women and has a negative effect on quality of life. Due to the limitations of existing clinical treatments for SUI, Clinicians and Physiotherapists are interested in complementary strategies for managing the symptoms. Studies have shown that mild-to-moderate physical activities reduce the risk of SUI by multiple mechanisms, such as reducing obesity and slow the reduction of estrogen levels. Therefore the objective of this study is to determine whether the Rumba dance combined with breathing training (RDBT) can reduce the severity of incontinence and improve the quality of life of patients with SUI.

METHODS: Randomized clinical trial involving sedentary postmenopausal women who reported mild to moderate SUI on 1-hour pad test, the volunteers were not already engaged in Rumba dance and not received estrogen replacement therapy. The patients were randomly assigned to RDBT group(N=14) and control group(N=11), The intervention included 90 minutes of RDBT three times a week for 16 weeks, the vaginal resting pressure(VRS), pelvic floor muscle(PFM) strength and endurance, 1-hour pad test, International Consultation on Incontinence Questionnaire-urinary incontinence short form (ICIQ-UI-SF) , quality-of-life questionnaire(QOL) were measured at baseline and 16 weeks. None of the participants reported adverse events.

RESULTS: The mean (+/-SD) age of the participants was 54.75±6.40 years. After 16 weeks, in the RDBT group, the VRS increased from 76.00±16.23cmH2O to 95.09±18.90cmH2O ($P<0.01$). The grade of PFM strength of class Ⅰ (2.77±2.01 VS 4.23±0.83, $P<0.01$)and class Ⅱ (2.62±2.26 VS 4.38±0.77, $P<0.01$) were both enhanced, and the PFM endurance of class Ⅰ (-3.15±1.99% VS -0.46%±0.97, $P<0.01$) and class Ⅱ (-0.69±0.95% VS -0.23±0.44%, $P<0.01$)were increased respectively. The urine leakage on 1-hour pad test were significantly decreased from 3.91±3.61g to 1.88±1.78g ($P<0.01$). Finally, the severity of self-reported (ICIQ-UI-SF) significantly reduced from the score of 6.12±2.15 to 3.81±1.68 ($P<0.01$), and the quality of life (QOL) improved from scores of 75.73±11.93 to 83.48±7.88($P<0.01$).

CONCLUSION: A 16-week RDBT program can increase the PFM strength and endurance to reduce the severity of incontinence symptoms and improve the quality of life in patients with SUI, demonstrating the feasibility of recruiting and retaining postmenopausal women with SUI into a RDBT therapeutic program.

## Psychology

### COACH INTERPERSONAL STYLE, COMPETENCE AND MOTIVATION IN HIGH PERFORMANCE ATHLETES

PINEDA-ESPEJEL, H., TREKO, M., ROMERO, T.

*UNIVERSIDAD AUTÓNOMA DE BAJA CALIFORNIA*

The self-determination theory (SDT; Deci and Ryan, 1985; Ryan and Deci, 2000) postulates that the motivational climate created by the coach is related to the motivation of athletes via the satisfaction of their psychological needs (Reinboth, Duda and Ntoumanis, 2004). The purpose of this study was to analyze the association between the interpersonal styles that athletes perceive the coach to generate (ie autonomy support, and controlling style), the competence need (satisfaction and frustration), and motivational regulations in high performance sport. A set of questionnaires was administered to 239 high performance athletes (117 woman, 122 man) with a mean age of 23.37 years (SD = 5.7) who participated in a variety of sports. The bivariate correlation results showed that the autonomy support style was positively associated with the competence perception ($r = .24$, $p < .01$, but not with frustration of competence). While the controlling style was negatively associated with the perception of competence ($r = -.13$, $p < .05$) and positively associated with the frustration of competence ($r = .27$, $p < .01$). The satisfaction of competence was associated positively with autonomous motivation ($r = .24$, $p < .01$) and negatively with controlled motivation ($r = -.21$, $p < .01$). The frustration of competence was related positively with controlled motivation ($r = .21$, $p < .01$) and amotivation ($r = . 20$, $p < .01$). In conclusion, this work partially supports the postulates of SDT within high-performance sports.

### IMPACT OF THE COVID-19 PANDEMIC ON ATHLETES BELONGING TO THE JAPAN PROFESSIONAL FOOTBALL LEAGUE

SASABA, I., MURAKAMI, K., HAYASHI, Y., SAKUMA, H.

*RITSUMEIKAN UNIVERSITY, TOKYO UNIVERSITY OF SCIENCE, NARAGAKUEN UNIVERSITY, KOSHIEN UNIVERSITY*

Introduction

The coronavirus disease of 2019 (COVID-19) pandemic has led to dramatic changes in the sports environment (Grix, Brannagan, Grimes, & Neville, 2021). The changes in the sports environment have impacted psychologically on athletes.

Methods

To clarify these psychological changes, a survey was conducted of 29 athletes belonging to a single Japanese Professional Football League (J-League) team. This measured the participants' motivation using the Sport Motivation Scale Questionnaire (SMS), and self-efficacy using the Psychological Performance SE Scale (SE) for a football season before and after the onset of the pandemic.

Results

A comparison of the participants' SMS (2019 = 73 points; 2020 = 69 points) and SE (2019 = 88 points; 2020 = 83 points) scores before and after the start of the pandemic, using the t-test, indicated a declining trend in both the motivation and self-efficacy of athletes for the 2020 season. No significant difference was found (SE: $t(28)=1.29$, $p=0.21$, SMS: $t(28)=1.50$, $p=0.15$). However, changes in individual players were evident. Seven athletes indicated a drop of more than 5% in their SMS scores for the 2020 season, with a further three athletes showing an increase of more than 5%. Regarding SE scores, five players displayed a drop of more than 5% for the 2020 season, with three athletes showing an increase of more than 5%.

Discussion

These results indicate that the pandemic may have had a negative psychological impact on the motivation and self-efficacy of these athletes. However, individual differences were found in athletes' responses to the crisis. Therefore, it is necessary to further examine the underlying factors behind the psychological changes observed in athletes during this period.

This work was supported by Individual Special Research Subsidy (Kwansei Gakuin University, 2020).

### INTERNATIONAL PILOT STUDY PARTICIPATION MOTIVATION IN IRANIAN STUDENTS

GHAZVINI, N.

*HUNGARIAN UNIVERSITY OF PHYSICAL EDUCATION AND SPORT SCIENCES IN BUDAPEST*

International pilot study participation motivation in Iranian students

Ghazvini, N., Soos, I., Hamar, P.

Hungarian University of Physical Education and Sport Sciences in Budapest

Introduction

Motivation is the force that causes movement in humans. In fact, any agent that causes (internal or external) activity in a living being is considered as a kind of motivation. According to the Motivation is the driver of guidance, control, and persistence in human behavior. Therefore, it is important to know the motivation for students participation in physical activities.

Methods

The sample consists of 50 Iranian female students aged 13 and 14 years old who filled out participation motivation questionnaires online in a pilot test. The Participation Motivation Questionnaire (PMQ) was designed by Gill, Gross, and Huddleston in 1983. This questionnaire consists of thirty questions and originally included eight possible factors that describe the possible reasons for participation in sport on a 5-point Likert scale (not at all important= 1 to extremely important= 5). The factor structure of the PMQ has been variable in prior research studies and so exploratory factor analysis was performed on the data.

Results

According to the varimax rotation, there were 7 factors. They consist of belonging to friends, team orientation, competition/ excitement, important people, fame/status, skill development, energy release. Intrinsic motivation factors included skill development, energy release, team orientation, and belonging to friends and extrinsic motivation factors included prestige/status, important people, and competition/excitement. Descriptive statistics indicated that the students most important motives for participating in physical activity were skill development, team orientation, and energy release.

Discussion

Findings of this pilot test showed that there are 7 factors for this questionnaire among Iranian students. Our finding is supported by Shafizadehs (2007) result. The results also showed that intrinsic motivation factors were the most important reason for students

participation in physical activity, which is in line with Yildirims (2021), Ignatova et al.s (2017), Zahariadis & Biddles (2000). In conclusion, a different approach should be considered in order to motivate adolescents, as intrinsic motivation (e.g. I want to participate) is more adoptable in this age group, rather than extrinsic motivation (e.g. I must participate).

Keywords: Motivation, Participation Motivation Questionnaire (PMQ), Iranian students

## THE MEDIATING ROLE OF EMOTIONAL SYMPTOMS IN THE ASSOCIATION BETWEEN FITNESS AND ACADEMIC PERFORMANCE: DADOS STUDY

MONZONÍS-CARDA, I., ADELANTADO-RENAU, M., BELTRAN-VALLS, M.R., MOLINER-URDIALES, D.

*UNIVERSITAT JAUME I*

The positive association between fitness and academic performance has been previously documented in adolescent population. Nevertheless, the mechanisms that may be behind this association need further exploration. Emotional symptoms could play an interesting role, since their presence has been negatively related with fitness and academic performance. Thus, the main aim of this study was to analyze the mediating role of the emotional symptoms in the association between physical fitness components and academic performance in a sample of adolescents. A total of 264 adolescents (126 girls) aged 13.9±0.3 years old and participants of the DADOS (Deporte, ADOlescencia y Salud) study were included in the analyses. Physical fitness components were assessed through the handgrip test for upper-limb muscular strength, standing long jump for lower-limb muscular strength, 4x10-m shuttle run test for speed-agility, and 20-m shuttle run test for cardiorespiratory fitness. The emotional symptoms index was evaluated through the Behavior Assessment System for Children and Adolescents. Academic performance was assessed by the final academic grades of math, language, and overall grade point average. Boot-strapped mediation procedures were performed and indirect effects with confidence intervals not including zero were considered statistically significant. The findings of this study showed that the positive association between lower-limb muscular strength, speed-agility, and cardiorespiratory fitness with academic performance indicators were mediated by the emotional symptoms index (percentage of mediation ranging from 27% to 77%). Enhanced physical fitness, particularly in lower-limb muscular strength, speed-agility, and cardiorespiratory fitness might decrease the presence of emotional symptoms, with potential benefits on adolescents' school grades.

## CAUSES OF FATIGUE IN ELITE FOOTBALL: A SURVEY OF ELITE FOOTBALL STAKEHOLDERS

BAHDUR, K.

*UNIVERSITY OF GLASGOW*

Introduction

In sport, burnout contributes to decreased performance, increased risk of injury, sports dropout and decreased mental and physical health. Mental fatigue (MF) and physical fatigue (PF) are precursors to burnout. Most research focuses on the physical load experienced during training and competition. In the modern game, elite football stakeholders are exposed to on and off-field stressors which may cause fatigue. The purpose of this study was to subjectively identify factors that contribute to fatigue and identify the type of fatigue that manifests because of exposure to these causes.

METHODS: An online questionnaire investigated whether a) football specific, b) associated professional factors, and c) psychosocial factors: i) caused fatigue, ii) the extent to which it caused fatigue and iii) the type of fatigue induced in elite football stakeholders (N=103).

Results

Both on and off-field factors contributed to fatigue. Only four factors were applicable to less than 80% of respondents (sponsor commitments (74%), safety at matches (77%), media scrutiny of football-related performance (76%) and non-footballing matters (73%)). Training and match stimuli including physical (always:51%- training; always 70%- matches) and mental (always:42%- training; always 32%- matches) loading, number of sessions (always:54%- training; always 64%- matches), recovery time between matches (always:75%) and travel time, particularly in relation to training (always:54%) domestic away matches (always:47%) and international travel (always:72%), were high contributors to fatigue. For these variables between 25% and 70% indicated they caused fatigue to a large extent. Off-field stresses related directly and indirectly to the job include feeling isolated (always:29%), safety concerns (always:26% in public; always 34% at matches) and lack of job security (always:41%) as well as interactions with other stakeholders. MF was just as pertinent as physical fatigue with most stimuli causing a combination of mental and physical fatigue. Stimuli that included mental loading only (such as fear, feeling isolated, identity, and football and non-football-related scrutiny from other stakeholders) resulted mainly in MF. Feeling isolated (80%), the attitude of family and friends towards their profession (79%) and fan scrutiny and judgement related to non-football matters (77%) were the dominant causes of MF. It must be highlighted that not all these were regular causes of fatigue.

Discussion

On and off-field occupational stressors cause fatigue in elite football stakeholders. The prevalence of both MF and PF requires more integrated fatigue management strategies which should be further studied to minimize the impact fatigue has on football performance and stakeholder wellbeing. These findings highlight the importance of approaching fatigue management from a holistic perspective and extending attention beyond just the current narrow scope of focus.

## STUDY ON THE EFFECT OF CONTINUED DANCE ACTIVITY ON THE PREVENTION OF FRAILTY - FROM INTERVIEWS WITH THREE ELDERLY WOMEN

OKA, C.

*OCHANOMIZU UNIVERSITY*

Introduction

In the research of dance practice for the elderly, the effects of dance on frailty prevention have not been adequately discussed. It is not clear in what aspects of frailty, i.e. physical, psychological or social, does dance have effect on and what kind of dance programs are appropriate for frailty prevention. Prior research has suggested that dance programs in senior care facilities may have an impact on reducing psychological symptoms, such as BPSD, and maintaining or improving quality of life by reactivating the mind-body connection.

The purpose of this study is to determine what kind of frailty prevention could be achieved when the elderly continues dance activities and what kind of program structure would be suitable for them.

Methods

We conducted questionnaire on and semi-structured interviews to three elderly women, Age 71.67±1.25 (n=3), The subjects do not have any disease, and they had been dancing at least twice a month for at least 2 years. The SF-12 ver.2 was used for the QOL survey. Questions for the interview included subjective changes subjective changes before and after the dance activity, motivation to continue the activity, and program content sought in the future.

Results

The three subscale summary scores of the SF-12 were calculated using the national standard value of 50. The average summary scores for the three study subjects were 43.37 for the physical component summary, 53.53 for the mental component summary, and 57.63 for the role/social component summary.

The interviewees felt a particular sense of comfort and openness in moving in accordance with the rhythm in dance compared to non-dance activities. As for the changes compared to before the activity, the respondents felt more psychological changes than physical changes. In terms of motivation for the activities, it was found that they were more interested in having a change of mood, a sense of liberation, and communications with other participants than in physical exercise. Although the activities were mainly focused on learning fixed movements and dancing in unison, two of the three participants expressed a desire for improvisational expressive activities in the future, while one participant was less motivated.

Discussion

The results suggest that the psychological and social effects of dance may be greater than the physical effects when older adults continue to dance. It also showed that elderly people participate in activities with the expectation of liberating themselves and communicating with others. From this we consider that creating programs to achieve such goals may enhance the effect of dance in frailty prevention. The two participants showing a willingness to participate in improvisational expressive activities, suggests that an improvisational dance program in which the elderly can participate with ease may be an appropriate program to be implemented further. We expect the effects of such activities to be verified in the future.

## HOW SPANISH ROWERS HAVE COPED WITH COVID CONFINEMENT PERIOD: A PSYCHOLOGICAL AND BEHAVIORAL STUDY.

GARCÍA-GONZÁLEZ, P., COSTA-AGUDO, M., VARELA, C., PEÑALOZA, R., MÉNDEZ-SÁNCHEZ, M.P., ALARCÓN, D., TRUJILLO, M., WILCZYNSKA, D., JAENES, J.C.

*UNIVERSITY PABLO DE OLAVIDE*

Spanish Sports situation during COVID-19 pandemic described as very hard: uncertainty, incredulity, and distress were reported, and included worry about the Olympics cancellation, future in general, future economic support and return to sports participation. The aim of this research is to present how Spanish rowers have been personally, and emotionally affected by the situation created; as well as to describe how they have coped with this negative situation. Participants: 193 rowers participated in the survey. (Mean age = 19.4 ± 3,9) Female: 40,9% Mean age = 19,4 ±3,8 53%; Men: 59,1% Mean age = 19.3 ± 3,9), 80,8% compete at Spanish National level and 19,2% at International level. Procedure: an online questionnaire named RECOVID-19, was designed to assess how athletes were living their lives during periods of home confinement. The main purpose of the questionnaire was to assess the impact of prolonged confinement on athlete's psychological, emotional, and behavioral performance, and included a validated Spanish version of Profile of Mood State, socio-demographic questions, training conditions at home, rule acceptance, motivation, stress, and other behavioral problems. Results showed that during confinement, (24,4%), of participating rowers practiced training routines at home between 8-10 hours per week and (29%). between 11-13 hours a week. Gender differences, tested by multi-group analysis, revealed that engaging in coping activities was more often associated with negative emotional states among female rowers, who scored higher in negative thoughts, anger, and fatigue. Lack of motivation and behavioral problems was associated in both men and women with negative emotional states. Rule acceptance was positively related to positive emotional states, whereas the ongoing availability of training information and future conditions were equally protective factors for both genders, increasing the vigor sensation, and decreasing fatigue, tension, and depression. Better training conditions in both also increased vigor sensation. During confinement, coping activities were important to reduce distress, and were used extensively. Video calls, online and other networking activities (96,4), reading (57,77), watching TV (84,5%), listening to music (80,8%), learning something new (52,3%) like cooking (19,2), practicing relaxation techniques (48,2%) or mindfulness (11,4%) were the most popular coping activities reported by rowers. Conclusions: Among this sample of Spanish rowers coping with confinement, women and men have presented different characteristics, and have experienced the situation differently. Coach information, and psychological information have been beneficial and have facilitated coping with this very new and difficult situation between Spanish rowers. Programs to protect athletes facing critical situations , should consider the different reactions between men and women in planning interventions.

## ASSOCIATIONS OF SPECIFIC SCREEN-BASED SEDENTARY BEHAVIORS WITH ANXIETY AND STRESS AMONG CHINESE COLLEGE STUDENTS

HUANG, T., ZHENG, K., YANG, Y., LI, S., ZHAO, Y.

*SHANGHAI JIAO TONG UNIVERSITY*

Background: Mental health issues, including anxiety and stress, are associated with an increased risk of morbidity and mortality. Some epidemiological studies found that prolonged sedentary time or screen-based sedentary time were negatively associated with anxiety and stress. However, the associations between screen-based sedentary behaviors and mental health may vary by type of screen time. Evidence showed that college students engage in a larger amount of sedentary time due to their time in class and time studying. The associations of specific screen-based sedentary behaviors with anxiety and stress remain to be clarified. Therefore, the objective of the study was to examine the associations between different types of screen-based sedentary behaviors with anxiety and stress among Chinese college students.

Methods: A total of 518 Chinese college students participated in this cross-sectional study. Screen-based sedentary behaviors on weekdays and weekends were self-reported using a questionnaire. The participants were required to report their content-specific screen-based recreational behaviors, including time on video viewing, social media, leisure reading, and video gaming. Anxiety symptoms were evaluated using the Self-Rating Anxiety Scale (SAS) and stress symptoms were evaluated using the Perceived Stress Scale (PSS). Physical activity and sleep were objectively measured using the Axivity AX3 (Newcastle, UK) wrist-worn triaxial Accelerometer. We categorized the participants into three groups ("0–60 min," "1–2 h," and ">2 h") based on the time spent engaging in each screen behavior. Independent associations between various types of screen behavior and prevalence of anxiety and stress were examined by one-way analysis of variance (ANOVA).

Results: The ANOVA revealed that the main effects of video viewing, social media, and leisure reading on anxiety were significant. College students who spent more than 2 h/day on video viewing (both weekday and weekend), social media (both weekday and weekend), and leisure reading (only weekend) had a higher score of anxiety than 0-60 min/day. The ANOVA revealed that the main effects of video viewing and social media on stress were significant. College students who spent more than 2 h/day on video viewing and social media had a higher score of stress than 0-60 min/day (both weekday and weekend). The ANOVA revealed that the main effects of leisure reading and video gaming on sleep were significant. College students who spent more than 2 h/day on leisure reading and video gaming had a worse score of sleep than 1-2 h/day. There was no association between objectively measured physical activity and anxiety and stress.

Conclusions: The present study revealed that the associations between screen-based sedentary behavior and anxiety and stress varied by the types of screen behaviors. Interventions targeting prolonged screen-based sedentary behaviors should consider the types of screen content.

## EFFECT OF EXAM PERIOD ON PHYSICAL ACTIVITY, COGNITIVE FUNCTIONING AND SLEEP VARIABLES AMONG STUDENTS DURING COVID-19

HADDAD, M.1, ABBES, Z.1, ABDEL-SALAM, G.1, MOUSSA-CHAMARI, I.1, BIBI, K.1, EMADI, A.1, CHAMARI, K.2

*1. QATAR UNIVERSITY; 2. ASPETAR*

PURPOSE

The main objective of the study was to explore the effect of the exam period on sleep, physical activity and cognitive functioning among physical education students during COVID-19 lockdown.

METHODS

Twenty-one senior male students from the physical education department voluntary participated in the study. ActiGraph GT9X Link was used for sleep scoring (Sleep Efficiency %, Total Sleep Time [TST], and, Wake time after sleep onset [WASO]). Sleep measurements included also sleep log, daily self-rating scale of the sleep quality, and sleep quality Assessment (PSQI). The Cambridge Neuropsychological Test Automated Battery (CANTAB) was used to measure accurately the cognitive functioning. The cognitive test batteries included Rapid Visual Information Processing (RVP), Paired Associates Learning (PAL) and Spatial Working Memory (SWM). RVP measured the Sustained Attention. PAL assessed the Visual Memory. SWM is a notable executive function demands and it measured the strategy as well as working memory errors. Physical activity was measured using step counter walking 3D pedometers. Data were collected two weeks before and during the mid-term exam period. Students had 5 mid-term exams with a senior project report.

A 1-way analysis of variance (ANOVA) for repeated measures was used to examine the difference before and after exam periods in physical activity, cognitive measurements and sleep variables. When significant F values were observed ($p<0.05$), paired comparisons were used in conjunction with the Holm's Bonferroni method for controlling type I error to determine significant differences.

RESULTS

No significant differences were found in cognitive measurements and sleep variables between periods ($p>0.05$). Repeated-measure ANOVA results revealed significant effects with the number of steps using pedometers ($F=4.71$, $p=0.006$, $ES=0.21$, $P=0.87$). Pairwise comparison showed that significant higher number of steps was observed during week 3 and 4 (exam period) comparing to week 2 (before the exam period).

CONCLUSION

Hence, the exam period increases the physical activity of the senior male students during COVID-19 lockdown but does not affect the cognitive function and sleep variables.

Keywords: mid-term exams, number of steps, Rapid Visual Information Processing, Paired Associates Learning, Spatial Working Memory, undergraduate students, pandemic.

## A PSYCHOLOGICAL STRESS ASSESSMENT MODEL BASED ON PHYSIOLOGICAL SIGNALS IN A VIRTUAL REALITY ENVIRONMENT

HUANG, Y.H., SUN, L.X., TAO, K.

*BEIJING SPORT UNIVERSITY*

A psychological stress assessment model based on physiological signals in a virtual reality environment

Yuhan Huang1, Lixin Sun1, Kuan Tao1

1 AI Sports Engineering Lab, School of Sports Engineering, Beijing Sport University

INTRODUCTION: With the development of virtual reality (VR) technology, virtual reality exposure therapy (VRET) offers a great opportunity to explore stress disorder recognition and treatment [1],[2]. With integrated sensors, VRET could acquire users' physiological data under specified stress. Physiological signals exhibit unique characteristics during stress, hence the extraction of features and classification of stress levels from signals are gaining enormous popularity and importance currently. Therefore, the aim of this study was to create a psychological stress assessment model based on physiological signals using the machine learning algorithm, which is adaptable to different stress conditions provided by VR.

METHODS: 57 adults (20.9±1.9 yrs) volunteered to participate in this study after signing informed consent forms. Participants were asked to first take the Short State Anxiety Inventory（SSAI）to assess benchmark stress states before putting on a heart rate belt, EDA (electrodermal activity) wrist band and a VR head-mounted display. Then they logged into the self-developed VR stress training system, which comprises of three stressful scenes with two stress modes and sit peacefully in a chair for 3 min, during which benchmark values of EDA, heart rate and eye-blink rate were recorded. Participants then entered the three VR scenes in a random order and complete the SSAI immediately after the experience of each mode.

The physiological dataset was divided into training and validation sets (sample size ratio 8:2) respectively, and stress levels were labeled as “no stress”（1-2）, “low stress”（2-3） and “high stress”（>3） based on the score intervals from SSAI. Moreover, the statistics of EDA, heart rate, and eye-blink rate per participant were calculated as the feature vector to feed into the machine learning models.

RESULTS: Rest-state values were significantly lower than those in stress modes. Average heart rate and EDA were higher in the high-stress mode than the low-stress mode. As for the self-reported stress ratings, results showed that all three VR scenes produced a higher stress level. In addition, mean, median, standard deviation, maxima and minima of EDA, heart rate and maxima of eye-blink rate were used as an eleven-element feature vector to feed into the SVM, LR, RF, kNN, XGBoost and bagging supervised learning algorithms. The performance metrics of bagging algorithm achieved the highest scores on accuracy (0.742), F1-score (0.709) and recall (0.774).

CONCLUSION: This study revealed the relationship between physiological data and self-reported stress ratings and the psychological stress assessment model adopted the bagging ensemble learning algorithm for the best classification results, which motivates the further investigations of stress disorder recognition and treatment.

### THE DEVELOPMENT OF WOMEN SPORT IN THE TIME OF COVID-19: THE ANALYSIS OF THE POLICY-PRACTICE IN TAIWAN AND UK

JIANG, R.

*NATIONAL TAIWAN UNIVERSITY OF SPORT*

[INTRO/AIMS] Since the spread of COVID-19 has caused an unprecedented global pandemic, the lockdown policy not only severely impacted the economy of the sports industry, but also limited the development of sports. This situation seems to gradually magnify the plight of the development of womens sports under the epidemic. This study seeks to analyze the impact, policy and countermeasures of the development of womens sports under the epidemic in two countries with different political, social, and economical backgrounds, namely, Taiwan and the UK. [METHODS] Two complementary theoretical approaches are adopted, those of governance theory and a strategic-relational approach, which allows us to identify how such outcomes were mediated and shaped, and in particular how different sets of interests were implicated, how power was exercised, and whose interests were met. The empirical analysis draws on a qualitative case-study approach, which was based on documentary materials and semi-structured interviews. [FINDINGS] The gender play gap seems to be a long-term problem in womens sports development. During the epidemic, even though women have the same work-from-home, telecommuting issues, or training programs as men, they have to deal with most of the family matters in addition. Due to prolonged isolation and closure of sports facilities, participation in sports has been seriously affected, the UK government and relevant units, such as Sport England have actively proposed various coping strategies, including the campaign of Joint the Movement, and This Girl Can. Although it has not been confirmed what benefits these programs can have on womens participation in sports, it seems that the government are paying more attention to womens sports. In Taiwan, there was no large-scale city lockdown, and a higher proportion of the population exercising regularly was created in 2021. Even though various gender inequalities hinder the development of womens sports, Taiwan reached a new high sports participation rate during the epidemic. However, while observing the policy side in Taiwan, it is less active than in the UK. Taiwan government and relevant units did not seem to have launched a sports development strategy under the epidemic. The weakness of womens participation in sports seems to have been forgotten in the policy context during the epidemic. The growth of the sports population, especially the female sports population, seems to be based on the Taiwanese peoples awareness of linking sport with health. [CONCLUSION] This study found that the development of the womens movement under the epidemic has different appearances due to the governments role and cultural background. The severity of the epidemic should not be completely linked to the development of womens sports. Sports promoters might use the epidemic to become a booster for the development of womens sports.

### A COMPARATIVE STUDY OF CONVENIENCE AND SATISFACTION BETWEEN COMPREHENSIVE COMMUNITY SPORTS CLUBS AND ORDINARY PUBLIC SPORTS CLUBS

SAKAGUCHI, H.1, AOYAGI, O.2, ANNOURA, T.1, SEO, Y.3, CHOI, T.4, HAN, N.4, HONG, T.4, KOO, K.5, NAM, Y.6

*1 JAPAN UNIVERSITY OF ECONOMICS. 2 FUKUOKA UNIVERSITY. 3 CHOSUN UNIVERSITY. 4 JEJU NATIONAL UNIVERSITY. 5 CHANGWON NATIONAL UNIVERSITY. 6 DUKSUNG WOMEN'S UNIVERSITY.*

INTRODUCTION: Comprehensive community sports clubs (CCSCs) are one of the sports promotion policies that the Japanese Ministry of Education, Culture, Sports, Science and Technology has implemented since 1995 in order to realize a society of lifelong sports in Japan and are region-based sports clubs. However, the promotion has not necessarily been successful. To further spread and develop CCSCs, it is important to know what contributors are required. As ways to seek the factors not to pervade, it is thought that it is necessary to make clear what differentiates those who want to go to CCSCs and those who do not, though they all want to exercise or play sports. Thus, this study aimed to examine the differences in convenience and satisfaction between those who belong to CCSCs and those who belong to sports clubs other than CCSCs (OTHER).

METHODS: A questionnaire survey was conducted on 334 people (CCSC = 140, OTHER = 194) who regularly play sports in sports clubs. Questionnaire items were nine: 1) Satisfaction with the equipment; 2) Convenience of the means of transportation; 3) Convenience of parking; 4) Comfort of use; 5) What is required of the facility; 6) Satisfaction with the sports environment; 7) Contribution to the improvement of physical fitness; 8) Satisfaction with the costs; and 9) Contribution to containing medical costs. Then, QTTT (Quantification Theory Type Two, which is discriminant analysis using dummy variables as independent variables) was conducted using the nine items as independent variables and whether to belong to CCSC as a dependent variable.

RESULTS: The results of the QTTT showed that the multiple correlation coefficient obtained was 0.780 and the correct discriminate ratio was 88.2%, indicating a good distinction. When considering partial correlations and ranges of category weights, a relatively large impact by independent variables were found in 1) Satisfaction with the equipment (partial correlation = 0.732 and range = 2.034); 4) Comfort of use (0.270, 1.186); 5) What is required of the facility (0.195, 0.638); 2) Convenience of the means of transportation (0.183, 0.491); and 6)

Satisfaction with the sport environment (0.150, 0.359). When examining the direction of the signs of the items with a large impact, a good evaluation of CCSC was found in 4) Comfort of use, but not in 6) Satisfaction with sports environment. Both extremely good and bad opinions for CCSC without any slightly good/bad opinions were found in 1) Satisfaction with the equipment and 2) Convenience of the means of transportation. This was also found in item 5) What is required of the facility, whereas OTHER showed expectations for professional instruction, and for CCSCs, there was a desire for hobbies/pastimes other than sports/exercise and the provision of useful information.

CONCLUSION: Bipolarization of good and bad evaluations was found in CCSC, which had expectations for another added value other than sports rather than professional instruction.

## Sport Technology

### EYE-TRACKING ANALYSIS DURING FENCING FIGHTING

KATO, T., ISHIGURE, U., KOIKE, M., UMEDA, K., INOUE, Y., YOSHII, I., SUGAJIMA, Y.

*ASAHI UNIVERSITY*

INTRODUCTION: Fencing is an interpersonal sport and has three disciplines: epee, foil and sabre, with different rules and using different swords. The aim of this study was to clarify the different characteristics of the three fencing disciplines of epee, foil and sabre from the viewpoint of the eye gaze.

METHODS: Eighteen members of the University Fencing Team (3 disciplines x 6 members) have participated in national level competitions such as the National University Student Championships and the National Sports Festival. Some of them have competed in international competitions. Each fencer wore a pair of Tobii Pro glasses 3 (Tobii Technology), an eye-analysis device, wearing a fencing mask with a polyethylene made transparent face, and competed against each other. Fights were played as the first person to reach five points wins. Two fights were played with the same fencer (once with and once without the glasses). The time of seconds it took each fencer to score (total time) was measured. The eye gaze sites were classified into following four: 1) mask to neck, 2) chest and shoulders, 3) arms and hands, and 4) other. For the analysis of the gaze time (dwell time), the first three fights were analysed, and the area with the longest dwell time before each point was scored was selected. All data are expressed as mean ± SD, and significance difference tests between disciplines and between retention sites were analysed using one-way ANOVA in SPSS, and Tukeys HSD was used for multiple comparisons.

RESULTS: The total time and dwell time for epee, sabre and foil were 16.7±10.4 and 15.7±10.5 sec., 9.6±6.4 and 8.9±6.3 sec., 4.1±2.7 and 3.6±2.5 sec., respectively. Epee had a statistically significantly longer eye dwell time than sabre (p=0.02), but no significant difference were found between epee and foil, and also foil and sabre. There were no significant differences in eye dwell time by site for epee and foil, but for sabre the musk to neck (6.0±2.1 vs. 1.5±1.0 and 2.3±1.5 sec) were significantly longer than the chest and shoulders, and others (p=0.005, p=0.028).

CONCLUSION: Because the effective surface of the epee is the whole body including the foot, the part of the body that is at more intensively focused when fighting might be lower than in other disciplines (arms and hands, 55.6%). In the sabre and the foil, the gaze was concentrated on the upper body (mask to neck 50.0%, chest and shoulders 28.6% and arms and hands 0% for sabre, chest and shoulders 46.7%, mask to neck 20.0% and arms and hands 13.3% for foil) because the effective surface was the upper body. In summerly, there is a difference among the disciplines in the duration of the eye dwell time and the eye dwell area tends to be slightly lower in epee than in foil and sabre. Sabre seems to have different eye dwell time characteristics by site compared to epee and foil.

### INVESTIGATING SENSOR LOCATION ON THE USE OF CONTINUOUS GLUCOSE MONITORING DURING EXERCISE IN HEALTHY ADULTS

BURR, J.F., COATES, A.M., COHEN, J.N.

*UNIVERSITY OF GUELPH*

INTRODUCTION: Continuous glucose monitors (CGM) have recently emerged as a biological monitoring tool for non-diabetic athletes, with the primary purpose of monitoring glucose levels during endurance exercise. These minimally-invasive sensors measure minute-by-minute glucose concentrations through interstitial fluid (ISF) sampling, and are typically worn on the back of the arm. As most endurance sports depend primarily on repetitive contractions of the leg muscles, there may be differences in site-specific glucose uptake if the sensors are worn on the leg rather than the arm. The primary aim of this investigation was to determine whether CGM placement on the inner quadriceps would result in discrepant recordings compared to placement on the triceps brachii during incremental cycling exercise following glucose intake in healthy adults. Secondary aims were to determine if heating or muscle contractions via involuntary stimulation could explain any variation between sensor-readings.

METHODS: Complete data from 9 healthy participants (M:6, F:3) was recorded for 30min following 100g glucose ingestion during four conditions: resting control, incremental cycling exercise, quadriceps electrical muscle stimulation, and skin heating via electric heating blankets. Each condition was randomized for order separated by ≥48h, and occurred in the morning following an overnight fast. As a comparator, finger-stick capillary glucose samples were taken during control and cycling conditions.

RESULTS: Under control conditions, the arm sensor better reflected capillary glucose samples with a mean absolute relative difference (MARD) of 12.4±9.3% vs 18.3±11.4% in the leg, and there was a main effect of sensor location (P=0.01) whereby the leg sensor was consistently lower than the arm over the 30min period. During incremental cycling exercise, there was a time-by-sensor location interaction (P=0.02) such that the glucose sampled at the leg was reduced directly after the maximal portion of the exercise test, but MARD between capillary and ISF samples were similar across sensor locations (arm:15.5±12.0% vs leg: 16.7±10.8%). Muscle contractions via electrical stimulation negated the resting differences between sensors (sensor location, P=0.8). Finally, skin heating caused leg-skin temperature to increase by 3.1±1.8°C, compared to only 1.1±0.72°C in the arm (P=0.002), and resulted in a much lower glucose profile in the leg compared to the arm (time-by-sensor location interaction, P<0.001).

CONCLUSION: These results suggest that, at rest, traditionally located ISF glucose sampling on the fat pad of the triceps may best reflect capillary blood glucose. However, during cycling exercise CGM placement on closer to the primary movers may offer greater insight to working muscle glucose concentrations, and this is likely due to greater blood-flow rather than due to the muscle contractions alone.

## SHOE CONSTRUCTION MODIFICATIONS TO REDUCE BRAKING FORCE PARAMETERS DURING RUNNING

ESPOSITO, M.J.S.1, BARRONS, Z.B.1, CLERMONT, C.1, WANNOP, J.W.1, TAM, N.2, LANE, B.2, STEFANYSHYN, D.J.1

*1. UNIVERSITY OF CALGARY 2. ANTA CO. LTD, XIAMEN, FUJIAN, CHINA*

INTRODUCTION: Higher peak braking forces have been associated with an increased risk of running related injuries [1]. To reduce braking forces during running, alterations in gait parameters through gait retraining, such as decreasing stride length and increasing stride frequency, have been successful [2,3]. Through alterations in footwear properties such as cushioning material or outsole design, reductions in peak braking forces may also be possible. One possible change would be to increase the heel-to-toe drop of the shoe. This modification may allow for the runner to run with an increased stride frequency. Another possibility would be increasing the heel portion of the midsole to extend back further. This modification is thought to shift the center of pressure anteriorly, which would bring the orientation of the ground reaction force closer to the center of mass of the runner. To date, no research has altered footwear with the objective of reducing braking force parameters; therefore, the purpose of this study was to evaluate the previously mentioned shoe midsole modifications on braking force parameters.

METHODS: Ten individuals participated in this study, with each participant running at a self-selected speed over a force platform, completing five trials in each of four shoe conditions (Control, Drop, Extend, Combo). The Drop condition had a 20 mm heel-to-toe drop and the Extend condition had a 60 mm rearward extension of the heel from the heel cup. The Combo condition was a combination of the Drop and Extend conditions. The variables of interest were peak braking force and braking impulse. Paired T-tests were performed between each shoe condition and the Control condition.

RESULTS: Peak Braking force was significantly lower in the Extend condition (Mean: 275.98 N, SD: 55.21, $p = 0.043$) and the Combo condition (Mean: 270.29 N, SD: 53.3, $p = 0.011$) compared to the Control (Mean: 289.93 N, SD: 46.19). Braking Impulse was significantly lower in the Extend condition (Mean: 19.00 Ns, SD: 5.34, $p = 0.070$) and the Combo condition (Mean: 18.96 Ns, SD: 5.12, $p = 0.053$) compared to the Control (Mean: 19.87 Ns, SD: 4.57). There were no differences between the Control and Drop condition for peak braking force ($p = 0.325$) or braking impulse ($p = 0.656$).

CONCLUSION: This study was the first to use shoe construction modifications to reduce braking force parameters. The results from this study indicate that shoe modifications can reduce braking force parameters, potentially reducing the risk of running related injuries.

## THE ACCURACY OF FORM SMART GOGGLE SWIMMING MATRICES: A VALIDATION STUDY

TSAI, T.C., CHOW, H.W., HUANG, T.H., CHANG, C.I., HUNG, C.Y.

*NATIONAL CHENG KUNG UNIVERSITY*

INTRODUCTION: Training with wearable technologies has become increasingly popular in many sports. This wearable technologies accuracy is essential for providing users or their coaches with reliable information about their progress and adjusting their training to achieve better performance. The Form smart goggle, an innovation that differs from the traditional wrist-worn aquatic wearable device, measures and delivers metrics like time and distance. Its accuracy and reliability have not been determined.

METHODS: Therefore, we recruited six college female swimmers (meanSD:22.3±1.70) to participate in a pilot study in a standard 50-meter pool. Trials consisted of two sessions (one week apart) of 4*50 m front-drawn swimming at the best of the participants ability. A GoPro Hero 8, a digital action camera, served as the gold standard for measuring temporal movement. The Pearson correlation coefficient, the intraclass correlation coefficient (ICC), and the Bland-Altman plot are used to measure the correlation and consistency between the smart goggles and the camera.

RESULTS: Results of all trials showed a high agreement of time ((r=.921; ICC=0.918) and the mean absolute error (MAE) is 0.217 seconds. Stroke counts show moderate correlation (r=.428) and low reliability (ICC=0.388). The Bland-Altman analysis revealed that the goggle underestimated the number of strokes of 8.2.

CONCLUSION: We conclude that Form Smart Swim Goggles offer good timing accuracy, but factors causing bias in stroke counts must be explored. To improve swimming training in the future, further research needs to examine its accuracy and reliability for different stroke styles and distances.

## DEVELOPMENT OF AN ALGORITHM FOR PERSONALIZED SNPE PROGRAMS FOLLOWING POSTURE ALIGNMENT EVALUATION

PARK, S.E., LEE, H., YOON, J., LEE, D.T.

*KOOKMIN UNIVERSITY*

INTRODUCTION: The purpose of this study was to develop a method that can lead users to self-evaluate body posture alignment using a mobile device, and to design an algorithm that enables a personalized self natural posture exercise (SNPE) program to improve posture alignment based on the evaluation. To achieve the goals, the imaging method, body region evaluated, evaluation method, diagnosis standard, and the outcomes are developed to design the final algorithm of exercise program.

METHODS: The postural alignment evaluation is performed by taking full-body images of the frontal and sagittal planes (right side) while the subject is standing upright. For the rotation evaluation, left (L) and right (R) side of eye, acromion, chest, anterior superior iliac spine, knee, and ankle of the frontal image were marked. And the horizontal distance of each body part from the body center line was measured. When the distance of each L and R was different, the body parts were considered as off-lined. For the slope evaluation, the markings during the rotation were utilized and the L and R horizontal line was assessed. When the line was not horizontal, it was considered as unbalanced. From the sagittal plane image, the anterior and posterior superior iliac spine were lined and evaluated whether it is horizontal. when the line was not horizontal, it was considered as off-lined. For the center of gravity evaluation, the side of the knee, acromion, and center of ear was marked from the sagittal plane image. After vertical lining from the ankle, the marked parts were assessed whether they were off the line. When they were off the line, they were considered as off-lined. During the three evaluations, the degree and direction were not considered.

RESULTS: After evaluating all three posture alignment, the off-lined body parts were extracted, followed by selecting and listing SNPE movements matching for the correction of the off-line parts. Since the SNPE consists of 8 motions, some motions could be listed more than

once. When listed more, it was considered as more important movement. Based on the number of listed, the intensity and duration of movements were decided and 70 min exercise program was designed.

CONCLUSION: The algorithm was developed based on the connection of evaluation, diagnosis, and individualized exercise prescription. Using this algorithm, one can easily identify body alignment and perform a optimal SNPE program. It will be used as a useful mobile-based exercise guide.

## Sports Medicine and Orthopedics

### RESULTS OF FUNCTIONAL SPINAL EXAMINATION OF PREPUBESCENT STUDENTS

NAGYVARADI, K., SZIGETHY, M., BIRÓNÉ ILICS, K., IHÁSZ, F.

*EÖTVÖS LORAND UNIVERSITY*

INTRODUCTION: Several studies have concluded that a sedentary lifestyle is spreading rapidly among the younger age group (Szigethy, 2020; Kun et al., 2019). A recent Health Behavior in School-Aged Children (HBSC) study found that less than one in five adolescents meet the World Health Organization's (WHO) physical activity recommendations (Jo Inchley et. al., 2020). The physical inactivity of prepubescents contributes to the development of pathological changes in the spine and to an increase in the detrimental effects of pre-existing degenerations. The aim of this research, which was launched with an emphasis on prevention, is to examine the spine of the students in the sample and to identify the postural weaknesses that contribute to the development of the lesions. In the light of the results, it is extremely important to compile a targeted prevention program.

METHODS: The study was conducted in November 2021 among 6th grade students of the Gárdonyi Géza Primary School in Győr, Hungary (n = 71). Using cross-sectional study, we studied the physiological curvatures of the spine in a standing position and under load (Matthias test). The Spinal Mouse was used to examine the spine. The instrument can examine the morphological characteristics and mobility of all vertebrae between C7 - S1 of the spine.

RESULTS: The study included girls (n = 30) as well as boys (n = 41). Their average height was 155.2 cm (girl: 156.08 cm, boy: 154.29 cm). Their average body weight was 45.5 kg (girl: 46.7 kg, boy: 44.3 kg). The vertebral segments of the lower back (Th10/11, TH11/12, Th12/L1) and the lumbar spine (L1/2, L2/3) are in the age-appropriate normal range. The Th10/11 vertebral position showed a significant difference ($p < 0.002$) between girls and boys. In the case of girls, an increased lordotic curvature is seen in the lumbar spine compared to that of boys. Based on the results of the Matthias test, it can be concluded that the curvatures of the girls spines are more maintained than those of the boys Th10/11 ($p < 0.001$), Th11/12 ($p < 0.030$), and also in the Th12/L1 transition ($p < 0.041$).

CONCLUSION: In addition to the differences due to the anatomical structure, it can be stated that the functional curvatures of the lower back and lumbar spine of boys are less maintained under load than those of girls. These segments are therefore the source of poor posture, so special attention should be paid to age-appropriate strengthening of the lower back, lumbar spine, and core muscles.

### EFFECTS OF REPETITIVE THROWING ON TRUNK MUSCLE STRENGTH AND THORAX AND SHOULDER KINEMATICS DURING PITCHING

ASO, T.1, KAGAYA, Y.2

*1.SHOWA UNIVERSTY FUJIGAOKA REHABILITATION HOSPITAL 2.SHOWA UNIVERSITY SCHOOL OF NURSING AND REHABILITATION SCIENCES*

INTRODUCTION: Repetitive throwing has recently been a focus on risk factor for shoulder injury in baseball players (Erickson et al.,2016). In addition, Control of movement of the thorax, which is located between the lower and upper extremities, is important for smooth shoulder movement, and trunk muscle strength is necessary for preventing shoulder injury. However, there have been few reports examining changes in trunk muscle strength and thorax and shoulder kinematics with repetitive throwing. This study was performed to investigate whether repetitive throwing changes trunk muscle strength and thorax and shoulder kinematics during pitching.

METHODS: In 12 healthy baseball players, we assessed trunk muscle strength in flexion, extension, and lateral flexion using a stopwatch. Throwing motions were analyzed using a three-dimensional motion analysis system, and thorax angles (anterior tilt, lateral tilt, and rotation) and shoulder angles (horizontal adduction, abduction, and internal rotation) were calculated at stride foot contact during the early cocking phase (SFC) and at the maximum shoulder external rotation position during the late cocking phase (MER). The participants threw 135 fastballs (9 innings with 15 throws per inning) at maximum effort. Trunk muscle strength was measured before and after the repetitive throwing task, and throwing motion was measured in the first, seventh, eighth, and ninth innings. The Wilcoxon signed-rank test was used to compare the trunk muscle strength before and after throwing. One-way analysis of variance and post hoc Bonferroni analysis were used to compare throwing motion between the first inning and the seventh, eighth, and ninth innings. Statistical significance was set at $p<0.05$.

RESULTS: Trunk muscle strength was decreased after repetitive throwing (flexion, $p=0.002$; extension, $p=0.002$; lateral flexion on throwing side, $p<0.001$; and lateral flexion on non-throwing side, $p<0.001$). Regarding the throwing motion, the thorax rotation angle at SFC increased toward the throwing side in the seventh ($p=0.009$) and eighth ($p=0.016$) innings compared with the first inning. In addition, the shoulder horizontal adduction angle at MER decreased in the seventh ($p=0.016$) and ninth ($p=0.009$) innings compared with the first inning. There were no differences in other variables.

CONCLUSION: It is reported that high muscle activity of the abdominal and trunk extensors occurs to control the thorax from the SFC to ball release (Hirashima et al.,2002; Watkins et al.,1989). We considered that muscle fatigue caused by repetitive throwing led to a decrease in trunk muscle strength. Among the results of throwing motion, the change in the shoulder horizontal adduction angle was important. A decreased shoulder horizontal adduction angle at MER was associated with shoulder posterior superior impingement syndrome (Jobe,1995; Walch et al.,1992), suggesting that repetitive throwing than 100 pitches may be a risk factor for shoulder injury.

**EFFECTS OF ACUTE RESISTANCE EXERCISE WITH DIFFERENT INTENSITIES AND EQUAL TRAINING VOLUME ON IMMUNE CELL RESPONSES**

CHEN, C.H.1,2, CHIANG ,C.Y.1, CHANG, H.C.1, LIU, H.W.1

*NATIONAL TAIWAN NORMAL UNIVERSITY1 & TAMKANG UNIVERSITY2*

INTRODUCTION: Previous studies have investigated the effects of different resistance training load schemes on immune cell migration, but the prescription design neglected training volume and inter-set rest, which led to inconsistent findings. Therefore, the relationship between resistance exercise prescribing variables and the immune response needs further investigation. The purpose of this study was to investigate the effect of an acute resistance exercise of varying load with equal training volume and inter-rest time on the immune response.

METHODS: Healthy young men (n = 11; age 23.0 ± 0.7 years, body mass index 21.5 ± 0.7 kg/m2) with no resistance exercise habits were recruited to perform three trials, including moderate-load RE (MOD; 4 sets of 8 repetitions at 85% 8RM), low-load RE (LOW; 4 sets of 15 repetitions at 45% 8RM) and control (CON; no exercise), in a randomized, crossover design. Blood was collected pre-exercise, 0, 30, and 60 min post-exercise for analysis of cortisol and immune cell counts. The data obtained were analyzed using a linear mixed model.

RESULTS: Total white blood cell counts and lymphocyte counts were significantly higher in MOD and LOW than in CON at immediately post-exercise ($p < 0.05$), with no significant difference between the MOD and LOW ($p > 0.05$). Cortisol were significantly higher in MOD than in CON at 30 and 60 min post-exercise ($p < 0.05$), with no significant difference between the MOD and LOW ($p > 0.05$).

CONCLUSION: Both moderate- and low-load RE induced a transient state of immune cell migration; such changes returned to basal level within 30 min after exercising. Acute stress response elicited by moderate-load RE has lasted longer, as evidenced by cortisol levels.

**CHANGES IN THE THORACIC SPINAL ROM AND SAC/HIP RATIO IN AN INTERVENTION PROGRAM AMONG ADOLESCENTS**

SZIGETHY, M.

*EÖTVÖS LORÁND TUDOMÁNYEGYETEM,*

INTRODUCTION: Adolescence is a critical period of growth and maturation. Rapid growth of the support system, including the skeletal system, can lead to functional problems. (STOKES, 2007). The muscles of the trunk cannot keep up with this rapid growth, so their load-bearing capacity is reduced. Some of the muscles responsible for posture weaken, while others become shortened and tense. (SOMHEGYI et al., 2003). As a result of the breakdown of muscle balance, certain muscles need more effort to maintain correct posture. In other cases, the curvatures of the spine flatten, the spine becomes inflexible, muscles along its length weaken and small joints become overloaded (BAJSZ et al, 2015). Prolonged uneven loading can lead to premature cartilage wear. (BAGI et al., 2016). The aim of the present study was to examine the impact of an intervention-related posture improvement program among school-age children.

METHODS: Adolescence is a critical period of growth and maturation. Rapid growth of the support system, including the skeletal system, can lead to functional problems. (STOKES, 2007). The muscles of the trunk cannot keep up with this rapid growth, so their load-bearing capacity is reduced. Some of the muscles responsible for posture weaken, while others become shortened and tense. (SOMHEGYI et al., 2003). As a result of the breakdown of muscle balance, certain muscles need more effort to maintain correct posture. In other cases, the curvatures of the spine flatten, the spine becomes inflexible, muscles along its length weaken and small joints become overloaded (BAJSZ et al, 2015).

Prolonged uneven loading can lead to premature cartilage wear. (BAGI et al., 2016). The aim of the present study was to examine the impact of an intervention-related posture improvement program among school-age children.

RESULTS: Pre-intervention (1) and post-intervention (2) data showed significant decreases in all assessed characteristics and similar increases in sacrum to hip ratio (Sac/Hip) (9.83±4.36 - 21.63±4.39); $p<0.000$. The greatest change was found in the Th11/12 dorsal vertebral body angles (4.50±2.05 - -0.30±0.25); $p<0.000$. As a result of the postural improvement program, the degree of pelvic tilt and, in parallel, the physiological curvature of lumbar lordosis was reduced to within the age-specific reference values.

The Hungarian Spine Societys control exercises were used to assess muscle strength and extensibility at the beginning of the intervention and repeated at the end of the intervention. The results of the 2nd measurement confirm the success of the program. We found improvements in all 12 exercises

CONCLUSION: In conclusion, our findings indicate that the flexibility training protocol performed for 16 weeks could improve the status of the spinal in pubertal children These data might be suitable for increasing knowledge about the methodology of spinal prevention gymnastics. In particular, this study showed that a specific workload pattern (set, repetitions, and type of exercise) could increase the status spinal in pubertal children.

**THE EFFECT OF EXERCISE INTERVENTION DURING PREGNANCY ON DELIVERY MODE AND MACROSOMIA RISK OF PREGNANT WOMEN WITH DIFFERENT PRE PREGNANCY BMI: META ANALYSIS**

YEMING, W.

*BEIJING SPORT UNIVERSITY*

INTRODUCTION: To systematically evaluate the effect of exercise intervention during pregnancy on delivery mode and risk of macrosomia in pregnant women with different pre pregnancy BMI by Meta-analysis. To provide reference for the clinical formulation of reasonable and safe exercise program during pregnancy, and to provide evidence-based basis for the formulation of systematic and comprehensive exercise guidelines during pregnancy.

METHODS: As of February 28, 2022, literature searches have been conducted in CNKI, WanFang, Web of Science and PubMed databases, with "pregnan *", "exercise", "physical activity" and "control group" as the subject words. Formulate the inclusion and exclusion criteria of documents, and eliminate the documents that do not meet the requirements of the inclusion criteria, duplicate data results and no full text.

RESULTS: A total of 59 RCT studies were included in this meta-analysis, from 5 continents (Asia, North America, South America, Europe and Oceania) and 18 countries, including 10833 people in the control group and intervention group. Exercise interventions during pregnancy include aerobic exercise, resistance exercise, meditation exercise (yoga) and specific exercise (pelvic floor muscle training). The overall methodological quality was high. The overall results showed that exercise intervention during pregnancy did not increase instrumental delivery (OR: 0.89 [0.76, 1.02], $P>0.05$), and helped to reduce the incidence of caesarean section (OR: 0.88 [0.80, 0.96], $P<0.01$) and macrosomia (> 4000g) (OR: 0.78 [0.65, 0.93], $P<0.01$). Subgroup analysis showed that exercise intervention during pregnancy not only

reduced the risk of instrumental delivery in pregnant women with normal BMI before pregnancy (OR: 0.80 [0.67, 0.94], P<0.01), but also inversely increased the probability of instrumental delivery in pregnant women with overweight or obese BMI before pregnancy (OR: 1.50 [1.01, 2.22], P<0.05). In addition, for pregnant women with overweight or obese BMI before pregnancy, exercise intervention did not affect the incidence of macrosomia (>4000g) (OR: 0.71 [0.44, 1.14], P>0.05), but reduced the risk of caesarean section (OR: 0.80 [0.67, 0.96], P<0.05).

CONCLUSION: Exercise intervention during pregnancy can significantly improve the delivery mode of pregnant women and the incidence of macrosomia (> 4000g), but the effect of exercise intervention in pregnant women with overweight or obese BMI before pregnancy is slightly lower than that in pregnant women with normal BMI before pregnancy. Due to the reduction of the incidence of caesarean section, pregnant women with overweight or obese BMI before pregnancy also have the risk of increasing the risk of instrumental delivery. It is suggested that this group should advance exercise intervention to the preparation period, Through the "pregnancy preparation + +pregnancy" double cycle exercise, strive to reduce the weight to normal value during pregnancy preparation, so as to reduce the risk of instrument delivery.

## IN VITRO EVALUATION OF DECELLULARIZED TENDON GRAFTS

MINTÁL, T.

*UNIVERSITY PÉCS*

INTRODUCTION: The incidence of various tendon injuries are increasing all over the world. The most common lesions are the anterior cruciate ligament, Achilles tendon, rotator cuff, hand flexor and extensor tendon ruptures. Understanding the disadvantages of auto- and allograft utilization and to avoid infection transfer and graft rejection, we predicted decellularized tendons may become an ideal graft choice for tendon reconstruction surgeries. Thus, in our studies we aimed to create decellularized tendon grafts with optimal mechanical properties and minimal antigenicity for clinical tendon reconstructions in the future.

METHODS: Our experiments were performed and validated by the Regional Comittee of Science and Research Ethics at the Univeristy of Pécs Medical School. Cadaveric human Achilles and hamstring tendons were harvested and divided into two groups. One group was fixed and underwent histological analysis (control group), the second group was decellularized by utilizing the following chemical decellularization protocols: (1) 1% tributyl-phosphate (TBP) for 24 hours, (2) 1% TBP for 48 hours, (3) 2% TBP for 24 hours, (4) 1% sodium-dodecyl-sulphate (SDS) for 48 hours and (5) 2% TBP for 48 hours. We performed histological analyses (hematoxilyn-eosin, picrosirius red staining) on the decellularized tendons, and compared them to the control group by nuclear counting and collagen structure investigation. We applied Friedman's Two-Way Analysis of Variance for statistical analyses.

RESULTS: We detected significant (p<0.001) decrease in the number of cell nuclei following decellularization. When applying protocols (1)-(4), beside a significant decrease in the number of cell nuclei, we observed celluar debris between the collagen fibres. Moreover, when utilizing 2% TBP for 48 hours (5), we detected severe collagen damage in semitendinosus tendons.

CONCLUSION: We conlude that all applied decellularization protocols were effective demonstrating a significant decrease in the number of cell nuclei. We haven't detected collagen lesion via 2% TBP for 48 hours treatment on Achilles tendons, however, a tensile strength testing should be still performed. If the mechanical parameters prove to become optimal, we suggest 2% TBP treatment for 48 hours may be a suitable decellularization protocol for human Achilles tendons.

## ARRHYTHMIA CLASSIFICATION USING DEEP NEURAL NETWORKS

GAO, B., TAO, K.

*BEIJING SPORT UNIVERSITY*

INTRODUCTION: The electrocardiogram (ECG) is a technique that portrays the human heartbeat and aids in the diagnosis of certain cardiovascular illnesses. ECG has been increasingly popular in sports medicine in recent years. ECG can be used to investigate exercise cardiology not only for diagnosis, but also to examine and determine the hearts adaptability to high-intensity training and significant volumes of exercise.

METHODS: We used datasets from the MIT-BIH arrhythmia database and the CSPC2021 competition. There are 48 dual-channel ambulatory ECG records in the MIT-BIH arrhythmia database. A total of 109,500 heartbeats are recorded, with irregular heartbeats accounting for around 30% of the total. Variable-length ECG record fragments derived from lead I and lead II of long-term dynamic ECGs, each sampled at 200 Hz, are provided in the CSPC2021 challenge datasets. These datasets contain the classes N, S, V, F, and Q, which stand for Nonectopic, Supraventriculr ectopic beat, Ventricular ectopic beat, Fusion beat, and Unknown beat.

This research offers a two-stage deep convolutional neural network (CNN) model for arrhythmia classification, with three highlights:

1.We discovered that the sample numbers of different heartbeat types are substantially diverse in these datasets. The sample size of the N type, for example, is 81468, while the sample size of the F type is only 723. The consistency of learning cannot be guaranteed by the model during the training phase. This is why the majority of the models exist. Although it has a near-perfect accuracy rate, it is unable to properly understand many sorts of characteristics in actual applications. As a result, we suggest the sample equalization approach, which we will train until the number of five sample types is not significantly different.

2.We discovered that just choosing a sample size was ineffective, therefore we extracted five types of R peak lengths and plotted them on a scatter plot, discovering that the lengths of different types were significantly varied. As a result, we try to choose different sizes for sampling and retraining based on the R peak length division intervals.

3.We observe that categories S and V are more similar and difficult to differentiate when we do simple training. As a result, we offer a method for both forms of secondary training. After the five classes have been trained for classification together, the samples and labels from the two classes S and V are recombined for the second training, which enhances classification accuracy.

RESULTS: When we didnt use the above three methods for simple training, the accuracy of arrhythmia classification was as high as 98.5 percent, but when we used the second method to balance the five types of samples, the accuracy rate dropped to only 89.4 percent, indicating that our samples arent balanced, which leads to highly accurate conjectures. As a result, we integrated the other two approaches on the basis of sample balance, and arrhythmia accuracy reached 93.5 percent. Calculate S and Vs forecast accuracy independently, ranging from 91 percent to 95.01 percent.

CONCLUSION: While no sample equalization algorithm can achieve high accuracy, it cannot learn the features of each class of samples thoroughly. After the sample has been balanced, the training is divided into intervals based on the length of the R peak, with secondary training for the categories that have poor outcomes improving the flexibility and accuracy of arrhythmia categorization.

This research proposes three concepts for arrhythmia classification based on the standard convolutional neural network. These ideas are successful and correct earlier flaws. This method is well suited to the practical application of ECG in sports medicine, and it is hoped that it will help researchers better understand athletes heart problems.

## CHARACTERIZATION OF THE EXERTIONAL HEAT STROKE CASES IN THE FRENCH ARMY: ANALYSIS OF PATIENTS PROFILE AND OF THE TYPE OF EXERCISE

CHARLOT, K., TARDO-DINO, P.E., JOUVION, A., MALGOYRE, A.

*INSTITUT DE RECHERCHES BIOMÉDICALES DES ARMÉES*

INTRODUCTION: Exertional heat stroke (EHS) is an association of hyperthermia (>39°C) and central nervous system disturbances occurring during a strenuous physical exercise affecting therefore athletes, laborers, and military personnel. The identification of risk factors is a complex task since multiple extrinsinc (thermal conditions and clothing) and intrinsinc (sociodemographic, anthropometric, fitness, genetic, and behavioral characteristics) factors may be involved. EHS is a main hazard in the French army (27 per 100000 person years) and identification of specific risk factors appear very important to limit EHS occurrences.

METHODS: We conducted a retrospective study among military personals after an EHS between 2013 and 2021 (n = 203). After an individual interview, body composition (bioelectrical impedance scale) and maximal oxygen uptake (VO2max on ergocycle) were measured. Then a subgroup (n = 107) filled a questionnaire assessing the perception of the exercise during which EHS occurred (10-cm visual analog scales).

RESULTS: 93% of patients were male and 74% were from army. Patients were mostly young (min = 18, 1st quartile = 22, median = 24, 3rd quartile = 28.8 yo, max = 41), had healthy BMI (19.0, 23.3, 24.8, 26.7, and 32.3 kg.m-2, respectively) and fat mass (4, 14, 17, 21, and 39% of BM, respectively) and had high fitness level based on VO2max (26.8, 38.6, 44.3, 49.5 and 69.8 mL.min-1.kg-1, respectively) or on performance during a “marche-course” (a 8-km race in battledress; 31, 37, 40, 43, and 60 min, respectively). Most of the EHS occurred in France metropolitan area (83%) and one quarter in June (24%) and 70% between May and September. Ambient temperature repartition (3, 15, 19, 23, and 32 °C) indicated that despite being very heterogeneous, thermal conditions were mostly considered as safe (heat index < 26 °C). Most of the EHS occurred during a “marche-course” (74%) and during an exercise with military clothing (92%). 67% of the exercises inducing EHS had a main importance for the military personnel. The motivation (0, 3.2, 5.7, 8.0, and 10.0, respectively) and stress levels (0, 2.3, 5.0, 6.7, and 10.0, respectively) were mainly perceived as moderate and the level of importance of this test was mostly perceived as high (0, 5.8, 7.2, 9.0, and 10.0, respectively).

CONCLUSION: These observations do not reveal a specific profile of personnel at risk to suffer from EHS. However they indicate that lean fit and young soldiers seems not specifically protected against EHS. However EHS seems to occur mostly during “marches-courses” with battledress, between June and September and high levels of objective and perceived importance strongly suggesting that this kind of exercises should be avoided as possible during these months or that medical support should be reinforced when these conditions are gathered. Sharper analysis of intrinsic factors is now required and particularly psychological profile related to the stake perceived.

## THE RESPONSE OF SALIVA AMYLASE ACTIVITY IN UNIVERSITY ATHLETES AFTER RETURNING TO TEAM TRAINING

IMAI, T.

*AICHI INSTITUTE OF TECHNOLOGY*

INTRODUCTION: The COVID-19 pandemic repeatedly disrupted sports activity. A prior study reported that detraining increase injury risk and cause rapid loss of training-induced physical and performance adaptation. [1] . Furthermore, suddenly interrupting training plan might be burden, in terms of physical and mental stress upon returning to regular training.

Therefore, an interruption in training may affect athletes condition upon return to training. Consequently, we focused on the salivary alpha-amylase activity (sAA), one of the physiologic stress markers, to assess university athletes’ condition after returning to team training. The sAA is associated with blood catecholamine level, which can evaluate the sympathetic nervous adrenomedullary system [2] . Therefore, this study aims to investigate the response of sAA whether there was an effect of interruption in team training on athletes still returning to training.

METHODS: Seventeen university track and field university athletes staying in a college dorm participated in this study. The measurement was performed before morning training, once a week, on Monday. They did not eat breakfast before measurements. Subjects took their own saliva on test strips. Their coach measured their sAA with an amylase monitor (NIPRO Co., Japan). Then, they reported their evaluation of subjective conditions from a scale of 1(bad) to 10(excellent). There were three examination periods was set, (I) after quarantine period, (Ⅱ) after team practice interruption, (Ⅲ) regular style training. The periods were each 5 weeks long.

RESULTS: The university athletes body characteristics and age were 171.0±5.4 cm and 55.8±5.7kg, and 19±1.0 years. Thirteen athletes participated in all the measurements, and these data were analyzed. Week 1, the sAA of I was significantly higher than the sAA of Ⅱ and Ⅲ（31.4±24.6 vs. 15.5±13.9 vs. 10.2±5.2 klU/L; p<0.05）. Week 2, sAA of I was significantly higher than the sAA Ⅱ and Ⅲ（29.4±20.5 vs. 9.3±6.2 vs. 9.8±5.7 klU/L; p<0.05）. Week 3, the sAA of I was higher than Ⅲ (15.7±17.0 vs7.1±5.1 klU/L; p<0.05). The subjective rating of the condition did not differ in the three periods.

CONCLUSION: Although the subjective condition scale did not differ in each period, the response of sAA was different in the detraining situation. Therefore, sAA may prevent underestimation of an athlete’s condition.

### ELITE ATHLETES HAVE SIGNIFICANTLY ELEVATED SERUM BILIRUBIN CONCENTRATIONS

WORONYCZOVÁ, J.1,2, NOVÁKOVÁ, M.2, LENÍCEK, M.1, BÁTOVSKÝ, M.4, BOLEK, E.2, CÍFKOVÁ, R.3, VÍTEK, L.1

*1. 1ST FACULTY OF MEDICINE, CHARLES UNIVERSITY, PRAGUE 2. SPORTS RESEARCH INSTITUTE OF CZECH ARMED FORCES, PRAGUE 3. 1ST FACULTY OF MEDICINE AND THOMAYER HOSPITAL, PRAGUE 4.SLOVAK ARMY SPORT C. DUKLA*

INTRODUCTION: Bilirubin is a potent endogenous antioxidant and immunomodulating substance, implicated also involved in cell signalization and various metabolic pathways. Mild elevation of its systemic concentrations provides substantial protection against numerous oxidative stress and inflammation-mediated diseases. Rare reports in the literature suggest that serum bilirubin might also be relevant to physical performance. The aim of the current study was to evaluate serum bilirubin concentrations and prevalence of Gilbert syndrome in elite athletes.

METHODS: The study was carried out in 536 consecutive healthy elite athletes and in 2,594 individuals of the Czech post-MONICA study randomly selected from the Czech general population. Serum bilirubin concentrations, prevalence of benign hyperbilirubinemia >17 umol/L (1 mg/dL, a phenotypic sign of Gilbert syndrome, GS), and variant of the UGT1A1 promoter gene (rs81753472) were evaluated in study subjects.

RESULTS: As compared to Czech general population, significantly higher serum bilirubin concentrations were found in elite athletes (9.6 vs. 11.6 umol/L, $p<0.001$), and this difference was observed in both men (11.3 vs. 12.6 umol/L, $p<0.001$) and women (8.3 vs. 10.5 umol/L, $p<0.001$). In addition, also the prevalence of a phenotypic GS was significantly higher in elite athletes (9.6 vs. 22%, $p<0.001$). Serum bilirubin concentrations in elite athletes were positively correlated with serum total antioxidant status ($p<0.05$).

CONCLUSION: Elite athletes have significantly higher serum concentrations of serum bilirubin, the most potent endogenous antioxidant substance. Simultaneously, also the prevalence of GS syndrome is much higher in elite athletes, suggesting that mild elevation of serum bilirubin might predispose to better physical performance.

### WHICH STIFFNESS INDEX COULD IDENTIFY SINGLE-LEG VERTICAL JUMP ASYMMETRY IN ACLR ATHLETES: A PILOT STUDY?

TZENG, Y.T., CHU, N., CHEN, Y.J., LEE, H.J.

*NATIONAL TAIWAN NORMAL UNIVERSITY*

INTRODUCTION: Stiffness comes from Hooke's law and considers the body as a spring, the ability of the body to absorb force and transfer it to movement. Several factors could affect stiffness, including muscle, tendon, ligament, cartilage, and bone. In addition, the asymmetries of kinetics and kinematics characters influence injuries as well. Limb asymmetry still could be found in patients with ACLR (anterior cruciate ligament reconstruction, ACLR) after one year of rehabilitation. Research indicates that the asymmetries of vertical stiffness could represent by ankle joint stiffness calculated from the landing mechanism in healthy men. However, the ankles critical impact on vertical stiffness asymmetries in the ACLR group was still unknown. This study aimed to discuss which joint stiffness index is essential to the ACLR group during single-leg vertical jump.

METHODS: There were 3 ACLR male athletes participated in this study. A 9 camera motion capture system (Vicon, 200Hz) and a force plate (Kistler, 1000 Hz) were synchronized to collect kinematic and kinetic data from single-leg vertical jump protocol. The vertical stiffness index (Kvert) was calculated from the ratio of peak ground reaction force (N) to peak center of mass displacement (m) and normalized by body weight (Kg). The joint stiffness index (Kjoint) of ankle and knee joints was calculated as the ratio of the change in joint moment (Nm) to the change in joint angular displacement. Asymmetries were calculated using the method of absolute symmetry index (ASI). Data was presented in a descriptive format.

RESULTS: All ACLR participants' affected side are left. Left Kvert (55.0) was smaller than right Kvert (61.2). Left ankle Kjoint (1.7) was smaller than right ankle Kjoint (1.9). Left knee Kjoint (2.4) was smaller than right knee Kjoint (3.6). The ASI of Kvert was 10.4. The ASI of ankle Kjoint was 11.1. The ASI of knee Kjoint was 45.8.

CONCLUSION: The present results of this study indicated that ACLR limbs demonstrated smaller stiffness in Kvert and Kjoint index. In addition, the results of ASI showed a similar pattern between Kvert and ankle Kjoint. The ACLR participants were able to return to sports normally. However, from the stiffness and asymmetry index, we could still discover differences between affected and non-affected limbs. ASI of Ankle Kjoint was similar to Kvert, which indicated ankle joint might play an essential role for ACLR athletes in single-leg vertical jump tasks. Therefore, in the future, rehabilitation for the ACLR group maybe not only focus on the knee but on the functional performance of the ankle joint as well.

### DYNAMIC POSTURAL CONTROL DURING SINGLE-LEG LANDINGS IN ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTED INDIVIDUALS AFTER RETURN TO PLAY- A PILOT STUDY

CHEN, Y.J., CHU, N., TZENG, Y.T., LEE, H.J.

*NATIONAL TAIWAN NORMAL UNIVERSITY*

INTRODUCTION: Dynamic postural control is a complicated coordinating result of individuals accepting signals from the visual, vestibular, and somatosensory systems, then processing them through the central nervous system and finally responding. It is known as the ability to transit from moving the action to a static state while maintaining stability. Landing tasks are often used as a screening procedure for dynamic postural control. Landing tasks provide more stimulation of feedforward components in sensorimotor control and higher ground reaction force than static balancing. They can also reflect our moving patterns in sports better. Anterior cruciate ligament injury is one of the most common non-contact injuries in sports. Patients with anterior cruciate ligament reconstruction (ACLR) have been found with altered landing strategies in injured legs even after return to sport and risk of re-injury due to the deficit of dynamic postural stability. Thus, this study would like to discuss dynamic postural control between legs of ACLR athletes through time to stabilization (TTS) and dynamic postural stability index (DPSI) during single-leg drop landing tasks.

METHODS: There were 3 ACLR male athletes participated in this study. A 9 camera motion capture system (Vicon, 200Hz) and a force plate (Kistler, 1000 Hz) were synchronized to collect kinematic and kinetic data from a 30cm height single-leg drop landing (SLDJ) and single-leg vertical jump (SLVJ). Three successful trials were conducted from each leg during tasks. TTS was defined as the time from landing to static state and was collected and calculated from ground reaction force (GRF) in 3 directions (anteroposterior (AP), mediolateral (ML), and vertical (V). DPSI was a combination measurement of mean squared deviations of GRF in 3 directions (AP, ML, and V). Data was presented in a descriptive format.

RESULTS: The AP_TTS, ML_TTS, V_TTS, and DPSI of ACLR limb in SLVJ were 2.78±1.03, 2.73±0.43, 1.36±0.64, and 0.13±0.01; and of healthy limb were 3.01±1.38, 3.12±1.11, 1.12±0.45, and 0.17±0.00 respectively. The AP_TTS, ML_TTS, V_TTS, and DPSI of ACLR limb in SLDJ were 2.14±1.04, 3.10±0.34, 0.97±0.51, and 0.18±0.03; and of healthy limb were 2.80±1.46, 3.61±1.47, 0.87±0.21, and 0.19±0.01 respectively.

CONCLUSION: There was no tendency of difference of AP_TTS, ML_TTS, V_TTS, and DPSI between healthy limbs and ACLR ones in both SLVJ and SDJL. More ACLR participants should recruit for this study for further analysis.

**DEVELOPMENT AND VALIDATION OF AN OVERUSE INJURY QUESTIONNAIRE FOR YOUTH ATHLETES: THE YOUTH OVERUSE INJURY QUESTIONNAIRE**

LAU, R., MUKHERJEE, S.

*NATIONAL INSTITUTE OF EDUCATION*

INTRODUCTION: Current overuse injury registration methods may underestimate the prevalence and severity of overuse injuries for youth athletes. This study developed and validated a new injury registration method for youth athletes based on the improved Oslo Sports Trauma Research Centre Overuse Injury Questionnaire (OSTRC-O2), termed as the Youth Overuse Injury Questionnaire (YOvIQ).

METHODS: A repeated measures study design with two time points (T1 and T2) was conducted (minimum interval of 7 days) among 42 competitive youth volleyball athletes between the ages of 12 to 18. Content validity, construct validity, and test-retest reliability were ascertained. Prevalence of “time loss” and “medical attention” injuries were also investigated.

RESULTS: In both T1 and T2, YOvIQ captured 5.1% more shoulder overuse problems and reported higher severity scores than OSTRC-O2. A substantially lower number of “time loss” and “medical attention” shoulder overuse problems were reported than YOvIQ in both T1 (n = 3, n = 1, n = 9) and T2 (n = 2, n = 2, n = 11), respectively. McNemar’s test for prevalence rates reported non-significant differences for construct validity (n = 39, p = .50) and test-retest reliability (n = 29, p = 1.00). Severity scores were valid and reliable (n = 39, rs (37) = 0.89, p < .001; n = 29, ICC = 0.86, 95% CI [0.72, 0.93]).

CONCLUSION: The YOvIQ is a valid instrument to determine the prevalence and severity of overuse injuries in youth athlete populations.

**INFLUENCES OF ELECTRICAL STIMULATION AT DIFFERENT TIMES ON FEMORAL BONE LOSS IN HINDLIMB-SUSPENDED RATS**

MINAMIZONO, W.1, ZENG, X.Q.1, SUITO, H.1, YASHIMA, N.1, YANG, C.1, NAKAI, S.2, FUJIKAWA, K.3, OHSAKO, M.4

*1 : GRAD. SCH. HUMAN LIFE DESIGN, TOYO UNIV. 2 : UNDERGRAD. SCH. HEALTH PROMO. SCI., TOKOHA UNIV. 3 : DEPT. ORAL ANAT. DEVELOPMENTAL BIOL. SHOWA UNIV. 4 : UNDERGRAD. SCH. HUMAN LIFE DESIGN, TOYO UNIV.*

INTRODUCTION: It is desirable to keep the duration of electrical stimulation as short as possible, considering the influences of electrical stimulations on the body. This study aimed to investigate the influences of electrical stimulation at different times using hindlimb-suspended rats in order to obtain an effective electrical stimulation time for bone loss associated with weight reduction.

METHODS: Forty-eight male rats (wistar strain, 7-week-old) were used as materials. They were divided into a hindlimb suspension group (HS), an electrical-stimulated group that received the electric stimulation during the period of hindlimb suspension (VP), and a control group (CO). Furthermore, VP were subdivided into 15, 30, 60 and 90minute groups (VP15, VP30, VP60 and VP90, respectively) according to stimulation time.

VP was stimulated electrically under the conditions of AC, voltage 67 mV, 0.13 mA, 20 kHz, for 5 days/week for three weeks, using an electric stimulation device (Sumida Electric Co., Ltd.). The electrical stimulation time of VP15, VP30, VP60, and VP90 was 15, 30, 60, and 90 minutes, respectively.

Femurs in each group were removed and histologically analyzed after the experimental period.

RESULTS: The thickness of the HS bone trabeculae was thinner than that of the CO. The trabecular bone of VP15 was as thin as HS, and the trabecular width of VP30, VP60, and VP90 was maintained. There was no difference between VP90 and VP60 in the thickness of the trabecular bone. In VP, trabecular width and density were maintained at energization times above VP30, with little difference between VP60 and VP90.

CONCLUSION: It was suggested that bone loss due to mechanical unloading might be suppressed by the electrical stimulation for 30 minutes or more a day.

**INFLUENCE OF TRANSCUTANEOUS ELECTRICAL STIMULATION ON THE HEALING PROCESS AFTER BONE INJURY**

NAO, Y.

*TOYO. UNIV*

INTRODUCTION: The purpose of this study is to histologically investigate the effect of transcutaneous electrical stimulation on the initial repair process of bone from the inflammatory phase to the callus formation phase among these repair processes.

METHODS: Seven-week-old male rats (wistar strain) were used as materials and divided into a bone injury / natural healing group (NH), a bone injury / transcutaneous electric stimulation group (TE), and a control group (CO). Bone injuries with a diameter of 2.0 mm were created in the tibia in NH and TE and they were euthanized on days 0, 1, 3, 5 and 7 after the bone injuries. TE was electrically stimulated Using a low-frequency treatment device (BioTrainer1 manufactured by Oshima Co., Ltd.), the electrical stimulation was performed from the left and right of the distal thigh under anesthesia. The electrical stimulation conditions were 60V direct current, frequency 50Hz, 200μsec, and carrier frequency 80kHz. Under these conditions, the electrical stimulations were performed for 10 minutes /day, every day for 1, 3, 5 or 7 days.

The tibia in each group was removed and various specimens were prepared for histological observation.

RESULTS: On days 1 and 2 of bone injury（NH1）, A small hematoma was seen in the injured area and a fibrous network formed around the hematoma. On day 3, the hematoma was extensive and the fibrous network was similarly extensive in NH3. On the other hand, it was recognized that the hematomas and cells tended to accumulate near the center of the bone injury in TE3. On day 5, a hematoma was seen near the center of the bone injury, but fibrous bone was formed in the fibrous network surrounding the hematoma that showed a pale purple color by toluidine blue staining in NH5. In TE5, bone tissue was formed to fill the bone injury as seen in NH7. Then, on day 7, the hematoma disappeared and the fibrous bone seen on day 5 was seen throughout the injured area in NH7. On the contrary, in TE7, the thickness of the bone that fills the injury part increased.

CONCLUSION: Hematomas formed at the site of bone injury with inflammation, which were shown to be more pronounced on day 3. On day 5, the hematoma tended to disappear, which was accompanied by the formation of fibrous bone in the fibrous network around the hematoma. In contrast to the repair by natural healing, the electrical stimulation shifted to the phase two days earlier, and it is considered that the energization stimulus increased the activity of the tissue. It was suggested that the electrical stimulation during the initial repair process of bone injury may have a repair-promoting effect.

### INJURIES AMNONG YOUTH EQUESTRIAN RIDERS – NORMS, ATTITUDES AND RISK-TAKING IDEALS ON SOCIAL MEDIA

BOIJE AF GENNÄS, K.

*FACULTY OF EDUCATION AND SOCIETY*

INTRODUCTION: Further research on injuries among youth athletes is needed not the least in relation to specificity in age, level and sport (Bergeron et al., 2015, Arvinen-Barrow et al., 2016; Finch & Donaldson, 2010; Verhagen et al., 2010). Cultural predispositions and values towards injuries can be dependent on what type of sport is studied (Arvinen-Barrow et al., 2016). Equestrian sport is a high-risk sport (Buckley et al., 2004) and the risk for injuries is highest among riders between 10-19 years old (Loder, 2008; Moss, 2002). Equestrian sport is divided into different disciplines such as showjumping, dressage, eventing and it is possible that values related to injury and risk for injury could vary between different disciplines. So far, injury risk assessment and risk-taking in equestrian sports has been studied using interviews with adult equestrians in eventing. Ekberg et al., (2011) found that attitudes to risk taking was the only predicting factor leading to injury. Furthermore, being in a competitive setting can encourage risk-taking (Thompson & Nesci, 2016). Attitudes towards the use of helmets were also related to risk-taking and a feeling of the inability to control the likelihood of accidents (Haigh & Thompson, 2015). However, there is sparse research on attitudes towards risk-taking (Thompson et al., 2015) in youth riders and their coaches and how this could influence the onset of injuries. This study will focus on values towards injuries, risk-taking attitudes and cultural ideals represented on social media in relation to equestrian sport and injuries.

The purpose of this study is to identify social media ideals, values towards injuries and in risk-taking attitudes among youth equestrian riders in relation to injuries in different disicplines.

METHODS: Netnography of multiple digital platforms will be conducted on digital content related to injuries in equestrian sport and children and adolescents. Relevant and commonly hashtags will be targeted as well as, at the moment, most popular influencers and coaches in the equestrian community. The media content is analyzed using a deductive thematic analysis (Graneheim & Lundman, 2004; Sparkes, 2014).

RESULTS: This study is still ongoing, but preliminary results show that a divide in the discussion about helmet-wear during elite level dressage is still ongoing. Photos and videos show a romanticized picture, literary, of riding on beaches without helmet. Moreover, children managing to stay put on difficult horses that misbehave is praised in the commentary section.

CONCLUSION: So, by looking on values towards injuries, risk-taking attitudes and cultural ideals in several disciplines and especially in the youth equestrian community on social media we hope to achieve a deeper understanding on how this influence the high risk for injuries among youth.

### EVALUATION AND RELATIONSHIP BETWEEN PAIN, FUNCTIONALITY AND MRI FINDINGS IN PATIENTS WITH PATELLOFEMORAL PAIN ACCORDING TO GENDER.

VICENTE-MAMPEL, J., BARAJA-VEGAS, L., GARGALLO, P., BAUTISTA, I.J., JAENADA, E., BLANCO, P., MARTÍNEZ, M., SEVILLA, P., BARRIOS, C.

*FACULTY OF MEDICINE AND HEALTH SCIENCE. DEPARTMENT OF PHYSIOTHERAPY, CATHOLIC UNIVERSITY OF VALENCIA, TORRENT, VALENCIA, SPAIN*

INTRODUCTION: Pathogenesis of patellofemoral pain (PFP) has been attributed in part to structural abnormalities of the patellofemoral joint. There is still concern about the role of degeneration of the retropatellar cartilage in PFP. To distinguish pathological features of early knee osteoarthritis from thise related with aging continues to be a great challenge. Women with PFP exhibited greater peak cartilage stress than males, which could possibly account for the greater prevalence of PFP in women. However, other biological and mechanical factors could definitely play an important role in this complex anterior knee pain. It is hypothesized that changes pain, functionality, and kinesophobia are not related to structural changes measured by quatitative MRIs. To evaluate the differences pain, functionality, and kinesophobia in patients with PFP and examine the relationship of each parameter to MRI findings.

METHODS: A cross-sectional study was design including 100 subjects with PF . There were 60 males (mean age, 45,52 years ± 11,59 SD; weight, 84,30 ± 14,67 SD and height 1,76 ± 0,07 SD) and 40 females (mean age, 47,56 years ± 12,83 SD; weight, 70,04 ± 15,13 SD and height 1,64 ± 0,06 SD). The Western Ontario and Mcmaster Osteoarthritis (WOMAC) index, Visual Analogue Scale (VAS) of 10 mm length, and the Tampa Scale of Kinesiophobia (TSK-11) were used to assess clinical findings of osteoarthritis in this sample. Knee cartilage T2 mapping images using 3.0 MRI system were also obtained. Analysis by gender was carried out.

RESULTS: Significant gender differences were found in most clinical variables (mean VAS: p=0.020; peak VAS: p=0.028; WOMAC pain: p=0.010; WOMAC stiffness: p=0.043; WOMAC functionality: p=0.004). Differences in TSK-11 scores were not statistically significant (p=0.052). No correlation were found in the measurements obtained of the osteochondral structure by MRI and the rest of variables. (Fig 1).

CONCLUSION: According to these findings, the cartilage state obtained through MRI did not differ between males and females, but significant differences were found between gender in the rest of the parameters. Furthermore, it appears that there is no strong association between MRI images and functional parameters among patients with PFP.

### LONG-COVID SYNDROME AND ITS INFLUENCE ON EXERCISE CAPACITY AND QUALITY OF LIFE

KERLING, A., DRICK, N., BEYER, S., HAUFE, S., LAMPE, V., ESCHRICH, J., SALZMANN, J., TEGTBUR, U.

*HANNOVER MEDICAL SCHOOL*

INTRODUCTION: Long-Covid syndrome is defined as the persistence of symptoms beyond 4 weeks after severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection. The most common symptoms include reduced exercise tolerance and capacity, fatigue, neurocognitive problems, muscle pain and dyspnea (1). The aim of our work was to investigate the exercise capacity and quality of life (Qol) in patients with diagnosed Long-Covid syndrome.

METHODS: We examined a total of 53 patients (19 male/ 34 female; age 46.1 ± 11.2 years; height 170.9 ± 9.6 cm; weight 84.4 ± 21.2 kg; BMI 28.8 ± 6.6 kg/m2) in whom we assessed exercise testing on a cycle ergometer, a 6-minute walk test, the extent of fatigue by Fatigue Assessment Scale (FAS) and QoI with the SF-36 questionnaire.

RESULTS: On average the FAS was 34.7 ± 7.4 points, VO2max/kg: 22.5 ± 6.0 ml/kg/min, the 6-min walk distance: 526 ± 88m, the physical QoI score 35.0 ± 9.0 points and the mental QoL score 40.8 ± 12.7 points. Compared with normative values the VO2max/kg was reduced by 28.0%, the 6-minute walk test by 12.2%, the QoI physical sum score by 30.3% and the mental score by 20.9%.

There was no significant linear correlation between the FAS and the percentage of Vo2max/kg: ($r = -0.20$, $p = 0.16$), There was a significant correlation between the performance of the 6-minute walk test ($r = -0.40$, $p < 0.01$) and the FAS as well as in the percentage to the norm of QoI (physical score: $r = -0.41$, $p < 0.01$; mental score: $r = -0.37$, $p < 0.01$)

CONCLUSION: Patients with diagnosed Long-Covid syndrome had reduced exercise performance and QoI compared to normative values, which implicates the need for a targeted treatment. This emphasises the necessity for further research into the resumption of daily activities and regular exercise that play an important role in individual well-being and health-related quality of life.

## RESEARCH ON THE STATUS AND HOT RESEARCH TOPICS OF THE PREVENTION IN SOCCER INJURY FROM 2001 TO 2021: A BIBLIOMETRIC ANALYSIS

XIAO, Y.

*TONGJI UNIVERSITY*

INTRODUCTION: To analyze the status and research focuses of the prevention in soccer injury, this paper used bibliometric softwareVosviewer v. 1.6.17 to analyze the data from Core Collection Database of the Web of Science by clustering analysis

METHODS: The data from Core Collection Database of the Web of Science was performed for the topic “soccer injury” and “prevention”, limited to document type (article or review) from 2001 to 2021.

RESULTS: 1.There are 2387 documents related to the prevention in soccer injury,the number of annual outputs has exceeded 300 per year.

2.The production of relevant articles in 79 countries between 2001 and 2021.The country with most publications was the United States (720, 20.6%),with an average of 46.97 citations, followed by the United Kingdom (293, 8.3%) Australia (232, 6.6%).

3. 2836 research institutions were included in this research. The University of North Carolina is in the first place with 74 publications(TLS=171),followed by the University of Cincinnati(TLS=234),with 66 publications and Ohio State University(TLS=140),with 65 publications.

4.The research on prevention in soccer injury is contained in 387 journals, among which the number of documents published of the top 10 journals accounted for about 38%. The top three journals in terms of number of publications are British Journal of Sports Medicine(163,TGCS=5060), followed by American Journal of Sports Medicine (156,TGCS=5041),Scandinavian Journal of Medicine & Science in Sports (100,TGCS=2333).

5.There are currently 54 subjects in the field of prevention in soccer injury. The area with the highest percentage of documents was Sports Science (1775,74.5%) followed by Orthopedics(548, 22.9%), and Rehabilitation (205, 8.6%).

6.High frequent keywords are: soccer 1072, prevention 821, risk-factors 796,injury589,training-program 115,neuromuscular control 93,acl 78.

CONCLUSION: 1.The research in this field has entered a stage of rapid development.Because of the COVID-19 epidemics,future research should focus on virtual training, players monitoring, taking more rigorous and long-term monitoring of clinical test results for soccer players.

2. About 74.36% of the papers are concentrated in sports science, orthopedics, rehabilitation and other fields, which shows that the research is not enough in other fields. Research institutions on football injury prevention are mainly concentrated in universities and scientific research institutions led by the United States, so this is one of the reasons why the United States has become the country that publishes the most articles in the field of football injury prevention.

3.The current hot researches mainly focus on training methods and monitoring methods of risk factors, such as Nordic hamstring training, FIFA11+ warm-up training, neuromuscular training, monitoring risk for injuries and machine learning, GPS medical treatment, data monitoring,so in the context of the COVID-19, future research should focus on how to develop better prevention methods with AI or VR.

## EFFECTS OF ELECTRICAL STIMULATION AT DIFFERENT FREQUENCIES ON STRUCTURAL CHANGES OF THE ARTICULAR CAPSULE OF RATS KNEE JOINTS BY IMMOBILIZATION

YANG, C.

*TOYO UNIVERSITY*

INTRODUCTION: A life in which joint activity is restricted due to cast fixation after a fracture or joint surgery leads to joint contracture. Moreover, meta-analysis reports that long-term fixation causes irreversible range of motion limitation and reduces the patients activities of daily living (ADL) and athletic performance. Therefore, the development of therapeutic and preventive methods is of great significance. Previous studies have shown that energization stimulation suppresses the progression of joint contracture. However, it has not yet been clarified how the frequency of energization is changed and how it affects the fibrosis of the joint capsule. On the other hand, immobilization causes a hypoxic state in the joint capsule and also begins to secrete the fibrosis-promoting cytokine TGF-β1, which acts on fibroblasts to myofibroblasts with high collagen-producing ability. The purpose of this study was to clarify the systematic changes in joint contracture caused by immobilization of different frequencies and the status of cytokines in the joint capsule.

METHODS: Using 30 7-week-old rats, they were divided into 5 groups, IM group CO group VP2kHz group, VP20kHz, VP200kHz (6 animals each). In this experiment, the immobility device is attached to the rat, and the immobility device is attached to both legs for 3 weeks. Furthermore, at the same time as immobilization treatment, continuous energization stimulation is performed for 30 minutes a day using a VP device. After the experiment was completed, he was euthanized and the knee joint was removed. Using them, decalcified paraffin sections and non-decalcified resin-embedded polished specimens were prepared, subjected to general staining and immunostaining, and observed with an optical microscope.

RESULTS: The fibrous layer of the IM group increased and adipocytes regressed. No increase in the fibrous layer was observed in the VP2kHz group and the VP20kHz group. On the other hand, in the VP200kHZ group, it was observed that the fibrous layer increased and

adipocytes regressed. As a result of immunostaining, the appearance rate of α-SMA positive cells in the immobile group was significantly higher than that in the control group. On the other hand, the appearance rates of VP2kHz and VP20kHz α-SMA positive cells were not significantly different from those of the control group.
CONCLUSION: Myofibroblasts in the posterior capsule proliferate due to activity restriction, but it was speculated that low-frequency electrical stimulation has the effect of suppressing the proliferation of myofibroblasts.

## Statistics and Analyses

### 1/F SCALING IN THE DYNAMIC BEHAVIOR OF TENNIS PLAYERS AS A SELF-ORGANIZING SYSTEM

KIM, H., JUNG, K.

*GEORGIA STATE UNIVERSITY, KOREA NATIONAL UNIVERSITY OF EDUCATION*

INTRODUCTION: The behavior of dual sports such as squash and tennis showed a systematic fashion as self-organized complex systems [1, 2]. Tennis players demonstrate coupled oscillators that layers tried to come back to the position near the center mark repetitively. The aim of this study was to investigate the dynamic behavior of elite tennis players in a competition, comparing the behaviors between the players in terms of the distance from the center mark as a nonlinear complex system.
METHODS: Three matches of male elite tennis players, including (1) top-ranked vs. low-ranked players, (2) top-ranked vs. top-ranked players, and (3) junior top-ranked vs. junior top-ranked players, were selected for assessment. From every match, we captured the frames (634, 1538, and 687 frames, respectively) using Kinovea. Displacements of tennis players on the court were tracked using the Matlab program. We calculated the distance from the player to the center mark on the baseline and built a distance-time series. There were two different time series when player #1 receives and player #2 hits. Another is when player #1 hits and player #2 receives. Detrended fluctuation analysis (DFA) has proved useful for detecting long-range correlations in time series [3]. DFA alpha between $0<\alpha<0.5$ indicates more rough and random fluctuations. The alpha values between $0.5<\alpha<1.0$ indicate a long-range correlation.
RESULTS: In a match between top-ranked and low-ranked players, the mean distance of the winner was 2.88 (SD = 1.74) meters, whereas 2.96 (SD = 2.00) meters for the loser. DFA revealed a distance-time series for the winner was 0.53 and 0.47 for the loser. In a match between top-ranked players, the winner had a mean distance of 2.72 (SD = 1.28), and the loser had 2.57 (SD = 1.66). Both players showed random correlations as 0.45 and 0.47, respectively. In a match between junior players, the mean distance of the winner was 2.43 (SD = 1.44) and 2.58 (SD = 1.49) for the loser. DFA alpha for the winner was 0.58, while the loser exhibited 0.41.
CONCLUSION: Partially consistent with Kim et al.'s study, the behavior of top-ranked professional players did not exhibit long-term correlations [4]. In contrast, the winner of the junior match showed a long-term correlation in the distance-time series, indicating the winner stays near the center mark. In addition, the top-ranked player displayed a long-term correlation when competing with the low-ranked player. This result might show DFA alpha differs depending on the level of expertise. Future studies should consider female players at different levels of expertise, and more sample matches are required.

### EXTERNAL AND INTERNAL MATCH LOAD OF INTERNATIONAL FEMALE FIELD HOCKEY PLAYERS ACROSS QUARTERS OF MATCH-PLAY

SPARKS, M.1, POWELL, C.1, PIENAAR, C.2

*1NORTH WEST UNIVERSITY, 2DURBAN UNIVERSITY OF TECHNOLOGY*

INTRODUCTION: The change in the format of international field hockey matches has led to a scarcity of research concerning match load for female field hockey players across quarters of match-play. The main aim of this study was to examine whether there are positional- and between-quarter differences in match load for international female field hockey players.
METHODS: Twenty-three international female field hockey players were equipped with Global Positioning Systems and heart rate monitors while competing over nine international matches. Players were categorised according to playing position, namely forwards, midfielders and defenders.
RESULTS: Players covered a mean relative distance, relative player load, and distance covered in the form of low-, moderate-, and high intensity activities of 107.5 m/min, 10.3 AU/min, 41.6%, 47.9%, and 9.9%, respectively. Defenders achieved significantly ($p \leq 0.05$) lower relative player load and covered the least distance in the form of high-intensity activities. Forwards and midfielders achieved the greatest relative load. Players spent a majority of match-play engaged at >85% of their maximal heart rate. Reductions in relative load were observed from quarters 1–4 across all positions. No significant between-quarter differences in internal load were observed.
CONCLUSION: The present findings provide a unique description of the work-rate profile of international female field hockey players, especially with regards to positional- and between-quarter match load. Findings highlight the need for coaches and conditioning coaches to implement conditioning programs that address the positional work-rate profile of players by closely replicating match activities. Therefore, training drills for Forwards and Midfielders should consist of repeated high intensity activities over shorter distances, incorporated with multiple accelerations, decelerations, and changes in direction, which closely replicate relative distance and relative player load observed during match-play. Although differences in external match load were observed from quarters 1–4, greater distances covered in the form of high intensity activities during quarter 4 compared to quarter 1 suggest that pacing strategies could be present. Findings highlight the importance of a well-developed aerobic- and anaerobic capacity to sustain bouts of high intensity activities as match-play progresses. No significant differences were observed for internal load between positional groups throughout match-play. This could be an indication that although the amount and intensity of work decrease as the match progresses, the physiological effect remains relatively stable. Findings on relative load from the current study allow coaches and conditioning coaches to prescribe conditioning programs specific to intensity zones of match-play.

## A PRELIMINARY OVERVIEW OF RESEARCH HOTPOTS IN SPORTS ARTIFICIAL INTELLIGENCE BASED ON KNOWLEDGE GRAPH

QI, A.1, TIANSHU, L.1, BINGYU, P.1

*1.BEIJING SPORTS UNIVERSITY, BEIJING, CHINA*

INTRODUCTION: Artificial intelligence (AI) has been evolving in the last few years, and it represents the transform of the focus in sports domain. Thanks to the invention of various sensors, such as wearable sensors and video-based tracking system, a large amount of spatial and temporal location data and event data were collected. Therefore, AI has been of great importance in sports data analysis. In this paper, we investigated the research hotpots in the field of sports and AI based on knowledge graph algorithms since 2010. Recent research efforts into implementation of AI in sports have demonstrated great promise in recognizing action of athletes in games, physical education, monitoring healthcare and sports medicine.

METHODS: First, we searched for manuscripts across different knowledge fields that have been reported in the last decade in database of Web Of Science. The keyword was defined as Sports and Artificial Intelligence. The topic was selected because it was observed in the current applications of sports research. Then we obtained 860 related papers. After removing the less relevant terms, we picked out 261 terms occurred more than ten times and above 60% correlation of a total of 21,246 keywords. We used VOSviewer bibliometrics software to illustrate the most recurring terms found.

RESULTS: From knowledge graph we obtained by VOSviewer, four different groups were found: data-set (red), sensor (yellow), artificial intelligence (blue), machine learning (ML) (green). Among these recurrence terms, ML accounted for 24.7% and sensors 19.2%. ML performed better on the area of predicting results [1] and potential risk [2]. Wearable equipment and sensing devices have been widely used in collecting data in real-time. Compare to the date of papers, we can observe that the number of publication showed an exponential increase after 2016, before that there is little change in volume. From the time-coverage map, Research highlights in sports AI before 2018 were human action recognition and sports video, while physical education, sports medicine, the internet of things, human computer interaction and deep learning(DL) algorithm have become the new hotpots after that.

CONCLUSION: In conclusion, the number of articles published in the field of sports artificial intelligence has grown exponentially in recent years. The core topics are sensor technology, machine learning algorithms, classification and recognition accuracy. The applications of AI in sports are gradually changing from competitive sports to mass sports and school sports and DL are increasingly used in sports data analysis. In application scenarios, sports training and sports performance analysis were gradually transformed to sports prescription[3].

## THE RELATIONSHIP BETWEEN ACUTE:CHRONIC WORKLOAD RATIO AND INJURY RISK DURING THE IN-SEASON IN ELITE JAPANESE RUGBY UNION PLAYERS

YAMAMOTO, H., TAKEMURA, M., FUKUHARA, K., ARIJIT, B., KURITA, K., TACHIBANA, M., SHIOTA, S., TSUJITA, J., HOJO, T.

*UNIVERSITY OF MARKETING AND DISTRIBUTION SCIENCES*

INTRODUCTION: Absolute weekly workloads (1-4 weekly) and acute workloads relative to chronic workloads have been investigated. However, the association between workload and injury may vary from sport to sport and competition league. Therefore, the purpose of this study was to investigate the association between workload and injuries in elite Japanese rugby union players.

METHODS: Fifty-two rugby union players (mean±SD; age, 27.7±3.2 years; height, 179.4±8.3 cm; body weight, 97.7±13.9 kg) from one elite Japanese rugby team were used as subjects during one in-season study. Training and match workloads were recorded as external loads (total distance, high-speed running (>5m/sec), acceleration and deceleration) using GPSPORTS-EVO (Catapult sports, Australia). All time-loss injuries were recorded during the period by a senior athletic trainer. Acute:chronic workload ratio (ACWR) was calculated by dividing acute workload (i.e. 1-week workload) by chronic workload (i.e. coupled and uncoupled rolling average 4-weekly workload). Players completed a Bronco test to assess injury risk in relation to fitness level. Generalized linear mixed model (GLMM) was used to analyze the relationship between ACWR and injury during the following week. These analyses can handle panel data (repeated individual measures). Model predictive accuracy was determined by area under the curve (AUC).

RESULTS: Greater association was found between high-speed running and injury than total distance, acceleration, or deceleration. High ACWR (>1.5) at high-speed running exhibited the greatest injury risk (Odds ratio = 7.14, 95% CI = 1.91 – 26.65) in the subsequent week.

Based upon the Bronco test performance, players with poor aerobic fitness had a greater risk of injury than players with better-developed aerobic fitness. Body fat percentage showed U-shape and was highly associated with an increased risk of injury for both high and low body fat percentage players.

CONCLUSION: We recommend that strength and conditioning coaches, involved in planning training for performance and injury prevention, monitor the ACWR, and avoid rapid changes of high-speed running that approach or exceed 1.5 in elite Japanese rugby union players.

## ESTABLISHING THE WEIGHTING OF POSSESSION ENDING FREE THROWS FOR FIBA MEN'S WORLD CUP

LAN, Y.C.1, LIU, Y.T.2

*1 NATIONAL YANG-MING CHIAO-TUNG UNIVERSITY , 2 NATIONAL TAIWAN NORMAL UNIVERSITY*

INTRODUCTION: In basketball, points per possession measures the performance efficiency. Although the number of possessions in a game is not usually recorded on the box scores, the number of field-goal-attempts (FGA), offensive-rebounds (OREB), turnovers (TOV), and free-throw-attempts (FTA) found on common box score data can be used to estimate the number of possessions in a game. The possession-ending free throws is only a fraction of the number of free throws that is not identifiable from the box score, and the commonly used weighting (λ) of 0.44 was based on the data from NBA (Kubatko et al., 2007). The purpose of the study was to examine the ratio of possession-ending free throws to the total number of free throws in a game for the FIBA men's world cup and to compare the recorded number of possessions to the estimated number of possessions from the box score data.

METHODS: Seventy-six games (48 games from the preliminaries) of 2019 FIBA men's World Cup were analyzed. The number of possessions and free-throw occurrences were recorded for both teams of every game by 2 independent observers. The Cohen's Kappas were 0.92 and 0.9 for the intra- and inter-observer reliability, respectively. Data were analyzed separately for the preliminary and advanced rounds. Paired Sample t-test was used to compare the number of FTA between data recorded and in box-score published from FIBA. Linear regression was used to derive λ values from the recorded data and the independent t-test was used to compare the λ values. In addition,

Wilcoxon Signed-rank Test was used to compare the recorded number of possessions with the estimated number of possessions based on the derived λ and the box score data.

RESULTS: There were no significant differences for the number of FTA between recorded and box-score data for the preliminary and advanced rounds. The λ values of 0.47 and 0.45 were found for preliminary and advanced rounds with R2 higher than 0.96 for both groups and they were not significantly different (p=.22). No significant differences were observed for the number of possessions between the recorded data and the estimations based on the λ values and the box score data for the preliminary and advanced rounds.

CONCLUSION: The λ values derived for the preliminary and advanced rounds of 2019 FIBA men's world cup were higher than 0.44 of NBA derived value. Although the λ values of the two phases did not reach significant difference, there is a trend of higher ratio for less advanced level. We suggest that the λ value for estimating the number of possessions from the box score data should be empirically established for different levels of basketball games.

Key word：box scores, notational analysis

### EFFECTS OF RACE DEVELOPMENT AND ORDERING STRATEGIES IN TRIATHLON MIXED RELAY

MORIYA, N.

*BUNKA GAKUEN UNIVERSITY*

INTRODUCTION: Triathlon mixed relay (MR) is characterized by the rapid race development and frequent changes of positions. However, the characteristics of MR race have not yet been fully clarified. The analysis of the race development and relay order of the 2019 World Triathlon MR Series indicated that 1) it is effective to maintain or improve the ranking in the third leg in order to finish at the top, and 2) it is effective to assign MR-specific members in the order formation. (Moriya, 2020).

This study aimed to examine to clarify the race development in MR in the Tokyo Olympics, and to obtain basic data regarding the strengthening strategy for the Paris Olympics.

METHODS: This study used Tokyo Olympic MR Results, Tokyo Olympic Individual Race Results, Olympic Qualification Rankings (OQR), and World Triathlon Rankings (WTR) published on the World Triathlon HP to analyze the relationship between them.

RESULTS: Race Development

1) As the race progressed, the time gap between leader and chaser increased.

2) The time difference increased significantly in run part of all legs.

3) In third leg, the time difference increased significantly in all three parts ($p<0.01$).

Relay Order

1) A tendency was observed to place higher performance athletes in first leg for female and in fourth leg for male.

2) The relationship between individual race, OQR, and WTR revealed that the correlation was higher in the order of individual race ranking < WTR < OQR.

3) The OQR total of two female athletes was found to have the highest correlation with MR ranking ($r=0.727$).

CONCLUSION: 1) The fact that no noticeable change in the race development appeared in two males legs can be attributed to the fact that two male from each country each had a high performance.

2) The performance difference between the contestants was greater for female than male. Therefore, many countries ordered athletes with higher performance in the first leg. This is thought to have led to a large time difference in the third leg.

3) The males and females legs are scheduled to be switched due to the revision of the WT competition rules starting in 2023. Therefore, the above trend is expected to change significantly.

## Training and Testing

### EVOLUTION OF PHYSICAL PERFORMANCE THROUGHOUT AN ENTIRE SEASON IN FEMALE SOCCER PLAYERS

REYES-LAREDO, F., LÓPEZ-LLUCH, G., PAREJA-BLANCO, F., RODRÍGUEZ-BIES, E.

*UNIVERSIDAD PABLO DE OLAVIDE*

INTRODUCTION: Female soccer is becoming worldwide, however, researchers related with its physical and physiological demands are still scarce, with a reduced prevalence respect male soccer (1). In this regard, abilities as change of direction, acceleration capacity, muscle strength and endurance performance are frequently assessed in men soccer (2). Thus, knowledge of the evolution of these parameters would allow to coaches improving training methodology and optimize physical performance in women soccer. Therefore, the purpose of the present study was to analyze the evolution of physical performance throughout an entire season in female soccer players.

METHODS: Twenty-seven young women soccer players (21.2 ±7.6 years) participated in this longitudinal study, which consisted of examining the evolution of physical performance during an entire season. The following battery of tests was performed at pre-season (PS), end of pre-season (EP), half-season (HS), end of season (ES): change of direction (V-cut test), 20-m running sprint time (T20), vertical countermovement jump (CMJ), maximal dynamic strength (1RM) in squat exercise, and intermittent fitness test (30-15 IFT). The values are reported as mean ±SD. Statistical significance was established at the level of $p\leq 0.05$. Normality of the data was verified using the Shapiro-Wilk test. One-way repeated ANOVA measures was used to detect differences between the different time-points in the assessed variables. Bonferroni t-test was used for all pairwise multiple comparison procedures.

RESULTS: A significant increase in V-cut performance was observed throughout the season ($p=0.032$; PS: 10.07±0.52; EP: 10.03±0.06; HS: 10.11±0.47; ES: 9.89±0.48 s). However, no significant changes were observed for CMJ height ($p= 0,457$; PS: 21.6±3.7; EP: 21.9±4.2; HS: 21.5±3.6; ES: 22.3±3.4 cm). With regard to sprint performance (T20) a significant "time effect" was observed through the season ($p=0,023$; PS: 3.57±0.18; EP: 3.58±0.16; HS: 3.53±0.16; ES: 3.54±0.17 s), with an improvement in performance at HS. In incremental test was observed significant improvements throughout the season ($p=0,001$; PS: 29.6±9.02; EP: 31.07±8.2; HS: 35.5±9.2; ES: 38.4±10.3 kg). Significant improvements in endurance capacity (30-15 IFT) were observed throughout the season ($p=0.001$; PS: 15.2±0.9; EP: 15.6±1.3; HS: 15.6±1.1; ES: 15.9±1.2 km·h-1)

CONCLUSION: Our findings suggest that change of direction capacity and intermittent endurance performance improved through the season, whereas jump and sprint capacity did not improve and even declined at some point during the season in female soccer players. We therefore suggest that specific sprint, jump and strength training should be included during the season with this specific population, which should be easily included before technical-tactical soccer training.

**ANALYSIS OF PT, TW, IPSILATERAL AND BILATERAL RATIO IN COLLEGIATE FEMALE HOCKEY PLAYERS**

YOON, J.R.

*KOREA NATIONAL SPORT UNIVERSITY*

INTRODUCTION: The purpose of this study is to diagnose and evaluate the balance ability between the left and right sides of the knee joint and the balance ability of the ipsilateral flexion force, which are important determinants of performance, by conducting an isokinetic muscle function test on H university womens hockey players of national representative level. At the same time, it aims to provide important reference points and implications for the prescription of professional physical training programs for each individual athlete.

METHODS: The subjects of this study were 16 college female field hockey players, who fully understood the purpose of this study and who actively expressed their intention to participate were selected. The physical characteristics of these athletes were age=19.79(±0.94)yrs, height=162.77(±5.75)cm, weight=57.14(±5.85)kg, body fat=25.76(±4.97)%. For the isokinetic muscle function test, the flexor force and extensor force of the knee joint were measured 5 times each at an angular velocity of 60$^{o}$/sec using Humac-Norm (USA). Preliminary measurements were performed twice in advance for the subjects adaptation. At this time, the rest time between measurements of the left and right knee joints was 1 minute to minimize the fatigue on the next measurement. For measurement variables, peak torque, total work, ipsilateral (H/Q ratio), bilateral (L/R ratio), and Left/Right Deficit were measured for isokinetic muscle function of the knee joint. For these muscle function variables, descriptive statistical techniques such as mean and standard deviation, maximum and minimum calculations were applied for each athlete using Window SPSS 17.0.

RESULTS: As a result of isokinetic knee joint function test of college womens hockey players, in extensors, peak torque was 222.88(±37.97)%BW, 225.56(±36.61)%BW, total work was 986.13(±145.85)%BW and 974.38(±131.14)%BW for the right and left sides, and the left and right deficit ratio were 8.56(±5.85)% and 10.31(±6.81)%, respectively. And in flexors, peak torque was 125.94(±25.45)%BW and 122.19(±27.74)%BW and total work was 622.38(±132.03)%BW 614.69(±110.46)%BW for right and left sides, and left and right (L/R) deficit ratio were 9.56(±7.69)% and 8.94(±7.44)%, respectively. The ipsilateral flexion/extension(H/Q) deficit was 56.88(±7.39)%, 66.81(±11.12)% for the right side, and 54.38(±8.44)%, and 65.00(±7.45)% for the left side, respectively.

CONCLUSION: In summary, the athletes participating in this study (1) the ipsilateral flexion ratio is lower than the standard value during peak torque, so hamstrings strength training that can be improved more than the current level is required. (2) Since both sides of the isokinetic muscle strength ratio in knee joints are in the normal range, it is recommended to sufficiently maintain the current muscle strength level.

**JUDO MATCH EXERCISE INTENSITIES IN THE JUDO WEIGHT DIVISIONS**

SANTOS, L.1, FEDEROLF, P.A.2

*1 UNIVERSITY OF LEÓN, SPAIN; 2 UNIVERSITY OF INNSBRUCK, AUSTRIA*

INTRODUCTION: The determination of the exercise intensities of the Judo match can be very useful for coaches and players to optimize training sessions. Thus, the goals of the current´s study were to determine the exercise intensities of the Judo match (for the male and female divisions) and to define the type of relationship (independency or dependency) between the exercise intensities of the Judo match and the Judo weight divisions.

METHODS: Ninety-six (forty-eight males and forty-eight females) national and international level judoists were clustered on six groups considering the official weight divisions: lightweight ([ML]; -60kg, -66kg, -73kg), middleweight ([MM]; -81kg, -90kg) and heavyweight ([MH]; -100kg, +100kg) for males, and lightweight ([FL]; -48kg, -52kg, -57kg), middleweight ([FM]; -63kg, -70kg) and heavyweight ([FH]; -78kg, +78kg) for females. They participated in only one match against an opponent of the same sex and weight division. Matches were conducted following special rules to guarantee that all matches lasted 5 min (Franchini et al., 2013). Players wore an accelerometer that was located on their belly buttons with an adjustable elastic belt. Data obtained from the accelerometers were: Judo match time at different levels of exercise intensity (sedentary, light, moderate, vigorous and very vigorous) in sec.

RESULTS: Players of all weight divisions predominantly fought at moderate and vigorous intensities (ML, 184.2±40.1 sec -61.3±13.3%- and 84.3±38.3 sec -28.1±12.8%-; MM, 170.6±32.9 sec -56.9±11%- and 99.2±42.2 sec -33.1±14.1%-; MH, 157.6±33.7 sec -52.5±11.2%- and 105.1±27.5 sec -35±9.1%-; FL, 209.4±46.2 sec -69.8±15.4%- and 50.4±28.7 sec -16.8±9.6%-; FM, 184.1±31.2 sec -61.3±10.4%- and 63.1±28.4 sec -21.1±9.4%; FH, 162.3±19.6 sec -54.1±6.5%- and 107.2±27.9 sec -35.7±9.3%-, moderate and vigorous, respectively). The chi-square test suggested independency between the exercise intensities of the Judo match and the Judo weight divisions ($\chi$2=25.62, p=0.1787).

CONCLUSION: In their training, judoists of the all weight divisions should predominantly prepare for matches of moderate and vigorous exercise intensities.

**IS SIDE-SHOT SKILL IN BASKETBALL INFLUENCED BY EXPERIENCE IN SPORTS EVENTS, LENGTH OF PAST BASKETBALL EXPERIENCE, GENDER, AND STANDING HEIGHT?**

TAGATA, S.1, AOYAGI, O.2, KOMURE, I.2, NAGAMINE, K.2, OHYAMA, Y.3

*1 HITACHI HIGH-TECH COUGARS, 2 FUKUOKA UNIVERSITY, 3 NATIONAL INSTITUTE OF TECHNOLOGY, SASEBO COLLEGE,*

INTRODUCTION: Skill tests are sufficiently valid to measure basic skills to be used in PE basketball classes, even in sports/PE-related universities or major courses. Favorite sports events that students in sports-related universities play every day might be involved in the measurement of the skill tests. Additionally, basketball experience so far, such as mini-basketball (basketball for elementary school boys and girls in Japan), gender, and standing height are thought to be involved in basketball skills. If these factors, in addition to learning effects in classes, are also related, grading in classes must be done taking these factors into consideration. Thus, the current study aimed to examine the associations of the side shot, one of the most important basketball skills, and these factors.

METHODS: 244 F-university students in the sports-related major course who took basketball PE classes were asked to participate a side-shot skill test. For the side-shot skill test, a shot was thrown from the side at a distant of 20.5 feet for males and 15 feet for females five times successively. This test was repeated four times. Additionally, the sports club they belonged to, gender, standing height, and

basketball experience from elementary school to high school were recorded. The sports clubs they belonged to were classified into basketball, ball games other than basketball, sports events other than ball games, and no club. However, the measurements of them were originally correlated because students to belong the same sport club practice identical training and the similar group of sports categories have similar movements. That is to say, there is a nested structure within each other. Thus, in this study, a mixed linear model was used with these factors as random effects.

RESULTS: When comparing deviance using a null model with only random effects (deviance =5100.8) and a full model with both random and fixed effects (deviance = 5072.8), significant model fitting was seen in the full model (chi-squared = 28.028, df=5, p<0.001). Variances as a random effect were 0.006 for individuals; 0.001 for clubs; 0.017 for sports categories; and 0.161 for residuals, indicating a significant difference in sport categories (p<0.001). This meant that the skill performance was thought to be determined by club categories which were grouped by roughly similar sports movements, but not individuals nor individual sports clubs. Regression coefficients as a fixed effect were -0.035 for males; 0.003 for standing height; and 0.003, 0.014, and 0.005 for basketball experience in elementary, junior high, and high schools, respectively. Among them, significant associations were found in standing height (to=2.505, df=233, p<0.05) and basketball experience in elementary school (to=3.585, df=235, p<0.001).

CONCLUSION: The side-shot skill test was involved in sports categories and was significantly influenced by standing height and basketball experience in elementary school.

## LONGITUDINAL CHANGES IN PASSING AND RUNNING SKILLS FOR AGILITY IN BASKETBALL ACCORDING TO SPECIALIZED SPORTS EVENTS

AOYAGI, O.1, KOMURE, I.1, NAGAMINE, K.1, TAGATA, S.2

*1FUKUOKA UNIVERSITY, 2HITACHI HIGH-TECH COUGARS*

INTRODUCTION: Skill tests have been used to measure basic basketball skills even in basketball PE classes at universities majoring in PE. However, in PE-majoring universities, since their students play their specialized sport events, their experience may influence skill tests. Simultaneously, it is thought that this also influences the effects of the PE classes. For instance, it is expected that students who play sports events similar to basketball will obtain poor PE effects and those who play different sports events will obtain good effects. Thus, this study investigated the longitudinal changes in passing and running skills for agility in basketball.

METHODS: Subjects were 244 university students (171 male and 73 female students) who take basketball PE classes in the PE-related faculty at F-university. They were asked to perform the Edgren ball handling test (Passing and running skill tests for agility, which measures the time required to throw the ball at a wall 10 times while running to the right and left within a 2m interval) twice. Then, their half-year development was examined according to their sports events and groups. The sports event groups were Basketball, Ball games except for basketball, Clubs except for ball games, No club in PE major, and No PE major. Since this repetition in each individual, sports event, and their groups was nested, a linear mixed-effect model was conducted using them as a random effect and time (before and after the classes), gender, and their interaction as a fixed effect.

RESULTS: As a result of deviance analysis of the Null model including only random effects (AIC=3777.6) and Full model including Time, Gender, and their interaction (AIC=3726.79), a significant level of fitness (Chi-square =56.81, df=3, p<0.001) was found. Through independent variable selection using likelihood ratio tests, the model (Selected mode, AIC=3719.5) removing the random effects of the slopes of the clubs and groups of clubs was chosen. Intraclass correlation coefficients were high with 0.764 and 0.798 in the intercept and slope of Individuals, but low with 0.268 and 0.486 in the intercepts of Clubs and Groups of Clubs. That is, an innate wide range variability was found in Clubs and Groups of Clubs, but a narrow range one in PE class effects, and irrespective of specified sports events, both the innate and classes effects at the individual level were large. The partial regression coefficients of Males, Time, and their interaction were -1.058, 0.033, -0.948, respectively, indicating that Males and interaction were significant. That is, a remarkable gender difference was found, males are superior to females, and only the PE class effect was found in Males, but not in the whole class.

CONCLUSION: A small impact on specified sports events was found with passing and running skills for agility in basketball and depended on individuals. In addition, a high PE class effect was detected in males, but not in females.

## EXAMINATION OF BODY TYPES OF POWERLIFTERS

BIRÓNÉ ILICS, K., NAGYVÁRADI, K., BÁRSONY, D.

*EÖTVÖS LORAND UNIVERSITY*

INTRODUCTION: Specific body sizes (Nádori, 1991; Balogh at all, 2015) and body types are important selection criteria for professional athletes (Biróné, 2014). The aim of this study is to determine the main body sizes and body types of competitors in the sport of powerlifting. The results are compared with those described in the international literature.

METHODS: All Szombathely-based male powerlifters aged 18 and over participated in our study (N = 18). Their mean age was 28.4 ± 9.4 years. The InBody720 Body Composition Analyser device was used for the examination of the body composition, and an anthropometric measurement (Martin & Saller, 1957; Weiner & Lourie, 1969) was performed to determine the body size, during which 24 different parameters were recorded. From the obtained data, we determined the body type of the subjects based on the 6 types developed for athletes by Mészáros (1990). Basic statistics and a correlation matrix were used to evaluate the results.

RESULTS: Athletes had an average height of 177.44 ± 7.12 cm, an average body weight of 97.01 ± 14.12 kg, an average body fat weight of 15.95 ± 6.77 kg, an average body fat percentage of 16 ± 5.12%, an average skeletal muscle weight of 47.2 ± 6.15 kg and an average BMI of 30.4 ± 2.91. A strong correlation was found between skeletal muscle mass and right and left arm mass (r = 0.99), and between skeletal muscle mass and torso mass (r = 0.99). BMI correlated with chest depth and circumference (r = 0.87) and with forearm circumference (r = 0.88). Skeletal muscle mass was significantly correlated with limb muscle mass (right arm r = 0.99, left arm r = 0.98, right leg r = 0.95, left leg r = 0.93) and torso weight (r = 0.99). The body type of the participants was endo - mesomorphic (8 individuals) and mesomorphic (10 individuals).

CONCLUSION: Since the goal in powerlifting is to move great weights, the sport assumes significantly developed musculature (Ferland at all, 2020), and the body type of athletes is characterized by the endo - mesomorphic and mesomorphic types (Mackenzie, 2001). According to the results obtained, the athletes in the study have the appropriate body type and muscle mass required for powerlifting. Half of their average body weight is muscle mass, distributed evenly to the right and left, and between the torso and the legs. From this it can be concluded that the training performed in the sample meets the criteria of the sport.

## RELATIONSHIP BETWEEN KNEE STRENGTH, CHANGE OF DIRECTION SPEED, AND LEG MUSCLE MASS AMONG ELITE YOUNG SOCCER PLAYERS

KOLTAI, M., GUSZTAFIK, Á.

*EÖTVÖS LORAND UNIVERSITY FACULTY OF EDUCATION AND PSYCHOLOGY*

INTRODUCTION: The Change of Direction Speed is one the most important factors that influences efficiency in ballgames. Different authors came up with varied findings while carrying out internationally standardized COD tests and studying their connection with dynamic leg strength.

METHODS: Subjects: Forty-nine elite young soccer players (U16-U17; 178.59±6.29; 69.08±7.78). Measured body parameters [1]: Height; Weight; Right Leg Lean Mass (RLLM, kg) Left Leg Lean Mass (LLLM, kg). Change of Direction Speed [3]: Illinois Agility Test (IAT, s), 505 Right and Left change (s). Isokinetic Knee Strength parameters [2]: Extension and flexion right and left leg 2 and 15 repetition (N); H/Q Right; H/Q Left (%). CMJ (cm), CMJ Concentric and Eccentric averages (N), CMJ Flight Time (s). Instruments: InBody770, Witty Wireless Training Timer; HumacNorm isokinetic dynamometer; ForceDecks. Data processing: IBM SPSS Statistics 28 ($p<.05$).

RESULTS: The young soccer players' lean leg mass turned out to be symmetric according to our research (RLLM, 10.07±1.02; LLLM, 10.01±.95). They performed at COD tests much better than the average at international level (IAT, 15.56±.40; COD505L, 2.57±.12; COD505R, 2.55±.12).

Their average performances measured with isokinetic dynamometer were well balanced: H2ER (224.43±32.27), H2EL (218.09±33.66), H2FR (148.89±29.62), H2FL (147.86±22.44), H/Q2R (63.91±12.44), H/Q2L (67.83±10.03), H15ER (125.37±16.48), H15EL (125.77±16.85), H15FR (101.17±15.21), H15FL (102.48±14.96), H/Q15R (78.70±10.06), H/Q15L (84.94±15.90). The data measured on force plate were according to their age: CMJ (32.28±3.97); CMJC (1467.90±139.07); CMJE (728.45±80.48); CMJFT (.77±.11).

The Changes of Direction Speed (IAT) showed no significant correlations with the right and left leg lean mass, or any isokinetic knee strength (extension and flexion) parameters.

The COD505 tests showed strong correlations when carried out with different legs ($r=.769$; $p<0.001$), they only related to one CMJ parameter ($r=.448$; $p<.05$), it was only related to Left Leg Lean Mass ($r=-.447$; $p<.05$). However, the CMJ Contractive averages showed strong correlations in the case of both legs ($r=.692$; and $r=.707$; $p<.001$).

The CMJ Eccentric averages and the Humac2FR, 2FL, 15ER and 15FL were also related to each other ($r=.488$ - $.744$; $p<.05$).

CONCLUSION: It is difficult to find the relations between leg dynamic strength and traditional CODS tests. That is why we suggest improving both skills at the same time.

## EFFECTS OF A SPRINT TRAINING PROGRAM WITH CONDITIONED BRAKING ON HAMSTRING

PÉREZ-GÓMEZ, J., CARLOS-VIVAS, J., ADSUAR, J.C., MENDOZA-MUÑOZ, M., RODAL, M., GIANIKELLIS, K.

*UNIVERSITY OF EXTREMADURA*

INTRODUCTION: Muscle strain injuries of hamstring in sports that involve running with acceleration and deceleration are very common and affects all levels of competition; furthermore, it's very common that a relapse occurs [1]. Hamstrings injuries during sprint usually occur in explosive gestures and biceps femoris is the most affected muscle [2].

Aim

To analyze the effects of a training program, based in sprint with forced braking, in muscle of posterior musculature of thigh.

METHODS: Material and methods

22 subject participated (22.0±2.2 years; 1.78±0.08m; 75.9 ±12.5 kg). Participants were randomly distributed into control group (CG, n=10) and experimental group (EG, n=12). Participants didn't follow any complementary resistance training or physical activity oblivious to the study. Training protocol consisted of 10 weeks training where EG performed 10 meter sprints at maximum intensity with a deceleration and forced braking of 2.40 m at the end of the sprint. The following variables were recorded before and after training program. Countermovement jump (CMJ) was recorded with force platform (IBV dinascan 600M). Lower leg strength was assessed with isokinetic dynamometer (Biodex System 3); concentric and eccentric torque peak was analyzed at different angular velocities (60º/s, 120º/s and 180º/s). Electromyography (EMG) was recorded for biceps femoris and semitendinosus in both legs (Delsys Trigno Wireless System) in breaking phase during 30 m sprint test and during 1RM in hamstring curl machine.

RESULTS: EG showed statistically significant differences in knee flexor and extensor muscles strength after training in concentric movement at 60º/s of angular velocity in both legs (pre = 93.8 Nm ± 24.2, post = 106.4 Nm ± 25.2, $p = 0.009$). EG improved eccentric strength at 60º/s in hamstring muscles of right leg (CG = -7.8 Nm ± 10.3, EG = 7.2 Nm ± 15.6, $p = 0.033$). Alike, right knee extensor muscles strength, at 120º/s, improved in left leg in EG (pre = 164.6 Nm ± 29.4, post = 188.4 Nm ± 23.3, $p = 0.001$). No statistically significant differences were found in EMG data.

CONCLUSION: Based on the results obtained in the present study, it is concluded that a sprint training program, based on accelerations with conditioned braking, favors the improvement of the eccentric and concentric force of the thigh posterior musculature.

### VARIABLES OF THE PHYSIQUE IN YOUNG BASKETBALL PLAYER GIRLS

FARKAS, A., BOSNYÁK, E., SZMODIS, M.

*HUNGARIAN UNIVERSITY OF SPORT SCIENCE*

INTRODUCTION: In the area of female sport it is an interesting and exciting topic, to investigate the differences of the bodily development level of matured and unmatured girls. In our sample the differences of the body parameters, if any, in a group of young basketball player girls, from Sopron, in Hungary were studied.

METHODS: Anthopometric parameters were taken (N=62, aged 9 to 16 years), somatotype components (Heath and Carter 1969), Conrad's growth type (1963), Drinkwater and Ross (1980) body fractionation method and body fat content (Pařizková 1971) were characterized by the maturational status. Menarcheal age was registered retrospectively. Basic statistics, Student t-test, linear correlation analysis were used to characterize and analyze the differences between the subgroups. Biological age was assessed by the morphological age (Mészáros and Mohácsi 1982).

RESULTS: The average menarcheal age of the girls (n=18) was 12,33 (±0,98) years, lower than the Hungarian menarche median (12.79 years). All the girls were taller and heavier than the reference values. The less differences occured in the 11 and 12 year subgroups. The largest differences occured in body mass at the age of 13yrs, and in stature from 13yrs on, presumably as the result of the selection. When comparing the matured and non-matured girls some characteristic differences were found: matured girls were more endomorphic, and less ectomorphic than non-matured ones. They had higher BMI (20.63±2,19 vs.17,82±3,24), body fat content (23,11±3,80 vs. 19,79±5,04), and lower bone percentage values. There were no differences in the muscle contents, supposingly because of the high variation.

CONCLUSION: It is important to understand the differences between matured and unmatured young athletes, especially because of the planning the workload and the evaluation of their performance.

### THE PE-CLASS EFFECTS OF BALL HANDLING SKILLS IN BASKETBALL ACCORDING TO SPECIFIC SPORTS EVENTS

NAGAMINE, K.1, AOYAGI, O.1, KOMURE, I.1, YAITA, A.2, TAGATA, S.3, ANNOURA, T.4, OHYAMA, Y.5

*1FUKUOKA UNIVERSITY, JAPAN, 2KYUSHU KYORITSU UNIVERSITY, JAPAN, 3HITACHI HIGH-TECH COUGARS JAPAN, 4JAPAN UNIVERSITY OF ECONOMICS, JAPAN 5NATIONAL INSTITUTE OF TECHNOLOGY , SASEBO COLLEGE, JAPAN*

INTRODUCTION: Even in basketball PE classes at sports-related universities, skill tests have been utilized to confirm the PE class effects of basic skills. However, it is thought that the fact that students in sports-related universities have on their own specific sport may possibly impact the measurements of basketball skills. The same effect may emerge in the development of skills in PE classes. For example, the PE effects of those who have played basketball or similar ball games to date may be small, and large PE effects can be expected in those who have not experienced them. So, this study aimed to investigate the PE-class effects of ball-handling skills in basketball according to specific sports events. However, since students who have experienced the same sport events regarding whether ball handling skills are used or not might be similar to each other, taking these dependencies into account, a linear mixed model was used.

METHODS: The Zone toss test was given to 171 male and 73 female university students who were taking PE basketball classes at F-university. In the Zone test, subjects tossed the basketball over a 3m 5cm-wide and 2m 15cm-high rope and caught it on the other side 1m 93cm apart from one side after running under the rope. This action was repeated 10 times and the time required was measured. This test was repeated twice per subject. The differences in the measurements after half a year were examined. Specific sport events were hierarchically categorized into Basketball, Ball games other than basketball, No club, and No PE major. When using the linear mixed model, the nested individuals, clubs, and groups of clubs were used as random effects and Time (before and after PE classes), gender, and their interaction as fixed effects.

RESULTS: The results of a deviance test between the Null model with only random effects (AIC = 4201.4) and the Full model, including fixed effects (AIC = 4169.6), showed a significant level of fitness (Chi-square = 37.8, df = 3, $p<0.001$). The selection of independent variables using a likelihood ratio test chose the model removing the fixed effects of the interaction of Gender and Time and the random effects of the slopes of the Clubs and Groups of Clubs and the intercept of Groups of Clubs AIC=4161.6). Intraclass correlations were high with 0.912 in the slope and 0.764 in intercept, but low in the intercept of Clubs. Namely, the variances of Clubs and Groups of Clubs were small but original and class effects in individual levels were both large. With fixed effects, the regression coefficients of Male and Time were significant with -1.531 and -1.308, respectively, but their interaction was not. That is, it can be said that originally the skills of males were better than those of females and PE effects were consistently found between males and females as a whole.

CONCLUSION: The PE class effect of ball-handling skills was dependent on individuals but not their specified sport events and was found in both males and females.

### DOES THE PROFICIENCY OF SERVE RECEPTION INFLUENCE THE RESULT OF ATTACK IN ELITE VOLLEYBALL AND TO WHAT EXTENT?

STAMM, R., STAMM, M., TIGANE, J.

*SCHOOL OF NATURAL SCIENCES AND HEALTH*

Introduction

Researchers have found an essential correlation between attack and the final result of the game in elite volleyball. Although attack is performed individually, it is preceded by cooperation between the setter and the receiver of serve (Drikos, Vagenas, 2011). Hughes and Daniel (2003) have found that proficiency of reception differentiates elite teams from mediocre ones.

Methods

The aim of the current study was to analyse players' individual proficiency of serve reception and its influence on the following attack in the Estonian national team during the qualification for the European Championship in 2016. The paper analyses eight games of the Estonian national team at the qualification tournament of the European Championship where a total of 31 sets were played. In the games played at the qualification tournament, 17 sets were won and 14 sets were lost.

The following indicators were written down from video recordings of the games: number of receptions of serve, proficiency of reception, reception zone, reception type. Attacks from zones 2, 3, 4 and the back zone were also counted – number of attacks, performer, zone of attack and proficiency.

Results and discussion

The results showed that the Estonian national volleyball team was most proficient at attack from grade five receptions (50.35%). In the case of very good reception, 91 points were scored from 139 attacks; 27 balls remained in play, and there were 21 errors. After receptions performed with grade four, the proficiency of attack was 40.86%; a total of 208 attacks were performed; 118 of them ended with a point for the Estonian team; 57 remained in play, and there were 33 errors. After receptions graded three and two, the proficiency of attack was considerably lower, 21.31% and -3.57% respectively. After receptions with grade three, 51 points were scored from 122 attacks; 46 remained in play and there were 25 errors. After receptions with grade two, from 28 attacks 6 points were scored, 15 remained in play, and there were 7 errors. This showed that, in the case of more successful serve reception, the Estonian volleyball team was more proficient at attack. Reception of serves by the Estonian team was more proficient in sets won than in sets lost; in the case of more successful reception the team was more proficient at attack than in the case of less proficient reception. The receivers of the Estonian national team were most proficient in the case of reception from above; serves were best received from zone 5.

**IDENTIFYING THE TRAINING LOAD OF SOCCER-RELATED DRILLS**

MICHAELIDES, M., PETROV, D., PARPA, K.

*UCLAN CYPRUS*

INTRODUCTION: The purpose of the study was to determine the internal and external load of 2 popular drills used in soccer training. Specifically, the study examined a conditioned soccer game involving the ball possession time known as rondo and the small-sided game (SSG) drills.

METHODS: Seventeen professional male football players (age =27.5 ± 5 years; weight 73.48± 7.02 kg; body fat% 9.85± 3.64; VO2max 58.11± 5.53 ml/kg/min) participated in this study. The data were collected using the Wimu Pro device (RealtrackSystems, Almería, Spain) during the annual training of the soccer players. The data analysis included comparing the average of 10 SSG versus the average of 10 rondos. The internal load variables examined was the max heart rate (HRmax) and the average Hr (AHr). The variables examined denoting the external load were: total distance(m), explosive distance(m), number of accelerations, number of decelerations, maximum speed(km/h), average speed(km/h) and metabolic power (W/kg).

RESULTS: Results were analyzed using a mixed ANOVA design to compare the mean differences between groups (playing positional differences) and the within-subjects differences in the drills as mentioned earlier internal and external load parameters. The results demonstrated that the playing position had no significant effect on either the internal or the external load parameters. Additionally, SSG resulted in higher external load in all the parameters above except the number of accelerations and decelerations that, in turn, were significantly higher ($p < 0.05$) in rondos. The internal load parameters were significantly higher ($p < 0.05$) in SSG.

CONCLUSION: Using technology, fitness coaches can now identify the physical demands of soccer-specific drills. The findings of this study demonstrated the difference in 2 popular drills in soccer. Fitness coaches may use the results of this investigation to develop exercise regimens targeting the bioenergetics systems of their soccer players accurately.

**BILATERAL AND IPSILATERAL ASYMMETRIES IN LOWER BODY STRENGTH: A COMPARISON OF PROFESSIONAL AND UNDER-17 FEMALE SOCCER PLAYERS**

PARPA, K., GIANNOU, E., MICHAELIDES, M.

*UCLAN UNIVERSITY OF CYPRUS*

INTRODUCTION: Although the risk of injury in soccer is multifactorial, the lower-limb strength, anterior-posterior balance and inter-limb asymmetries should be monitored for both performance and injury prevention purposes. Soccer players have shown differences in strength between the dominant and non-dominant limbs, which may be due to the technical elements performed during the games and training. Therefore, this study examined the lower-limb strength, bilateral and ipsilateral asymmetries in professional and Under-17 female soccer players.

METHODS: Thirty-seven players (professional =19, Under-17= 18) volunteered to participate in this study. The isokinetic knee strength and asymmetries were assessed utilizing the Humac Norm and Rehabilitation device. Testing included three maximal concentric flexion and extension repetitions at an angle speed of 60°/s.

RESULTS: Professional female soccer players exhibited significantly greater strength levels for the left quadriceps [$t(35)=2.39$, $d=0.79$, $p<0.05$] and both left [$t(35)=2.74$, $d=0.90$, $p<0.05$] and right [$t(35)=3.87$, $d=1.28$, $p<0.05$] hamstring muscles. Concurrently, the right leg ratio [$t(35)=2.76$, $d=0.92$, $p<0.05$] was significantly greater for the professional compared to Under-17 players. Lastly, professional players demonstrated significantly greater bilateral imbalances [$t(35)=3.13$, $d=1.04$, $p<0.05$] for the quadriceps muscle group.

CONCLUSION: The results of this study indicated that professional female soccer players demonstrate greater imbalances than Under-17 players, which may be attributed to the longitudinal effects of high-level soccer. Conclusively, soccer practice and competition at the professional level may induce greater lower limb asymmetries. Therefore, the isokinetic parameters can be useful for planning strength and conditioning interventions during the pre-season and in-season periods in order to reduce or prevent those imbalances.

**COMPARISON OF MUSCLE ACTIVITY OF 108 BOWS AND BURPEE TEST**

LEE, J.Y., LEE, S.H., SEUNG, D.H., PARK, G.D.

*KYUNGPOOK NATIONAL UNIVERSITY*

INTRODUCTION: The 108 bow is known as a religious ritual, but it is a full-body exercise that complements the weak balance with incorrect physical activity or lifestyle and effectively uses each part of the body. The Buffy Test was developed in 1930 by American physiologist Royal H. Buffy as a way to evaluate physical strength and was used to evaluate agility and endurance, and was lying face down in a standing position. Not only athletes but also ordinary people are in the spotlight as a whole-body exercise to improve their physical strength because they can maximize the effect of exercise in a short period of time by repeating standing up movements. Several previous studies on 108 bows and burpee test exercise have reported that it is an effective exercise for improving physical strength and muscle strength, but scientific and quantitative research on the active muscles between each exercise is insufficient. Therefore, the purpose of this study is

to compare changes in muscle activity during 108 bows and burpee test exercises, which are similar exercises performed on the floor, and to present an effective exercise method.

METHODS: This study classified 22 adult men and women into 108 bows group (A) and burpee test group (B). An average value was applied after 10 operations, and a constant speed of 30 bpm was performed using a metronome. The body composition was measured by an inbody 720 measuring instrument, and the muscle activity of four muscles was measured through Noraxon MR3.

RESULTS: The results of this study are as follows. First, the comparison results of the muscle activity of Rectus Abdominis showed high muscle activity in all the buffy tests on the left and right, and a statistically significant difference between the two populations was observed in the comparison of the muscle activity of the right rectus abdominis($p<.05$). Second, the comparison results of the muscle activity of Rectus Femoris The muscle activity of both buffy tests appeared high, and there was a statistically significant difference between the two populations on both the right side ($p<.001$) and the left side ($p<.01$).

CONCLUSION: This study compared the muscle activity of erector spinae, gluteus medius, rectus abdominis, and rectus femoris between 108 bows and burpee test exercises, and found significant differences in both 108 bows and burpee tests. Based on the difference in muscle activity between 108 bows derived from this study and the two movements of the burpee test, cardiopulmonary endurance along with pre- and post-exercise studies can be measured and provided as basic data for more effective exercise program development.

## EFFECTS OF MOVEMENT AND STRENGTH TRAINING ON RUNNING ECONOMY IN ELDER RECREATIONAL MARATHON RUNNERS.

TOKUI, M.

*KYUSHU KYORITSU UNIVERSITY*

INTRODUCTION: Recently, the efficacy of strength training for long distance runners has attracted attention, because strength training leads to an improvement in the running economy. Many of these studies have targeted young runners in their 20s and 30s, and the effect of strength training on running economy in elder runners have not been investigated yet. The purpose of this study was to investigate the effects of movement and strength training on running economy in elder recreational marathon runners.

METHODS: Six male and six female healthy elder recreational marathon runners (age, 59.0±8.0 and 53.7±7.8 yr; height, 170.4±5.6 and 160.5±6.2 cm; weight, 66.4±7.2 and 51.5±6.9 kg, respectively) voluntarily participated in this study. The runners performed strength and movement training twice a week (for once of each in group and in individual) for twelve weeks and running economy, quantified as oxygen cost of running at a given velocity on the treadmill, was evaluated before (PRE) and after the training period (POST). The movement training consisted of the drills to improve running movements; swing back of swinging leg and landing under center of mass, body propulsion with hip and hamstrings muscles of supporting leg and transmission of power to swing leg through pelvis. The strength training constructed of self-weight trainings with trunk, hip, waist and hamstrings, which leads to the above target running movements. The runners ran at three velocities for every 4 minutes (total twelve minutes) according to their performance level chosen by each runner, followed by a 5-minute break, and 1-min step incremental running test was carried out until an exhaustion point. Pulmonary gas exchange ($VO_2$) was continuously measured throughout the running test.

RESULTS: Running economy, expressed as $VO_2$ measured at three stages of three-constant velocities, in PRE and POST showed similar values for female runners (31.9±8.0 vs. 31.3±4.2 ml/kg/min in the first stage, 32.1±8.0 vs. 32.4±5.5 ml/kg/min in the second stage and 34.4±8.3 vs. 33.7±7.6 ml/kg/min in the third stage, respectively). On the other hand, the values in male runners were slightly lower in POST but not significant (31.0±3.6 for PRE vs. 30.2±2.4 ml/kg/min for POST in the first stage, 37.2±3.6 for PRE vs. 34.7±4.4 ml/kg/min for POST in the second stage and 43.7±8.7 for PRE vs. 41.5±5.0 ml/kg/min for POST in the third stage, respectively). Furthermore, $VO_2$peak in PRE and POST were almost the same values (38.5±7.6 vs. 39.0±5.2 ml/kg/min in female runners and 47.7±5.5 vs. 47.7±5.6 ml/kg/min in male runners).

CONCLUSION: The movement and strength training performed by elder runners in this study resulted in an insignificant improvement in running economy, suggesting that more longer training period than one used in this study or another training method may be needed to improve the running economy for elder recreational marathon runners.

## THE RELATIONSHIP BETWEEN BOUNCE-SHOT SKILLS AND VARIOUS FACTORS IN BASKETBALL EXAMINED USING A MIXED LINEAR MODEL

OHYAMA, Y.1, AOYAGI, O.2, KOMURE, I.2, TAGATA, S.3, NAGAMINE, K.2

*1 NATIONAL INSTITUTE OF TECHNOLOGY, SASEBO COLLEGE, 2FUKUOKA UNIVERSITY, 3 HITACHI HIGH-TECH COUGARS*

INTRODUCTION: To measure basic skills in basketball, skill tests are adopted in PE basketball classes, even in sports-related universities. They are utilized also for grading students. As factors affecting the skills, in addition to gender and standing height, the influence of experience in childhood might have an impact, especially on basic skills, as well as on the latest playing experience. In addition, since students in a sports-related university/faculty have their own favorite/specific sports events, their experience might also influence it. If it affects skill evaluation, grading must be done taking it into consideration. Thus, this study aimed to examine the association between bounce-shot skill tests that measure a compound skill with dribbling and shooting and related factors.

METHODS: Two hundred and forty-four university students majoring in PE at F-university in Japan (71 males and 73 females) were asked to conduct a bounce-shot skill test four sets. The bounce-shot skill test was measured using the following procedure: Subjects were asked to shoot after dribbling from two spots 18 feet from the basket oriented at a direction of 45 degrees to the end line. This is repeated 10 times, alternatively right and left, as fast as possible. The scores of getting the basket were recorded. Additionally, they were classified into the following club categories: basketball, ball games other than basketball, sports clubs other than those for ball games, and no clubs. Since the data for students who are playing identical sports events seemed to be correlated, it was analyzed with a mixed linear model using individual repetition, clubs, and club categories as random effects because they were nested in this order.

RESULTS: Deviance analysis between the null model consisting of only random effects (deviance = 12135) and the full model consisting of both random and fixed effects (deviance = 12038) revealed that the full model represented significantly better fitness (chi-squared = 96.486, df=5, $p<0.001$). The obtained variances were 0.016 in individuals, 0.009 in clubs, 0.007 in club categories, and 0.195 in residuals, indicating that significant differences were found in individuals and clubs at the 1% level and in categories at the 5% level. From the viewpoint of fixed effects, the obtained regression coefficients were 0.0084 in males (The coefficient of females is set to 0 because of reference.), 0.003 in standing height, 0.036, 0.056, and 0.012 in elementary, junior high, and high schools, respectively. Then, significant

differences were found in gender (to=3.520, df=234, p<0.001); standing height (to=2.186, df=228, p<0.05); basketball experience in elementary school (to=4.086, df=230, p<0.001); and that in junior high school (to=4.015, df=227, p<0.001).

CONCLUSION: Significant variability was found in individuals, clubs, and club categories, and significant effects were found in all fixed effects, except high school experience.

### IS THERE A "WINDOW OF OPPORTUNITY" FOR FLEXIBILITY DEVELOPMENT IN YOUTH? A SYSTEMATIC REVIEW WITH META-ANALYSIS

DONTI, O.1, KONRAD, A.2, PANIDI, I.1, DINAS, P.C.3, BOGDANIS, G.C.1

*1SCHOOL OF PHYSICAL EDUCATION & SPORT SCIENCE, NATIONAL & KAPODISTRIAN UNIVERSITY OF ATHENS, GREECE; 2INSTITUTE OF HUMAN MOVEMENT SCIENCE, SPORT AND HEALTH, UNIVERSITY OF GRAZ, AUSTRIA, 3FAME LABORATO*

INTRODUCTION: Flexibility is an important component of physical fitness for competitive and recreational athletes. It is generally suggested that flexibility training should start from childhood (6 -11 years of age) to optimize joint range of motion (ROM) increases; however, evidence is limited and inconsistent. Therefore, the aim of this study was to examine if there is a difference in the effect of stretching training on flexibility during childhood (6-11 years of age) and adolescence (12-18 years of age).

METHODS: We searched PubMed Central, Web of Science and Scopus to conduct this systematic review and meta-analysis. Randomized controlled trials and non-randomized controlled trials were eligible. No restriction in date of publication was applied. Risk of bias was assessed using Cochrane RoB2 and ROBINS-I tools. Meta-analyses were conducted via an inverse variance random-effects model. GRADE analysis was used to assess the level of the quality evidence.

RESULTS: From the 836 records retrieved, 24 studies were included in the meta-analysis (n=1676 participants). Risk of bias was low in 66% of all criteria. Confidence in cumulative evidence was moderate. We found that stretching was effective in increasing ROM in children (SMD = 1.09; 95% CI = 0.77 to 1.41; Z = 6.65; p < 0.001; I2 = 79%) and adolescents (SMD = 0.86; 95% CI = 0.65 to 1.08; Z = 7.86; p < 0.001; I2 = 82%), with no differences between children and adolescents in ROM improvements (p = 0.25; I2 = 24.8%). However, when stretching volume was considered, children exhibited greater increases in ROM with higher than lower volumes (SMD = 1.21; 95% CI = 0.82 to 1.60; Z = 6.09; p < 0.001; I2 = 82% and SMD = 0.62; 95% CI = 0.29 to 0.95; Z = 3.65; p < 0.0003; I2 = 0%, respectively; subgroup difference: p < 0.002; I2 = 80.5%), while adolescents, responded equally to higher and lower stretching volumes (SMD = 1.00; 95% CI = 0.38 to 1.62; Z = 3.17; p = 0.002; I2 = 89%, and SMD = 0.84; 95% CI = 0.63 to 1.06; Z = 7.76; p < 0.001; I2 = 77%, respectively; subgroup difference: p = 0.64; I2 = 0%).

CONCLUSION: Systematic stretching training increases ROM during childhood and adolescence. When the effect of stretching volume is not examined, flexibility can be similarly developed throughout childhood and adolescence following systematic training. However, when higher stretching volumes are applied, larger ROM gains are induced in childhood than in adolescence.

### TRAINING PROGRAMME BASED ON INCREASING INTENSITY AND REDUCING VOLUME ON PERFORMANCE IN AMATEUR SWIMMERS PARTICIPATING IN OFFICIAL COMPETITIONS.

NAHAR, N.1,2, GONZALEZ-JURADO, J.A.3, SANCHEZ-OLIVER, A.J.4

*1. PUBLIC ADMINISTRATION, EDUCATION, CULTURE AND SPORT. GENERALITAT VALENCIANA, SPAIN. 2. PHD, STUDENT PABLO DE OLAVIDE UNIVERSITY, SPAIN 3. PHD, PABLO DE OLAVIDE UNIVERSITY, SPAIN 4. PHD, SEVILLE*

INTRODUCTION: In recent years, training to prepare competitive swimmers has changed, introducing longer sessions (more volume) and higher intensity (Tate et al., 2012), leading to increased swimmer fatigue as a consequence of poor recovery (Lay et al., 2014). The aim of this study is to test whether the Ultra-Short Race Pace Training (USRPT) variant, which is based on High Intensity Interval Training (HIIT) methodology, improves swimmers performance, respecting the prevailing swimming style.

METHODS: During 12 weeks, 100 amateur swimmers participating in official competitions with different swimming clubs in the "Marina Alta" (Comunidad Valenciana, Spain), took part in this research. Aged between 11 and 21 years. All swimmers performed the crawl test and the styles test before, during and after the study. They performed intervallic training of 4 hours, distributed in 3 days per week, and reduced their weekly volume by 28%. The HIIT training included two sets. Set 1: USRPT 16X25m (400m) with 30 seconds recovery every 25m. Set 1: USRPT 8X50m (400m) with 30 second recovery breaks every 50m. Between sets, 300m of active rest using smooth crawl and technique. Recovery every 25 and 50 metres decreased to 25 seconds in both sets in weeks 9 to 12. The Critical Swim Speed (CSS) test and the Swolf test were used as tools to monitor performance.

RESULTS: There were significant improvements in performance. In the crawl 80.88% of the swimmers improved their personal best times. A similar result was obtained in the 100m styles, where 75.93% of the 54 swimmers improved their personal bests.

CONCLUSION: The performance of amateur swimmers participating in official competitions improved with a 12-week series-based HIIT training programme (USRPT), despite having reduced their training volume by 28%.

### INFLUENCE OF RACE WALKING TREADMILL TEST PROTOCOL ON VENTILATORY THRESHOLDS

BABIC, V., KOLIC, L., SENTIJA, D.

*UNIVERSITY OF ZAGREB*

INTRODUCTION: In race walking (RW) there are no standard graded treadmill tests for determination of aerobic capacity parameters as it is the case in running. Test protocols with linearly progressive load which are used for running are not suitable for walking, since in the high intensity zone there is an exponential growth of energy consumption which significantly shortens duration of the test; moreover, lower VO2peak values are reported for walking in comparison to running. The aim of the study was to establish the influence of RW treadmill test protocol on the two ventilatory thresholds (aerobic, AeT; anaerobic, AnT) and related parameters (oxygen uptake, VO2; heart rate, HR; breathing frequency, BF; tidal volume, Vt; ventilation, VE).

METHODS: 34 amateur race walkers (19 men and 15 women) preformed two different graded race walking tests to exhaustion (at 1% treadmill grade), in random order: 1. with speed increments of 0,5 km/h every 30 sec (standard protocol used for running, T05) and 2. with speed increments of 0,3 km/h every 30 sec (finely graded load increments, T03). Quark b2 (Cosmed) metabolic cart was used for breath-by-breath data collection and analysis. Data were averaged for each step, at 30 sec periods, and the AeT and AnT were defined by the modified V-slope method. The Students t-test was used to determine differences, while Pearson correlation coefficient (r) was used to determine the relationship between parameters of the two tests.

RESULTS: At the AeT, the ventilatory parameters (VO2, BF, Vt, VE) did not differ between tests ($p > 0.05$ for all parameters). However, in T03 the RW speed was slightly, but significantly lower (7.01±0.60 : 7.32±0.76, p = 0,02) as well as HR (131±15 : 136±16, p = 0.01). Significant, but moderate relationships at the AeT were found between the tests (r = 0.50-0.80, $p < 0.05$). At the AnT, the ventilatory parameters (VO2, BF, Vt, VE) as well as HR did not differ between tests ($p > 0.05$ for all) while the RW speed was higher (8.69±0.77 : 9.06±0.83, p = 0.008). The highest maximum (technically correct) RW speed achieved in T05 was also higher (10.94±0.88 : 11.21±0.98, p = 0.005). Significant, but moderate relationships at the AnT were found between the tests (r = 0.55-0.85, $p < 0.05$).

CONCLUSION: Determination of VO2 and ventilatory parameters at the ventilatory thresholds for race walking is not protocol dependent. However, caution is warranted in test protocol implementation as race walking speeds at AeT and AnT are protocol dependent.

**INFLUENCE OF RACE WALKING GXT PROTOCOL ON VO2PEAK**

SENTIJA, D., KOLIC, L., BABIC, V.

*FACULTY OF KINESIOLOGY, UNIVERSITY OF ZAGREB*

INTRODUCTION: Unlike in running, in race walking there are no standard graded treadmill tests to assess aerobic capacity. The suitability of test protocols with linearly progressive load which are used for running is questionable for race walking, since in the high intensity zone there is an exponential growth of energy consumption, which significantly shortens duration of the test. The aim of the study was to compare two different test protocols and establish the influence of race walking treadmill test protocol on VO2peak.

METHODS: Thirty four amateur race walkers (19 men and 15 women) preformed two different graded race walking tests to exhaustion (at 1% treadmill grade), in random order: 1. with speed increments of 0.5 km/h every 30 sec (standard protocol otherwise used for running, T05) and 2. with speed increments of 0.3 km/h every 30 sec (finely graded load increments, T03). Quark b2 (Cosmed) metabolic cart was used for breath-by-breath data collection and analysis. Data were averaged for each step, at 30 sec periods, and the maximal VO2 value for a single step was considered as VO2peak. Students t-test was used to determine differences in functional parameters between the tests at VO2peak and the Pearson correlation coefficient (r) was used to determine the relationship between parameters of the two tests.

RESULTS: In the finely graded test a significantly higher VO2peak was found compared to T05 (47.1±6.2 : 45.9±6.0 ml/kg/min, p = 0.037), as well as higher maximum heart frequency (183.5±13 : 186.5±13/min, p = 0.004) and maximum minute ventilation (117.1±32.1 : 111.2±29.5 L/min, p = 0.013). On the contrary, a significantly higher maximal (technically correct) race walking speed was achieved in T05 (10.94±0.88 : 11.21±0.98, p = 0.005). Significant, high relationships were found between parameters of the tests (r = 0.76-0.95, $p < 0.05$).

CONCLUSION: In comparison to running (as a load modality), a more finely graded test protocol is recommended for race walking to determine parameters of aerobic capacity.

Sentija D. et al., 2009.

**HANDGRIP STRENGTH CAN BE USED AS A PROXY FOR UPPER EXTREMITY MUSCLE STRENGTH IN OLDER ADULTS - A CROSS-SECTIONAL STUDY.**

TELJIGOVIC, S., LEYH, S., SØGAARD, K., SANDAL, L., SJØGAARD, G.

*UNIVERSITY OF SOUTHERN DENMARK*

INTRODUCTION: Handgrip strength measurement is relatively easy to perform, requires minimum equipment and is widely used to assess physical functioning in older adults. Therefore, it would be advantageous if handgrip strength could also be used as a proxy for upper extremity strength. Although a few studies have reported these associations in younger populations, there is a need to investigate these associations in older adults (1, 2). This study aimed to investigate the association between handgrip strength and upper extremity strength and evaluate how handgrip strength predicts upper extremity strength.

METHODS: 115 older adults (70 females) with a mean age of 74.7 (SD 6.3) years commenced physical rehabilitation in a Danish municipality. Handgrip strength (SAEHAN, hydraulic dynamometer), elbow flexion strength, elbow extension strength and shoulder abduction strength (microFET2, dynamometer) were assessed bilaterally. Wilcoxon signed-rank test showed no significant differences between the left and right sides for either gender, so an average across arms was used for correlational analysis. Multiple linear regression models were conducted, with the additional predictors´ age, gender, segmental fat-free mass for upper extremity and BMI, and the residuals tested for normality.

RESULTS: The median for the handgrip strength was 19.3kg [IQR 11.8 kg] for females and 36kg [IQR 16.5 kg] for males, which was lower compared with normative values (3). Spearmans correlation for handgrip strength and elbow flexion strength was (r=.84, p<.00), for handgrip strength and elbow extension strength (r=.83, p<.00), and handgrip strength and shoulder abduction strength (r=.75, p<.00). The multiple linear regression models accounted for 78% of the variation in elbow flexion strength, 79% of the variation in elbow extension and 59% of the variation in the shoulder abduction strength in the adjusted models.

CONCLUSION: The suggested regression models can predict strength in elbow flexion, extension, and shoulder abduction in older adults. The correlational coefficients presented in this study are generally consistent with previous studies in other populations (1, 2). The clinical implication of this study is that handgrip strength is strongly correlated with upper extremity strength in older adults commencing physical rehabilitation and can therefore be used as a proxy measure for upper extremity strength.

**EFFECTS OF POST-ACTIVATION ENHANCEMENT (PAPE) IN ELITE VOLLEYBALL PLAYERS**

MASEL, S., MACIEJCZYK, M.

*UNIVERSITY OF PHYSICAL EDUCATION IN KRAKÓW*

INTRODUCTION: Post-activation performance enhancement (PAPE) is a widely described physiological phenomenon showing increases in exercise performance after previous muscle activation (1). Throughout the years authors have been studying the phenomenon but so far there was not found a consensus what are the ideal parameters of a conditioning activity (CA) to induce PAPE (2). However, authors generally tend to focus on different parameters of a CA and its responses on a given test. Our approach was different - we decided to evaluate the responses of the same CA in two different jumping tests: countermovement jump (CMJ) and squat jump (SJ). Additionally, accommodating resistance via elastic band was used to induce PAPE - a training method that is widely used in the sport and was already used in PAPE research (3).

METHODS: Twelve elite volleyball players experienced in resistance training (relative 1RM in a trap bar deadlift with accommodating resistance 1.92 ± 0.12 kg/kg body mass) performed four conditions: CMJ or SJ at the baseline (after standardized general warm up) and 90 seconds post CA [3 repetitions with 80% 1RM (aproximately 15% 1RM of elastic band) of a trap bar deadlift] and control conditions without CA.

RESULTS: The CA used in the study failed to enhance performances in SJ and CMJ in a group of all players. The difference between baseline and after CA in jump height (JH) was found to be statistically insignificant ($p>0.05$): in CMJ baseline 44.9 ± 4.3 cm to post 45.3 ± 4.6 cm; in SJ baseline 42.6 ± 4.2 cm to post 43.7 ± 3.6 cm. However, analysis of individual data showed more participants positively (changes in JH ≥ 0.1 cm) responding to a CA in SJ (8 out of 11, 73%; 1 player not performed it due to an ankle injury) than CMJ (6 out of 12, 50%). Additional analysis of players who responded positively to a CA showed a significant improvement in JH in CMJ and SJ.

CONCLUSION: We observed an individual PAPE response to a given CA. Even though baseline to post changes in JH for both jumps after CA were found to be statistically insignificant for all players, we noticed a different response regarding to a jumping test performed - more participants responded positively in SJ than CMJ. Despite both jumps having an existing movement direction specificity to a CA, SJ has the same type of a muscle contraction type as a trap bar deadlift (concentric from isometric position) while CMJ is an eccentric-concentric type of movement. Therefore, selecting the same muscle contraction type of a CA to an explosive exercise could be an additional component to consider while creating an effective protocol to induce PAPE.

**BALLISTIC EXERCISE VERSUS HEAVY RESISTANCE EXERCISE PROTOCOLS: WHICH RESISTANCE PRIMING IS MORE EFFECTIVE?**

TAKUYA, N.

*WASEDA UNIVERSITY*

INTRODUCTION: Recent studies have shown that ballistic performance may be enhanced for up to 48 hours following resistance exercise. This phenomenon is termed “delayed potentiation,” with resistance exercises performed for delayed potentiation being termed “resistance priming.” Harrison et al. (2019) suggested that low-load (30–40% 1 repetition maximum [RM]) ballistic exercise or high-load (≥ 85% 1RM) traditional exercise appears to be most effective resistance priming. However, it remains unclear which resistance priming is more effective on the day before a competition. Therefore, the current study aimed to determine which ballistic exercise priming (BEP) or heavy resistance priming (HRP) is more effective for improving ballistic performance 24 hours after.

METHODS: 10 resistance-trained men (age: 21.9 ± 1.8 years, height: 170.0 ± 4.3 cm, body mass: 69.6 ± 7.4 kg, half squat 1RM: 149.5 ± 16.8 kg, sports training background: 13.4 ± 2.9 years, resistance training experience: 4.2 ± 1.7 years, mean ± SD) performed BEP (5 × 4 jump squats at 40% 1RM with 3 minutes rest) and HRP (1 × 2 half squats at 60% 1RM followed by 3 × 2 half squats at 85% 1RM with 3 minutes rest) conditions 72–144 hours apart in a randomized and counterbalanced order. Jump performances (0 and 40% 1RM squat jump [SJ] height, countermovement jump [CMJ] height, and drop jump [DJ] reactive strength index [RSI = DJ height/ground contact time]) were assessed before and 24 hours after BEP and HRP sessions. The normality was tested using the Shapiro–Wilk test. Paired-samples t-tests were used to compare (a) jump performances 24 hours after the priming session with baseline in BEP and HRP conditions and (b) percentage changes in jump performances from baseline to 24 hours after BEP with HRP. Statistical significance was set at $p \leq 0.05$.

RESULTS: In BEP condition, 0% 1RM CMJ height 24 hours after the priming session was greater than baseline (+3.62%, $p = 0.002$), but not 0 and 40% 1RM SJ height, 40% 1RM CMJ height, and DJ RSI ($p > 0.05$). In HRP condition, none of the jump performances were improved ($p > 0.05$). Percentage change in 0% 1RM CMJ height in BEP condition was greater than in HRP condition ($p = 0.015$), but not 0 and 40% 1RM SJ height, 40% 1RM CMJ height, and DJ RSI ($p > 0.05$).

CONCLUSION: These results suggest that BEP is more effective than HRP for improving 0% 1RM CMJ performance 24 hours after. Therefore, practitioners should consider prescribing resistance priming using low-load ballistic exercise rather than high-load traditional exercise when planning to enhance athlete performance on the following day.

**PASSIVE ISOKINETIC CYCLING COMBINED WITH ELECTROMYOSTIMULATION IMPROVES MUSCLE STRENGTH IN THE ELDERLY**

OGISO, K.

*COLLEGE OF EDUCATION, PSYCHOLOGY AND HUMAN STUDIES, AOYAMA GAKUIN UNIVERSITY*

INTRODUCTION: Regular exercise maintains and promotes physical fitness and also improves physical and mental health. However, such exercise can be a challenge for elderly individuals who are not good at, do not like, or are too frail to exercise. Exercise itself can discourage exercise habits if it involves physical exertion or mental anguish. Therefore, we investigated whether passive isokinetic cycling (PIC) combined with electromyostimulation (EMS) can improve muscle strength in the elderly without physical exertion or mental anguish.

METHODS: Participants were 4 healthy men aged 64 to 78 years who performed PIC 3 times a week for 3 weeks followed by a 1-week break and then performed PIC combined with EMS (PICE) for 3 weeks. They were instructed not to pedal voluntarily and to completely relax their muscles during 10 min of cycling at 40 rpm. The EMS intensity used in the second 3-week period was based on the current value

at which the knee extension torque began to be increased by the EMS applied to the anterior thigh muscles in the supine position with the knee joint fixed at 90 deg. The intensity was set at 100% of the baseline value in week 4, 110% in week 5, and 120% in week 6. Morphometric parameters, jump parameters, muscle strength parameters, and kinesthetic sensation during exercise were measured to evaluate the effects of training before the start of the training period, 3 days after the end of week 3, and 3 days after the end of week 6.

RESULTS: PICE decreased body fat percentage by 4.0%, increased counter movement jump height by 8.2%, and increased maximal isometric knee extension and flexion torque by 19.5%–26.0% and 11.3%–60.6%, respectively, at all measured knee joint angles (20 deg, 45 deg, and 70 deg). In contrast, PIC decreased maximal isometric knee flexion torque by 23.2% at a knee joint angle of 20 deg. Both PICE and PIC increased the scores of the 30-sec chair stand test by 11.2% and 23.5%, respectively. All participants showed similar changes in the above areas, and the percent changes are the averages values for each measurement item. Despite the improvement in maximal strength after PICE, the participants did not perceive it as the kinesthetic sensation.

CONCLUSION: The results suggest that PICE with low-intensity EMS applied to all thigh muscles may improve physical fitness and body composition with only a short duration of training. Such an approach without physical exertion or mental anguish could be of benefit to a number of different populations. However, the finding that participants hardly perceived any improvement is not desirable for enhancing intrinsic motivation to develop and maintain exercise habits through physical competence. Therefore, combining PICE with a method for such competence may improve the effectiveness of the present method.

## COMPARISON OF SHOULDER MUSCLES ACTIVITY BETWEEN BARBELL PULLOVER AND CABLE PULL-DOWN EXERCISES

TORRADO, P., MARINA, M., ILLERA, V., BRU, I.

*INSTITUT NACIONAL D'EDUCACIÓ FÍSICA DE CATALUNYA, UNIVERSITAT DE BARCELONA*

INTRODUCTION: The barbell pullover (BPO) is a popular exercise which emphasizes the muscle action of the pectoralis major compared with the latissimus dorsi (LD) [1]. However, other exercises that involve the same movement but different force lever arm could imply changes in muscle participation, as the cable straight-arm pull-down (CPD). Since the shoulder extension is the prime movement of the BPO [2] and the CPD, other muscles besides the PM and LD act during this exercises due to their role during shoulder extension [3]. Considering that assessment of muscle activity is a necessary step before selecting the appropriate exercises for physical conditioning, we aimed to compare the electromyographic activity (EMG) of 8 muscles during 2 exercises with the same movement but with different body positions.

METHODS: Ten volunteers performed 5 repetitions of both BPO and CPD at 50% of the estimated one repetition maximum (RM). EMG activity was obtained for the LD, the clavicular (PMc) and sternal portion (PMs) of the Pectoralis Major, Anterior (AD) and Posterior deltoid (PD), Serratus Anterior (SA), superior part of the Trapezius (ST) and the long head of the triceps (LHT). Root mean square (RMS) was calculated for the concentric and eccentric phases and normalized with the value obtained during maximum voluntary contractions for each muscle (nRMS). Paired T-test was used to detect significant differences ($p<0.05$) between the 50%RM load used in both exercises. Separate two-way ANOVAs were used to detect differences in nRMS among exercises during the concentric and eccentric phase.

RESULTS: No statistical differences were observed among the averaged 50%RM load determined for each exercise ($p>0.05$). Except for the SA, significant exercise effect was observed for all muscles. The post-hoc analysis revealed higher nRMS values during BPO for PMc, PMe and DA muscles ($p\leq0.009$). In contrast, significant greater activity was observed in LD, TS, TR and DP during CPD ($p\leq0.033$). The phase effect resulted significant for PMe, SA, LD, TR and DP, that showed higher values during the eccentric phase ($p<0.008$). Furthermore, a significant interaction was found for PMe, LD, TR and DP, with a higher activity during the concentric phase of the CPD ($p\leq0.001$) and during the eccentric phase of the BPO for the TR ($p=0.002$).

CONCLUSION: The same movement performed in different positions induces differences in the activity of the muscles that act on the shoulder joint, possibly because of the differences in the moment arm. From a practical perspective these observations should be considered during resistance training programs when selecting each one of these exercises in a "pulling" or "pushing" session.

## RELATIONSHIPS BETWEEN AEROBIC AND ANAEROBIC PARAMETERS AND THE CRITICAL POWER MODEL IN MALE JAPANESE COLLEGIATE ATHLETICS

OGA, R.1, FUJITA, F.2, KAJI, T.1, YOTANI, K.1, TAMAKI, H.1, OGITA, F.1

*1 NATIONAL INSTITUTE OF FITNESS AND SPORTS IN KANOYA; 2 OSAKA INSTITUTE OF TECHNOLOGY*

INTRODUCTION: The critical power (CP) model has been proposed as a method of assessing both aerobic and anaerobic work capacity in athletes. There are, however, few reports on the application of this model to all track and field athletics events. In this study we examined the relationships between parameters describing aerobic and anaerobic work capacity and those of the CP model, as well as the application of the CP model to each event group with respect to young male Japanese track and field athletes.

METHODS: We recruited 20 male Japanese track and field athletes with a mean age of 20 ± 1 y: five sprinters, four jumpers, and two decathletes (the SJC group); four middle- and long-distance runners (the ML group); and five throwers (the T group). They performed the CP test, the maximal anaerobic power test, and the 30-second Wingate test (WT) with a cycle ergometer. The CP test was performed at four exercise intensities (100%, 110%, 125%, 200% of $VO_2$ max) until exhaustion. We estimated CP and work capacity above CP (W') based on the linear relationship between time to exhaustion and total work. We measured maximal oxygen uptake ($VO_2$ max) as a parameter of aerobic work capacity and maximal accumulated oxygen deficit (MAOD), maximal anaerobic power, peak power, mean power, and percent decrease in power during WT as parameters describing anaerobic work capacity. We used correlation coefficients to determine the relationships between parameters of the CP model and those describing aerobic and anaerobic work capacity for each group of athletes.

RESULTS: The CP was significantly higher in the ML group than in the other groups, while W' was significantly lower in the ML group than in the other groups. There were significant differences in $VO_2$ max, maximal anaerobic power, peak power, and mean power during WT, but not in MAOD, among the groups. The percent decrease in power in the ML group was significantly smaller than in the T group. CP was strongly associated with $VO_2$ max in the SJC ($r = 0.774$, $p < 0.01$) and ML ($r = 0.958$, $p < 0.05$) groups, but not in the T group. W was strongly correlated with the peak power ($r = 0.999$, $p < 0.01$) and percent decrease in power ($r = 0.965$, $p < 0.05$), but only in the ML group.

CONCLUSION: These results suggest that the CP test is useful for assessing the aerobic work capacity of young male Japanese track and field athletes, excluding throwers. W may be useful for predicting anaerobic work capacity in middle- and long-distance runners.

**RELATIONSHIP BETWEEN LOWER LIMB MECHANICAL CAPABILITY OBTAINED FROM FORCE-VELOCITY RELATIONSHIP DURING THE BRAKING PHASE OF COUNTERMOVEMENT JUMPS AND JUMP FORCE-TIME CHARACTERISTICS**

NISHIUMI, D.

*WASEDA UNIVERSITY*

INTRODUCTION: The mechanical outputs (i.e., force, rate of force development: RFD) during the braking phase of the countermovement jump (CMJ) are related to the force of the start of the concentric phase and horizontal deceleration ability. Recently, these have been considered to be important because these lead to improved jump and change of direction performance. However, there is no known index of the mechanical capability (i.e., maximum power obtained from the force-velocity relationship: Pmax) of the braking phase to generate the mechanical outputs. It is important to understand the mechanical capability when designing training program to improve the mechanical outputs. The purpose of this study was to quantify the mechanical capability index during braking phase of CMJs and to investigate its relationship to CMJ mechanical outputs.

METHODS: The subjects were 16 healthy males. They performed CMJs on a force plate with 0%, 32 kg, 60, 80, 100, and 120% body weight. The mean force and mean velocity during the braking phase of each CMJs were calculated and scatter plots were drawn. The small sample unbiased Akaike information criterion (AICc) was calculated by fitting each to a linear regression equation, a quadratic regression equation, and a cubic regression equation, and a one-way analysis of variance was conducted to investigate which regression equation was the best fit and Bonferroni's post-hoc test was used to check pairwise comparisons. The x and y intercept values (V0 and F0, respectively) were obtained using the regression equation with the best fit one, and the mechanical capability (Braking Pmax) was calculated as Braking Pmax = V0 × F0 / 4. Furthermore, Pearson's correlation analysis was performed to evaluate the relationships between the Braking Pmax and the CMJ variables at body weight. A p value of 0.05 was accepted as the level of significance.

RESULTS: The regression equation for mean force and velocity during the braking phase was a significantly better fit of the linear regression equation than a quadratic regression equation and a cubic regression equation ($p = 0.047$, $p < 0.001$, respectively). The Braking Pmax obtained from the linear regression equation was significantly correlated with peak force and RFD during the braking phase of CMJ at body weight ($r = -0.94, -0.88$; $p < 0.001$, respectively).

CONCLUSION: Mechanical capability of the braking phase during the CMJs may be quantified by linear regression equation, and the Braking Pmax obtained from it was strongly related to the mechanical outputs during the braking phase of CMJ at body weight. Further studies are required to examine why force-velocity relationship during the braking phase of CMJ is likely to be quasi-linear. As a practical application, decelerate training at various velocity ranges from high to low may improve Braking Pmax, which in turn may effectively improve the mechanical outputs during the braking phase of CMJ at body weight.

**MUSCLE ACTIVATION PATTERNS IN TRIAL RIDERS**

BOU, S., MARINA, M., TORRADO, P., GIRÓ, M.

*INEFC BARCELONA*

INTRODUCTION: Sport Science research has paid little attention in motor sport, particularly concerning motorbike racing. Some investigations focused in physiological demands (1, 2) and speed racing (3). Nevertheless, other motorbike competition disciplines, such as trial, have not been investigated so far. Knowledge about the interplay of muscular activity when handling the motorcycle in real condition, should be considered as a prior step before designing specific programs of physical conditioning.

The objectives of the study were: 1) comparing muscles activity levels among different sectors of a pre-conditioned trial´s trail and 2) comparing activity levels among the solicited muscles.

METHODS: Nine elite trial riders of international level took part in the study. Surface EMG (sEMG) was used to analyze the root mean square (RMS) from eight muscles: Rectus Femoris (RF), Biceps Femoris (BF), Flexor Digitorum superficialis (FD), Extensor Digitorum (ED), Pectoralis Major (PM), Triceps Brachii (TB), Biceps Brachii (BB) and Anterior Deltoid (AD). Muscle activity recorded when riding a standardized obstacle trail was normalized with a maximal voluntary contraction whose tests were designed to be representative of the maximal solicitation for each muscle. The trail was divided in six sectors categorized according to three types of global riding gestures: single jump (sectors 1 & 2), single landing (sectors 3 & 5) and successive jumps (sectors 4 & 6). Three trials were allowed with a resting period of 2 min in between. Multivariate analysis of variance was used to: 1) detect differences in sEMG activity of each muscle among the sectors, 2) compare overall sumated muscle activity in each sector separately. When a significant effect was found, Sidak post-hoc procedures were carried out. Significance was set at $p<0.05$.

RESULTS: While activity of the forearm muscles did not differ among the sectors, significant differences were observed in RF, BF, PM, BB and AD: 1) Landing sectors were less demanding ($p\leq0,048$), particularly with the BF ($p=0,032$), 2) The higher RF activity correspond to single jump sectors ($p\leq0,035$) which are even more demanding than successive jumps ($p=0,022$). In sector 2 and 3, AD is more activated than BB ($P\leq0,049$). Activity of RF and BF is similar in all sectors.

CONCLUSION: Each type of sector induces different degrees of muscle activity. Forearm muscles are highly activated during the whole trail because riders must to steer the handlebar continuously. Activity of inferior limb muscles is not as high as expected, especially in landings. Possibly the absorption capacity of the motorcycle suspension and the propulsive effect of the gas handle technique could explain these relatively low levels of muscle activity with the inferior limb.

### RELIABILITY AND CORRELATION BETWEEN TWO PHYSICAL TESTS DOING SPECIFIC MOVEMENTS BY PARAKARATE ATHLETES

VILLACIEROS-RODRÍGUEZ, J.1,2, ROLDÁN-CRUZ, A.2, CASAS-CASTELLANO, E.2, MARTÍN-MORELL, A.M.2, MUÑOZ-CUTULI, L.1

*1: SPORTS PERFORMANCE, DISABILITY AND SCHOOL SPORTS. CENTRO UNIVERSITARIO LA SALLE. SPAIN, 2: SCHOOL OF COACHES. KARATE FEDERATION OF MADRID. SPAIN*

INTRODUCTION: Nowadays, it is very common to find athletes with intellectual disability (ID) practicing karate. To assess their physical fitness, it is necessary to use appropriate tools which allow the assessment of their physical capacities taking into account their specific characteristics (Cabeza-Ruiz, 2020). The aim of this work is to study the reliability and correlation of two tests doing specific movements applied to karate for people with intellectual disabilities.

METHODS: Thirteen athletes with ID of both sexes, who train in the Karate Federation of Madrid between the ages of 18 and 32, participated in this study. The athletes performed two attempts of the hand grip dynamometry (takei Ltd.) making use of both sides in order to evaluate the manual force and the countermovement jump (CMJ) (Chronojump, Boscosystem) to calculate the height of the jump. In addition, they performed a punch (giaku tsuki) and a kick (mae geri) to analyze the time of execution using the Kinovea software (v. 0.8.15) in order to find a correlation with the tests mentioned above. Intraclass correlation coefficient (ICC), with a confidence interval (CI) of 95%, and the standard error of measurement (SEM) were used to analyze the Intrasession reliability. Pearson correlation was used to relate the two tests with the execution time of punch and the kick.

RESULTS: The ICC intrasession values obtained were 0.91 and 0.87 for CMJ and dynamometry, respectively. SEM was lower than 0.01 m for CMJ and 0.61 N for dynamometry. Additionally, the relationship between the execution time of the dominant side of the punch as well as the force of the hand of the same side had a correlation of $r = 0.908$, $p < 0.01$. Furthermore, the relationship between the execution time of the dominant side of the kick and the height of the jump had a correlation of $r = 0.892$, $p < 0.01$.

CONCLUSION: ICC intrasession was excellent in both tests. Taking into account the data found in our study, it can be concluded that CMJ test and the hand grip dynamometry test are highly recommended to evaluate the height jump and the force of the upper and limbs of people training Karate, due to it presents very significant levels of correlations according with the time of execution of a kick and a punch when practicing this sport. This information may be helpful in order to plan training through simple and low cost tests as well as to detect talent.

### SEX DIFFERENCES BETWEEN HIP THRUST AND DEADLIFT IN LOAD-VELOCITY PROFILE.

NIETO-ACEVEDO, R.1, MONTALVO, A.2, ROMERO-MORALEDA, B.3

*1 UNIVERSIDAD POLITÉCNICA DE MADRID; 2 UNIVERSIDAD EUROPEA DE MADRID, 3 UNIVERSIDAD AUTÓNOMA DE MADRID*

INTRODUCTION: Velocity Based Training (VBT) has been developed to provide accurate and objective data to support resistance training prescription [1]. The interest by VBT is increasing in recent years, but some studies have shown differences in the velocity-profile between men and women in exercises as squat, bench press or shoulder press [2,3]. Due to these, current evidence about the validity of using bar velocity to estimate relative load in women in exercises not analyzed until now can be questioned. Although Men's equation applied to women showed a high level of agreement [2], it would be more reliable use equation validated for women. This study aimed to examine the differences in the load-velocity profile between hip-thrust and deadlift exercises in men and women.

METHODS: Fourteen men and fourteen women were tested during the Hip-Thrust (HT) and deadlift (DL) exercises. The individual load-velocity profiles were determined by means of an incremental loading test (from 20% to 100% of the one-repetition maximum [1RM] in approximately 5% increments). Relationship between mean propulsive velocity and each percentage of 1-RM were analyzed. A second-order polynomial equation for predicting the corresponding velocity of each percentage of 1-RM was developed for men and women. We used the nonparametric Mann-Whitney U test to compare each % 1-RM between hip-thrust and deadlift exercises in men and women. Significance was set at $P < 0.05$.

RESULTS: The results of the nonparametric Mann-Whitney U test showed the mean propulsive velocity was significant lower in woman than men ($p < 0.05$) with loads <85% in hip-thrust and <70% in deadlift. Close relationships between bar velocity and relative load were observed in both sexes for hip thrust and deadlift. 〖(R)〗^2:0.88-0.93)

CONCLUSION: These results reveal that load-velocity relationship during HT and DL is markedly steeper in men than in women. The same result (i.e., lower velocities at low % 1RM in women) has been reported in other studies when compared bench press, squat or shoulder press exercises [2,3]. In summary the results confirm that men present higher mean propulsive velocity, especially under 85% 1-RM, compared to women during hip-thrust and deadlift exercises.

### THE SIMULATION OF TRANSIENT FATIGUE IN RUGBY LEAGUE

HIGHTON, J., MULLEN, T., TWIST, C.

*UNIVERSITY OF CHESTER*

INTRODUCTION: Transient fatigue, defined as a temporary reduction in the ability to maintain high-intensity running, is a common phenomenon in team sports [1]. In rugby league, this transient fatigue is also accompanied by reduced skill quality, which could have important implications for match outcomes [2]. The large match-to-match variability in running metrics in rugby league has meant that simulation protocols are often used to explore changes in performance owing to an intervention. However, to our knowledge, no simulation has attempted to replicate transient fatigue. Accordingly, the aim of this study was to determine if rugby league transient fatigue can be simulated, and whether this fatigue is associated with a reduction in skill.

METHODS: Nine sub-elite rugby players consented to participate in the study (age = 21 ± 2 yrs, stature = 178.4 ± 6.8 cm, body mass = 86.2 ± 14 kg). With institutional ethics approval, participants completed two abbreviated (~23 min) versions of the Rugby League Movement Simulation Protocol for Interchanges (RLMSPi) in a randomised cross-over design. One trial involved 4x ~5.7 min blocks of repeated activity (CON), as previously described [3]. In another trial (INT), the second ~5.7 min block was intensified to incorporate six more sprints and

three more contacts. Participants wore a 10Hz GPS throughout the protocol, and completed a passing test (comprising 12 passes to different targets) every ~5.8 min.

RESULTS: Heart rate (~5.2 b/min), rating of perceived exertion (~2.7), blood lactate (~4.7 mmol/L), distance covered (~115.9 m) and high-intensity running > 14 km/h (~56.1 m) all increased during the intensified ~5.7 min relative to CON ($P < 0.05$). The intensified period resulted in a decline in high-intensity running in the subsequent ~5.7 min compared to CON (~17.7 m), as well as a greater time to compete the rugby passing test (CON = 51.5 ± 3.6 s, INT = 57 ± 5.7 s; $P < 0.05$).

CONCLUSION: This study has demonstrated that the transient fatigue reported in rugby league matches can be simulated using an adapted rugby league simulation protocol. Furthermore, as with matches, this transient fatigue was accompanied by an impairment in technical performance. Future studies can use this simulation to explore the effects of training and nutritional interventions on transient fatigue in rugby league.

**MAXIMAL STRAIGHT SPRINT SPEED OF AUSTRIAN SOCCER PLAYERS COMPETING AT DIFFERENT LEVELS**

WALLNER, D., GRIMM, P., HAGENAUER, M.

*FH JOANNEUM*

INTRODUCTION: Sprinting skills are becoming increasingly important in modern soccer (Haugen et al., 2014). Straight sprinting is the most frequent action in goal situations in professional football (Faude et al., 2012). This study aimed to analyse the maximal straight sprint speed of Austrian soccer players competing at different levels.

METHODS: 130 Austrian soccer players (age: 23.0±4.5 yrs; height: 179.0±5.8 cm; BMI: 23.5±1.9 kg) performed a 30 m straight sprint test. Maximum running speed was calculated on split times for meters 20 and 30. The best of two attempts counted. The players were divided into groups by league: professional (n=29), semi-professional (n=44), amateur (n=33) and hobby players (n=24). Data were analysed by one-way ANOVA und Tukey post-test.

RESULTS: Body height and BMI did not differ between groups ($p>0.05$). The maximal sprint speed was 31.2±1.1 km/h, 30,8±1.3 km/h, 29.7±1.5 km/h and 29.6±1.3 km/h, respectively and revealed significant differences between groups. Players competing at higher levels show higher maximal straight sprint speed, statistically significant differences were given between professional players and hobby ($p<0.001$) and amateur players ($p<0.001$), and semi-professional and hobby ($p<0.01$) and amateur players ($p<0.01$), respectively.

CONCLUSION: Most players competing at a semi-professional level in Austria are former professional players and/or skilled players trained in a national soccer academy. This may explain the lack of a difference in maxima straight sprint speed performance between professional and semi-professional players. In Austria, professional and semi-professional players may differ in other physical characteristics (e.g. endurance performance) or technical skills.

**SOMATIC DETERMINANTS OF THE SPORT PERFORMANCE OF ELITE POLISH SPRINTERS**

OZIMEK, M.1, NOWAK, M.1, KRAWCZYK, M.2

*1 UNIVERSITY OF PHYSICAL EDUCATION, KRAKOW, POLAND, 2 UNIVERSITY OF APPLIED SCIENCES, TARNOW, POLAND*

INTRODUCTION: Sprint running is considered to be a relatively simple sport competition despite the fact that many different factors influence its outcome. An important role in short-distance running, which is the result of a number of scientific investigations, is attributed to somatic structure parameters of sprinters and their relationship with sports performance [1].

The aim of this study is to determine the determinants of somatic physique evaluation at different levels of sport performance (international - elite, national and club). Moreover, to determine the correlations between the results in the 100 m and 200 m runs and the examined somatic parameters in sprinters and comparison groups (students).

The study involved a selected group of athletes, which consisted of sprinters (n=113). They were members of the Polish National Team (n=17), Polish National Team reserves (n=14) and competitors of the Club Champion of Poland - AZS AWF Krakow Sports Club (n=20). The athletic level of the competitors, according to the athletic standards of the Polish Association of Athletics (PZLA), was determined by the sports class (master - international level, first - national level, second - club level). The comparison group (n=62) consisted of male students of the second year of full-time studies in physical education at the University of Physical Education in Kraków.

METHODS: The scope of the study included measurements of the somatic body build features: body height (BH) and body mass (BM), trunk and leg length, shoulder and hip width, thickness of skin-fat folds on the arm (R - over triceps skin-fold), abdomen (B - on abdonmen skin-fold), subscapular skin-fold (L), width of ankle, knee and elbow, circumference and amplitude of chest mobility, circumference of arm, neck and hip, circumference of the largest forearm, shank and thigh.

RESULTS: Of the 23 somatic traits studied, in our study only a significant effect (7 at 100 m and 3 at 200 m) of selected parameters characterizing body constitution on sports performance was observed depending on the sports level.

CONCLUSION: The results indicated a significant effect on the improvement of the 100 m score in sprinters have parameters such as: "shoulder width", "hip width", "lower limb length", "skin-fold B" (on abdonmen skin-fold), "skin-fold L" (subscapular skin-fold), "skin-fold R" (over triceps skin-fold), while at 200 m "circumference of largest lower leg", "skin-fold R" and "sum of skin-fold R+L" (over triceps + subscapular skin-fold). There is little intergroup variation among the sprinters with regard to the somatic build traits such as "Hip width", "Elbow width", "Arm circumference", "Greatest thigh circumference". In the vast majority of cases of the examined somatic traits, the non-training group (students) deviates statistically significantly from the athletes.

### RELATIVE AGE EFFECT IN FRENCH ALPINE SKIING : PROBLEM AND SOLUTION

DELAROCHELAMBERT, Q.

*IRMES, IMB, FFS*

INTRODUCTION: The objective of this study is to identify the potential bias of the relative age effect (RAE) in French alpine skiers and to propose a mathematical correction adjustment for such bias.

METHODS: All performances and birthdates of skiers on the national and international circuit were collected from the 2004 up to 2019. A goodness-of-fit chi-square test and the residuals were used to study distribution of birth trimesters in youth competitors. A linear relationship between the distribution of performances and the months obtain a calibration coefficient allowing to rebalance the performance by considering the effect of RAE.

RESULTS: Individuals born at the beginning of the year are over-represented in the elite young selections in all disciplines for both genders. A coefficient based on the relationship between month of birth and performance adjusts individual performance and cancels out the effect of RAE.

CONCLUSION: The RAE is present in French alpine skiing. We present a method allowing to consider the effect of the RAE in the performances realized in each gender and discipline. This method allows coaches to have a more objective opinion on performance and to reduce selection bias.

### COMPARISON OF VO2/KG BETWEEN THE FRONT AND REAR RIDERS IN A 6-MIN TANDEM BICYCLE RIDE USING THE DOUGLAS BACK METHOD

ONODERA, S.1, WADA, T.2, UKIDA, Y.1, SO, G.1, YOSHIOKA, A.3, MATSUO, K.1, HAYASHI, S.4, ISHIDA, Y.5, YAMAGUCHI, H.6, TAKAHARA, T.6, KATAYAMA, K.7

*1KAWASAKI UNIV.MED WELFARE , 2TOTTORI COL, 3KANSAI UNIV.SOCIAL WELFARE, 4FUKUYAMA CITY UNIV., 5OKAYAMA UNIV. SCI, 6KIBI INT UNIV. 7NAGOYA UNIV.*

INTRODUCTION: In tandem bicycle exercise, the exercise intensity for the front rider is larger than that for the rear rider. In the present study, experiments were conducted using the Douglas back method so that statistical results could be obtained. We hypothesized that, in a tandem bicycle ride, the front rider has more VO2/kg than the rear rider. The purpose of this study was to test and prove this hypothesis.

METHODS: Six healthy Japanese men participated in a 6-min tandem bicycle ride. The course was laid out as 6 laps around a 400-m tartan track. During the ride, the participants' heart rate was measured using a heart rate monitor, and VO2/kg was measured using the Douglas back method. The rear rider operated the cock of Douglas back. The unpaired t-test was used to calculate the difference between each of the data, and the statistical significance level was less than 5%.

RESULTS: Each pair of participants cycled 6 laps around the 400-m track for 6 min. The average speed was 18.3 km/h for each lap. The average heart rates of the front riders and the rear riders were 166 ± 19 beats per minute and 156 ± 29 beats per minute, respectively ($P<0.05$). The average VO2/kg values of the front riders and the rear riders (each pair of three) were 27.0 ± 3.58 ml/kg/min and 22.9 ± 4.76 ml/kg/min, respectively.

CONCLUSION: The study hypothesis was proved by statistical analyses. Our results showed that the exercise intensity for the front rider during tandem bicycle exercise was larger than that for the rear rider in terms of VO2/kg. The results of previous study support those of the present study. The difference between the front and rear riders was considered to be caused by handle, brake, and gear operations and wind pressure. These results indicate that the relative physiological stress of front riders is greater than that of rear riders during a tandem ride. Acknowledgment; This work was supported by JSPS KAHENHI Grant Number 17K10950.

### A RAMP SPRINT TEST TO ASSESS MAXIMAL OXYGEN CONSUMPTION AND CRITICAL POWER

PAPETTI, G.

*UNIVERSITY OF PAVIA*

INTRODUCTION: Maximal oxygen uptake (V'O2max) is widely considered to be the gold standard measurement for the assessment of physiological adaptations to exercise [1]. It is usually determined during an incremental maximal test when no increase in V'O2 respect to power or speed occurs but a V'O2 plateau is not always observed [2]. A subsequent constant work-rate test (CWR) has been suggested as verification trial [1] but the best exercise intensity of CWR has not been defined yet [3]. It is known that all-out exercise lasting 1.5–3 min yields V'O2max, representing also a valid method of estimating the boundary between the heavy and the severe exercise intensity domains (critical power, CP) [4]. A previous study showed that CP and V'O2max can be estimated from a maximal sprint at the end of a ramp incremental test (RST) by setting the flywheel resistance on body mass [5], but calculations were based on the variable relationship between body mass and CP. The aim of this study was to evaluate a RST with the maximal sprint performed with an individualized flywheel resistance based on physiological parameters as a valid approach.

METHODS: Twenty-one highly trained endurance subjects (26±5ys; 70±11kg) attended three separate testing sessions. On the first day, subjects completed an RST composed by a ramp incremental phase (25W*min-1) until exhaustion followed by a 2 minutes maximal sprint. The flywheel braking force was set according to the power output attained between gas exchange threshold (GET) and V'O2max (50%GET-V'O2max) at the preferred cadence by the known equation [6]. The average power attained in the last 30 seconds of maximal sprint was defined as sprint power (SP). On two separate occasions, in a randomized order, two CWR to exhaustion were carried out at 90%SP and 110%SP, respectively. Breath-by-breath pulmonary gas exchange, hear rate (HR) and capillary blood lactate (Lab) were monitored.

RESULTS: Peak power output (PPO) and V'O2max were 358±66W and 52.4±7.9ml*min-1*kg-1, respectively. Maximal sprint resulted in a SP of 272±57W, corresponding to 75±4% of PPO. The highest V'O2 of maximal sprint was not different from V'O2max (52.4±8.3ml*min-1*kg-1, $p>0.05$). Time to exhaustion was significantly lower in 90%SP than 110%SP (1965±605s vs 399±158s, $p<0.01$). A delayed steady state in V'O2 was attained only in 90%SP whereas is linearly increased up to V'O2max in 110%SP. At the end of exercise, V'O2, HR and Lab were significantly lower in 90%SP than 110%SP (3.26±0.67 vs 3.62±0.70L*min-1; 171±9 vs 175±8bpm; 5.74±2.3 vs 9.87±2.7Mm, respectively; all $p<0.01$).

CONCLUSION: Our results suggest that a maximal sprint performed within severe domain is a valid approach to verify V'O2max and it estimates the boundary between the heavy and the severe exercise intensities.

## EFFECT OF TIME DURATION ON OUTPUTS OF WINGATE AND FUNCTIONAL POWER THRESHOLD TESTS IN FEMALE CYCLISTS

SENDRA PEREZ, C., OFICIAL-CASADO, F., ENCARNACIÓN-MARTINEZ, A., PRIEGO-QUESADA, J.I.

*UNIVERSITY OF VALENCIA*

INTRODUCTION: Currently, there are many studies about the validation of cycling tests, but few involve female cyclists. Therefore, there is a lack of knowledge about if these tests are optimized to their women's characteristics. For this reason, the aim was to analyse the effect of modification of the duration of two different functional tests: Wingate (WAnT) and Functional Power Threshold (FTP); over performance and perceptual variables in female cyclists.

METHODS: Fourteen female cyclists (27 ±8 years, 1.66 ±0.08 m, and 60.6 ±7.2 kg) performed a protocol consisting of 2 test days with a 48-hour of recovery between tests, varying the functional test duration randomly (WAnT 20- or 30-sec, and FTP 8- or 10-min). During the tests, eumenorrheic women were in the early follicular phase and contraceptive pill users in abstinence week. Cadence (rpm), relative power output (W.kg-1), heart rate (bpm), lactate (mmol.L-1), rating perceived exertion (Borg Scale 6-20) were assessed. Moreover, the muscle oxygen saturation (%SmO2) on the vastus lateralis (Moxy) was extracted and the execution inclination was calculated [1].

RESULTS: Time duration did not affect the relative power output and the mean cadence at the entire test in WAnT and FTP tests ($p>0.05$). However, WAnT of 20-sec, compared with the test of 30-sec, resulted in a lower cadence decrease in the last 5-sec ($p<0.01$, ES=1.3), lower heart rate peak ($p<0.01$, ES=0.7), and higher execution inclination of local oxygen saturation ($p<0.05$ and ES=1.0). Modification of FTP duration did not alter any of the outcomes assessed ($p>0.05$), except in the execution inclination that was higher at the shorter duration ($p<0.05$ and ES=1.1).

CONCLUSION: Conclusion

In conclusion, the time variation assessed did not alter power outcomes in female cyclists. Regarding the FTP, we suggests use the short version for time economization reason, as to the WAnT test suggests the use of the test of 20-sec because of the less acute fatigue observed.

## PHYSIOLOGICAL, PERCEPTUAL AND NEUROMUSCULAR RESPONSES TO DIFFERENT WORK DURATIONS DURING SHORT HIGH INTENSITY INTERVALS

TWIST, C.

*UNIVERSITY OF CHESTER*

INTRODUCTION: The duration of the work interval is a key variable influencing the response to high intensity interval training (HIIT). The aim of this study was to examine the physiological, perceptual and neuromuscular responses of team sport athletes to two short (i.e. < 60 s) cycling HIIT sessions comprising the same total exercise volume but different work interval durations.

METHODS: With ethics approval, seven male team sport athletes (20.5 ± 0.8 years, 181.3 ± 5.5 cm, 72.6 ± 6.3 kg) visited the laboratory on three separate occasions. After an incremental test to exhaustion on a cycle ergometer to establish VO2max (48.2 ± 7.0 ml/kg/min) and peak power output at VO2max (pVO2max; 286 ± 62 W), two HIIT sessions (15 s effort: 15 s passive recovery [15 s trial] and 30 s effort: 30 s passive recovery [30 s trial]) were completed in a randomised order. HIIT comprised 2 x 6 min bouts of 15 s or 30 s efforts at 120% pVO2max, with bouts separated by 5 min active recovery at 40% pVO2max. VO2, time spent >90% VO2max and heart rate (HR) were monitored throughout exercise. Blood lactate concentration (B[La]) was taken at 5 min and differential RPE for overall exertion (dRPE-O), leg exertion (dRPE-L) and breathlessness (dRPE-B) was taken 15 min after exercise. Maximal voluntary contraction (MVC) of the knee extensors was measured before and immediately after each HIIT session. Data were analysed using effect sizes (ES) ± 95% confidence intervals and p-values.

RESULTS: Trivial differences in mean VO2 (36.3 ± 4.7 cf. 36.4 ± 3.8 ml/kg/min, ES = 0.02 ± -1.03 to 1.07, P = 0.851) and time >90% VO2max (117 ± 129 cf. 106 ± 115 s, ES = -0.09 ± -1.13 to 0.96, P = 0.162) were observed between 15 s and 30 s trials, respectively. Mean HR (159 ± 12 cf. 165 ± 11 b/min, ES = 0.52 ± - 0.58 to 1.55, P = 0.007) and B[La] (6.1 ± 2.0 cf. 10.1 ± 2.6 mmol/L, ES = 1.72 ± 0.40 to 281, P = 0.001) were higher in the 30 s trial. dRPE-O (53.6 ± 18.0 cf. 66.4 ± 20.8 AU, ES = 0.66 ± -0.46 to 1.68, P = 0.09), dRPE-L (55.4 ± 17.0 cf. 69.9 ± 21.4 AU, ES = 0.75 ± -0.38 to 1.78, P = 0.02) and dRPE-B (45.7 ± 22.1 cf. 60.3 ± 21.5 AU, ES = 0.67 ± -0.45 to 1.70, P = 0.132) were all higher in the 30 s trial. MVC was lower after both trials (ES = -0.74 ± -1.77 to 0.39, P = 0.001), albeit reductions in force were similar between 15 s and 30 s trials (-78.5 ± 52.4 cf. -88.7 ± 44.2 N, ES = 0.21 ± -1.25 to 0.85, P = 0.540).

CONCLUSION: Team sport athletes using short duration cycling-based HIIT can use 15 s or 30 s work intervals to elicit similar aerobic and neuromuscular responses. However, where lower blood lactate accumulation and perception of effort are required, 15 s intervals might be more appropriate for athletes when using short duration HIIT.

## OPTIMAL LOAD FOR MAXIMAL POWER OUTPUT DURING THE JAMMER PRESS IN WELL-TRAINED RUGBY UNION PLAYERS.

DRURY, B., FORD, T., WALSH, M., HENRY, G.

*HARTPURY UNIVERSITY*

INTRODUCTION: Rugby union (RU) is a contact sport that involves high-intensity bouts of exercise exertion, contact, tackling, acceleration and scrummaging (Duthie et al. 2006). To meet the physical demands of RU, high levels of strength and power are required (Furlong et al. 2021). Indeed, the ability to produce high levels of mechanical power is strongly associated with athletic performance and can also differentiate between playing standards (Argus et al. 2012). As a result, it is important that practitioners are aware of training methods which they can use to maximise this quality. Whilst previous research has widely investigated and subsequently reported the loads which can maximise mechanical power during lower-body resistance training exercise (Soriano et al. 2015) there is a paucity of information regarding upper-body resistance training exercises. Research which has actually focused on upper-body exercises, however, has largely only focused on the bench press exercise (Soriano et al. 2020). This may limit the transfer to sporting actions during sports such as RU which involve standing activities as well as unilateral upper body movements. Therefore, this study investigated the optimal load to maximize mechanical power during a more functional upper-body, unilateral, horizontal exercise called the Jammer Press.

METHODS: Ten well-trained rugby union players were included in this study. All participants were free from injury and had over two years of resistance training experience. A repeated measures study design was used in which all participants performed the Jammer Press

exercise using a range of loads corresponding to their 1 repetition maximum unilateral bench press score (i.e. 20%, 40%, 60% & 80% 1RM). Using their dominant arm, the participants performed three repetitions at each load in a randomized order with 15 seconds rest provided between repetitions and five minutes rest provided between conditions. A GymAware device (Kinetic, Canberra, Australia) was attached to the Jammer Press handle with peak and mean power (W) as well as peak and mean velocity (m.s-1) recorded for each repetition. The average of the three repetitions for each load were then used for data analysis.

RESULTS: All data were normally distributed. A one-way ANOVA found that the optimal load for mechanical mean and peak power was achieved at 60% 1RM.

CONCLUSION: This is the first study to investigate the optimal load for mechanical power during the Jammer Press exercise. The % loading found here to maximize power is higher than those previously reported for the traditionally used bench press throw exercise (e.g. 20-40% 1RM). This has important implications for practitioners as these results demonstrate that different upper-body exercises have different optimal power loads and therefore each exercise requires a tailored approach. Accordingly, for athletes aiming to increase their upper-body unilateral horizontal power, the Jammer Press can be prescribed with a load corresponding to 60% their 1RM.

## COMPARISON OF EFFECTS OF STATIC STRETCHING AND FOAM ROLLING ON PAIN AND LOWER EXTREMITY FUNCTION IN PATIENTS WITH ITFS

MAO, S., QIANG, L.

*BEIJING SPORT UNIVERSITY*

INTRODUCTION: Background: Studies have confirmed that static stretching (SS), as a traditional relaxation technique, and foam rolling (FR), as a relatively new relaxation technique, can relieve iliotibial band and the tension of the surrounding muscle groups. However, which one is more advantageous for alleviating symptoms in patients with iliotibial tract friction syndrome (ITFS) is still controversial. Objective: To compare the effects of SS and FR on pain and lower extremity function in patients with ITFS.

METHODS: On the campus of the Sports University, a total of 43 college patients were recruited through advertisements, 30 of whom (15 males and 15 females) met the inclusion criteria and agreed to participate in the experimental study throughout. The 30 patients with ITFS were randomly divided into 3 groups for 6w-intervention: FR, SS, and control groups of 10 patients each. The intervention was as follows: (1) group FR: A bout consisted of rolling the iliotibial band, adductors, quadriceps, hamstrings, and glutes with rollers for one minute each, a bout/day, 7 days/wk. (2) group SS: A bout consisted of statically pulling the iliotibial band, adductors, quadriceps, hamstrings, and glutes for 30 seconds each, 2 bouts/day, 7 days/wk. (3) group C: maintained the same level of physical activity as group FR and group SS without extra exercise. The pain level and lower extremity function were measured before and after 6 weeks of intervention. The pain levels of patients were assessed using the visual analogue scale (VAS). Lower extremity function was assessed using the lower extremity functional scale (LEFS).

RESULTS: After 6 weeks of intervention, (1) compared to the C group, the pain level was significantly reduced in both FR and SS groups (FR: from 3.80±1.14 to 1.80±1.03; SS: from 3.90±0.99 to 2.20±1.01; both $P<0.01$). (2) compared to the C group, lower extremity function score was significantly improved in both FR and SS groups (FR: from 65.30±3.30 to 78.00±1.33; SS: from 66.20±2.70 to 76.30±1.57; both $P<0.01$). (3) There was no significant difference in pain level or lower limb function score between FR group and SS group (both $P>0.05$).

CONCLUSION: Conclusion: Both foam rolling and static stretching intervention for 6 weeks relieved pain and improved lower extremity function in patients with ITFS, and there was no difference in efficacy between the two. Acknowledgment: This work was supported by the Qinghai province science and technology project (Grant No. 2021-SF-156).

## AEROBIC EXERCISE FOR EIGHT WEEKS PROVIDES PROTECTIVE EFFECTS TOWARDS LIVER AND CARDIOMETABOLIC HEALTH AND ADIPOSE TISSUE REMODELING UNDER METABOLIC STRESS FOR ONE WEEK: A STUDY IN MICE

KIM, Y.J., KIM, H.J., LEE, S.K., KIM, D.H., GO, H.S., LEE, W.J., SEONG, J.K.

*SEOUL NATIONAL UNIVERSITY*

INTRODUCTION: Aerobic exercise training significantly alleviates the symptoms of multiple metabolic disorders [1-4]. However, the underlying mechanisms that modulate metabolic homeostasis in response to exercise training remain poorly understood. Most previous studies concentrated on identifying the effectiveness of exercise interventions in alleviating the symptoms of metabolic disorders or skeletal muscle functions. The findings from these studies, however, do not delineate the role of exercise in reducing obesity and metabolic disorders. Hence, the preventive effect of exercise training on fatty diet-induced metabolic dysregulation is yet to be explored.

METHODS: Our experimental design involved initial exercise training followed by a high-fat diet (HFD) challenge. Eight-week-old male was trained under voluntary wheel running aerobic exercise for eight weeks to determine the systemic metabolic changes induced by exercise training and whether such changes persisted even after discontinuing exercise. The mice were given either a normal chow diet (NCD) or HFD ad libitum for one week after discontinuation of exercise (CON-NCD, n = 29; EX-NCD, n = 29; CON-HFD, n = 30; EX-HFD, n = 31).

RESULTS: Our study revealed that metabolic stress following the transition to an HFD in mice that discontinued training failed to reverse the aerobic exercise training-induced improvement in metabolism. We report that the mice subjected to exercise training could better counteract weight gain, adipose tissue hypertrophy, insulin resistance, fatty liver, and mitochondrial dysfunction in response to an HFD compared with untrained mice. This observation could be attributed to the fact that exercise enhances the browning of white fat, whole-body oxygen uptake, and heat generation. Furthermore, we suggest that the effects of exercise persist due to PPARα-FGF21-FGFR1 mechanisms, although additional pathways cannot be excluded and require further research. Although our study suggests the preventive potential of exercise, appropriate human trials are needed to demonstrate the efficacy in subjects who cannot perform sustained exercise; this may provide an important basis regarding human health.

CONCLUSION: In summary, we identified exercise training as an effective antidote against metabolic stress. Our data showed that exercise altered insulin sensitivity, oxidative capacity, and browning capacity, as well as induced the activation of the PPARα-FGF21 axis to ensure metabolic homeostasis, which persisted in mice regardless of training cessation. Although the mouse model suggests the possibility of exercise-induced alterations, appropriate human trials are needed to demonstrate the efficacy and safety in subjects who cannot perform sustained exercise training, such as injured, hospitalized, and elderly populations, as well as healthy populations.

**EVALUATION OF A STANDARDIZED TEST PROTOCOL TO MEASURE THE WHEELCHAIR-SPECIFIC ANAEROBIC AND AEROBIC EXERCISE CAPACITY IN HEALTHY NOVICES ON AN INSTRUMENTED ROLLER ERGOMETER**

JANSSEN, R.J.F., VEGTER, R.J.K., HOUDIJK, H., VAN DER WOUDE, L.H.V., DE GROOT, S.

*UNIVERSITY OF GRONINGEN, UNIVERSITY MEDICAL CENTER GRONINGEN*

INTRODUCTION: This study aims to evaluate whether a test protocol with standardized, yet individualized resistance settings leads to valid wheelchair Wingate and graded exercise tests (GXT) in healthy novices.

METHODS: Twenty (10M/10F) able-bodied individuals performed -in a fixed sequence- an isometric strength test, sprint test, Wingate test and GXT on a computer-controlled wheelchair ergometer. Based on earlier established relations, the individual's isometric strength outcome was used to estimate the Wingate result (P30est), from which an effective individual Wingate resistance was derived. The subsequently measured Wingate test outcome (P30meas) was used to estimate the GXT outcome (POpeakest) and to scale the individual GXT resistance steps. Estimated outcomes were compared with measured outcomes. The Wingate test protocol was considered valid when peak velocity < 3m·s-1. The GXT protocol was considered valid when test duration was between 8-12min.

RESULTS: The P30est did not differ from the P30meas and one participant did not have a valid Wingate test. The POpeakest was 10% higher than the POpeakmeas and six participants did not have a valid GXT.

CONCLUSION: The isometric strength test can be used to individually scale the test protocol for the Wingate test in able-bodied individuals. The Wingate outcome scaled the protocol for the GXT less accurate, resulting in shorter than desired test durations. The participants mainly ended the GXT because of local fatigue in their arms, not cardiorespiratory fatigue what could be due to the lack of wheelchair propulsion experience. Future research should evaluate this standardized, yet individualized test protocol in an (athletic) wheelchair-dependent population.

**NEUROMUSCULAR ACTIVITY OF YOUNG SOCCER PLAYERS IN SSGS WITH AND WITHOUT GOALKEEPERS**

FERNANDO, S.1,2,3, CÁTIA, F.1, MÁRIO, E.1,3

*1POLYTECHNIC INSTITUTE OF SETÚBAL, SCHOOL OF EDUCATION; 2FACULTY OF HUMAN KINETICS, UNIVERSITY OF LISBON; 3LIFE QUALITY RESEARCH CENTRE*

INTRODUCTION: Football research, notably in training load monitoring, has made great advances as a result of technological development (1). GPS and accelerometers parameters allow quantifying external load values (2). Accelerometry is a recent method to quantify the workload (3), providing important information of neuromuscular demands (4). The objective of our research is to analyze neuromuscular demands in SSGs, with and without GK, in three age groups through different Ac/Dec zones and PL.

METHODS: Twenty-four football players participated in the study. The players belong to the U-12 (n=8), U-15 (n=8) and U-23 (n=8) age groups and play in clubs certified as formative entities by the Portuguese Football Federation. Participating players compete in the district football championships 7 and 9, national under-15 championship and U-23 Revelation League.The data were collected through GPS devices, certified by FIFA, Wimu ProTM, placed on the upper back of the trunk, using wimu-specific vests for this purpose. The tasks analyzed were The SSG1 - 4x4 and SSG2 - GK+4x4+GK, in a game space 20 x 30 meters. The data were analyzed using the Wimu Spro computer program.We used descriptive statistics (mean and standard deviation), t-test to compare between SSG and Anova One Way to compare between age groups. It was still the effect sizes.

RESULTS: The use of GK promoted a higher neuromuscular intensity, being evident with the increase of Ac (U-12, SSG1 - 6.02±6.02, SSG2 - 12.58±10.00; U-15, SSG1 - 12.83±6.90, SSG2 - 21.99±14.18) and Dec (U-12, SSG1 - 11.71±7.97; SSG2 - 17.84±4.41; U-15, SSG1 - 14.65±7.61, SSG2 - 20.90±10.30) >3 m/s2.The effect size, with the use or not of GK, is large in the U-12 in Max Dec (ES=1.44), in the U-15 in Dec 1-2 m/s2 (ES=1.39) and Dec 2-3 m/s2 (ES=1.26) and in U-23 for PL (ES=1.49). There was also a very large effect on the use of GK in the age groups U-15 for Ac 1-2 m/s2 (ES=2.46) and PL (ES=2.41).Players age has a large effect size on SSG1 at Ac 1-2 m/s2 (ES=0.43), Ac >3 m/s2 (ES=0.59), Dec 1-2 m/s2 (ES=0.60), Dec 2 -3 m/s2 (ES=0.18), Dec >3 m/s2 (ES=0.27), Max Ac (ES=0.19) and PL (ES=0.24), in SSG2 to Dec 1-2 m/s2 (ES=0.22), Dec 2-3 m/s2 (ES=0.18), Max Ac (ES=0.20) and PL (ES=0.23).

CONCLUSION: GK intrusion in 4x4 SSG is a promoter of higher neuromuscular activity of high intensity (>3m/s2), as a result of more accelerations/decelerations, with more evidence in the U-12 and U-15 levels. The use of GK has a big effect on PL in the U-15 and U-23 tiers. The age of the players is influencing the values in the different zones of accelerations/decelerations and PL in SSG1 . In SSG2 the age effect is not as evident in accelerations, but is more evident in decelerations, Max Ac and PL.

INTRODUCTION: The force and power generation capacities of the lower limb muscles are improved by speed skating training in speed skaters (Nemoto et al. 1990, de Koning et al. 1991). There are differences in aerobic and anaerobic power output between short-distance and middle- to long-distance skating (de Koning et al. 2005). On the other hand, there is little knowledge about the age-related differences in such physical fitness characteristics in speed skaters. Especially, there is very little knowledge about the difference between senior athletes and junior skaters regarding maximal and sub-maximal power generation capacity among top athletes. This study therefore evaluated the maximal and sub-maximal power generation capacity and physiological responses of senior and junior Japanese internationally competitive speed skaters.

METHODS: Participants were Japanese female all-round speed skaters. They were divided into two groups according to age category: senior skaters (SS; 19 years old and over) and junior skaters (JS; 18 years old or younger). Their maximal and sub-maximal power generation capacity was evaluated by incremental bicycle pedaling tests. The subjects gradually increased the power output from 40w by 20w every minute and recorded the time to exhaustion and the maximum power. And, Oxygen consumption (VO2) and heart rate (HR) were continuously measured. The aerobic threshold (AT) was calculated from the regression equation of oxygen uptake and carbon dioxide emission, and the power at AT (P@AT) were calculated.

RESULTS: The power at all-out was significantly higher in SS skaters than in JS skaters. In addition, SS skaters had significantly higher VO2max per body weight than JS skaters. On the other hand, P@AT did not show a significant difference between the SS and JS skaters.

CONCLUSION: From these results, it became clear that senior speed skaters have superior maximum power output to junior skaters. It can be inferred that such a difference in maximum athletic performance is caused by the enhancement of high-quality high-intensity training conducted after the junior period.

### MUSCLE MECHANICAL AND METABOLIC RESPONSES TO HYPERTROPHIC- AND POWER-TYPE RESISTANCE EXERCISE TRAINING

PELTONEN, H., CRONIN, N., MULTANEN, J., WALKER, S., IHALAINEN, J., SELÄNNE, H., YLINEN, J., AHTIAINEN, J.

INTRODUCTION: This study quantified differences in acute mechanical and metabolic strain response to hypertrophic- versus power-type resistance exercise. Depending on the type and mode of resistance exercise regimens, trained skeletal muscles undergo structural and functional changes in response to the exercise stimulus.

METHODS: Seven previously untrained men performed two different leg press exercises: hypertrophic (HYP, 5 × 10 x 80% of 1RM with 2 min rest between sets) and power (POW, 10 × 5 x 60% of 1RM with 3 min rest between sets) before (Pre) and after 12-week (Post) hypertrophic-maximum strength type resistance training period (RT). During the leg press sets, fascicle shortening of m. vastus lateralis (VL) and patella tendon elongation were measured with ultrasound, the muscle oxygenation level of VL was measured with near-infrared spectroscopy, and blood lactate concentration was determined. Maximum leg press strength and cross-sectional area of VL by ultrasound were measured at baseline and Post-RT. At Post-RT, muscle biopsies were obtained before and after both leg press exercises from VL to assess changes in phosphorylation of Erk1/2(p44/p42), p38 MAPK, p70S6K, and rpS6 signaling proteins.

RESULTS: Muscle strength (+24±13%) and cross-sectional area (+10±6%) increased ($p<0.05$) by RT. A significant difference ($p<0.05$) in muscle oxygenation (-8.9 ± 6.3% vs -3.0 ± 1.8%) between HYP and POW was observed in Pre-RT, but not in Post-RT (-8.2 ± 5.1% vs -4.7 ± 3.6%). In addition, the responses in blood lactate (+10.6 mmol/L vs +1.7 mmol/L) were statistically significant ($p<0.05$) after both HYP and POW exercises in Pre-RT, but only after HYP (+7.9 mmol/L; $p<0.05$) exercise in Post-RT (POW +0.9 mmol/L; ns.). Patella tendon elongation and VL fascicle shortening varied logically with the amount of load to be lifted. However, statistically significant differences were not observed in patella tendon elongation or VL fascicle shortening, or the activity of signaling proteins between HYP and POW. No changes were observed from Pre- to Post-RT.

CONCLUSION: Although fascicle shortening and tendon elongation did not statistically differ between HYP and POW, the present study suggests that they are feasible methods in detecting mechanical strain in the muscle. HYP induced more significant metabolic stress indicated by decreased muscle oxygenation, which might be an essential stimulus for exercise-induced muscle adaptations.
