COMPARISON OF PARTICIPATING MECHANISM OF LEISURE MARATHON AMONG CHINA, THE UNITED STATES AND JAPAN

CHEN, X., BYON, K.K., ZHAO, Q., QU, Y., ZHOU, L.

GUANGZHOU SPORT UNIVERSITY

Purpose – The goal of this study is to test whether the leisure constraints negotiation model is effective in cross-cultural sports participation scenarios, to understand whether the negotiation strategy helps people overcome leisure sports participation constraints, and further explain the participation behavior mechanism of marathon runners.

Design/methodology/approach – Based on using quantitative research methods and comparative research methods, this study developed the "China-US-Japan Marathon Questionnaire on Participation Behavior Mechanism" in collaboration with experts from three countries. A total of 356 valid questionnaires were collected from the U.S., 308 from China and 305 from Japan through online surveys (M-Turk, Questionnaire Star, off-line,etc.), snowballing referrals, contacting clubs and participating in marathons. Structural equation modeling was used to verify the direct effects of constraints, motivation, negotiation, and participation loyalty on engagement behavior, and the indirect effects of negotiation and loyalty. Then multigroup invariance using AMOS was operated to compare in details with the differences in the formation path of marathon participation mechanism among China, the United States and Japan .

Findings – Results showed that (a) the general revision model paths were all significant except for negotiation to participation behavior, also (b) motivation had significant impact on negotiation and participation loyalty, (c) constraints and motivational factors indirectly and positively influenced participation loyalty and behavior through negotiation, and (d) both negotiation and motivational factors indirectly and positively influenced participation behavior through participation loyal-

ty. (e) In respective country, constraints had a significant impact on negotiation and participation loyalty in Japanese and U.S., also (f) the motivation for participation behavior and negotiation for participation loyalty were significant in China and the US. Negotiation was significant for participation behavior only in the US, and participation loyalty was significant for participation behavior only in Japan.

Practical implications – This study expects to understand whether negotiation strategies could help people overcome the constraints of marathon participation, and what behavior mechanism existed in the participation process of recreational marathon runners so as to provide for national authorities with suggestions about formulating or guiding people to promote active leisure participation. This has important practical implications for countries to formulate and implement leisure-based health promotion programs.

Originality/value – The above findings contribute to the literature in the following points. In the first place, the relationships between motivation, constraints, negotiation, participation loyalty and participation behavior were tested, also spotlight on the chain mediating role played by negotiation factors and participation loyalty. In another, this study confirms that the overall model is basically applicable in the China-USA-Japan cross-cultural scenario. Additionally, this study confirms that the most effective way to increase runner participation behavior is to activate the motivational factors of the marathon runners in China, the US and Japan.

EXERCISE PROVIDERS IN THE UK ARE NOT USING THE PHYSICAL ACTIVITY GUIDELINES TO INFORM THEIR STRENGTH PRESCRIPTION WITH OLDER ADULTS

GLUCHOWSKI, A.

UNIVERSITY OF MANCHESTER

Strength recommendations have been embedded within the United Kingdoms (UK) Chief Medical Officers' physical activity guidelines since 2011. There is limited evidence that these recommendations are used by exercise instructors in the community to underpin strength prescription in the older adult population. This study aimed to explore exercise instructors' utilisation of the guidelines when prescribing strength training to their older adult clientele. Fifteen exercise instructors working with older adults in the UK participated in one online interview. A general inductive approach was conducted to allow for major themes to be identified from the raw data. We found that most exercise instructors, but not all, were familiar with the guidelines. Only one of 15 instructors had reportedly implemented the guidelines into their practice; other instructors reported that the guidelines were irrelevant. The interviewees each had their preferred sources of information that they relied on to underpin their exercise prescription, and each had their own interpretation of 'evidence-based strength training.' This individualised interpretation resulted in exceptionally varied prescription in the community and does not necessarily align with the progressive, evidence-based prescription known to build muscular strength. We suggest that i) an improvement to the guidelines, ii) an additional handbook on how to implement the guidelines, iii) an update to theoretical and practical teaching materials and courses, and/or iv) a re-(education) of exercise instructors already in the field may be necessary to bring about a consistent, evidence-based strength prescription that would be required for the best possible outcomes for our ageing population.

A STUDY ON THE RELATIONSHIP AMONG PHYSICAL FITNESS AND ACADEMIC PERFORMANCE, SPORTS CLUB PARTICIPATION, TIME SPENT ONLINE, AND SLEEP

WU, H.F., TSAI, S.H., DONG FANG, J.D., CHEN, S.Y.

SOOCHOW UNIVERSITY

Introduction: The internet, is a modern tool used in computers and mobile phone, providing vast chances to its users changing their lifestyle such as education, entertainment and social communication, (Öz, et al.,2015). Given the quick and easy access of the internet, leading excessive use causing a negative outcome which is known as internet addiction. However, excessive and dysfunctional uses of the Internet causes certain problems. One of these negative outcomes is described as internet addiction and could lead to poor sleep quality (Chou et al., 2005). Poor sleep quality and related sleep disorder has caused great influence on student's university life reveal that sleep-related disorders and have a great impact on students' daily life (Schlarb et al., 2017). Studies have found that physical exercise showed beneficial for individuals mental and physical health. (Gust & Bryan, 2021). Decreasing the danger of long-lasting diseases such as, lipids and hyperglycemia (Pourtaghi et al., 2021). Furthermore, it enables wellbeing social engagement, healthy lifestyle, improves depression related problems and obesity (Chu-Ko et al., 2021).

Method: Physical fitness tests for cardiorespiratory endurance, instantaneous strength, muscular endurance, and flexibility, as well as internet use and sleep quality were analyzed. A total of 31,356 students (11,274 males and 20,082 females) were enrolled in our physical education program from 2017 to 2020 academic years and analyzed the changes in physical fitness of students from university in Taiwan.

Result: The results showed that physical fitness was positively associated with academic performance ($r = .033$, $p < .05$) and sports club participation ($r = .087$, $p < .05$); physical fitness was negatively associated with time spent on the Internet ($r = -.021$, $p < .05$) and physical fitness was not associated with sleep. The results are consistent with most previous studies (Castelli et al, 2007, Wu, 2010, Tseng, Jong-Wei et al, 2012, Han, Ma-Li et al, 2014) which confirmed that students physical fitness is positively associated with academic performance.

Discussion: In order to implement the national policy to promote students physical fitness and to revitalize the campus to improve students vitality and health. The study proposed and analyzed the changes in physical fitness of students from university in Taiwan during 2017 to 2020 to evaluate the rate of physical fitness test and pass rate during the period before and after the COVID-19 epidemic, and to further understand the relationship between physical fitness and various students learning and school activities habits such as; time spent on the internet, and sleep. Furthermore, we further observed the differences in academic performance, time spent on the Internet, and sleep among students of different fitness levels. This studied fund that,= physical exercise showed a positive relationship among students academic performance, internet use and sleep.

WALKING CHARACTERISTICS OF TOP FASHION MODELS DURING PARIS AND MILANO COLLECTIONS IDENTIFIED BY QUANTITATIVE ANALYSIS OF PUBLICLY AVAILABLE MOVIES -VOGUES OVER PAST THREE DECADES-

KOBAYASHI, Y., SAITO, S., MURAHORI, T.

NATIONAL INSTITUTE OF AIST, FAESCIENTICS

[Introduction]

Aesthetic walking has been raised as one of the goals of walking training for various ages. Understanding the characteristics of aesthetic walking is, therefore, essential for the various services that aim to promote such walking (e.g., physical trainers). Walking styles of fashion models who walk the runway of world's top collections could be considered as one of the good examples of an aesthetic walking. Traditionally, it was not easy to assess their walking styles. Recent advancement of computer vision technology and movie sharing services, however, enable us to analyze such walking characteristics. This study quantitatively analyzed the publicly available movies of Paris and Milano collections of world's top brands over past three decades, to understand (1) the walking characteristics of top fashion models, and (2) the vogues of walking characteristics on the runway over time.

[Methods]

The videos of 72 female fashion models who walked the runways of the Paris and Milan spring/summer collections of Dolce & Gabbana, Louis Vuitton, Valentino, Versace, and Yves Saint Laurent from 1989 to 2023, shot from the front, have been quantitatively analyzed by the following process. First, skeletal coordinates of the models have extracted by using the human pose detection library (Vision Pose). Second, Principal Component Analysis was applied to the time-normalized data to reduce the dimensions of datasets. Third, Hierarchical Cluster Analysis was applied to the principal component scores of extracted principal component vectors to classify the characteristics of models' walking. Finally, the stick figure animations that representing the walking characteristics of each cluster have reconstructed by using the component matrixes.

[Results and Discussion]

The walking characteristics of top fashion models were classified into six clusters. From the reconstructed stick figure animations of each cluster and the basic information of the movies (brands and year of the show), we found that the cross-legged walking style, which is commonly imagined as the models walking styles, is rarely seen since the early 2010s. After the late 2010s, walking style without crossing their legs has become common. Further, asymmetric left-right motion was observed in many models. Because of the ways this study took, we cannot fully determine whether these results are caused by the models themselves changing the way they walk, the effect of the dress, shoes, or the location of the show, or the effects of other aspects such as the advancement of filming technology. However, it is very interesting to notice that such differences of walking styles have found from the films released as a record of the worlds top brand shows. This study clearly showed the walking characteristics of top fashion models on the runway and the vogues over time as a good example of an aesthetic walking.

A LONGITUDINAL STUDY ON EXERCISE HABITS AND MENTAL HEALTH AMONG SWEDISH POLICE STUDENTS

BJÄRSHOLM, D.1, JANSSON, A.2, KRUGLY, S.2, INGRELL, J.3, VIKMAN, J.2

1 LINNAEUS UNIVERSITY; 2 & 3 MALMÖ UNIVERSITY

Introduction

In Sweden, police education should promote students' physical activity and mental health. According to national goals, police students should be provided with sufficient conditions to develop and maintain advantageous exercise habits and tools to handle various mentally and physically demanding tasks. The national goals also state that students' physical fitness must be better at graduation than what the requirements are for admission (see Krugly et al., 2022). Although the improvement of students' physical fitness and mental health are national goals, there is a general lack of knowledge regarding: 1) police students physical and mental health, especially from a Swedish perspective; and 2) how well police education promotes students' level of physical activity during education. Against this background, the aim is to explore police students' mental health and level of physical activity during police education in Sweden.

Methods

The data derives from the largest project in Sweden on police students' physical and mental health, and consists of longitudinal data on police students answers of a self-rated questionnaire about exercise habits and mental health (N = 785). The data used in this study was gathered between 2019–2021, and consisted of four data collection points, from two police educations in Sweden. The analysis was conducted in two steps. First, exploratory- and confirmatory factor anal-

yses were conducted to create scales for mental health orientation. Second, these scales, together with the variable exercise habits, were used as outcome variables in t-tests, X2 test and ANOVA. Effect size measurements were calculated and interpreted based on established guidelines.

Results

The results show high psychometric support for two scales named positive health orientation and negative health orientation. Based on the scales and the variable of exercise habits, three primarily results emerge: 1) the levels of physical training for men decrease during education; 2) there are gender differences showing that women have a more negative health orientation; and, 3) the positive mental health orientation decreases during education for both men and women.

Discussion

Swedish police education should prepare students for physically and mentally demanding work. However, as this study concludes, this tends to not be the case, especially given that both the level of physical activity and the positive mental health orientation decrease during education. This raises questions on whether the Swedish police education is doing "enough" to provide the students with adequate conditions for improving their mental and physical health.

STAND UP UNIVERSITY, BREAK SEDENTARY BEHAVIOURS: UNIFIT STUDY

SCOPPOLINI MASSINI, M.1, PINELLI, E.1, MASINI, A.2, ZANNONER, A.2, DALLOLIO, L.2, BRAGONZONI, L.1

1-DEPARTMENT FOR LIFE QUALITY STUDIES, CAMPUS OF RIMINI, UNIVERSITY OF BOLOGNA 2-DEPARTMENT OF BIOMEDICAL AND NEUROMOTOR SCIENCE, UNIVERSITY OF BOLOGNA

Many studies show that sedentary behaviour is strongly associated with higher risk of cardiovascular and metabolic diseases in adults. The World Health Organisation (WHO) recommends limiting the amount of time spent in sedentary behaviour suggesting that every move counts for health. Active breaks (ABs), defined as short (2-10 minutes) bursts of PA incorporated in the working hours, were shown to be an effective strategy to improve physical and mental health. The aim of this study is to collect different perspectives from a group of employees of the University of Bologna (Italy) on incorporating ABs in the workplace and to demonstrate the feasibility of such interventions.

We conducted three focus groups (FGs). Participants were recruited on a voluntary basis: PhD student, research fellows, medical residents and administrative staff of University of Bologna (N=18). The age of participants was between 27-64 years. After the focus groups, a questionnaire was administered to participants and it was subsequently analysed to determine the barriers and facilitators of implementing ABs in the workplace.

88,8% of the participants responded that they had a sedentary lifestyle. 94,4% showed interest in incorporating ABs in the workplace. The most common barriers identified were lack of time and a suitable space, along with social acceptability and need for appropriate clothing. However, time flexibility, different types of exercises and group activity are major facilitators in organising ABs in the workplace. Participants also felt that structuring ABs with an effective outcome was very important for facilitating the participation of workers.

This study highlights that ABs could be an acceptable intervention for breaking-up sedentary behaviours among university employees. FG is a valid technique to evaluate the barriers and facilitators of an ABs intervention in the workplace.

HOW PHYSICAL ACTIVITY INTENTION IS INFLUENCED BY MOTIVATION, RESILIENCE, MOOD AND PERSONAL AND SOCIAL RESPONSIBILITY

SOOS, I., OZSVÁTH, K., HAMAR, P., WHYTE, I., VALERO VALENZUELA, A.

HUNGARIAN UNIVERSITY OF SPORTS SCIENCE

Introduction

Physical activity intention is an essential part of health-related behaviour. However, physical activity intention and its outcome are influenced by a number of factors. These factors comprise intrinsic motivation (Hein et al., 2004), basic psychological needs in exercise (Vlachopoulos & Michailidou, 2006), resilience (Manzano-Sanchez et al., 2021), mood (Pedrosa et al., 2014), and personal and social responsibility (Li et al., 2008). The aim of our study was to investigate the relationships between physical activity intention, motivation, basic psychological needs in exercise, resilience, mood and personal and social responsibiliy in university students through the lenses of the Self-Determination Theory (Deci and Ryan, 1985) and the Dual-Process Framework (Cheval and Boisgoutier, 2021).

Method

Following ethical clearance, 105 university students from Budapest (mean age = 22.6 years (s=4.24); 46% female, 54% male) participated voluntarily in our study. Participants completed the Academic Motivation Scale (AMS; Vallerand el al., 1992), Basic Psychological Needs in Exercise Scale (BPNES; Vlachopoulos & Michailidou, 2006), Resilience Scale (RS-14; Domasio et al., 2011), Trait Meta-Mood Scale (TMMS-24; Fernandez-Berrocal et al., 2004), Personal and Social Responsibility Questionnaire (PSRQ; Li et al., 2008), and Intention to be Physically Active after School Graduation Questionnaire (IPA; Hein, 2004). Data were analysed by employing IBM SPSS v.25, and performing inferential statistics, Pearson correlations, and Mann.Whitney U Test in order to test group differences.

Results and Conclusions

Results showed significant relationships (p<0.01) between physical activity intention and external regulation (r = 0.31), competence (r = 0.44), relatedness (r = 0.38), resilience (r = 0.34) and personal responsibility (r = 0.41). According to Mann.Whitney U Test, females scored significantly (p=0.008) higher in social responsibility, younger participants reported higher (p=0.019) perceived competence as opposed to older participants, and older participants demonstrated higher (p=0.013) emotional clarity than younger ones. Younger university students that have greater competence of their basic psychological needs may feel more motivated to continue their physical activity participation after their graduation. Female students demonstrating higher social responsibility may want to improve in their academic studies as well as sport activities. Older respondents having higher emotional clarity are aware of their emotions during different activities, such as physical activity behaviours.

In conclusion, our investigation confirmed that studies of factors that influence physical activity intention is helpful for researchers to promote health-related behavious among university students.

Key words: physical activity intention, motivation, basic psychological needs, resilience, mood, personal and social responbility

BODY (DIS)SATISFACTION: COULD THE EVALUATION BE INFLUENCED BY SEX?

PAPALE, O., FESTINO, E., FUSCO, A., CORTIS, C.

UNIVERSITY OF CASSINO AND LAZIO MERIDIONALE

INTRODUCTION: Body image is a multidimensional and complex construct, which includes cognitive, perceptual, emotional, and behavioural aspects. It varies along sex and the aging process with relations to weight control. Body image may be defined in simple terms as the way a person perceives or thinks about his body and how it looks to others. The negative interaction of the mentioned factors could generate body (dis)satisfaction (1). Previous research has shown that body dissatisfaction could result in risky weight-loss behaviours and concerns about both weight and muscularity, in females (F) and males (M), respectively (2). Therefore, the aim of the present study was to investigate male and female body dissatisfaction in relation to body size.

METHODS: One hundred-five volunteers took part in this study. Fifty M (age:25.3±9.2yrs; body mass:72.5±8.7kg; height:176±7cm; BMI:23.3±2.2kg/m2) and fifty-five F (age:27.6±10.6yrs; body mass:61.9±13kg; height:166±6cm; BMI:22.5±3.9 kg/m2). To assess the individual's body dissatisfaction in relation to body size, the Body Image Dimensional Assessment (BIDA) instrument was used (3). BIDA assesses the subjective and emotional dimensions of body image by means of a neutral silhouette-based scale. The questionnaire consists of four questions (Q1 to Q4) ranging from 1.8 to 5.2, with increment of 0.1, related to individual's perceived and ideal body shape to calculate the Body Dissatisfaction (BD=(Q1-Q2)×100/3.4), the most appropriate body shape for their peer for Comparative Body Dissatisfaction (CBD=(Q1-Q4)x100/3.4) and the most appreciated body shape by the opposite sex, to calculate the Sexual Body Dissatisfaction (SxBD=(Q1-Q3)×100/3.4). Body Dissatisfaction Index (BDI=(BD+SxBD+CBD)/3) was sequentially calculated. Means, standard deviations and ranges were calculated separately for M and F for each variable. To evaluate sex differences, two-sample t tests were performed for all variables.

RESULTS: Sex differences emerged for BD (F: 12.4±14.9% range:-17.6-58.8; M:-1.4±12.4% range:-29.4-29.4, p=0.000), SxBD (F: 9.0±17.6% range:-28.2-58.8; M:-1.1±14% range:-29.4-20.5, p=0.0016), BDI (F:15.2±7.4% range:2.9-29.4; M:12.2±5.7% range:0-24.5, p=0.02). No differences emerged for CBD.

CONCLUSION: BIDA proved to be effective in detecting body image differences in relation to sex. Although sex differences emerged, both M and F are exposed to body dissatisfaction, with F at a higher risk regarding BD and SxBD. Literature (3) suggested BDI values higher than 30% as a threshold to define subjects at risk of body image disorders. While based on our results the sample of the present study could be defined not at risk, findings suggest to draw attention to the tendency to became at risk.

SHORT-TERM EFFECTS OF EXERCISE ON BODY IMAGE

FESTINO, E., PAPALE, O., CORTIS, C., FUSCO, A.

UNIVERSITY OF CASSINO AND LAZIO MERIDIONALE

INTRODUCTION: Body image (BI) is a multidimensional construct focused on body's appearance and function, representing how subjects see, feel, think and behave regarding their bodies (1). Weight dissatisfaction and negative body image

are predictors of health-related problems such as depression, weight control and eating disorders. Since the regular practice of physical activity (PA) has physical and psychological health benefits, it could also play a key role in improving BI. Therefore, this study aimed to evaluate the short-term effects of exercise on BI in physically active adults.

METHODS: Twenty-one physically active adults (age:30±12.9yrs; mass:66.4±12.4kg; height:167.6±6.8cm; body mass index (BMI):23.55±3.7kg/m2) participated in the study. Before (pre) and after (post) their individual not structured workout, the Body Image Dimensional Assessment (BIDA) questionnaire (2) was administered. BIDA assesses the subjective and emotional dimensions of BI by means of a neutral silhouette-based scale, ranging from 1.8 to 5.2. Participants had to indicate their perceived and ideal body shape, the most appropriate body shape for their peers and the most appreciated body shape by the opposite sex. The Body Dissatisfaction Index (BDI) was estimated through the mean of the absolute values of Body Dissatisfaction, Sexual Body Dissatisfaction and Comparative Body Dissatisfaction. The BDI ranges from 0 to 100AU, with people scoring > 30 considered at risk of BI disorders. At the end of their individual workout, to evaluate the overall exercise intensity, rating of perceived exertion (RPE) was collected using the Borg category-ratio-10 scale. A paired t-test was used to examine the effects of a single workout on BDI. Statistical significance was set at $p<0.05$.

RESULTS: The mean RPE at the end of the workout was 6.8±1.9AU indicating a vigorous intensity session. No significant differences ($p=0.61$) in BDI were found between pre (16.8±3.3AU) and post (17.5±6.9AU) workout.

CONCLUSION: Although most BDI participants' scores changed after the workout, no significant differences emerged between pre and post values. It might be assumed that BI is not immediately affected by a single workout session. Probably, to improve physical wellness and psychological benefits to observe changes in BDI, a longer period of training is required. In addition, the participants' post exercise responses could have been influenced by the knowledge of their previous answers due to the short time between the pre and post administration. Moreover, since participants had a normal range of BMI and were physically active, future researches could investigate the effect of a single workout session on BI in individuals with different BMI categories or sedentary individuals.

THE EFFECT OF HIIT ON BODY COMPOSITION, CARDIOVASCULAR FITNESS, PSYCHOLOGICAL WELL-BEING, AND EXECUTIVE FUNCTION OF FEMALE YOUNG ADULTS WITH OVERWEIGHT/OBESITY

GUO, L.1, CHEN, J.1, YUAN, W.1

DALIAN UNIVERSITY OF TECHNOLOGY

INTRODUCTION: Higher prevalence of physical inactivity among female young adults resulted in constantly rising rate of overweight and obesity, which in turn caused a variety of physical, cognitive, and mental issues [1]. The main barrier to regular exercise is generally "lack of time". The training program of HIIT, which characterized with time-effectiveness in health promotion, was of a great deal of interest in recent years [2]. Given that the previous findings are inconsistent and dose-response relationship of health/fitness adaptations to HIIT was still vague [3], the purpose of the current study was to evaluate a short-term HIIT program on selected health-related parameters for female young adults with overweight/obesity in a university context.

METHODS: 48 participants were randomly divided into two groups. The exercise group (HIIT) received a HIIT intervention of aerobics for four weeks, while the control group (CON) received no training. Body composition including waist circumference (WC), body fat percentage (BF%), Cardiorespiratory fitness (VO2max), the score of Self-Rating Depression Scale (SDS), and Stroop word-color test (SCWT) results were assessed before and after the intervention along with within- and between-group comparisons.

RESULTS: All the indices were significantly improved in HIIT group ($P < 0.01$) after 4 weeks of intervention. No significant changes were found in CON. There were significant differences between HIIT and CON in cardiovascular fitness ($P < 0.01$), SDS ($P < 0.01$) and SCWT ($P < 0.05$) before and after 4 weeks. In addition, weekly measurements of HIIT effects showed significant changes ($P < 0.01$) from the second week in the variables of body composition, VO2max, SDS and SCWT when compared with the baseline and maintained the tendency till the end of program.

CONCLUSION: The short-term HIIT aerobics of campus program conducted in non-lab setting induced significant improvements in body composition, cardiovascular fitness, psychological well-being and executive function in young female adults with overweight. In the future, the minimum training volume and its combination with training intensity in HIIT that could produce the improvement of health outcomes are of interest for further exploration.

COMBINED PHYSICAL ACTIVITY AND MINDFULNESS MEDITATION INTERVENTION FOR WEIGHT LOSS AND EATING DISORDERS IN OBESE INDIVIDUALS

EL HAJJ, A., NOULHIANE, M., LEMAÎTRE, F.

UNIVERSITY OF ROUEN NORMANDY

INTRODUCTION: Today, obesity is considered one of the most important health issues in the world due to its health, social, and economic costs (1). Physical activity (PA) is a key element of obesity management (2). However, a strand of literature exploring the effect of mindfulness-based interventions (MBIs) including mindfulness meditation (MM) on weight loss and obesity-related eating disorders has developed recently (3,4). The aim is to collect and then evaluate the results of the aforementioned studies to indicate potential future research paths.

METHODS: A literature review was conducted on the effects of MBIs on weight loss and eating disorders in people with obesity. Pubmed and Google Scholar databases were searched for original studies as well as review articles. Keywords related to mindfulness were entered in conjunction with terms related to weight loss and eating disorders (e.g., "(mindfulness-based interventions OR mindfulness meditation OR mindfulness) AND (weight loss OR eating disorders OR eating behaviors)").

RESULTS: The database search yielded 241 records. Subsequently, based on the inclusion criteria, 214 records were excluded, and the final sample included 27 RCTs and reviews. MBIs lead to a lasting behavioral change and better emotional regulation, help develop body awareness, and improve the persons relationship with both food and their body. MBIs help people achieve weight loss goals by decreasing stress, improving self-regulatory capacities, and by helping individuals become more resilient, well prepared, and motivated to overcome challenges.

CONCLUSION: The review results are promising and offer potentially valuable insights to clinicians. Moreover, by identifying gaps in the literature, it opens new research paths. For instance, the underlying mechanisms of MM are indicated as offering potentially valuable synergic effects with the standardized, PA-centered treatments. However, despite these promises, the effects of a combined treatment are still to be investigated.

A CROSS-OVER EXAMINATION OF EXERCISE INTENSITY AND ITS IMPACT ON THE ACUTE RELEASE OF IRISIN IN INDIVIDUALS OF DIFFERENT OBESITY STATUS

SÉNÉCHAL, M., RIOUX, B.V., PAUDEL, Y.

UNIVERSITY OF NEW BRUNSWICK

INTRODUCTION: During acute exercise, skeletal muscle releases myokines, which play a key role in exercise-related health benefits. Irisin, an adipo-myokine mainly secreted by skeletal muscle, has been shown to increase during acute exercise. However, limited data exist regarding the impact of different exercise intensities on irisin release and its association with insulin sensitivity in individuals of different obesity status.

The purpose of this study was to investigate: 1) the impact of exercise intensities on the acute release of irisin in non-obese (NOB) and overweight-obese individuals (OB), and 2) if irisin release during an acute bout of exercise was associated with greater insulin sensitivity among NOB and OB individuals.

METHODS: A randomized controlled crossover design study was conducted on 26 NOB (body mass index (BMI: <25kg/m2)) and 28 OB (BMI: >27kg/m2) adults (19-50 years). Participants performed, in a random order, a 1) resting condition (in a reclined position for 35 mins), 2) a moderate continuous intensity (MCI) exercise session (50% of heart rate reserve for 35 mins), and 3) a high-intensity interval training (HIIT) exercise session (35 mins with intervals increasing from 50% to 85-90% of heart rate reserve for 2 mins, every 5 mins. Blood samples were taken at 0, 14, 28, and 35 mins to quantify irisin via ELISA and western blotting. Each participant underwent a 2-hour oral glucose tolerance test from which insulin sensitivity (Si) was estimated using the Matsuda index. For analysis purposes, NOB and OB participants were categorized as low-Si (<25 percentile Si) and high-Si (>25 percentile Si).

RESULTS: There was no significant difference in irisin release between NOB and OB individuals during the control condition ($p>0.05$). However, NOB individuals displayed significantly higher irisin release compared to OB individuals during acute MCI exercise ($p<0.05$), while no such differences were observed for acute HIIT exercise ($p>0.05$). NOB individuals had greater insulin sensitivity compared to OB individuals (NOB: 38.7 ± 26.3 vs. OB: 19.8 ± 23.6; $p< 0.001$). Insulin sensitivity was negatively correlated with BMI ($r=-0.55$; $p< 0.001$) and positively correlated with change in irisin during MCI exercise ($r= 0.29$; $p<0.05$). NOB individuals with low-Si had a 1.58-fold ($p<0.05$) increase in irisin during HIIT exercise, while NOB with high-Si had a 3.58-fold ($p=0.06$) increase. OB individuals with low-Si and high-Si had a 1.85 and 1.11-fold increase in irisin (all $p<0.05$) during HIIT.

CONCLUSION: The results of this study confirm that irisin is released differently with varying intensities of exercise. In addition, these data suggest that the release of irisin varies according to obesity status, with healthy individuals releasing more irisin compared to individuals with obesity.

BIBLIOMETRIC ANALYSIS OF RESEARCH TRENDS IN RELATIONSHIP BETWEEN PHYSICAL EXERCISE AND OBESITY

LETUKIENE, A., GINEVICIENE, V.

FACULTY OF MEDICINE, VILNIUS UNIVERSITY

INTRODUCTION: The relationship between physical activity and obesity has attracted an increasing number of researchers in recent years. Obesity is a complex, multifactorial disorder of the energy homeostasis system. Growing evidence suggests that skeletal muscle produces myokines in response to physical exercise, which allow for crosstalk between the muscle and other organs (such as adipose tissue, brain, liver etc.) in order to maintain homeostasis. It is known physical inactivity is one of the primary contributors to the obesity. However, the relationship among obesity, physical activity and myokines were still not fully understood. Our study aimed to identify the current research hotspot, status and trend in this field by using bibliometric and visualization analysis.

METHODS: Articles published in the PubMed database in the period 2010-2022 were filtered using keywords 'physical activity', 'exercise', 'myokines' and 'obesity'. Bibliometric analysis was done using VOSviewer tool (version 1.6.19). Two standard weight parameters were applied - "links attribute" and "total link strength attribute" (TLS) to find out the most common keywords and its links, trending themes, organizations and authors who research these topics the most.

RESULTS: In total 410,106 scientific articles were published between 2010 and 2022, including both clinical trials (19.9 %) and reviews with keyword 'physical activity' and 325,649 scientific articles with keyword exercise during the same period, 22.3% of them are clinical trial type (TLS 77), and associated with keyword 'myokines'. Publications number of authors who studies the connection between myokines and exercise in the top 100 range from 4 to 20. B.K. Pedersen (Denmark) was the most productive author in this field (number of publications = 20) and was cited 51 times (TLS 82). The most citated articles was written by A. Lucia (Spain). He published 11 articles and was cited in 74 other articles (TLS 113). The most related keywords to exercise and myokines theme were keywords 'irisin', 'skeletal muscle' and 'obesity'. Keyword 'obesity' had 68 occurrences (TLS 361) and irisin appears to be the most researched myokine, having 206 occurrences (TLS 974).

CONCLUSION: The relationship between physical activity /exercise and obesity was well-discussed topic in recent years and number of publications grows exponentially. Our study showed that the study in this field mainly focused on physical exercise, role of skeletal muscle and myokines. Irisin is one of these myokines, and its link with different types of physical exercise was investigated. Irisin a newly identified exercise responsive myokine has emerged as a promising therapeutic strategy (using exercise) in the prevention and management of obesity.

COVID-19 LOCKDOWN EFFECT ON WEIGHT AND FAT MASS IN FRENCH ELITE ATHLETES

NGUYEN-BOUSSUGE, S.

INSEP

INTRODUCTION: Medical-technical staff around athletes had to adapt to minimize the negative effects of 2020 Covid-19 lockdown on performance [1], as well as changes in body composition associated with isolation [2]. Our objective was to evaluate the effects of the COVID-19 lockdown on mass and body fat in French elite athletes.

METHODS: 122 French elite athletes (23.3 ± 5.2 years old; 43% of female athletes) training at the National Institute of Sports (INSEP) during the 2019/2020 season and from 17 different sports were included. Weight and fat mass data from the medical consultation, the post-confinement anthropometric assessment and a questionnaire were compared with their pre-confinement values. The influence of gender, training load, nutrition management and injuries was also explored.

RESULTS: The statistical analysis shows a significant increase in weight (71.23 ± 13.75 vs. 72.03 ± 14.50; P =.002) and in fat mass (15.01 ± 6.28 vs. 15.86 ± 6.42; P < .001) during lockdown. Regarding the gender, only men significantly increased their weight (77.61 ± 12.92 vs. 78.80 ± 13.89; P =.002) but women and men increased their body fat by +0.9 ± 2.7% and +0.8 ± 2% respectively. Athletes whose training load decreased between before and during lockdown gained significant weight (70.17 ± 12.98 vs. 71.12 ± 13.85; P =.002) and fat mass (14.52 ± 5.86 vs. 15.56 ± 6.21; P <.001). Athletes who were not injured during lockdown gained significant weight (70.72 ± 14.40 vs. 71.45 ± 14.83; P =.01) and fat mass (14.82 ± 6.61 vs. 15.76 ± 6.64; P <.001). Finally, weight was significantly increased in athletes reporting difficulties in weight and nutrition management (70.41 ± 15.84 vs. 71.81 ± 16.59; P =.004) compared to athletes not reporting difficulties (P = NS).

CONCLUSION: Changes in the sport practice and lifestyle of elite athletes had a negative impact on the management of their body composition. If this type of isolation occurs again, vigilance must be exercised to at least maintain the training load and accompany athletes who have difficulties in managing their weight and their diet. It also appears that athletes injured prior to lockdown were already deconditioned compared to non-injured athletes. Thus, particular attention should be paid to the management of weight and fat mass from the beginning of the athletes' injury.

THE EFFECT OF TRAINING TIME AND MATURITY STATUS ON BONE GROWTH IN CHILDREN TENNIS PLAYERS

PALAIOTHODOROU, D.1, ANTONIOU, T.2, VAGENAS, G.1

1.NATIONAL AND KAPODISTRIAN UNIVERSITY OF ATHENS, SCHOOL OF PHYSICAL EDUCATION AND SPORT SCIENCE, 2.BLOCKS REHAB FILOKTITIS REHABILITATION CENTER, MEDICAL IMAGING DEPARTMENT, ATHENS, GREECE

INTRODUCTION: Tennis has been a model in studying the effects of physical activity on bones [1]. Compared to the non-racket arm (NRA), the induced racket arm (RA) bone hypertrophies are more pronounced during growth and correlate with training [2, 3]. As this data stem merely from cross-sectional testing, this study used Tanner stage (TS) and maturity offset (MO) to explore bone change over a 9-month period in children tennis players.

METHODS: Four groups of players aged 7.5-13 years were tested: I (Tanner I-I, MO -3.5 ± 0.8 yrs, N = 17); II (Tanner I-II, MO -2.6 ± 0.8 yrs, N = 14); III (Tanner II-III, MO -1.4 ± 1.0 yrs, N = 7); IV (Tanner III-IV, MO -0.3 ± 1.4 yrs, N = 8). Bone mineral content (BMC) and bone area (BA) of both arms were measured using DXA. Descriptive statistics and multiple regressions assessed the effects of maturity status (MS) and training time (TT) on bone change.

RESULTS: During the 9-month period significant RA bone hypertrophies were developed in all groups. BMC hypertrophy changed for group I from 7.7 ± 5.0 grams (16.2 ± 11.9%) to 9.0 ± 6.4 grams (16.4 ± 11.4%), for group II from 9.0 ± 5.7 grams (15.9 ± 9.8%) to 12.6 ± 5.6 grams (19.6 ± 9.2%), for group III from 12.7 ± 3.9 grams (20.4 ± 6.9%) to 16.1 ± 4.2 grams (22.5 ± 8.4%), and for group IV from 18.5 ± 7.7 grams (19.6 ± 7.6%) to 19.3 ± 8.0 grams (18.1 ± 7.2%). BA hypertrophy changed for group I from 7.8 ± 5.7 cm² (10.2 ± 8.1%) to 9.4 ± 6.2 cm² (11.3 ± 7.3%), for group II from 10.0 ± 4.0 cm² (11.3 ± 4.6%) to 12.3 ± 6.3 cm² (12.8 ± 6.8%), for group III from 12.1 ± 5.1 cm² (12.7 ± 6.1%) to 12.9 ± 5.8 cm² (12.5 ± 7.5%), and for group IV from 14.5 ± 5.7 cm² (11.5 ± 4.8%) to 12.5 ± 6.4 cm² (8.8 ± 4.7%). Regressions ($p < 0.001$, $R^2 > 36\%$) revealed that MO change is the best determinant of bone gains in both arms (BMC: $p < 0.001$, LMG: 71% & 78%; BA: $p < 0.001$, LMG: 77% & 83%), while TT change is much impactful for the RA (BMC: $p < 0.005$, LMG: 23%; BA: $p < 0.05$, LMG: 18%) and mostly for BMC ($p < 0.01$, LMG: 56%) than BA ($p = 0.084$, LMG = 13%) hypertrophy.

CONCLUSION: The transition from Tanner stage I to II and from Tanner stage II to III is the optimal period for the bones to benefit more from exercise. The respective rate of osseous improvement from Tanner stage III to IV appears much slower. While change in maturity status affects about equally both arms' skeletal growth, training becomes highly determinant mostly for bone content and less for bone size. The results have health and growth implications, with prior ideas for more symmetric training during childhood [3] appearing reasonable.

DETERMINATION AGE-RELATED DEFICIENCY OF FUNCTIONAL MOVEMENT PROFICIENCY AND LOWER BODY STRENGTH IN ADOLESCENT SOCCER PLAYERS

IMAL, O.

CHARLES UNIVERSITY IN PRAGUE FACULTY OF PHYSICAL EDUCATION AND SPORT

INTRODUCTION: Quality of movement improves physical performance and reduces injury risk. It is known that biological maturation status (BMS) has a significant impact on the development of physical performance. However, strength development and functional movement (FM) competence show differences depending on BMS in adolescent soccer players. The goal of this study was to investigate the differences between different age categories (U13-U16) on FM proficiency and lower body strength (LBS) based on BMS of adolescent soccer players.

METHODS: A sample of 79 male soccer players, aged 12,24 ± 0,26 to 15,21 ± 0,42 years, were recruited from a professional soccer club and examined into four age groups (U13, U14, U15 and U16). The Functional Movement Screen (FMS), counter movement jump (CMJ), squat jump (SQJ), counter movement jump free-arm (CMJ-FA) and isokinetic quadriceps/hamstring (Q/H) knee test by 60°s, 180°s, 300°s speeds were administered to assess FM proficiency and LBS based on peak height velocity (PHV) level of the individuals. Mirwald (2002), maturation offset was used to calculation of BMS, respectively.

RESULTS: In this study, ANOVA showed a significant between-group effect in peak height velocity (PHV), FMS, isokinetic strength of Q/H (except H at 300°s), jump height (JH) of CMJ-FA, CMJ and SQJ and jump impulse relative of SQJ ($p < 0.05$). Along with this, there was found significant differences between older groups (U15, U16) and younger groups (U13, U14) in all the JH results of vertical jumps by ANOVA test ($p < 0.05$). When an ANCOVA was applied to account for the influence of biological maturation (PHV) on between-group differences, FMS and JH of all the jumps no longer displayed any signifi-

cant differences between age groups. In addition, ANCOVA presented significant differences between older groups (U15, U16) and younger groups (U13, U14) in all the speeds of isokinetic strength ($p < 0.05$). Given that, PHV was found a significant covariate for all isokinetic strength tests, JH of CMJ-FA, CMJ and SQJ.

CONCLUSION: The outcome of this study, FM competence and LBS methods were found to be affected differently depending on maturation. It was observed that vertical jump performance, which is a complex movement depending on maturation, did not change in direct correlation with FM, but isokinetic strength increased in the older groups depending on maturation. Moreover, biological age (PHV) was found one of the key indicators to observe whether any differences between age groups in FM proficiency and LBS. Future research should focus on developing targeted intervention studies within divided age groups according to PHV level of the players to improve FM quality and physical strength in the young population.

SYSTEMATIC REVIEW OF PARENT-BASED MOBILE HEALTH INTERVENTION TO PROMOTE PHYSICAL ACTIVITY, DIETARY BEHAVIORS AND REDUCE SLEEP PROBLEMS IN PRESCHOOLERS

PENG, Z.

HONG KONG BAPTIST UNIVERSITY

INTRODUCTION: Preschoolers' lifestyles have become physically inactive and sedentary, their eating habits unhealthy, and their sleep routines increasingly disturbed. These changes have led to an ever-increasing prevalence of obesity. Parents have a profound impact on the healthy lifestyle of preschoolers and are the key agents of behavioral modification. Improved access and lower costs make mobile health (mHealth) interventions appealing. However, it is currently unclear whether parent-based mHealth intervention may be harnessed to improve the aforementioned lifestyle behaviors. This study aims to systematically review the current literature concerning the effectiveness of parent-based mHealth intervention to improve preschoolers' physical activity (PA), dietary behaviors (DB) and sleep problems.

METHODS: This systematic review conforms to the Preferred Reporting Items for Systematic Reviews and Meta-analysis (PRISMA) statement. Six databases (EMBASE, PubMed, MEDLINE, Web of Science, SPORTDiscus and PsycINFO) were retrieved for the period from January 2000 to August 2022. Studies were eligible if (1) they were quantitative study designs; (2) they targeted parents of children aged 3-6 years and used an mHealth modality; and (3) at least one variable included in either the primary or secondary outcome should be concentrated on PA, DB, and sleep. The risk of bias was assessed based upon Version 2 of the Cochrane risk-of-tool for randomized trials (RoB2).

RESULTS: Seven studies were screened. Two studies focused on DB and sleep respectively, the remaining five studies included more diet modules than PA and sleep ones. PA was examined in four studies, which all reported a significant changes within the intervention group at the post-intervention, but only two studies found a significant group-by-time difference. Five of six studies that reported on DB outcomes indicated significant improvements compared with the control. Two studies evaluated sleep outcomes, one demonstrated significant improvements in sleep between intervention and control groups, while the other did not. The quality of the interventions was generally not high; therefore, these results should be interpreted with caution.

CONCLUSION: Studies reviewed either emphasized one variable (e.g., sleep or diet) or failed to balance the dosage of PA, diet, and sleep modules and consider the intervention sequence during the intervention period. It is recommended that high-quality, robust designed research studies to balance the intervention content and sequence are needed to determine the effectiveness of mHealth interventions to support behavior change in Chinese preschoolers and target parents as an agent of behavioral change.

THE EFFECTS OF A MOVEMENT SKILLS TRAINING PROGRAMME ON GROSS MOTOR SKILLS, EXECUTIVE FUNCTION, AND SOCIAL COMPETENCE: PRELIMINARY FINDINGS FROM A GROUP-RANDOMISED CONTROLLED TRIAL

CAPIO, C.M., HO, H.C.M., LEE, K.

EDUCATION UNIVERSITY OF HONG KONG

INTRODUCTION: Children who have more proficient movement skills tend to have better cognitive skills and social competence. However, most evidence has been drawn from associational studies, which limits the understanding of the underlying mechanisms. We explored the relationship of movement proficiency with the cognitive and social domains of child development by implementing a targeted movement skills training program and measuring motor, cognitive and social outcomes.

METHODS: The study design is a group-randomized controlled trial. Participants consisted of children aged 3-5 years (N = 140) from a local kindergarten who were randomly allocated by class to either a training or active control condition. A 10-week training program focused on the gross motor skills curriculum of the kindergarten; the active control consisted of typical movement activities following the local curriculum guide. The outcomes consisted of locomotor and object control skills proficiency (1), executive function (2) and social competence (3). Tests were administered at baseline, post-training, and following a 4-month period of pandemic-related school suspension. Mixed-models repeated measures analysis of variance was performed on each variable while controlling for known correlates.

RESULTS: There was a significant main effect of test ($F(4,132)=34.08$, $p<0.001$) and an interaction between test and group ($F(4,132)=6.45$, $p<0.001$) on locomotor and object control skills. The training group displayed greater improvements post-training than the control group. Following school suspension, both groups displayed improvements in object control but not in locomotor skills. There were significant main effect of test ($F(2,130)=89.46$, $p<0.001$) and interactions of test with fine

motor skills (F(2,130)=5.05, p=0.008) and group (2,130)=7.84, p=0.001) on executive function. The training group displayed greater improvements post-training than the control group. Following school suspension, the groups' improvements were comparable. There was a significant main effect of test (F(2,134)=40.87, p<0.001) on social competence; interactions of test with sex and group were not significant. Both groups displayed improvements post-training and declines following school suspension.

CONCLUSION: The findings showed that a movement training program can facilitate improvements in gross motor skills and executive function but not social competence. These findings contribute to the growing evidence of the relationship between motor and cognitive development in young children. Children displayed a lack of improvement in locomotor skills and a decline in social competence following a period of school suspension, highlighting the negative impact of pandemic-related disruptions on child development.

THE IMPACT OF CARDIORESPIRATORY FITNESS TRAJECTORIES THROUGH ADOLESCENCE IN THE ASSOCIATION OF BDNF WITH COGNITIVE AND ACADEMIC PERFORMANCE

BELTRAN-VALLS, M.R., ADELANTADO-RENAU, M., MONTEAGUDO, P., MONZONÍS-CARDA, I., MOLINER-URDIALES, D.

UNIVERSITAT JAUME I

INTRODUCTION: Brain-derived neurotrophic factor (BDNF) is a protein implicated in neuronal development, differentiation, and survival [1], which has led to suggest that it could benefit cognitive and learning processes. However, previous studies showed conflicting results regarding the association of circulating BDNF and cognitive performance, since both significant and non-significant results have been reported [2]. Interestingly, cardiorespiratory fitness (CRF) is suggested to positively influence cognition and brain function [3]. Yet, the role of the CRF levels in the association of BDNF with cognitive and academic performance has not been previously investigated in adolescents. Thus, the aims of this study were: I) to analyze if changes in circulating BDNF predict changes in cognitive and academic performance and II) to analyze the impact of CRF trajectories in this association.

METHODS: A total of 163 adolescents (79 girls) aged 13.9±0.3 years at baseline and 15.8±0.3 at 2-year follow-up were included in the analyses. Plasma BDNF concentration was measured using a commercially available ELISA kit after an over-night fasting. Cognitive performance was assessed through the overall score of the Science Research Associates Test of Educational Abilities. Academic performance was calculated through the average of the final scores achieved in all participants. CRF was assessed by the 20-m shuttle run test. Participants were classified as fit or unfit based on the sex and age specific 60th CRF percentile [4]. CRF trajectories were established as follows: persistently high (fit at baseline and at follow-up), increasing (unfit at baseline but fit at follow-up), decreasing (fit at baseline but unfit at follow-up), persistently low (unfit at baseline and at follow-up). We performed linear regression analyses between changes in BDNF and changes in cognitive or academic performance; level of significance p<0.05.

RESULTS: The change in circulating BDNF was positively associated with the change in academic performance (β=0.178; p=0.02), but not with the change in cognitive performance (p>0.05). When considering the trajectories of CRF, only participants with persistently high CRF showed a significant association between the change in circulating BDNF and the change in academic performance (β=0.233; p=0.01).

CONCLUSION: Our results contribute to understand the physiological mechanisms influencing academic performance. Maintaining a fit CRF level during adolescence seems important to achieve the benefits that BDNF may exert on academic performance. Interventions aiming to boost educational performance in adolescents should promote CRF improvement through physical exercise practice.

THE IMPORTANCE OF SKILL COMPETENCE AS A KEY PREDICTOR OF THE ENERGY EXPENDITURE ASSOCIATED WITH PERFORMING FUNDAMENTAL MOVEMENT SKILLS

MACKINTOSH, K.A.1, HILL, P.J.1, PFEIFFER, K.A.2, DUNCAN, S.3, MCNARRY, M.A.1

1.SWANSEA UNIVERSITY; 2.MICHIGAN STATE UNIVERSITY; 3.AUCKLAND UNIVERSITY OF TECHNOLOGY

INTRODUCTION: The association between physical inactivity and many non-communicable diseases is now well established. Physical activity is a complex and multi-dimensional behaviour, with proficiency in fundamental movement skills (FMS) recognised as a key correlate of increased physical activity levels, as well as being positively associated with further health outcomes. In children and adolescents, the associated energy expenditure (EE) of performing discrete tasks has been shown to be influenced by biological and developmental characteristics. The present study aimed to identify the

influence of FMS proficiency, along with age, sex, and biological maturation, on the associated EE of FMS in children and adolescents.

METHODS: 27 youth (14 girls: 12.0 ± 2.2 years; 13 boys: 12.2 ± 2.4 years) participated in the study. Using the Test of Gross Motor Development - version 3 (TGMD-3), five FMS (overhand throw, kick, two-handed strike, hop and slide) were assessed independently in a randomised order for six bouts of 30 seconds, separated by 15 seconds recovery. Associated EE was measured using indirect calorimetry and predicted maturity offset was recorded as estimated years from peak height velocity. Separate linear mixed models were performed, with the associated oxygen uptake (VO2) in absolute (l·min−1) and allometrically scaled (VO2ALLOM) terms as the outcome variables.

RESULTS: Boys were found to have a higher VO2 (l·min−1; β = .66; p=≤0.01) and VO2ALLOM (β = 13.1; p=0.03) across all skills performed. A significant sex*maturity interaction was found in boys (β = .23; p=≤0.01) for VO2. For VO2ALLOM, a significant interaction was observed between skill competence and skill type in the kick (β = 4.68; p=0.01), hop (β = 7.86; p=≤0.01) and slide (β = 10.24; p=0.01). Similarly, for VO2 (l·min−1), a significant interaction was observed between skill competence in the kick (β = .10; p=0.02) and hop (β = .17; p=≤0.01).

CONCLUSION: The approach taken to measuring the absolute and allometrically scaled EE associated with FMS has further extended understanding of the related energy costs of these movements. The present findings showed skill competence to be a significant factor for the EE associated with FMS, and further highlights the potential health-enhancing benefits associated with achieving proficiency in FMS. The findings not only highlight the inter-individual variance that exists when performing these skills but also contributes to extending knowledge on the respective EE associated with those activities most commonly participated in during childhood and adolescence. From an intervention perspective, these findings reinforce the contribution of FMS towards both direct (i.e. associated EE) and indirect (i.e. physical activity, weight status, health-related fitness) health-enhancing benefits.

AGE-RELATED CHANGES AND TRACKING OF CARDIORESPIRATORY FITNESS FROM CHILDHOOD TO LATE ADOLESCENCE

INGVARSDOTTIR, T.H., ROGNVALDSDOTTIR, V., ARNARDOTTIR, N.Y., STEFANSDOTTIR, R., JOHANNSSON, E.
UNIVERSITY OF ICELAND

INTRODUCTION: Cardiorespiratory fitness (CRF) is an important indicator of health in childhood and adolescence and is believed to have both short- and long-term effects on various health-related factors [1,2]. Longitudinal studies on age-related changes in CRF during this period are scarce. The aim of this study was to assess age-related changes and tracking of absolute (L/min) and relative (mL/kg/min) VO2max from childhood to late adolescence.

METHODS: Participants were Icelandic children born in 1999 measured at the age of 7 (n=190), 9 (n=163), 15 (n=239) and 17 (n=201). CRF was assessed with maximal cycle ergometer test and expressed as absolute (L/min) and relative (mL/kg/min) VO2max. International standards were used to classify participants with healthy CRF (relative VO2max ≥42 mL/kg/min for boys and ≥35 mL/kg/min for girls) [3]. Linear mixed-effects models were used to study age-related changes in CRF and tracking was assessed with Pearson correlation coefficients and odds ratios.

RESULTS: Boys had higher absolute and relative VO2max than girls at all time points (p<0.001). Absolute VO2max increased by 0.11 (95% CI: 0.11 to 0.12) L/min per year for girls and 0.21 (95% CI: 0.20 to 0.22) L/min per year for boys, while relative VO2max decreased by -0.8 (95% CI: -0.9 to -0.7) mL/kg/min and -0.2 (95% CI: -0.4 to -0.1) mL/kg/min per year for girls and boys, respectively. Proportion of participants with healthy CRF changed from 88.7% and 79.8% at age 7 to 50.0% and 51.8% at age 17 for girls and boys, respectively. Pearson correlation coefficients for CRF at different ages ranged from 0.36 (age 7 to 17, p<0.001) to 0.91 (age 15 to 17, p<0.001). Those who had healthy CRF at the age of 7, 9 and 15 were 2.1 (95% CI: 0.6 to 8.7), 2.4 (95% CI: 0.8 to 8.6), and 23.6 (95% CI: 8.5 to 84.8) times more likely to still have healthy CRF at the age of 17, respectively.

CONCLUSION: Absolute CRF increases while relative CRF decreases for both girls and boys from age 7 to 17. Girls have lower CRF than boys and present higher decline of relative CRF than boys from childhood to late adolescence. Tracking of CRF is high in late adolescence, indicating that interventions that aim to increase CRF should be implemented before adolescence.

CHANGES IN PHYSICAL ACTIVITY, BODY COMPOSITION AND CARDIORESPIRATORY FITNESS FROM 15 TO 17 YEARS OLD

RÖGNVALDSDÓTTIR, V.

UNIVERSITY OF ICELAND

INTRODUCTION: Decreased levels of physical activity (PA) challenge health outcomes among European adolescents as levels of moderate to vigorous PA declines [1]. Participation in regular PA has been linked to higher cardiorespiratory fitness (CF) and more favorable body composition [2]. The aim of the study was to assess changes in PA, sports participation, body composition and CF in adolescents from age 15 to17.

METHODS: PA was measured over one week with wrist actigraphy in 154 adolescents (98 girls), with data from two time points, 2015 and follow up in 2017. From questionnaire, sports participation and general PA were assessed. CF was measured with a maximal cycle ergometer test and calculated as VO2max ml/kg/min. Body composition was assessed with dual-energy X-ray absorptiometry (DXA) scan.

RESULTS: PA was significantly lower all days (16.7%), on school days (20.9%) and non-school days (8.6%) between age 15 to17 years ($p<0.001$). Sports participation decreased from 69.1% to 50.3% between ages 15 and 17 and general PA, at least 4 hours/week, decreased from 74.3% to 64.7%. Between ages 15 to 17 body mass index (BMI) and lean mass index (LMI) increased significantly ($p<0.001$), trunk fat percentage increased significantly between the two years ($p=0.006$) and total body fat percentage increased significantly for girls ($p=0.006$) but not for boys. CF lowered significantly from 40.1±8.9 to 38.1±8.9 between the two years ($p<0.001$). PA was positively associated with CF at ages 15 and 17 $r=0.205$ ($p=0.015$) and $r=0.170$ ($p=0.044$). At both 15 and 17 years, lower BMI ($r=-0.543$, $r=-0.435$), body fat percentage ($r=-0.863$, $r=-0.861$), trunk fat percentage ($r=-0.839$, $r=-0.839$), was associated with higher values of CF and LMI was positively associated with CF ($r=0.274$, $r=0.343$), all $p<0.001$.

CONCLUSION: Conclusion: Higher PA levels and sports participation are associated with more favorable body composition and higher CF. Recreational and formal sports participation may therefore serve as an important tool in increasing PA and overall fitness.

CP-SH03 Physical education teachers

EYE-TRACKING AND PROFESSIONAL VISION OF TEACHERS

WITT, J., SCHORER, J., LOFFING, F., RODEN, I.

UNIVERSITY OF OLDENBURG

While the importance of visual attention has been shown in coaches and athletes, PE teachers were hardly studied. This is surprising, because Physical education teachers constantly perceive teaching situations while deriving possible teaching actions or movement corrections in highly stressful and noisy surroundings. The aim of this systematic review is to identify quantitative perceptual research using eye-tracking on professional vision (PV; van Es & Sherin, 2002) in classroom contexts and to discuss existing studies in the context of possible applications to physical education.

Eight databases were systematically searched according to PRISMA using the term ("professional vision" OR "eye tracking") AND (education OR teach* OR classroom OR school). The initial results (n=2,141) were reduced to quantitative expertise-dependent eye-tracking studies of lessons or naturalistic instructional videos in student teachers and teachers through the application of systematic inclusion and exclusion criteria.

In addition to eight quantitative approaches, six studies with mixed-method designs were identified. In addition to existing incongruences regarding applied expertise criteria, the systematic review compares different analysis procedures of the gaze measures within the studies. The studies, mostly performed within STEM subjects and languages, show result-pattern with longer fixation sequences and more consistent gaze patterns among experts. This can also be deduced from coefficients reported in the studies, which show a more evenly distributed gaze behaviour for experts. PV is only discussed in a content-unspecific way for classroom management or the recognition of inattentive, off-task students, but not in a subject-specific way for the individual challenges and needs of physical education lessons.

The application of a mixed-method design using eye-tracking and post-hoc interviews could address this desideratum in order to use findings on gaze behaviour also for the training of "noticing" and "reasoning", especially for physical education teachers in training. Expertise studies with increased perceptual complexity of dynamic processes in physical education, together with qualitative approaches already performed in physical education, such as video-club work for learning teaching practices, could contribute to bridging to existing concepts of adaptive teaching competence. By doing so, the professionalisation processes of physical education teachers could be evaluated and further developed by using eye-tracking hand in hand with qualitative reflective practices.

TASK ANALYSIS SKILLS OF GERMAN PHYSICAL EDUCATION TEACHERS – WHAT INFLUENCES THE QUALITY OF TASK-RELATED JUDGEMENTS?

HENDRICKS, P.
TU DORTMUND UNIVERSITY

Introduction

Teachers should adapt the tasks in physical education (PE) to the prerequisites of the students in the sense of individual support. Therefore, they need to be able to assess the demands of each task (Rieu et al., 2020). The ability to choose tasks according to the individual needs of the students is an important aspect of PE-teachers' professional competence but has rarely been investigated. This study aims to answer the questions if teachers can assess motor and cognitive task demands in PE and what factors may influence the quality of their assessments.

Methods

Tasks were systematically developed and then assessed by experts (each n=6 of university professors, sports didactics PhDs, and PE subject leaders) in terms of their motor and cognitive demands. Based on this, eight pairs of tasks differing in the level of motor and cognitive demands were formed. Finally, in a pairwise comparison, PE-teachers (N=62) rated the respective higher cognitive and motor demand level of the tasks.

Results

The results show that PE-teachers are better at assessing cognitive (76,6% correct assessments) than motor demands (67,6% correct assessments). Furthermore, there is no correlation between the ability to assess cognitive and motor demands. These findings may indicate that the assessment is based on different abilities. The study also demonstrates that work experience has no influence on the quality of the assessments. The results and potential implications for teacher education will be discussed in consideration of the professional competence of PE-teachers.

THE USE OF GYMNASTIC RINGS IN PHYSICAL EDUCATION CLASSES: AN EMPIRICAL VIEW ON GERMAN HIGH SCHOOL TEACHERS

ROHLEDER, J., DAZY, A., VOGT, T.
GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: Gymnastic rings have ordinarily been installed in most school sport gymnasiums to serve as basic equipment. Concomitantly, gymnastic rings have been reported to decline in popularity not least due to a lack of teachers' expertise and material requirements (Badic et al., 2012). Thus, the present study aimed to examine today's scope of gymnastic rings' used by Physical Education (PE) teachers (i.e., German high schools). It was hypothesised that gymnastic rings are only used infrequently and that the frequency of usage is related with the teachers' self-assessment of expertise and the given infrastructural conditions.

METHODS: 250 PE teachers (age: 41.4±8.9 years; female: n=123, male: n=127) from North Rhine-Westphalia participated in a questionnaire-based cross-sectional study. With respect to gymnastic rings' usage, a preceding literature review disclosed frequency, expertise and infrastructure as variables to be defined by items and rating scale tasks. Following a three-stage pre-test phase obtaining content- and structure-related feedback of five trainee PE teachers, the revised questionnaire was applied within a 29-day data collection phase using SoSci Survey. After excluding eleven drop outs, data of all valid questionnaires was processed for descriptive analyses. In addition, X^2-tests were calculated using Cramer's V as effect size to estimate frequency distributions. Statistics were computed using IBM SPSS (28.0). The level of significance was set at $p<.05$.

RESULTS: Descriptive analyses revealed 90.4% of those surveyed to use gymnastic rings in their PE classes. Of these, 81.0% stated an infrequent to very infrequent usage. Of these again, 68.6% rated their expertise as competent and 63.7% appraised the usage as secure. The X^2-test showed a significant relation between the variables frequency and expertise ($p<.05$, $V=0.22$). Furthermore, 66.4% of those who stated an infrequent to very infrequent usage of gymnastic rings report good infrastructural conditions. The X^2-test showed no significant relation between the variable's frequency and infrastructure ($p>.05$).

DISCUSSION: The present study's main findings showed that the vast majority of teachers reported fundamental experience in using gymnastic rings; their infrequent usage, however, is in line with our initial hypothesis. Moreover, the hypothesised relations of the frequency of gymnastic rings' usage can only be confirmed for the self-assessed expertise, but not for the infrastructural conditions. Taking further termed inhibitory problems into account (i.e., organisational efforts, the students' physical conditions), future research is suggested to evaluate teaching strategies for intensifying students' movement time by the use of gymnastic rings.

EVALUATION OF THE STRESS LAB – A VIDEO-BASED TOOL FOR PROSPECTIVE PHYSICAL EDUCATION TEACHERS

HARTMANN, U., KLEINERT, J., PELS, F.

GERMAN SPORT UNIVERSITY COLOGNE

Introduction

Prospective physical education (PE) teachers often experience stress (1). In order to prepare PE students to deal with potentially stressful teaching situations, the stress lab was developed for PE teacher education programs. The aim of the present study was to find out whether PE students felt better prepared for stressful teaching situations after participating in the stress lab.

Methods

The study was conducted with 100 PE students who were allocated to one of two groups: One group took part in the whole stress lab consisting of two parts, an e-learning unit to impart knowledge about stress and coping, and a practical unit to practice dealing with potentially stressful situations based on real-live videos (ELPU group, n = 47). The other group took part exclusively in the practical unit (PU group, n = 53). Students were asked before (t0) and after (t1) participation how prepared they feel for stressful teaching situations using an adaptation of a German questionnaire assessing stressful PE situations (ABIS, (2); e.g. pupils' discipline problems). Data were analyzed using 2x2 ANOVAs (time x group).

Results

Results showed a significant increase for both groups of feeling prepared for pupils' discipline problems ($F(1, 69) = 5.84$, $p = .018$), inadequate facilities and equipment (facilities) ($F(1, 69) = 6.75$, $p = .011$), physical strain ($F(1, 69) = 5.87$, $p = .018$), noise ($F(1, 69) = 19.87$, $p < .001$) and pupils' heterogeneity ($F(1, 69) = 12.49$, $p < .001$). No effect of group was found. A significant interaction was found for facilities ($F(1, 69) = 10.24$, $p = .002$), problems with colleagues ($F(1, 69) = 6.82$, $p = .011$) and noise ($F(1, 69) = 6.22$, $p = .015$). In these items, the ELPU group showed higher values compared to the PU group.

Discussion

Results showed that PE students felt better prepared for a variety of stressful teaching situations after participating in the stress lab. This suggests that practicing coping strategies make PE students feel being able to handle stressful teaching situations. Moreover, the interaction effects showed that the benefit was particularly for the ELPU group. The reason could be that the ELPU group received information on stressful teaching situations and coping strategies by additionally participating in the e-learning unit. It can be concluded that PE students benefit from both parts and therefore both should be integrated into the education of PE teachers.

EXPERIENCES OF TEACHER-FACILITATORS OF PROFESSIONAL LEARNING IN SCHOOL PHYSICAL EDUCATION

YOMODA, K.

NAGOYA GAKUEN UNIVERSITY

Background: Physical education (PE) is generally taught by classroom teachers in primary schools. Improving the quality of PE depends upon professional development of teachers. Effective professional development is assumed to be based on the teachers' needs, embedded in their workplace, and taken place in collaboration with their colleagues. Therefore, the role of a teacher-facilitator who leads and supports teachers' professional development within the school is critical. However, there is little research on how classroom teachers are empowered to facilitate professional development for teaching PE. This study examined the experiences of primary school teachers who engaged in a district-based project for promoting PE and physical activity among pupils.

Methods: Participants were four primary school teachers in separate schools who engaged in the project as teacher-facilitators and three researchers as external facilitators. Data were collected through interviews with the teacher-facilitators and from the reflective journals maintained by the external facilitators over one year of observing meetings and visiting the schools. Qualitative data were analysed with a thematic analysis method.

Findings: The results were summarised in terms of challenges faced by the participants, their experiences as teacher-facilitators, and their perceptions of their involvement in the project. The teacher-facilitators realised that the difficulties in implementing the project plan at their schools included classroom teachers' burden of teaching all subjects, insufficient time, and their inadequate knowledge of teaching PE. Based on these issues, they developed basic instructional resources for teaching strategies and developing pupil's fundamental movement skills. However, instead of imposing them on other teachers, they provided the resources in appropriate opportunities that could be used immediately or demonstrated their use in practice through their own classes. They also contributed to be intermediaries when external facilitators provided lesson assistance in their schools. Through their involvement in the project, they realised and valued that they had improved their professional abilities by sharing their ideas and practices with external facilitators and teachers

from other schools. The development of instructional resources further enhanced their desire to share the outcomes with their colleagues.

Conclusions: Facilitator-teachers encountered some challenges in promoting PE in their schools. However, they were able to support their colleagues with careful consideration of the teachers' reality and function as intermediaries to collaborate with external facilitators within their schools. It is also important to empower teacher-facilitators- themselves to see the value in their own professional growth and enhance their willingness to share their achievements.

TEACHERS' EXPERTISE WITH DIAGNOSTICS IN PHYSICAL EDUCATION AND THEIR ATTITUDE TOWARDS THE USE OF MOTOR TESTS

FOKKEN, I., STAUB, I., VOGT, T.

GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION

Diagnostic competences are considered to be a core aspect of teachers' expertise [1]. In physical education (PE), teachers need to gather information about the students' motor skills in relation to the sports content being taught. Findings suggest that PE teachers often fail in adequately assessing their students' motor skills [2,3]. However, little is known about the extent to which teachers are prepared for their diagnostic tasks in their teachers' education (i.e., academic studies followed by traineeship). As part of our survey on the diagnostic approach of teachers in swimming lessons, we further investigated (1) teachers' experiences with diagnostics in PE during their teaching training and (2) their attitudes towards the use of formal motor tests.

METHODS

A two-step approach was used for data collection. Subsequent to qualitative interviews (n=10) with teachers from German primary and secondary schools (n=10), a quantitative online survey (n=551) was conducted reaching out to all PE teachers in North Rhine-Westphalia. The interviews were transcribed, double-coded and categorically analysed [4]. The statements for the online survey were derived from the teachers answers in the qualitative study. The teachers participating in the quantitative online survey were asked to comment on these statements using a five-point scale (i.e., 1 = strong disagreement to 5 = strong agreement).

RESULTS

(1) Many of the teachers gained little to no experience with diagnostics in PE during their teachers' education. 54.9% did not learn any diagnostics in PE during their academic studies. 62.1% of the teachers state no specific diagnostics for students' motor skills were taught in the traineeship either. (2) The teachers' attitudes towards the use of formal motor tests varied. 60.6% of the teachers believe motor tests to be helpful in determining the learning prerequisites in PE, whereas 40.1% consider the use of motor tests to be difficult from an organisational point of view. Overall, very few teachers (11.8%) regularly use formal diagnostics (e.g., motor tests) to determine the students' learning prerequisites.

CONCLUSION

Only few teachers can rely on knowledge from their academic studies or traineeship for their diagnostic work. This is despite the fact that diagnostic competence is considered to be of great importance [1]. Formal testing procedures, which are less prone to error than informal or semiformal approaches, are rejected by many teachers, mainly for organisational reasons. The preconditions of PE teachers for accurately assessing their students' learning prerequisites must therefore be considered unfavourable.

THE EFFECT OF STEAM PROGRAM ON JUMPING SKILL OF TEACHER TRAINING COURSE STUDENTS

ISHIZAWA, J.1, SASAKI, R.2

1SHIRAYURI UNIVERSITY, 2KEIO UNIVERSITY

INTRODUCTION: Human exercises are carried out based on physical mechanisms. Therefore, teachers need to understand the anatomical structure and tips of movement when they teach children movement skills. However, most students tend to be unable to imagine the relationship between the mechanisms of exercise which they learned in science and their own body movements. Thus, we thought STEAM (Science, Technology, Engineering, Arts, Mathematics) education, which includes making a model and doing experiments, will be useful to understand these movements. In our previous research we developed the STEAM learning program on Jumping in physical education for teacher training course students (Ishizawa et.al, 2022). This study aimed to analyze the effect of this program.

METHODS: Participants were the teacher training course students (N=9, third-year, female) who took "Jumping" program in the physical education teaching method class. The contents of the STEAM program were as follows: self- and peer-evaluation by observing jumping motions using video recording (Science, Technology), making a lower limb model using a paper cup and rubber bands to understand mechanism of jumping movements (Engineering, Arts), doing experiments

for long jump using a paper cup rocket to find the appropriate angle and strength for long jump (Science/Mathematics). After learning the movement mechanisms, they planned and practiced the activities including jump for children(4-8 years old) based on what they learned(STEAM). The students took the questionnaire about the Jumping movement itself and their confidence in teaching it, before and after the program, and wrote the final report as well. We compared the answers of the questionnaires and analyzed the reports.

RESULTS: According to the answers to the questionnaires, the students' knowledge of jumping skills and their confidence in teaching children were significantly higher than before. They noted in their final reports as follows, 1) It was easy for them to understand the jumping mechanisms, due to evaluating their movements observationally and making leg models. 2) They noticed the importance of children having various kinds of jumping movement experiences.

Discussion & CONCLUSION: There seems to be a good effect on the confidence of teaching jumping to children once they have learned the principles of movement and implemented the knowledge in the kids program. All of the students were not aware of STEAM education beforehand, however, this program helped them scientifically understand jumping. In addition, they noticed the need for cross-curricular learning and STEAM education. To conclude, it is suggested that the STEAM program on jumping skills is effective for teacher training course students.

PERCEIVED STRESS AND SOURCES OF STRESS IN PRIMARY SCHOOL PHYSICAL EDUCATION TEACHERS IN GERMANY

ZAMMIT, N., HARTMANN, U., KLEINERT, J., PELS, F.

PSYCHOLOGY

Introduction

Secondary school PE teachers, PE pre-service teachers and PE students in the German schooling system experience moderate levels of stress. The most frequent sources of stress encountered are inadequate facilities, the curriculum and the low social status of PE teachers [1]. However, to date, no data on perceived stress and the occupation-related sources of stress, as well as their relation is present for primary school PE teachers in Germany. The aim of this study was therefore to examine (1) perceived stress intensity, (2) the sources of stress, and (3) the association between perceived stress intensity and sources of stress in primary school PE teachers.

Method

Participants were 70 primary school PE teachers in Germany (59 females, 11 males, age: 44.25 ± 11.61 yrs). Perceived stress intensity in the past 4 weeks was measured using the Perceived Stress Questionnaire (response scale: 1 = rarely to 4 = frequently) [2]. PE-related sources of stress were measured using the German language questionnaire assessing occupational sources of stress in PE teachers (1 = never to 6 = regularly) [3]. Descriptive statistics were calculated for perceived stress intensity and sources of stress, and a linear regression analysis was used to investigate the statistical prediction of perceived stress intensity by the sources of stress.

Results

Primary school PE teachers reported moderate perceived stress intensity (2.29 ± .54). The most frequent sources of stress were noise (3.59 ± 1.25), heterogeneity of pupils (3.09 ± 1.5) and discipline problems of pupils (3.04 ± .85). The results of the whole regression model indicated a large goodness of fit ($R2 = .388$, $F(4.83) = 7.77$, $p < .001$). However, no source of stress significantly predicted perceived stress intensity.

Discussion

The perceived stress intensity found in primary school PE teachers was moderate, and comparable to, albeit slightly higher than those found in secondary school PE teachers [1]. The same applies to the frequency of sources of stress. The finding that none of the sources of stress measured were significantly associated with the perceived stress intensity may be due to the low number of participants included, and to the fact that the frequency of sources but not their appraisal was assessed. It may therefore be useful to further investigate the association between perceived stress intensity and sources of stress with a larger sample and a measure of appraisal.

BEYOND SPORT: THE EFFECTIVENESS OF TEACHING LIFE SKILLS TRANSFER THROUGH PHYSICAL EDUCATION CURRICULUM

PAN, Y.H., HUANG, C.H., ZHANG, Y.Y., LIN, C.P., HSU , W.T.

NATIONAL TAIWAN SPORT UNIVERSITY

Introduction: Adolescents with good life skills are able to adapt to social changes and face the challenges in life. According to previous research, students could develop life skills through school sport and physical education. However, there is

a lack of empirical studies in physical education regarding the life skills transfer to different life domains. It is worth to explore what kind of pedagogical model could improve life skills transfer through physical education lessons. The purpose of this study was to examine learning effects that teacher integrated teaching life skills transfer into different physical education curriculum. Method: This study adapted the research method of quasi-experimental design. All participants attended 32 weeks with 64 physical education lessons in a Taiwan middle school. A physical education teacher taught the experimental group and the control group, and the experimental group integrated teaching life skills transfer into sport education model (TLST-SE), and the control group integrated teaching life skills transfer into traditional teaching model (TLST-TT)". The particpants contained that the experimental group had two classes with a total of 59 students (Mage=14.74 ± 0.50 years) and the control group had two classes with a total of 49 students (Mage =14.41 ± 0.50 years). The " Youth Life Skills Transfer Scale for Physical Education (YLSTS-PE)" was used to measure students' learning effect. YLSTS-PE has 7 components, including teamwork, goal management, time management, emotional skills, interpersonal interaction, problem solving and reflection. Data analysis was carried out through dependent sample t-test and analysis of Covariance (ANCOVA). Results:1. The posttest scores of the TLST-SE (experimental group) and TLST-TT (control group) were both significantly higher than those of the pretest in all components of life skills transfer. 2. The posttest scores of the experimental group were higher than those of the control group in all components of life skills transfer, it meant that TLST-SE model had significantly higher learning effects than TLST-TT in life skills transfer. Conclusion: This study confirmed that integrated teaching life skills transfer into physical education curriculum, whether TLST-SE with team-based learning approach or TLST-TT with individual-based learning approach, both of them could reinforce students' life skills transfer in life domain. Moreover, team-based learning has higher learning effect of life skills transfer than those of traditional individual-based learning.

Plenary sessions

PS-PL01 Fifty shades of fatigue: which colour is the elephant in the room?

EXTREME EXERCISES AND CHRONIC DISEASES: THEY SHARE MORE THAN YOU THINK!

MILLET, G.

JEAN MONNET UNIVESITY

Running 170 km with 10,000 m of elevation is an extreme experience. And so is going through an intensive care unit (ICU) stay after Covid-19 or a cancer. In both cases, neuromuscular function is severely altered although the causes are totally different: central and peripheral fatigue and muscle damage in ultramarathon vs ICU acquired weakness/cachexia in pathological conditions. In both cases, sleep is affected although not similarly: acute total sleep deprivation vs chronic partial sleep deprivation. In both cases, individuals go through an unusual affective experience, although it is chosen by ultramarathon runners and not by patients. Nevertheless, none of these factors can explain by themselves the subjective fatigue experienced by both the athletes and the patients, nor the performance they can accomplish. By performance, we mean the speed in runners and the amount of daily exercise that a patient can do. In this lecture, we will show how neuromuscular fatigue/function can play a role in the perceived effort/fatigue that both ultramarathon runners and cancer/ICU/multiple sclerosis patients may experience throughout feedback and feedforward mechanisms.

In this context, the role of central fatigue deficit as well as the need to measure neuromuscular fatigue appropriately (Brownstein et al. 2022), i.e. using dynamic exercises involving large muscle mass and with no recovery thanks to an innovative ergometer (Doyle-Baker et al. 2018) will be discussed. Yet in both extreme athletes and patients, the neuromuscular function cannot fully explain the perceived effort or the chronic fatigue so that using a more holistic approach that consider sleep alterations, mental fatigue, emotions, pain, etc., is mandatory. Although initially developed to explain ultramarathon performance, we will discuss the relevance of applying the "flush model" (Millet 2011) to fatigued patients, i.e. we will show that perceived fatigue/effort is the most common outcome that determine strategy (pacing in runners vs energy conservation in patients) and eventually performance in both populations. The model also contains a security reserve that may be helpful during extreme exercise to not put athletes into danger but may be counterproductive and thus must be minimized in patients. In summary, applying the flush model to what happens in daily life of a fatigued patient may help to understand the multifactorial nature (i.e. physiological, biological, psychosocial, behavioural parameters) of her/his chronic fatigue. It may also help to avoid the patients to enter in the vicious circle of fatigue throughout a tailored exercise intervention, i.e. a training program that should address the involved components of fatigue, specific to each patient.

MANY NAMES, ONE MEANING: A BIBLICAL CONCEPT OF FATIGUE?

PATTYN, N.

ROYAL MILITARY ACADEMY/VRIJE UNIVERSITEIT BRUSSEL

The holistic approach described in Lecture 1, consider sleep alterations, mental fatigue, emotions, pain, etc., is also what drove the conceptualization of a new transactional model of fatigue (Pattyn et al., 2018), applicable to patients, athletes and extreme performers alike. This model identified three components that are essential to understand the occurrence of fatigue: the perception of effort; the propensity to exercise effort, which is the product of a decision-making process; and the motivation. As most of the human decision-making is beyond the reach of our consciousness, all three identified critical components are the result of a constant interaction between conscious and subconscious processes, the measure of which is, by definition, outside of the scope of human conscious experience.

This second lecture will illustrate this holistic approach with data from chronic patients, fundamental research in cognitive psychology, and performance in extreme environments. These different data-sets show the remaining "gaps" in the current fatigue narrative: how both the resource depletion and overload models fall short in explaining all the clinical and experimental findings; how neither functional brain imagery, nor metabolic measures, nor subjective ratings are able to coherently explain performance decrements along the performance continuum, from chronic patients to elite performers; and how one size does not fit all in terms of fatigue reference frameworks.

One of the reasons why fatigue researchers seem to keep hitting a brick wall in our attempts to uncover all the aspects of this protean phenomenon might be the methodological vagueness of the concept: fatigue can still mean a cause, a mechanism, or an outcome, depending on the research question, field of work or specialty of the researcher. Hence the necessity to promote multidisciplinary approaches, where a method of "converging indicators" might allow, if not to pinpoint the exact mechanisms, at least to rule out the less relevant ones.

Furthermore, we will illustrate how the currently available models in the literature may differ in a conceptual way regarding the mechanistic elucidation of the cause of fatigue, yet how there seems to be a growing rift between the current theoretical debates and the applied research field practice demands. Almost two decades after Abbiss and Laursen (2005), and now that mental fatigue seems to have convinced most researchers of its pre-eminence over peripheral or metabolic limitations, we will repeat the exercise of a critical comparison between the milestone models in the field, expanded with the more recent ones (e.g.Millet, 2011; Marcora, 2016; Pattyn et al., 2018).

Furthermore, we will summarize how the scientific evolutions in clinical research (e.g. Mairesse & Neu, 2016) or fundamental cognitive mechanisms (e.g. Van Cutsem et al., 2022) need to be considered, if we wish for exercise science to remain at the forefront of the fatigue research.

Invited symposia

IS-SH03 Safeguarding athletes in sport: The past, present and future

WHAT HAVE WE LEARNED SO FAR ABOUT SAFEGUARDING IN SPORT?

KERR, G.

UNIVERSITY OF TORONTO

Research into safeguarding in sport over the past 10 years has diverged enormously, partly based on the increase in media attention of athletes speaking out about the abuse received and the lack of infrastructure to help best safeguard athletes. Notable examples include Barry Bennell who sexually abused children within English football, the systematic verbal, emotional and sexual abuse within National Women's Soccer League, and the racial discrimination at Yorkshire County Cricket Club. While such examples appear extreme, cases of athletes being physically, psychologically, and sexually abused are exposed frequently. Nearly a third of athletes across all sports have indicated that they have been victim of abuse at some point in their career, which can cause drop out in sport, disordered eating, acute and chronic depression and anxiety, self-harm, and suicide.

Given the above, the aim of this session is to provide a brief historical review of the safeguarding in sport literature and highlight notable examples and the prevalence of abuse in sport. The session will provide definitions of the types of abuse athletes can experience, such as physical, psychological, sexual and neglect, with notable examples at an individual, interpersonal, and organisational level provided. Special emphasis will be given to at risk population groups, such as disabilities, children, and adolescents, and what facilitates abusive behaviours in these groups. Finally, the challenges of conducting research will be highlighted, emphasising the barriers that athletes may experience in speaking out about abuse in fear of reputational damage or via ignorance, silence, and collusion.

WHAT ARE WE DOING ABOUT SAFEGUARDING ATHLETES?

HURST, P., CHATZIEFSTATHIOU, D.

CANTERBURY CHRIST CHURCH UNIVERSITY

Research and attention related to safeguarding in sport is rapidly increasing, and there is now international and national recognition of the significant harassment and abuse athletes can experience in sport. There is also a greater understanding of when athletes are more at risk of receiving abuse, and the safeguarding measures that can be implemented to prevent, deter, and detect it. Centralised sport integrity bodies, organisation, and services, at both a international and national level are in place, which are specifically aimed at safeguarding athletes. These organisations are often devoted to targeting multiple forms of safeguarding issues, including competition manipulation, doping, discrimination, inequity, anti-social behaviour, and governance with the prevention and response to abuse in sport. Such organisations are global and span various sports and countries, including Sport Integrity Australia, the Athletics Integrity Unit, Japan Sport Council's Sport Integrity Unit, the International Hockey Federations' Integrity Unit, and the Equestrian Community Integrity Unit.

The aim of this session is to provide an overview of the organisations in place to target abuse and what they are doing to safeguard athletes. Emphasis will be given in highlighting the behaviours and cultures within sport organisations that are known to facilitate and encourage abuse, and what methods can be put into practice to prevent this from occurring. The session will provide examples of the policies sport organisations have adopted to prevent abuse in sport, how athletes themselves can foster a safe sport environment and the significant role sport science researchers and practitioners can do to help further engender a safeguarding culture that protects athletes' participation in sport.

WHAT STILL NEEDS TO BE ACHIEVED TO BEST SAFEGUARD ATHLETES IN SPORT?

RULOFS, B.

GERMAN SPORT UNIVERSITY COLOGNE

Although the protection of athletes and the absence of abuse are the overarching goals of safeguarding policies and organisations, there is a significant lack of research examining the effectiveness of safeguarding programmes. Similarly, research monitoring the implementation of child protection policies in sport organisations is scarce, while introducing athletes' protection to sport organisations usually evokes resistance. It is therefore central that strategies for developing athletes' protection in sports organisations can overcome resistance to change. To highlight this, we conducted a study on sport clubs in Germany, and applied the theoretical framework of organisational capacity to examine whether a sport organisation's organisational capacity influenced their activation towards child protection. While it is a wide-spread and often-used argument by sport managers that sports federations do not have sufficient financial resources to implement

child protection activities, this study confirms that financial factors are of secondary relevance, and that human resource capacity and structural capacity are more important.

To progress knowledge and understanding of the influence safeguarding programmes have on the prevalence of abuse in sport, and taking into consideration the issues mentioned above, the aim of this session is to address the following two questions. First, how can sports organisations be developed and implemented to reduce resistance to the adoption of athletes' protection measures and ensure a positive mindset for the protection of children and young people? Second, which specific structural and human resource capacities are relevant for the development of athletes' protection activities in sports organisations and how can they be generated?

Invited symposia

IS-AP04 Technology and Performance in Sports

IDENTIFYING THE ADVANTAGES AND LIMITATIONS OF SPORTS PERFORMANCE WHEN USING AUGMENTED REALITY

MADELEINE, P., EISENHARDT, D., KRISTIANSEN, M.V.

AALBORG UNIVERSITY

In all sports, sportsmen strive for the highest level of performance. The development of modern electronics and computer enable today to feed the sportsmen with metrics that inform about their current level of performance. Combining real environment with added sensory information using audio, tactile or visual feedback places the sportsmen in an augmented or extended reality. Such approaches are becoming used in both laboratory and real-life settings. In laboratory, goalkeepers can rehearse penalty sessions in virtual environment. Augmented reality has also entered real life as commercial products like running watches and swimming googles provide visual information about running or swimming style, effort level and progress. For such applications, data from e.g., accelerometer and inclinometer are fused to feed algorithms that benefit from large datasets by means of machine learning approaches.

This offers a vast number of possibilities that can affect the performance level positively. However, feeding the sportsmen with additional sensory information can also have negative effect especially if the added information increases the cognitive load or changes the focus of the sportsmen. In this talk Pascal will review recent development related to augmented reality describing both pros and cons of the approaches in sports.

The target audience covers experts in performance assessments as well as sport engineers developing applications providing feedback on performance level to athletes and sportsmen.

UNDERSTANDING THE PLAYER/RACKET INTERACTIONS BASED ON EMBEDDED ACCELEROMETERS DURING RACKET SPORTS PERFORMANCE

CHADEFAUX, D.

UNIVERSITÉ SORBONNE PARIS NORD

The equipment is crucial for sport performance. It determines the quality of the athletes' gesture, but also plays a key role in the mitigation of injury risks. Among other parameters, the equipment's vibrations and radiated sound are empirically used by athletes to assess the comfort and the quality of the performance. In racket sports, shock-induced vibrations are likely to be driven by various performance parameters as the racket properties, the grip-force, the segment's alignment, or the playing techniques (ball speed and spin).

However, no robust method has so far been developed, that can efficiently guide the athletes in choosing their equipment. The main limitation to develop such a method is our little knowledge concerning the effects of the equipments mechanical properties on the biomechanical aspects of sport performance. In this talk, Delphine will present some recent work aiming at understanding the links between rackets, i.e., tennis and padel properties and athletes' perception of the equipment quality.

The target audience is people interested in evaluating the quality of sports equipment based on vibration analysis to optimize it with regard to athletes perception, performance and injury risk.

THE WEARION PROJECT: USING REAL-TIME FEEDBACK FROM INSOLE TECHNOLOGY TO IMPROVE THE BIOMECHANICS OF RUNNING AND REDUCE INJURY RATES.

MEIJER, K.

MAASTRICHT UNIVERSITY

Real-time biofeedback from wearables may help to guide and optimize running training and contribute to enhance performance and potentially avoid injuries. Recent advances in insole sensing and app development have created the opportunity to provide feedback on key biomechanical outcomes related to

running technique. Key challenges to capitalize on these developments are optimization of system design for accurate biomechanical assessments, validation of outcome variables against ground truth data and rigorous evaluation of different feedback approaches.

The aims of the WEARION project were i) to redesign the insole sensors to optimize assessment of loading parameters, ii) to validate the sensor design via mechanical and human testing at the CAREN system, ii) develop new AI algorithms to provide real-time feedback on running technique and loading parameters and iv) to evaluate the optimized system in a 6-month lasting RCT in which the effect of two different feedback modes on injury rate in running was tested .

While there are numerous applications of real-time feedback provided by wearables to enhance performance, there are also several limitations and challenges that need to be overcome to ensure these methods are effective. This talk will discuss the lessons learned from the WEARION project and highlight

limitations and challenges in this emerging field of application.

The target audience includes individuals interested in using technology and in particular wearables to optimize running performance.

Oral presentations

OP-PN05 Physiology: Energy Metabolism

LOW ENERGY AVAILABILITY IN FEMALE ENDURANCE TRAINED ATHLETES IMPAIRS EXERCISE PERFORMANCE AND INCREASES OXIDATIVE STRESS IN IMMUNE CELLS

JEPPESEN, J.1, CALDWELL, H.2, LOSSIUS, L.1, ATTI, J.1, BANGSBO, J.1, HELLSTEN, Y.1

1DEPARTMENT OF NUTRITION, EXERCISE AND SPORTS, UNI OF COPENHAGEN, DENMARK, 2CENTRE FOR HEART, LUNG AND VASCULAR HEALTH, SCHOOL OF HEALTH AND EXERCISE SCIENCES, UNIVERSITY OF BRITISH COLUMBIA, CANADA

INTRODUCTION: Low energy availability (LEA), defined as an inadequate amount of dietary energy available to sustain physiological functions, is an established phenomenon that is prevalent among female endurance athletes. Some reports suggest negative effects of LEA however, there is a paucity of well-controlled studies investigating the physiological consequences of a period of LEA. This study aimed to determine the impact of 14 days of LEA, with a particular focus on exercise performance and immune function in female endurance athletes.

METHODS: Twelve female endurance athletes participated in a randomized blinded crossover study. The athletes were assigned to begin with either 14-days of an energy balanced (EB) diet (50 kcal/kg FFM/day) or LEA (22 kcal/kg/FFM/day) followed by 3 days of EB recovery (REC). The athletes maintained their training volume throughout the study. Exercise performance was assessed by a 20-min time trial (20TT) and time to exhaustion (TTE) at 110% of power output at VO2max. Before and after each diet period, blood samples were obtained at rest and immediately following the exercise performance tests, and used for isolation of peripheral blood mononuclear cells (PBMC). The PBMC were analyzed for mitochondrial respiration and emission of reactive oxygen species (ROS) by high-resolution respirometry (OROBOROS, Oxygraph-2k). Further characterization of PBMC and analysis of immune-related plasma proteomics are ongoing. A linear mixed model for repeated measurements was used to estimate within- and between-period effects of EB and LEA.

RESULTS: Energy intake was 47% lower ($P < 0.001$) during LEA compared to the EB period. The LEA period lowered whole-body weight by 2.7±0.6 kg ($P<0.01$). Performance (20TT and TTE) decreased by 7.7% (17±4W) ($P<0.01$) and 18% (23±8s) ($P < 0.05$) after the LEA period, respectively. In LEA, 20TT performance remained reduced by 6.7% (16±4W) ($P<0.01$) after REC. PBMC ROS emission in complex II ($P<0.01$) and I+II ($P<0.01$) was 99% and 89%, higher ($P<0.05$), respectively after LEA. The rate of mitochondrial respiration in PBMC was unaltered by LEA. Acute exercise performed after LEA caused a 33% smaller increase in white blood cell count ($P<0.05$). Systemic cortisol was increased ($P<0.01$) by 22% (147±71 nmol/L) after LEA. No differences were found after EB.

CONCLUSION: A brief period of LEA in female endurance athletes acutely impaired exercise performance and lasted for at least 3 days into recovery with EB. LEA also increased immune cell ROS emissions at rest, blunted the rise in immune cells after acute exercise, and increased resting plasma cortisol levels, indicating a stress response which may affect recovery and adaptations to exercise and potentially increase susceptibility to infections. Collectively, our data may indicate that LEA is detrimental to the health of female athletes.

Funding: The study was supported the Danish Ministry of Culture and Team Danmark.

LOW ISOMETRIC KNEE-EXTENSION FORCE AND SLOW FREE-LIVING SIT-TO-STAND TRANSITIONS PREDICT PHYSICAL FUNCTIONAL DECLINE AMONG OLDER ADULTS: 4-YEAR FOLLOW-UP STUDY.

LÖPPÖNEN, A.1,2, KARAVIRTA, L.1, FINNI, T.1, PALMBERG, L.1, PORTEGIJS, E.3, RANTANEN, T.1, DELECLUSE, C.2, VAN ROIE, E.2, RANTALAINEN, T.1

1 UNIVERSITY OF JYVÄSKYLÄ, FINLAND, 2 KU LEUVEN, BELGIUM, 3 UNIVERSITY OF GRONINGEN, NETHERLANDS

INTRODUCTION: Lower-extremity strength is an important factor in maintaining a high level of physical functioning among older adults (1, 2), but it is unclear how free-living strength-demanding activities predict a future decline in lower-extremity functioning. The aim of this study was to examine whether isometric knee-extension force and the number and intensity of free-living sit-to-stand (STS) transitions can predict a decline in lower-extremity functioning over a 4-year follow-up among community-dwelling older adults.

METHODS: Older adults (n=340, 60% women), aged either 75, 80 or 85 years at baseline, participated in a baseline and 4-year follow-up measurement. At baseline, maximal isometric knee-extension force was measured in a dynamometer and a thigh-worn tri-axial accelerometer was used to estimate the number and intensity (mean and maximal thigh angular velocity) of STS transitions in a free-living environment (continuous monitoring for 3-7 days). A decline in lower-extremity functioning was defined as at least a two-point drop in the Short Physical Performance Battery (SPPB) from baseline to follow-up. Logistic regression analysis was the main statistical method.

RESULTS: A total of 85 (25 %) of the participants (75 % women) experienced a decline in physical function over a 4-year follow-up. After adjusting for age, sex, baseline SPPB points and the number of diseases, higher knee extension force (OR = 0.64; 95% CI = 0.50-0.81, per 1 N/kg increase) and higher free-living maximal angular STS intensity (OR = 0.84; 95% CI = 0.73-0.97, per 10 deg/s increase) protect against a future decline in lower-extremity functioning. When comparing the odds ratios of the standardized values, isometric knee-extension force was a better protector against functional decline (OR = 0.53; 95% CI = 0.37-0.75) than free-living maximal angular velocity (OR = 0.70; 95% CI = 0.51-0.94). No significant interaction between force and STS performance was observed. The number of STS transitions and mean angular velocity were not significantly associated with functional decline.

CONCLUSION: Free-living STS performance can predict a future decline in lower-extremity functioning. Even though laboratory tests of muscle force appear a better predictor of future decline, the assessment of STS performance in a free-living environment would allow frequent remote assessments. This in turn allows detecting changes in performance in an early stage, so that preventive strategies can be initiated in time.

SHORT BOUTS OF WALKING UP STAIRS REQUIRE MORE METABOLIC POWER THAN LONGER ONES: PHYSIOLOGICAL AND MECHANICAL DETERMINANTS.

LUCIANO, F., RUGGIERO, L., MINETTI, A.E., PAVEI, G.

UNIVERSITY OF MILAN

INTRODUCTION: Breaking up sedentary time with brief walks improves health, but the energy demands of such activity are poorly understood. Previous studies showed that short walking bouts require proportionally more oxygen than longer ones (1) and have a lower efficiency, the ratio of mechanical to metabolic power (2). This discrepancy could be due to variable demands during walking, or fixed ones to start or end the bout. To clarify these mechanisms, studies with standardised mechanical powers and bout durations are needed. This study assessed the power and efficiency of short bouts of stair walking; such activity was chosen as it mainly requires positive mechanical power (Pmech) to move the body centre of mass, with minimal contribution from elastic storage, and negative or internal power.

METHODS: Based on sample size estimation, ten participants (5 F; 27±5 y; 69±15 kg) walked up on a Technogym Climb Excite escalator at Pmech of 1.3, 1.6 and 2.3 W/kg for 10, 30, 60, 90, and 240 second bouts in randomised order. Net oxygen uptake was measured by a Cosmed K5 metabograph and time-integrated during bout and recovery to give total oxygen consumption (VO2bout; mL/kg). Metabolic power (Pmet) and efficiency were calculated with two methods: i) VO2bout was divided by bout duration and multiplied by the energy equivalent of oxygen (EqO2; J/mL) at steady state (2), and efficiency was given by Pmech/Pmet. ii) Four more 240-second VO2 on-kinetics were collected at Pmech 2.3 W/kg, interpolated, averaged, and fitted with an exponential model: cardiodynamic oxygen transfer was calculated as in (3) and subtracted to VO2bout. The resulting oxygen volume was multiplied by a time varying EqO2 accounting for changes in energy substrates during bout (4), and the mechanical work to start walking was included in efficiency calculation (2).

RESULTS: At all Pmech, increasing bout duration decreased Pmet (mixed linear model, fixed effect [95%CI]: -1.9*10-2 [-2.6*10-2; -1.3*10-2]) and increased efficiency (2.4*10-4 [1.7*10-4; 3.0*10-4]). The differences in metabolic power were explained by the cardiodynamic oxygen transfer, the mechanical work to start walking, and changes in EqO2, leading to a duration-independent efficiency (9.8*10-5 [-5.8*10-6; 2.0*10-4]) of about 20%.

CONCLUSION: Short bouts of walking up stairs require more metabolic power than longer ones. This increase is partially apparent, due to the fixed amount of oxygen consumed during the cardiodynamic phase, while the rest is explained by the work to start walking and differences in EqO2 during the on- and off-VO2 transient. These results provide a framework for studying locomotion bioenergetics when a steady state is not achieved and shed light on the physiology of a common practice to promote physical activity.

STRESS FRACTURES, MENSTRUAL IRREGULARITIES AND LOW ENERGY AVAILABILITY IN ITALIAN ÉLITE TRACK AND FIELD ATHLETES

SPINELLO, G.1, GRIGOLETTO, D.1, MARCOLIN, G.1, CASALI, N.2, CEREA, S.1,2, GHISI, M.2, PAOLI, A.1, MORO, T.1

UNIVERSITY OF PADUA

INTRODUCTION: Élite athletes, due to the intense mental and physical demand, may experience injuries and hormonal dysfunction, including overuse injuries and menstrual disorders. Both these factors are influenced by Low Energy Availa-

bility (LEA), so this study aims to determine the relationship between menstrual irregularities, stress fractures and LEA in Italian élite track and field athletes.

METHODS: The study included 149 high level (national, European, world and Olympic) female track and field athletes specialized in sprints, jumps, hurdles, combined events, middle and long distance. They were asked to answer a questionnaire about stress fractures (SF), a questionnaire to identify presence of LEA (LEAF-Q) [1] and consequentially to be at higher risk of developing the Triad and 66 of them also filled a food diary.

RESULTS: The 50.3% of the total sample had at least one SF and the 45% of the total sample has or had menstrual irregularities. Specific disciplines have a significant impact on SF number (p=0.012), with middle- and long-distance runners resulting more exposed to SF (62.5% of them had at least one SF), even if sprinters and hurdlers had also high percentages of SF (respectively 50% and 43.2%). Athletes who had at least one SF had higher probability than not injured athletes of having menstrual irregularities ($\chi 2$=8.42 p=.015). It was found a significant negative correlation between age of menarche and lowest BMI (r=-.315 p=.008), a positive correlation between LEAF-Q scoring and age at menarche (r=.314 p=.001) and between number of SF and age of menarche (r=.37; p=<.001) and LEAF-Q scoring (r=.33; p=<.001). Analyzing the food diary of the athletes, by reference to ISSN exercise and sport recommendation guidelines[2], we observed that 27.7% was under the recommended amount of protein, the 12.1% was under the recommended amount of fats, the 84.8% was under the recommendation of carbohydrates and last the 84.8% of the athletes was considered under the estimated range of caloric needs (40-70kcal/kg/day).

CONCLUSION: The results of the present study underline that menstrual irregularities and bone stress injuries are common problems in élite athletes; early intervention and injury prevention can be achieved by implementing management strategies. Nutritional factors play also a significant role in the risk of developing SF and the Triad, moreover, it was unexpected that carbohydrates had the biggest impact on the falling to reach the recommended energy intake. These data underline that even among élite athletes is necessary more awareness of the importance of nutrition intervention to support trainings, performances and to avoid injuries.

WITHIN-DAY ENERGY BALANCE AND SYMPTOMS OF RELATIVE ENERGY DEFICIENCY IN SPORT (RED-S) IN RECREATIONAL FEMALE ATHLETES

MOORE, H.L., BOWDEN DAVIES, K.A., JOANISSE, S., MORSE, C.I., STEBBINGS, G.K.

MANCHESTER METROPOLITAN UNIVERSITY

INTRODUCTION: Relative Energy Deficiency in Sport (RED-S) is a syndrome whereby low energy availability (LEA) causes downregulation of physiological processes, resulting in health and performance consequences. Energy availability is normally calculated over 24-hrs, however this may conceal energy deficient periods in the day. Such periods of energy deficiency have been associated with menstrual and endocrine dysfunction in female athletes (1) however high training loads may influence this interaction. This was the first study to explore within-day energy balance (WDEB) in relation to various RED-S consequences in recreationally active women (4-6 hours per week moderate-vigorous physical activity). Furthermore, our understanding of RED-S within this population stems primarily from self-report questionnaires, thus our study extended this by combining questionnaire, lab, and field-based measures to assess LEA prevalence and RED-S symptoms in premenopausal, recreational female athletes.

METHODS: Seven-day food and training diaries alongside accelerometry and heart rate were used to estimate 24-hr energy availability and hourly WDEB. The largest within-day energy surplus and deficit, the number of hours spent in a surplus and deficit, and the maximum number of consecutive hours in each, were calculated daily and averaged across the 7-days. Body composition, quantitative ultrasound of bone, hematocrit, hemoglobin, total cholesterol, maximum voluntary contraction at the knee during flexion and extension, VO2peak and lactate profile were all assessed. Questionnaires assessed menstrual function, psychological, immunological, and gastrointestinal health, disordered eating, and injury history.

RESULTS: Of the 16 participants (age=27±6 yrs., height=1.67.0±0.05 m, mass=63.5±8.2 kg) only 12.5% had low energy availability (<30 kcal/kgFFM/day), yet 75% had subclinical energy availability (30-45 kcal/kgFFM/day) typically associated with weight loss. Partial correlations accounting for energy availability showed menstrual health was negatively correlated with mean largest energy surplus (p=0.045). Body fat percentage was positively correlated with mean number of hours (p=0.003) and mean maximum consecutive hours (p=0.020), spent in an energy deficit. Relative muscle strength variables were positively correlated to within-day energy surplus variables (p=0.008-0.026). VO2peak and lactate threshold were negatively correlated with within-day energy deficit variables (p=0.001–0.022). Radius T- and Z-scores were positively correlated with absolute largest energy surplus (p=0.004 and p=0.010, respectively).

CONCLUSION: In conclusion, 24-hr LEA is not highly prevalent in recreationally active women, but WDEB may have health and performance implications that are overlooked when assessing LEA alone.

OP-BM04 Neuromuscular Physioloogy

RUNNING IN THE HEAT DOES NOT AFFECT OPERATING FASCICLE LENGTHS COMPARED TO TEMPERATE ENVIRONMENT

MORNAS, A., BROCHERIE, F., HOLLVILLE, E., DEROUCK, T., RACINAIS, S., GUILHEM, G.
FRENCH INSTITUTE OF SPORT

INTRODUCTION: Muscle mechanics is paramount in our understanding of motor performance. Growing literature demonstrated the decoupling of gastrocnemius medialis (GM) muscle fascicle and tendinous tissues during running, highlighting the crucial role of soft tissue dynamics during locomotion (1). GM operating fascicle lengths also demonstrated a leftward shift over their force-length relationship in response to an increase in running velocity from 10 to 16 km.h-1 (2). However, little is known regarding the sensitivity of fascicle dynamics and soft tissues stiffness to exercise duration and ambient temperature during running, which both have an impact on muscle temperature. This study aimed to determine GM fascicle and muscle-tendon unit dynamics in vivo during running in temperate and hot conditions. Given that lower-limb stiffness was shown to decrease after running a marathon in hot environment (3), it was hypothesized that soft tissue stiffness would be reduced when running in the heat, potentially decreasing fascicle operating lengths.

METHODS: Fifteen trained runners (8 males, 7 females, 26 ± 3 yr) were tested before (pre-), during and after (post-) a running task (40 min at 10 km.h-1) performed in temperate (TEMP: ~23°C) and hot (HOT: ~38°C) conditions. During running, fascicle dynamics was assessed using ultrafast ultrasound at 2 and 40 min. During pre- and post-testing, we assessed maximal voluntary contraction (MVC) force, passive muscle stiffness (i.e. shear modulus of the triceps surae) and active Achilles tendon stiffness. GM fascicle force-length relationship was built using electrically-evoked contractions and ultrafast ultrasound measurements before the running task.

RESULTS: Core, skin temperatures and heart rate increased from the beginning to the end of the exercise, and in a larger extent in HOT than TEMP ($P < 0.001$). The physiological stress elicited did not alter running mechanics over time and condition, with stride duration from 737 ± 31 to 745 ± 36 ms in TEMP and from 737 ± 32 to 748 ± 41 ms in HOT ($P \geq 0.291$) and elicited unchanged GM fascicle operating lengths over time (2 vs. 40 min; $P \geq 0.248$) and across conditions (TEMP vs. HOT; $P \geq 0.248$). MVC peak force tended to decrease after exercise (from 548 ± 116 to 505 ± 107 N in TEMP, from 565 ± 113 to 467 ± 109 N in HOT; $P = 0.060$), while soft tissue stiffness did not show neither time ($P \geq 0.281$), condition ($P \geq 0.256$) nor time × condition interaction ($P \geq 0.465$) effect.

CONCLUSION: The present findings show that a prolonged running exercise at moderate intensity (i.e. 40 min at 10 km.h-1) did not modify muscle-tendon unit properties and interplay, neither in temperate nor in hot environment. These findings may rule out potential detrimental effects of heat on muscle properties and strongly encourage further investigations on longer and more intense running exercise.

A 3D ULTRASOUND APPROACH TO ASSESS STATIC LENGTHS AND THE LENGTHENING BEHAVIOUR OF THE GASTROCNEMIUS MEDIALIS MUSCLE AND THE ACHILLES TENDON DURING WALKING IN VIVO – A VALIDITY AND RELIABILITY STUDY

HABERSACK, A.1,2, ZUSSNER, T.1, THALLER, S.1, TILP, M.1, SVEHLIK, M.2, KRUSE, A.1
1 UNIVERSITY OF GRAZ, GRAZ, AUSTRIA; 2 MEDICAL UNIVERSITY OF GRAZ, GRAZ, AUSTRIA

INTRODUCTION: Gaining information about adaptations in the lengths and lengthening behaviour of the gastrocnemius medialis (GM) muscle and Achilles tendon is important to develop efficient training strategies. However, assessing the tissues' lengths is difficult using 2D ultrasound (US) alone. Therefore, various US approaches exist (1–4), though those have several drawbacks (e.g., lying perfectly still is obligatory, only static measurements are possible, 2D simplification, etc.). Therefore, we developed a 3D ultrasound (3D US) approach for the assessment of the static lengths and dynamic lengthening behaviour of the GM muscle-tendon unit (MTU), muscle belly, and Achilles tendon during ankle dorsiflexion movement (5) and overground walking in vivo. The aim of this study was to evaluate the validity and reliability of the novel 3D US approach.

METHODS: Altogether 16 healthy participants were included in this study. For the evaluation, two US measurement sessions and one magnetic resonance imaging (MRI) assessment were performed. By combining 2D US, 3D motion capture, and vector algebra, the tissues' lengths were assessed in static condition, during passive ankle dorsiflexion movement, and throughout gait cycles. Validity and reliability were determined using Bland-Altman plots, coefficients of variation, standard errors of measurement (SEM), minimal detectable changes (MDC), and intraclass correlation coefficients (ICC).

RESULTS: The 3D US approach slightly underestimated the tissues' lengths in comparison to MRI by 0.7%, 1.5%, and 1.1% for the muscle belly, Achilles tendon, and MTU, respectively. The approach showed excellent reliability with small SEMs (≤

1.3 mm), MDCs (≤ 3.6 mm), and excellent ICCs (≥ 0.94) for assessments under dynamic conditions. Even better reliability was found for assessments of static lengths.

CONCLUSION: The proposed 3D ultrasound approach is valid and reliable to assess the static GM MTU, muscle belly, and Achilles tendon lengths and the tissues' lengthening behaviour during passive ankle dorsiflexion movement and gait. These findings support its potential as useful tool for investigations of the effects of training interventions or therapeutical treatments in the future.

COMPARISON OF THE EFFECTS OF LONG-LASTING STATIC STRETCHING AND STRENGTH TRAINING ON MAXIMAL STRENGTH, MUSCLE THICKNESS AND FLEXIBILITY IN THE PLANTAR FLEXORS

WARNEKE, K.1,3, HILLEBRECHT, M.2, BEHM, D.G.3, SCHIEMANN, S.1

<1> LEUPHANA UNIVERSITY LÜNEBURG, <2> CARL VON OSSIETZKY UNIVERSITY OLDENBURG, <3> MEMORIAL UNIVERSITY OF NEWFOUNDLAND

INTRODUCTION: Maximal strength measured via maximal voluntary contraction is known as a key factor in competitive sports performance as well as injury risk reduction and rehabilitation. Maximal strength and hypertrophy are commonly trained for by performing strength training programs. However, literature shows that long-term, long-lasting static stretching interventions can also produce significant improvements in maximal voluntary contraction. The aim of this study is to compare increases in maximal voluntary contraction, muscle thickness and flexibility after 6 weeks of stretch training and a conventional strength training intervention.

METHODS: Sixty-nine (69) active participants (f=30, m=39; age: 27.4±4.4 years, height: 175.8±2.1 cm, and weight: 79.5±5.9 kg) were divided into three groups: IG1 stretched the plantar flexors continuously for one hour per day, IG2 performed a strength training for the plantar flexors commonly used to achieve hypertrophy (5x12 reps, three days per week), while CG did not undergo any intervention. Maximal voluntary contraction, muscle thickness, pennation angle and flexibility were the dependent variables. A 2x2 ANOVA with a Scheffé test as post-hoc test was used for data analysis.

RESULTS: The results show significant increases in the intervention groups compared to the control group with significant interaction effects ($p<0.05$) for maximal voluntary contraction ($\eta^2=0.143$-0.572, $p<0.006$), muscle thickness ($\eta^2=0.11$-0.228, $p<0.021$), pennation angle ($\eta^2=0.006$-0.163, $p=0.006$-0163) and flexibility ($\eta^2=0.089$-0.426, $p<0.046$) for both the stretch and strength training group without significant differences ($p=0.37$-0.98, $d=0.03$-0.4) between both intervention groups.

CONCLUSION: It can be hypothesized that mechanical tension plays a crucial role in improving maximal voluntary contraction and muscle thickness irrespective of whether long-lasting stretching or strength training is used. Results show that for the calf muscle the use of long-lasting stretching interventions can be deemed an alternative to conventional strength training if the aim is to increase maximal voluntary contraction, muscle thickness and flexibility. Therefore, since mechanical tension via stretching could be performed without active joint movements, practical applications can be seen especially in the rehabilitation after serious injury and/or surgery leading to prologned times of immobilization, without the possibility to perform a commonly used strength training routine.

KNOWING OR NOT KNOWING - EFFECTS OF A SUSTAINED MVC ON PERFORMANCE FATIGABILITY OF THE CONTRALATERAL HOMOLOGOUS HAND MUSCLE.

MAFFEI, L., DREIJER, N., ZIJDEWIND, I.

UNIVERSITY MEDICAL CENTER GRONINGEN

INTRODUCTION: Human performance during exercise is limited by performance fatigability (1). Several studies have investigated cross-over effects of fatigue on non-exercised muscles (non-local muscle fatigue; NLMF). Although physiological mechanisms of NLMF have been extensively studied, little information is available on psychological effects on NLMF (2,3). Hence, in the present study we investigate the effect of prior knowledge of a task on NLMF.

METHODS: Twenty subjects (13 females; mean age 25 ± 3 years old) participated in three sessions, separated by 1 week. Custom-made force transducers measured the index finger abduction force of both hands. Electrodes were placed on the left and right ulnar nerve to evoke superimposed twitches and doublet forces at rest. Visits started with assessing maximal voluntary contractions (MVC), followed by a sustained MVC (2 min) with either the left or right hand (randomized) including 7 superimposed stimulations of the ulnar nerve. After the sustained MVC, doublets were evoked at rest. The first visit served to induce subjects to think that they had to perform a single sustained MVC. However, during the second visit they were ordered to perform a second sustained MVC with the contralateral hand directly after the first sustained contraction. During the third visit, the protocol was the same as the second, but subjects were aware that they had to perform 2 consecutive sustained MVCs. A mixed effect model in which subjects were treated as a random factor was used to analyze the data.

RESULTS: The mean force during the first and last 6 seconds of the sustained MVCs showed that the force was significantly lower in the second sustained MVC (initial 6s: 89.5±0.9 vs. 83.9±0.9 %MVC; p<0.001, last 6s: 30.7±1.3 vs. 28.2±1.1 %MVC; p=0.029). Additionally, the mean voluntary activation was lower in the second sustained MVC (90.3 ±7.1 vs 86.3±8.1 %; p=0.004), but no differences were observed in the post-doublet force (41.5±2.0 vs. 40.4±1.4 %, p=0.46). We found no differences in the force across the second and third visit (initial 6s: 86.1±0.94 vs. 87.3±1.1 %MVC, p=0.30; last 6s: 29.3±1.3 vs. 29.6±1.1 %MVC, p=0.78), mean voluntary activation (89.3±1.4 vs. 87.3±1.4 %. p=0.17) or post-doublet force (40.1±2.0 vs 41.8±1.4 %, p=0.22). No effect of hand-dominance or sex were found on any of the parameters.

CONCLUSION: The additional force decline in the first and last 6 s of the second sustained MVCs provides further evidence of the presence of NLMF. This decline was mainly due to reduced voluntary muscle activation. In contrast to our expectation, we found that prior knowledge of the task did not increase NLMF. Thus, although subjects knew that they had to perform a second sustained MVC they did not use pacing strategies to reduce their force decline.

ONE-WEEK QUERCETIN INTERVENTION ALTERS THE MOTOR UNIT ACTIVITIES IN YOUNG ADULTS.

NISHIKAWA, T.1,2, HIRONO, T.1, TAKEDA, R.1, OKUDAIRA, M.1, OHYA, T.2, WATANABE, K.1

CHUKYO UNIVERSITY - TOYOTA CAMPUS: CHUKYO DAIGAKU - TOYOTA CAMPUS

INTRODUCTION: Ergogenic aids, such as caffeine, can improve physical performance. Quercetin, found in onions, has effects similar to caffeine and improved endurance performance [1]. Quercetin and caffeine affect the neuromuscular system by promoting neurotransmitter release. A high dosage of quercetin glycosides modulates motor unit firing patterns [2]. Investigating the impact of chronic low-dose quercetin ingestion on the neuromuscular system is important for quercetins potential use as an ergogenic aid. This study aims to investigate the impact of a one-week low dosage of quercetin on motor unit and muscle properties, hypothesizing a decrease in recruitment threshold and an increase in neuromuscular efficiency.

METHODS: Twenty young adults were randomly assigned to either quercetin (QUE) or placebo (PLA) groups, in a double-blind study. They performed knee extensor muscle measurements before (PRE) and after (POST) 7 days of either 200mg quercetin or placebo ingestion. The measurements included maximum voluntary torque (MVT), motor unit recruitment threshold (RT) and torque normalized by motor unit firing rate (NFR) by high-density surface electromyography, and force-frequency relationship (FFR) by electrically elicited contraction by skeletal muscle electrical stimulation at 10, 20, 40, and 80 Hz. The sample size was ascertained through a statistical power analysis, which was based on the stated assumptions of an effect magnitude of 0.40, a significance level of 0.05, and a desired power of 0.80, extrapolated from the previous study and taking into account the probability of dropout. Statistical methods were selected based on Shapiro-Wilk test: parametric (t-test) for normal data and nonparametric test (Wilcoxon/Mann-Whitney) for non-normal data.

RESULTS: There was no difference in MVT with intervention in both conditions. From PRE to POST, QUE significantly decreased the RT (29.1±9.1 to 27.1±9.5 %MVT) and increased the NFR (1.06±0.18 to 1.10±0.18 %MVT/pps), whereas PLA remained unchanged (29.8±10.4 to 28.9±9.7 %MVT; 1.06±0.20 to 1.07±0.18 %MVT/pps). Compared to PLA, QUE significantly decreased the RT (QUE: -8.5±14.0 %; PLA: -1.9±10.5 %) and significantly increased the NFR (QUE: 6.2±13.7 %; PLA: 1.9±10.0 %). FFR was unaffected by the intervention in both conditions.

CONCLUSION: The present study indicated that a one-week quercetin intervention in young adults decreases the RT of motor units and increases the NFR. The intervention did not alter muscle contractile properties. These findings imply that the ingestion of quercetin influences the central nervous system, but not the peripheral. The changes in motor unit recruitment patterns and neuromuscular efficiency induced by quercetin ingestion may contribute to the potential mechanisms behind the enhancement of endurance exercise performance.

EXERCISE TOLERANCE IN PATIENTS WITH FRIEDREICH'S ATAXIA

VUKAJ, X., NERI, M., FICHERA, M., NANETTI, L., MARCHINI, G., PORCELLI, S., MARIOTTI, C., MARZORATI, M.

NATIONAL RESEARCH COUNCIL, MILAN, ITALY

INTRODUCTION: Friedreich's ataxia (FA) is a rare inherited neurodegenerative disease caused by decreased expression of frataxin, a protein involved in many cellular metabolic processes, including mitochondrial oxidative phosphorylation [1]. In many of these patients, a reduced exercise tolerance and the associated easy fatigability significantly affects quality of life.

Our objective was to assess peak exercise capacity in adults with FA as compared to age-matched healthy controls using the classic open circuit method. Moreover, skeletal muscle fractional O2 extraction was evaluated by near infra-red spectroscopy (NIRS), a non-invasive tool able to detect mitochondrial dysfunction in clinical populations [2,3].

METHODS: Sixteen FA patients, aged 26±8 years, and sixteen healthy subjects (CTRL), aged 26±3 were included. All patients were able to walk without support, and had a mean total score at the Scale for Assessment and Rating of Ataxia (SARA) of 16±1 points [4]. Each participant performed an incremental exercise on a recumbent cycle ergometer up to voluntary exhaustion. Breath-by-breath pulmonary O2 uptake (V'O2), heart rate (HR), and rate of self-perceived exertion (RPE), using the validated Borg's Scale [5] were determined. Concentration changes of deoxygenated hemoglobin and myoglobin (Δ[deoxy(Hb+Mb)]) from resting values, determined by NIRS positioned on vastus lateralis, were considered an index of O2 extraction.

RESULTS: FA patients attained significant lower peak workload and V'O2peak values (57±33 W and 19.2±5.8 ml*kg-1*min-1, respectively) compared to CTRL (194±64 W and 34.3±9.4 ml*kg-1*min-1, respectively; both $p<0.001$). A significant ($p=0.013$) negative correlation was observed between SARA score and V'O2peak. Peak HR was 150±20 b*min1, corresponding to 77±11% of the age-predicted maximum value in FA, suggesting that some of FA patients did not attain maximal effort. By contrast, peak HR was 182±10 b*min1 corresponding to 94±4% in CTRL. RPE was similar between FA (16±3.2) and CTRL (18±1.5; $p=0.063$). Peak Δ[deoxy(Hb+Mb)] was lower in FA (27.8±11.2%) compared to CTRL (56.0±24.9%; $p<0.001$).

CONCLUSION: FA patients showed a reduced exercise tolerance compared to healthy controls, at least partially attributable to impairment in fractional oxygen extraction at skeletal muscle level. A significant negative correlation was observed between SARA score and V'O2peak. However, it should be considered that severe limb coordination deficits in FA disease prevented the optimal execution of the incremental test on the recumbent cycle ergometer up to the maximum effort, thus limiting the interpretation of the results and reducing the applicability of this test as a tool to assess exercise tolerance in FA.

EFFECTS OF PLYOMETRIC EXERCISES WITH BLOOD FLOW RESTRICTION ON POSTACTIVATION PERFORMANCE ENHANCEMENT IN MALE BASKETBALL PLAYERS

HSIN, F.Y.1, CHEN, H.H.1, SANG, M.S.1, FANG, C.C.1,2, ONG, Y.Y.1, CHAN, K.H.1

INTRODUCTION: Plyometric exercises (PLY) have been used as conditioning activity to enhance subsequent performance by eliciting postactivation potentiation (PAP), which is called postactivation performance enhancement (PAPE). Studies also indicated that exercises combined with blood flow restriction (BFR) may increase the PAP response. Therefore, the aim of this study was to examine the effects of warm-up exercise by PLY with BFR (PLY-BFR) on jumping and sprinting performance as well as changes in blood lactate (LA) and creatine kinase (CK) levels as indicators of exercise intensity. We hypothesized that PLY with BFR would have better performance enhancement than PLY or BFR only, and the intensity of this exercise is similar to the others.

METHODS: Fourteen male basketball players (19.57 ± 1.55 yrs, 184.57 ± 10.26 cm, and 82.86 ± 12.27 kg) were recruited into the study. A crossover and counterbalanced manner was used to investigate the PAPE after warm-up by PLY, BFR, and PLY-BFR. The PLY consisted of 40 drops of ankle hops, hurdle hops and drop jumps. In BFR, the cuff pressure of 80% arterial occlusion pressure was applied to subjects' quadriceps of dominant leg. The venous blood samples were drawn before and 15 min after warm-up exercises to analysis the blood levels of LA and CK. Performance of countermovement jump (CMJ) and 14 m sprint were measured before and 5, 10, 15 min after warm-up exercises. A two-way ANOVA with repeated measures was used to compare differences among trials and time points. Statistical significance was set at $\alpha = .05$. All data are expressed as mean ± SD.

RESULTS: The CMJ heights at the 10-min time point in BFR trial was significantly higher than before exercises [40.21 ± 7.31 vs. 38.41 ± 5.87 cm, $p < .05$, effect size (ES) = 0.27]. Moreover, the CMJ heights at the 5-, 10- and 15-min time points in both PLY-BFR and PLY trials were significantly higher than before exercises (PLY-BFR: 39.55 ± 7.36, 40.66 ± 7.44 and 39.50 ± 6.95 vs. 37.71 ± 6.37 cm, respectively, $p < .05$, ES = 0.27, 0.43 and 0.27, respectively; PLY: 40.00 ± 7.98, 40.10 ± 7.82 and 39.77 ± 7.21 vs. 37.60 ± 6.72 cm, respectively, $p < .05$, ES = 0.33, 0.34 and 0.31, respectively). However, there were no significant difference among trials. No significant difference was observed in 14 m sprint among trials or time points. Furthermore, there were no significant changes in blood levels of LA or CK after 15 min of warm-up exercises among trials.

CONCLUSION: The results of present study indicate that the exercise intensity of plyometric exercises with blood flow restriction is similar to plyometric exercises or blood flow restriction only. Plyometric exercises with blood flow restriction could enhance subsequent jumping performance of male basketball players for 15 min, with a medium effect size after 10 min of rest. However, it had no effect on 14 m sprint.

A PRIOR HIGH-INTENSITY INTERVAL OR CONSTANT-LOAD WORKOUT DOES NOT ALTER CENTRAL AND PERIPHERAL FATIGUE RESPONSES AT TASK FAILURE

ZHANG, J., ANKLOVITCH, E., GRUNAU, M., MCCLEAN, Z., PASSFIELD, L., MACINNIS, M.J., ABOODARDA, S.J.
UNIVERSITY OF CALGARY

INTRODUCTION: Performance fatigability – an exercise-induced decline in central motor drive and/or muscle contractile properties (1) – is a key determinant of exercise performance. Numerous athletic and professional events require consecutive exercise tasks, the intensity of which can determine acute neuromuscular and perceptual consequences. Based on the 'critical threshold of peripheral fatigue' theory (2), the central nervous system should stop exercise to avoid surpassing a level of catastrophic muscle function impairment, yet it is unknown how this threshold is modulated by pre-inducing a fatiguing task, and whether the intensity of such prior task can affect this relationship. We hypothesized that following a fixed moderate-intensity (MOD) compared to high-intensity interval training (HIIT), more work will be performed in a subsequent time to task failure (TTF) trial , but measures of performance fatigability at the end of TTF will show the same results.

METHODS: Following a cycling ramp incremental test to determine peak power output (PO), 17 participants (8 females) completed 3 experimental sessions in randomized order whereby a TTF trial at 80% PPO was performed following HIIT, MOD, or rest (CTRL). HIIT consisted of 10×2-min work intervals at 80% peak PO separated by 2-min at 25% PPO, whereas MOD was set at a fixed-PO to match work and duration completed in HII. Isometric maximal voluntary contraction (MVC) force of the knee extensors, coupled with evoked superimposed and resting femoral nerve stimuli, was performed prior to exercise, after work-matched tasks, and post-TTF to measure voluntary activation (VA; central fatigue) and twitch force (Qtw; peripheral fatigue). Ratings of perceived exertion, dyspnea, and leg pain were also assessed at the same timepoints.

RESULTS: TTF duration and work performed were greater in CTRL (10±2min; 112±47kJ) than MOD (4±2min; 46±32kJ), which was greater than HIIT (2±1 min; 20±18kJ) ($P<0.05$). Immediately after the work-matched tasks, MVC force (HIIT: -26±10%, MOD: -15±7%; $P=0.005$) and Qtw (HIIT: -44±18%, MOD: -21±18%; $P<0.001$) declined more in HIIT. After the TTF trial, despite no changes for MVC, Qtw still remained lower in HIIT than MOD ($P=0.008$), with neither differing from CTRL. VA declined similarly for all conditions at work-matched and task failure. All perceptual responses were exacerbated following HIIT compared to the other conditions ($P<0.001$), but ended at similar levels after the TTF trial.

CONCLUSION: HIIT exacerbated neuromuscular and perceptual attributes of fatigability; however, these measures demonstrated similar responses after a TTF trial for all 3 conditions. This suggests that the central nervous system processes ensembled sensory feedback generated during exercise to ensure exercise cessation prior to reaching a critical level of peripheral fatigue that may become homeostatically catastrophic.

INFLUENCE OF INCREASED VALINE INTERMEDIATE 3-HYDROXYISOBUTYRIC ACID IN BRAIN TISSUES ON THE ENDURANCE EXERCISE ABILITY IN RATS

MIYAZAKI, T.1, EBINA, K.2, HONDA, A.1
1. TOKYO MEDICAL UNIVERSITY IBARAKI MEDICAL CENTER, 2. UNIVERSITY OF TSUKUBA

INTRODUCTION: Branched-chain amino acids (BCAAs) are catabolized for energy substrates in the skeletal muscles to fulfill high energy demands during endurance exercise. In the BCAA catabolic pathway, a small molecule 3-hydroxyisobutyric acid (3HIB) is produced in the mitochondria as an intermediate of valine, some of which is released from the skeletal muscle into the blood circulation, dependently on endurance exercise activity. Severe brain damage has been observed in the patients with 3-hydroxyisobutyric aciduria as an inherited deficiency of an 3HIB catabolic enzyme, 3-hydroxyisobutyryl-CoA dehydrogenase. So, we hypothesized that the 3HIB released from the skeletal muscle during the endurance exercise might be also transported into the brain, and have inhibitive effect roles on exercise performance. The present study evaluated the dynamics of 3HIB concentration in the brain during endurance exercise and the effect of the increase of 3HIB concentration in the brain on exercise performance.

METHODS: Wister male rats were divided into the Control and Injected groups; saline and 3HIB (60 mg/kg body weight) were intraperitoneally injected, respectively. After 15 min, the rats in both groups were loaded on a transit treadmill running at 20 m/min for 0 min, 120 min, or until exhaustion (n=7/condition). Thereafter, 3HIB concentration in serum, brain (cerebrum, cerebellum, and hippocampus), liver, and skeletal muscle (gastrocnemius) was measured by LC-MS/MS system.

RESULTS: In the Control group, 3HIB concentration in the brain tissues increased significantly in an exercise time-dependent manner, along with its significant increase in serum and skeletal muscle. In the Injected group, brain 3HIB concentration increased significantly after the 3HIB injection, and then, further increased depending on the exercise time. In serum, liver, and skeletal muscle, 3HIB concentration was also significantly increased by the injection, but no more increased by the exercise. Exercise time to exhaustion was significantly shorter in the Injected group than in the Control group, and the exhaustion was dependent on increased 3HIB concentrations in the brain, not in other tissues.

CONCLUSION: The exercised rats were exhausted when the 3HIB concentration in the brain tissues reached a higher certain level. Therefore, the present results suggest that 3HIB in the brain might induce central fatigue in endurance exercise.

URINARY EXCRETION OF ANABOLIC STEROID HORMONES DURING THE MENSTRUAL CYCLE IN TRACK AND FIELD ATHLETES

SIPPL, J., PLATEN, P.

RUHR UNIVERSITY BOCHUM

INTRODUCTION: The menstrual cycle (MC) is characterized by fluctuations of the sex steroids estrogen and progesterone. However, the cyclic fluctuations of anabolic steroid hormones such as testosterone and its metabolites, which are secreted from both ovaries and adrenal cortex, and the influence of hormonal oral contraception (OC) are largely unknown in elite female athletes. As the phases of MC might have influence on athletic performance and strength training adaptations (1), a deeper understanding of the secretion and metabolism of anabolic steroid hormones through the MC is needed. The aim of the present study was to investigate the urinary profiles of these hormones during the MC in elite athletes with and without OC (wOC/noOC).

METHODS: 22 elite track and field athletes participated in a longitudinal study of MC monitoring in sports. 10 athletes with normal MC (n=18 cycles) and 5 athletes with OC (n=10 cycles) (26±6 y, 172±5 cm, 68±7 kg) were included in the analysis. Intravaginal body temperature was measured daily for 24-h to detect ovulation. Further, athletes collected morning saliva and urine, and capillary EDTA blood prior to training every day or every second day. Urinary steroid hormones were analyzed by GC-MS/MS. Linear mixed models were used to compare Testosterone (T) and the sum of 5α-diol, 5β-diol, 5α-dion, 5β-dion, androsterone and etiocholanolone (SUM) during different phases of MC/noOC (4(7)-phases: menstruation, follicular phase (FP, mid and late), ovulation, and luteal phase (LP, early, mid and late)) and wOC (7-"phases": 28 days/ 7). The average of T and SUM was used for statistical comparison between noOC and wOC using Mann-Whitney-U test.

RESULTS: Neither T nor SUM showed any MC phase dependencies in the 4-phase model. In the 7-phase model, however, T and SUM were significantly higher during ovulation compared to mid LP (T: ovulation: 7.11±6.15 ng/ml; mid LP: 4.08±2.71 ng/ml; 95% CI [0.70 4.69], p=.048; SUM: ovulation: 4856±3049 ng/ml; mid LP: 3342±1858 ng/ml; 95% CI [391 2286], p=.034). Further, steroid hormone concentrations in wOC did not differ between the respective "phases". Mean T concentration was higher in noOC compared wOC (noOC: 4.84±3.71 ng/ml; wOC: 2.55±2.91 ng/ml; 95% CI [-2.67 -1.80], p<.001), while mean SUM did not differ between both groups.

CONCLUSION: In regular menstruating athletes urinary T concentrations and the sum of T-metabolites were about 45 % higher around ovulation compared to the mid luteal phase. This result and findings of higher serum T concentrations around ovulation support the rationale for a periodization of the training according to MC. Results between athletes without and with OC are contradictory concerning T and its metabolites. Hormonal changes in the MC were highly variable and require individual analysis and interpretation. This project was funded with research funds from the Federal Institute for Sports Science based on a decision by the German Bundestag.

THE INTRA- AND INTER-VARIABILITY OF MENSTRUAL CYCLES IN PROFESSIONAL FEMALE FOOTBALLERS; THE USE OF DAILY HORMONE MEASUREMENTS TO DETERMINE OVULATION.

ANDERSON, R., ROLLO, I., MARTIN, D., BURDEN, R., RANDELL. R.K., TWIST, C., GRAZETTE, N., MOSS, S.

UNIVERSITY OF CHESTER, GATORADE SPORT SCIENCE INSTITUTE, UNIVERSITY OF LINCOLN, ENGLISH INSTITUTE OF SPORT, LOUGHBOROUGH UNIVERSITY, LIVERPOOL JOHN MOORES UNIVERSITY, MANCHESTER CITY WOMEN'S FC.

INTRODUCTION: Menstrual cycle (MC) variability exists in the general population [1], but it's variability within athletic populations has not been reported. Advances in technology enabling a practical method of assessing daily reproductive hormone concentrations provide an avenue for such research. Accurate determination of ovulation is necessary to identify follicular (FP) and luteal phase (LP) lengths, which are pivotal to assess the impact of the MC on performance and health metrics [2]. Although a range of methods have been proposed to assess ovulation day and subsequent MC variability, agreement between methods remains unknown. Hence, the first aim of this study was to compare three methods of determining ovulation: (1) positive urinary luteinising hormone (LH) test, (2) sustained rise in progesterone above critical difference, and (3) countback regression equation (CRE). The second aim was to assess the variability in MC length, phase length, and concentrations of oestradiol and progesterone for each method.

METHODS: Eight professional female footballers provided morning saliva samples, daily, for three consecutive MCs; the start of each cycle was characterised by the onset of bleeding. Samples were analysed to measure oestradiol and progesterone concentrations. Each MC was separated into the FP and LP relative to the day of ovulation, using three different methods (as above). To make comparisons between the sub-phases, both the FP and LP were normalised to 14 d each

and split into early (first 4 d), mid (middle 6 d), and late (last 4 d). An ANOVA and Tukeys HSD post hoc was used to compare between methods and phases. The significance level was set at $p < 0.05$. All data are expressed as mean ± SD.

RESULTS: MC length (all cycles) ranged from 16-43 (29.3 ± 5.7) days; the intra-CV (16.3%) was greater than the inter-CV (11.4%). Ovulation determined using method 2 (17.4 ± 3.0 d) was significantly later ($p < 0.001$) than method 1 (13.3 ± 2.0) and 3 (14.1 ± 1.8), thus longer FP and short LP lengths were established when using method 2 ($p < 0.001$). Mean oestradiol and progesterone concentrations were significantly different between sub-phases ($p < 0.001$). For methods 1 and 3, progesterone was highest in the mid-LP. For method 2, progesterone was highest in the early-LP and mid-LP. For all methods, oestradiol was lowest in the early-FP and highest in the late-FP, early-LP, mid-LP, late-LP, and during ovulation.

CONCLUSION: Day of ovulation was later when determined using a sustained rise in salivary progesterone compared to both the positive urinary LH test and the CRE. Given the importance of identifying when ovulation occurs, the misalignment of methods observed here underlines the need for more research to establish the efficacy of current practice. Furthermore, intra and inter-variability in MC length, phase length, and concentrations of oestradiol and progesterone challenge the narrative for generic MC recommendations in elite sport.

EFFECTS OF TRAINING PERIODIZATION ON CONDITION CHANGES WITH MENSTRUAL CYCLE IN FEMALE ATHLETES

MOMMA, R., NAKAMURA, M.

JAPAN INSTITUTE OF SPORT SCIENCE

INTRODUCTION: Athletes are expected to perform at important competitions, but it has been reported that many athletes fall ill with the common cold before international competitions and other events. To avoid such a situation, it is important to evaluate the condition of athletes. One of these is the use of immune function evaluation indices. Athletes also train on a daily basis based on training periodization, which can be divided into two main periods: the preparation period and the competition period. In addition, it has been reported that the condition of female athletes changes with the menstrual cycle. However, the effect of training periodization on menstrual cycle-related condition fluctuations in female athletes has not been determined. The purpose of this study was to investigate the effects of training periodization on menstrual cycle-related changes in condition in female athletes using secretory Immunoglobulin A (SIgA).

METHODS: The subjects were 15 college female track and field athletes (jumper and thrower, age 20.0±1.1 years, height 162.6±5.2 cm, weight 55.9±6.5kg). The subjects were asked to collect saliva samples in a fasting state after waking up during the menstrual, follicular, and luteal phases of the competition period and preparatory period. From subject's saliva samples, saliva flow rates and SIgA concentrations were determined and SIgA secretion rates were calculated.

RESULTS: A two-way repeated ANOVA showed a significant difference in the interaction effect on salivary secretion rate ($F(2,28)=3.648$, $p=0.039$, partial $\eta 2=0.207$), and a simple main effect test showed that salivary secretion rate during the menstrual phase was significantly lower in competition period ($p=0.006$) and in the preparatory period were significantly lower in the follicular phase than luteal phase ($p=0.029$). SIgA concentrations did not show significant differences in menstrual phases or training periods ($F(2, 28)=2.144$, $p=0.136$, partial $\eta 2=0.133$). SIgA secretion rates showed a significant difference in the interaction effects ($F(2,28)=3.891$, $p=0.032$, partial $\eta 2=0.217$), and a simple main effect test showed that SIgA secretion rates in the preparatory period were significantly lower in the follicular phase than luteal phase ($p=0.013$).

CONCLUSION: In female athletes, training periodization was found to influence SIgA changes with the menstrual cycle.

HORMONAL FLUCTUATIONS IN WOMEN ARE ASSOCIATED WITH CHANGES IN NOCTURNAL HEART RATE AND HEART RATE VARIABILITY

IHALAINEN, J.K.1, AHOKAS, E.K.1, HANSTOCK, H.G.2, LÖFBERG, I.1, NYMAN, M.1, WENNING, P.1, KYRÖLÄINEN, H.1, MIKKONEN, R.S.

1> FACULTY OF SPORT AND HEALTH SCIENCES, UNIVERSITY OF JYVÄSKYLÄ, FINLAND 2> SWEDISH WINTER SPORTS RESEARCH CENTRE, DEPARTMENT OF HEALTH SCIENCES, MID SWEDEN UNIVERSITY, ÖSTERSUND, SWEDEN

INTRODUCTION: Heart rate variability (HRV) has become a widely used non-invasive tool for monitoring autonomic nervous system activity, which has been shown to reflect a person's recovery and training status (Schmalenberger et al. 2019). The aim of this study was to investigate the differences in nocturnal heart rate (HR) and HRV within a cycle in naturally menstruating women (NM) and women using combined hormonal contraceptives (CU) or progestin-only hormonal contraceptives (PU).

METHODS: Physically active participants were recruited into three groups: NM (n=19), CU (n=11), and PU (n=12). Participants' HR and HRV were monitored using the Bodyguard 2 HRV monitor (Firstbeat Technologies Ltd., Jyväskylä, Finland), and blood hormones were measured during one menstrual cycle (MC) (NM-group) or for 4 weeks (CU and PU-groups). Estradiol, progesterone, and luteinizing hormone were analyzed from fasting blood samples collected four times in the NM (M1 = bleeding, M2 = follicular phase, M3 = ovulation, and M4 = luteal phase) and PU groups (M1 = lowest E2; M2 = M1+7 days; M3 = M1+14 days; M4 = M1+21 days) and twice in the CU group (active and inactive pill phases). After each blood collection, nocturnal HR and HRV (as root mean square of successive differences between normal heartbeats,RMSSD) were recorded and examined as an average of two nights. The effects of the MC or HC phase on HR, HRV variables, and measured hormones were analyzed separately for each of the three groups using generalized estimating equations.

RESULTS: Hormone concentrations differed (p<0.05) between the MC phases in the NM- and PU-groups, but not between the active and inactive phases in the CU-group. In the NM-group, RMSSD values were higher during M2 compared to M3 (p=0.013) and M4 (p=0.009). HR was lowest in M2 and highest in M4. In the CU-group, RMSSD (p=0.014) was higher in M1 compared to M2. Furthermore, HR was lower during M1 compared to M2 (p=0.038) and M4 (p=0.020). In the NM-group, ΔE2 from M1 to M3 was negatively associated with RMSSD (B=-0.05, p<0.001) and positively associated with HR (B=0.01, p<0.001). In the NM-group, ΔP4 was positively associated only with HR (B=0.35, p<0.001). ΔE2 nor ΔP4 were not significantly associated with HC phases in the PU group.

CONCLUSION: In physically active women, the MC and hormonal phases of the cycle influence the autonomic nervous system, as reflected in measures of nocturnal HR and HRV. This study suggests that endogenous and exogenous hormones should be taken into account when assessing recovery data from women.

MATCH WORKLOAD IN FEMALE FOOTBALL PLAYERS VARY ACROSS MENSTRUAL CYCLE PHASES

ANTERO, J., CHASSARD, T., BLANQUET, L., DELAROCHELAMBERT, Q., TOUSSAINT, J.F.

INSEP

INTRODUCTION: Sex hormones variations seem to impact work load among female football players. Quantitative measures of load parameters across either the menstrual cycle (MC) or combined oral contraception (OC) phases are scarce. We aimed to quantify the players match load across their MC or OC phases of a French National club trough an entire season.

METHODS: 16 elite football players (23.7 ± 4.4 years) volunteered to take part in the study. We followed up their match load trough GPS data and their cycle phases (menstruation, mid and late follicular, early, mid and late luteal), based on a calendar method and an algorithm for phases estimation [1] for MC (n = 12) or according to the pills taking/pause in OC users (n = 4) through 24 games of the 2021-2022 season. For each load variable, a mixed model considering the group and individual players effect was performed to explain each variable according to the cycle's phases in MC or OC. We calculated the odds ratio on the fixed parameters of the models to identify an overall effect of the phases on each load variable.

RESULTS: Among MC players we found a significantly greater total match load, total distance, total acceleration and average velocity in the mid-cycle (mid and late follicular) in comparison with the begging and the end of the cycle (menstruation and late luteal) (p<0.05). The gap between the phases with the greatest and the lowest load ranged from (5 to 13%).

CONCLUSION: The workload among elite football players vary across menstrual cycle phases, displaying a cyclicity, where higher load values were found in the middle of their cycle, around the fertile period, and lower values in the premenstrual et menstrual phases. We have not identified any significant variation between the hormonal phases among OC users. These findings based on quantitative data of a collective sport suggest the interest of more studies investigating the effect of the menstrual cycle on female athletes' performance.

OP-AP30 Pacing and Performance

HOW DO WE LEARN TO PACE THE RACE? EXPLORING THE ROLE OF AGE AND COGNITION IN EFFORT REGULATION.

MENTING, S.G.P., KHUDAIR, M., ELFERINK-GEMSER, M.T., HETTINGA, F.J.

UNIVERSITY MEDICAL CENTER GRONINGEN

INTRODUCTION: The self-regulation of effort during exercise (i.e. pacing) is key in sports performance. However, younger athletes seem to struggle to effectively pace their efforts over the full length of an exercise task. Based on the framework proposed by Elferink-Gemser and Hettinga (2017), it was hypothesized this is due to the age-related development of (meta-) cognitive functions involved in pre-exercise planning, including an accurate estimation of the task duration.

METHODS: Groups of 18 adolescents (15.6±2.5 old, 9 female) and 26 adults (26.8±3.1 years, 13 female) performed a 4-km cycling time trial in a well-controlled laboratory environment. The assessment of task duration was calculated as the absolute percentage difference between estimated and actual finish time of the trial. Psychobiological elements of pacing were quantified by the mean power output (PO) per 500m, the rate of perceived exertion (RPE) per 1 km, and the percentage difference between the PO at 3500m and 4000m (i.e. 'end-spurt'). Analyses included between-group (ANOVA) and within-group comparisons (correlation) (p<0.05).

RESULTS: Adolescents were less accurate in their assessment of the task duration (44.4±28.4%), compared to adults (27.7±26.5%) (p<0.05). The adolescents' overestimation of task duration was accompanied by pacing behaviour conform

the expectation of a longer trial (i.e. a more even distribution of PO, lower RPE, larger end-spurt). Within the adolescent group, a higher accuracy in the estimation of the task duration correlated with age ($r = 0.48$, $p<0.05$) and a smaller end-spurt ($r = -0.45$, $p<0.05$).

CONCLUSION: The capability to accurately estimate an exercise task's duration seems to develop during adolescence, which leads younger individuals to struggle with distributing their efforts over the given exercise task. Practice sessions aimed at familiarising younger athletes with the demands of the set exercise task and the exploration of alternative pacing strategies could improve their exercise performance.

HOW ACCELERATIONS AND FORCES CHANGE WITH OF RUNNING SPEED AND TECHNIQUE? A PERSPECTIVE STUDY.

KROMBI, M., VALDES-TAMAYO, L., BOURGAIN, M., CHADEFAUX, D., PROVOT, T.

EPF

INTRODUCTION: The description of running is mainly made using force platforms which provide informations related to the contact phase [1]. Because these systems are restricted to an acquisition zone, the use of these tools makes difficult to study running in real conditions. Thus, many studies have turned to embedded accelerometers. However, the measurements are much more complex to interpret because of the sensitivity to the measurement point and the capacity of the sensors [2]. The objective of this work is to study if a comparison between force and accelerometer signals is possible during running and to understand how running condition (speed, technique and level) influence the signals.

METHODS: Five participants were recruited. Two were considered as elite runner (ER), and three as amateur runner (AR). The participants ran ten times on a straight line of 60m equipped with 6 force platform on the middle. All participants were equipped with a 3D accelerometer mounted on each tibia. Both systems were synchronized. Two speed were tested depending of the level of the participant (ER: V1=16 and V2=20km/h; AR: V1=10 and V2=14km/h) and participants were guided using marks on the track coupled with audio signals. The impact of running speed and technics were observed on the vertical ground reaction force (VGRF) and the longitudinal acceleration only for the stance phase. The stance phase for force and acceleration was extracted based on events observed on the VGRF signal [3]. Three indicators were computed for the VGRF: the passive peak (PP), the active peak (AP) and the loading rate (LR). Only the peak tibial acceleration (PTA) was computed for the acceleration. For each indicator, mean and standard deviation were computed for each group and each running speed.

RESULTS: For ER the results of the different indicators were AP:2.4±0.3BW; PP:1.5±0.2BW; LR:47.4±10.9BW/s and PTA:8.9±3.1g for V1 and AP:2.7±0.1BW; PP:1.8±0.3BW; LR:62.4±17.1BW/s and PTA:13.2±4.9g for V2. For AR the results were AP:3.2±0.1BW; PP:2.6±0.3BW; LR:79.4±13.4BW/s and PTA:15.9±0.4g for V1 and AP:3.4±0.1BW; PP:3.1±0.1BW; LR:105.7±30.9BW/s and PTA:21.8±3.5g for V2.

CONCLUSION: The values of PP, AP, LR and PTA change with increasing speed at all levels. This may suggest that there is a positive correlation between these indicators and speed [2,4]. The variability of PTA for ER between V1 and V2 seems to be explained by a change in stride technique for one runner from a forefoot to a rearfoot stride. A difference in all indicators was observed between the AR and ER groups. This difference can be explained by the difference in speed. However, while the AR seemed to have a rearfoot stride, it was observed that for ER, the running technique changed with speed. It could be hypothesized that elite runners modify their stride to adapt to the increased speed and demands of running. Future studies could consider a larger population to confirm the observations of this prestudy.

GREATER RELATIVE ANAEROBIC CONTRIBUTION TO 1500 M THAN 2000 M MAXIMAL ERGOMETER ROWING PERFORMANCE

ASTRIDGE, D., PEELING, P., GOODS, P., GIRARD, O., DENNIS, M., WATTS, S., BINNIE, M.

UNIVERSITY OF WESTERN AUSTRALIA

INTRODUCTION: World Rowing recently announced that the official Olympic racing distance for the 2028 Olympic Games will be shortened from 2000 m to 1500 m [1], which has implications for competition preparation and race performances. Previous studies have estimated that the anaerobic energetic contribution to 2000 m ergometer rowing performance ranged 12-30% [2]. The shorter event distance means that energetic contribution to performance may differ compared to the traditional distance, yet has never been quantified. Therefore, this study aimed to compare energetic contribution to 2000 m and 1500 m maximal ergometer rowing.

METHODS: On separate visits (>48 h apart, random order), eighteen trained junior (16.9 ± 0.5 y) male rowers (maximal oxygen uptake: 56.1 ± 5.0 mL/kg/min) completed three trials on a rowing ergometer: 1) 7x4 min graded exercise test to determine the relationship between power output and oxygen uptake; 2) a maximal 2000 m time trial (TT); 3) a maximal 1500 m TT. Respiratory gases were measured continuously by a metabolic cart. The power to rate of oxygen consumption relationship from the graded exercise test was used to determine the accumulated oxygen deficit or each TT. A repeated-measures ANOVA was used to detect differences, with effect sizes (ES) expressed as partial-eta squared, in mean power

output, anaerobic contribution, maximum heart rate, rate of perceived exertion, and post-effort blood lactate concentration between TTs.

RESULTS: Completion times were 6:51.3 ± 0:10.2 and 5:03.6 ± 0:08.0 min for 2000 m and 1500 m TTs, respectively. Mean power output was lower for 2000 m (324 ± 25 W) than 1500 m (341 ± 28 W) TT ($p<0.001$, ES=0.70). Anaerobic contribution was significantly greater for 1500 m than 2000 m TT (15.2 ± 4.7 vs. 9.8 ± 3.6%; $p<0.001$, ES=0.71). Compared to 1500 m TT, heart rate (190 ± 6 bpm vs. 192 ± 6 bpm; $p = 0.032$, ES = 0.24), rate of perceived exertion (18.7 ± 1.3 au vs. 19.3 ± 0.7 au; $p = 0.023$, ES = 0.27) and blood lactate concentration (10.7 ± 2.7 vs 12.9 ± 2.6 mmol/L; $p = 0.003$, ES = 0.41) were all significantly higher for 2000 m TT.

CONCLUSION: This study identified a significantly greater (+5.4%) relative anaerobic contribution to the maximal performance of a 1500 m ergometer TT, which coincided with a ~5% increase in mean power output and approximately 100 s decrease in performance time, compared to a 2000 m TT. In the lead up to the 2028 Olympic Games, these findings may provide evidence for a required change in how elite rowers prepare for optimal performance. Coaches and athletes should consider whether changes to their pacing strategies, technical set up (such as gearing), and training periodisation toward the adoption of more high-intensity training may aid performance in the shorter race distance where anaerobic contribution appears greater. Future research should investigate physiological differences between maximal on-water 1500m and 2000m rowing.

DOES SHOOTING PERFORMANCE INFLUENCE PACING STRATEGIES IN SPRINT AND INDIVIDUAL BIATHLON COMPETITION?

JONES, T.W.1,4, IHALAINEN, S.2,4, WANNER, J.3,4, MCGAWLEY, K.4

1NORTHUMBRIA UNIVERSITY,UK; 2 KIHU, FINLAND; 3INSEP, FRANCE; 4MID SWEDEN UNIVERSITY, SWEDEN

INTRODUCTION: The importance of effective pacing strategies within biathlon competition is well documented (1), as is the fact that shooting performance is a key determinant of competitive success (2). Despite pacing and shooting being important performance indicators within biathlon, the interaction between these two performance factors is yet to be investigated. As such, the purpose of the present study was to examine the influence of shooting performance on pacing within sprint and individual biathlon

METHODS: Eight female biathletes (age 27 ± 2 years, International Biathlon Union points 45 ± 18) competing at the 2019 IBU World Championships gave their written informed consent to participate in the study. Global navigation satellite system, shooting accuracy and range time data were collected during the sprint and individual competitions. Shooting bouts within each race and lap were classified as "accurate" or "inaccurate" and "fast" or "slow". For accuracy quartiles 1 and 2 = accurate, quartiles 3 and 4 = inaccurate (sprint <80% prone <80%, standing; individual prone <90%, standing <90%). For shooting speed quartiles 1 and 2 = fast, quartiles 3 and 4 = slow (sprint >24.6 s prone >23.3 s, standing; individual prone >29.3 s, standing >25.9 s). Data were analysed to examine pacing strategies and determine if skiing speed differed following accurate or inaccurate and fast or slow shooting bouts.

RESULTS: Terrain differed across the courses for both sprint and individual competitions ($p<0.001$). In both cases courses were primarily comprised of mixed terrain (~63%), with the remaining ~20%, ~15% and ~2% of the courses being comprised of downhill, incline and severe incline. Effects of terrain were observed for skiing speed (both $p<0.001$), with biathletes skiing fastest downhill and slowest across terrain classified as severe incline. Biathletes skied fastest in the first and final laps of both sprint and individual competitions (all $p<0.05$). No differences in shooting accuracy were observed between laps within sprint and individual competitions. Within the sprint competition biathletes took significantly longer ($p=0.034$) to complete all 5 shots in lap 1 than lap 2. Within the individual competition biathletes took significantly longer to complete all 5 shots in lap 3 than laps 2 ($p=0.041$) and 4 ($p<0.001$). Skiing speed was not different in either event following fast, slow, accurate or inaccurate shooting bouts.

CONCLUSION: Within this small sample of elite biathletes shooting performance did not impact on pacing strategies in sprint and individual competitions. This preliminary data indicates that pacing across laps and within races is independent of shooting performance. Future research should seek to examine this in a larger sample across differing competition formats.

Invited symposia

IS-MH02 Muscle plasticity in immobilisation and trauma and inflammation

NEUROPHYSIOLOGICAL ADAPTATION TO IMMOBILISATION

GAFFNEY, C.

LANCASTER UNIVERSITY

The loss of muscle strength during human volunteer immobilisation is far greater than the loss of muscle mass and the mechanistic basis of this common observation remains unresolved. This presentation will focus on the neurophysiological basis of immobilisation induced muscle functional decline, and novel insight of neuronal morphology changes in an

animal model during space flight. Focus will also be given to the efficacy of repeated bouts of transcranial magnetic stimulation at offsetting functional decline in human immobilisation. Dr Gaffney is a member of the ECSS reviewing panel with research interests in the impact of space flight and immobilisation on physiological homeostasis.

PLASTICITY OF THE MYOTENDINOUS JUNCTION AND MUSCLE IN INJURY AND RECOVERY

MACKEY, A.

UNIVERSITY OF COPENHAGEN AND BISPEBJERG HOSPITAL

The myotendinous junction is a common site for injury due to the high forces it can experience during exercise. However, understanding of its adaptation to force loading and recovery from injury is poor. This presentation will be delivered by an expert from the field of connective tissue and muscle adaptation to exercise in ageing and injury. The talk will demonstrate the heterogeneity of collagen type in the human myotendinous junction and adaptation in mRNAs, macrophage and satellite cells to exercise, injury and recovery. Dr Mackey is an ECSS Fellow and is highly respected in the areas of satellite cells, myotendinous junction, muscle injury, muscle hypertrophy and muscle ageing.

THE IMPACT OF IMMOBILISATION AND TRAUMA/INFLAMMATION ON THE REGULATION OF MUSCLE MASS AND INSULIN RESISTANCE

GREENHAFF, P.

UNIVERSITY OF NOTTINHAM

Loss of muscle mass and insulin sensitivity are common phenotypic traits of both immobilisation and trauma/inflammation. However, there is a lack of understanding of shared and/or divergent mechanisms responsible for these common physiological traits. This presentation will therefore focus on potential mechanisms responsible for the loss of muscle mass and insulin sensitivity during immobilisation, and whether the impacts of combined immobilisation and increased inflammatory burden are additive in situations such as surgical fixation of ankle fracture. Professor Greenhaff is an ECSS Fellow with research interests in muscle metabolism and physiology in exercise, inactivity, ageing and disease.

OP-PN21 Strength

ANODAL-TDCS IMPROVES SHORT-TERM STRENGTH TRAINING ADAPTATIONS OF THE KNEE EXTENSORS IN HEALTHY RECREATIONAL INDIVIDUALS.

ANGIUS, L., ANSDELL, P., ŠKARABOT, J., GOODALL, S., THOMAS, K., HOWATSON, G.

NORTHUMBRIA UNIVERSITY

INTRODUCTION: Transcranial direct current stimulation (tDCS) is a non-invasive neuromodulation technique capable of altering brain function in a controlled and temporary manner. The acute application of tDCS has been shown to induce ergogenic effect on endurance performance and maximal force production (Chinzara et al., 2022). Despite this, no studies have investigated the potential ergogenic effect of tDCS in addition to lower limb strength training and its neurophysiological adaptations (Angius et al., 2018). As the motor cortex (M1) excitability might be important for strength training adaptations, moderation of this by means of tDCS may provide changes in subsequent training adaptation (Hendy et al., 2015). Given the primary role of lower limbs for daily activity and several sports disciplines, this study aimed to investigate the effect of tDCS combined with lower limb strength training.

METHODS: A total of 24 healthy and recreationally active participants were recruited (mean ± SD age, 30 ± 7 years; stature, 172 ± 8 cm; mass, 72 ± 15 kg; 8 females, 16 males) and randomly allocated to perform either strength training with anodal tDCS (a-tDCS) or strength training with sham tDCS (SHAM) over a 3-week period. Participants completed 3 sets of 10 unilateral isometric knee extension contractions of the dominant limb of 5 s duration, at 75% of the daily maximal isometric voluntary contraction (MVC), three times per week. a-tDCS was applied over the contralateral M1 at 2 mA for 10 min prior to each training session. Outcome measures included: MVC, voluntary activation (VA) assessed by the interpolated twitch technique over the femoral nerve, cortical and spinal excitability, short-interval intracortical inhibition (SICI) and long-interval intracortical inhibition (LICI). a-tDCS adverse effects were evaluated via questionnaire during each training session.

RESULTS: All participants completed the study and none of them reported a-tDCS adverse effects during or after the completion of the training period. The period of training improved the MVC in both groups ($P < 0.001$), with a greater increase for a-tDCS compared to SHAM (6%, $P = 0.043$), which was accompanied by a greater increase in VA (2%, $P = 0.044$) and cortical excitability (9%, $P = 0.047$). No changes in spinal excitability, SICI and LICI were observed in either group (all $P \geq 0.186$).

CONCLUSION: The addition of anodal tDCS over the M1 prior to isometric strength training induced enhancements in maximal force production, motor cortex excitability, and voluntary activation compared to a sham treatment. These results might provide preliminary applications for athletes to facilitate training adaptations. However, further experiments are warranted to examine the long-term effects of anodal tDCS combined with strength training or sport-specific tasks in athletes.

ACUTE METABOLIC AND NEUROPHYSIOLOGICAL RESPONSES TO HIGH-INTENSITY FULL-SQUAT SESSIONS DIFFERING IN SET CONFIGURATION.

NINE, I.1, RIAL-VÁZQUEZ, J.1,2, FARIÑAS, J.1, RÚA-ALONSO, M.1,3, RIVERA-MEJÍA, S.L.1, REVUELTA, B.1, MÁRQUEZ, G.4, IGLESIAS-SOLER, E.1

1 PERFORMANCE AND HEALTH GROUP, UNIVERSITY OF A CORUNA 2 REY JUAN CARLOS UNIVERSITY 3 CIDESD 4 UNIVERSITY OF A CORUNA

INTRODUCTION: The manipulation of load parameters significantly affects acute responses to resistance exercise (1). Set configuration allows modifying the intensity of effort, by redistributing sets, repetitions and rest periods (2). Short set configuration reduces mechanical fatigue and the accumulation of metabolites (3). The aim of this study was to compare acute metabolic and neuromuscular responses to training sessions differing in set configuration.

METHODS: 10 healthy men were recruited. 4 different deep squat sessions were performed with equal volume (54 reps) and total rest (20min): 18 sets of 3 reps with 71 seconds between sets (3R), 9 sets of 6 reps with 150 seconds (6R) and 6 sets of 9 reps with 240 seconds (9R) with the 12RM load.

The oxygen uptake (VO2), carbon dioxide production (VCO2), respiratory exchange ratio (RER) and metabolic equivalent (MET) were recorded during the entire session and averaged at three moments: 30min before, during and 30min after exercise. Capillary blood lactate concentration (La) was collected before and 1min after exercise.

Voluntary activation (VA) was assessed before and after exercise by twitch interpolation technique. Subjects performed 2 maximal voluntary isometric contractions (MVC) of 3 seconds in leg extension machine with the right knee at 110º. During each MVC a high-frequency pulse was superimposed in femoral nerve. Then at rest, the same potentiated pulse (Db100p), a doublet low-frequency pulse (Db10p) and a single pulse were applied 2.5 seconds apart.

RESULTS: For VO2 main effect of moment, session and moment×session interaction was detected ($p<0.05$). Greater values of VO2 were observed in 3R compared with 6R and 9R ($p<0.05$). Similar values of VO2 were recorded in pre and post exercise for 3R and 9R but greater were registered in post compared with pre for 6R. Only a moment effect was detected for VCO2 ($p<0.001$) (exercise > pre and post).

Considering METs, greater values were recorded in 3R compared with 6R and 9R ($p>0.01$). METS were higher in post compared with pre only for 6R ($p=0.036$).

Regarding RER, similar baseline values were observed in all sessions ($p>0.05$). 6R and 9R showed higher values in post compared with pre exercise.

For La, lower values were registered in 3R compared with 6R ($p=0.001$) and 9R ($p<0.001$).

For markers of peripheral fatigue, the results in MVC, Db100p and Db10p showed lower values after the three protocols. Changes in VA were not detected.

CONCLUSION: Set configuration may modulate the metabolic response, with shorter sets promoting greater VO2 and METs consumption but lower La compared with longer sets.

Neuromuscular fatigue was similar among sessions due to the high load intensity and performed volume.

COMPARISON OF REPEATED BOUT PROTECTIVE EFFECT BETWEEN DIFFERENT ECCENTRIC CONTRACTION MODES

CUTTELL, S.A.1, BAROSS, A.W.1, COSTELLO, J.2, MACHADO, L.1, KAY, A.D.1

1. NORTHAMPTON UNIVERSITY 2. PORTSMOUTH UNIVERSITY

INTRODUCTION: Prior unaccustomed eccentric exercise can provide an adaptive protective effect commonly termed the repeated bout effect (RBE) [1], evidenced by the attenuation of the exercise-induced muscle damage symptoms in subsequent bouts of exercise [2]. As several eccentric exercise modes are frequently used in athletic settings and investigated in research, the purpose of this study was to compare the RBE of downhill running (DHR), drop jumps (DJ), and isokinetic eccentric contractions (ISOK) during maximal voluntary isometric contractions (MVIC) of the knee extensors.

METHODS: Thirty participants were stratified (using knee extensor torque) into three experimental groups (DHR [n = 10], ISOK [n = 10], DJ [n = 10]) with DHR performing a 30 min run at ~70%VO2max and 15% decline, ISOK performing 100 unilateral isokinetic eccentric contractions at 50% MVIC, and DJ performing 100 drop jumps from a height of 0.6 m (5 sets of 20 jumps with 1 min rest between sets). Maximum voluntary isometric knee extensor torque (N.m) was measured during MVIC tests before (Pre) and 24, 48, 72, 96 hr post-exercise [bout 1], with identical exercise and testing repeated a week

later [bout 2]. The index of protection (RBE) was calculated as the change in torque from Pre to 24 hr post-exercise in the first bout, minus the change in the second bout, divided by the change in the first bout, multiplied by 100 [3].

RESULTS: Compared to baseline, there was a significant ($P \leq 0.05$) reduction in knee extensor torque after bout 1 for DJ (24, 48, 72, 96 hr timepoints) and DHR (24hr) but no difference for ISOK. The greatest mean reductions in knee extensor torque occurred after bout 1 for all groups (DJ: $\Delta = 15\%$ at 48 hr; DHR: $\Delta = 8.1\%$ at 24 hr; ISOK $\Delta = 6.1\%$ at 24 hr). There was no significant reduction in knee extensor torque after bout 2 in any group ($\Delta = 0.9\%$ to 3.4%), with a significant difference between bout 1 and 2 percentage change at 24hr ($P \leq 0.01$). The index of protection was greatest for DJ (93%) followed by ISOK (69%) and DHR (62%) groups, but there were no significant differences between groups index of protection ($P \geq 0.05$).

CONCLUSION: This is the first study to compare these commonly used eccentric contraction modes to induce symptoms of muscle damage and assess the index of protection on maximal torque production. Whilst drop jumps reported the greatest mean index of protection, it was not significantly greater than other contraction modes. These data suggest that all contraction modes conferred similar levels of functional protection that may have implications for exercise prescription and injury risk during repeated performance over several days following intense exercise.

RELIABILITY OF INDIRECT ASSESSMENT METHODS OF RETICULOSPINAL TRACT FUNCTION IN HUMANS.

THOMAS, K., GOODALL, S., HOWATSON, G., ANSDELL, P., ŠKARABOT, J., ATKINSON, E.

NORTHUMBRIA UNIVERSITY

INTRODUCTION: The reticulospinal tract (RST) is an important descending pathway for the control of locomotion and generation of high forces. Preliminary evidence from non-human primates suggests the RST might adapt to resistance training (Glover & Baker, 2021), but this is yet to be demonstrated in humans because of the implausibility of measuring RST function directly. A range of methods that exploit the acoustic startle reflex have been shown to hold promise as indirect measures (Furubayashi et al., 2000; Baker & Perez, 2017) but their reliability has not been studied.

METHODS: Twenty-four volunteers (26±5 years) completed familiarisation, and two experimental visits separated by seven days. RST function was measured indirectly via the StartReact protocol (Baker & Perez, 2017), and evoked responses to electrical stimulation of the cervico-medullary junction (CMEP), and transcranial magnetic stimulation of the motor cortex (MEP) paired with conditioning startling auditory stimuli (Furubayashi et al., 2000). Conditioned responses were expressed relative to the unconditioned response. Visual (VRT), auditory (ART), and startle (SRT) reaction times were measured for StartReact. RST gain (the difference in VRT and SRT, with respect to the difference in VRT and ART), and the SRT-ART difference were derived as indices of RST function. Responses were recorded from the elbow flexors and extensors during a light (20% of maximum) isometric action. Paired-samples t-tests were used to assess systematic error. Typical error as a coefficient of variation (CV, %) and intra-class correlation coefficients (ICC) were calculated to assess random error and relative reliability, respectively. All analyses were performed using a published spreadsheet (Hopkins, 2001).

RESULTS: For elbow flexors, StartReact VRT, ART, and SRT showed good reliability (CV=8–10%, ICC=0.75-0.80). For elbow extensors, reaction times were faster on trial 2 for VRT (p=0.03) and ART (p=0.01). However, the reliability of elbow extensor reaction times was similar to flexors (CV=9–11%, ICC=0.75-0.83). Variables derived from reaction times as indices of RST function showed poor reliability for both flexors & extensors (CV=29-51%, ICC=0.28-0.67). CMEP and MEP responses in flexors were more reliable (CV=11 & 13%, ICC=0.64 & 0.66) than in extensors (CV=15 & 20%, ICC=0.72 & 0.00).

CONCLUSION: The StartReact protocol is a reliable measure in elbow flexors and extensors, but measurement in extensors requires multiple practice trials. The relatively high degree of random error observed in the conditioned, evoked responses is consistent with previous assessments of neurological function. The data presented here could be used to estimate appropriate sample sizes for intervention studies aimed at measuring changes in RST function.

INTRODUCTION: Introduction: The molecular transducers of benefits from different exercise modalities are unclear. Mitochondria have a main role in providing cellular energy and fulfill a key function in cellular calcium management. Exercise training is known to be the most powerful intervention to increase mitochondrial number, size, and density in a tissue such as skeletal muscle. Traditionally, it has been considered that cardiorespiratory training is appropriate for improving mitochondrial function, while resistance training programs are appropriate for inducing hypertrophy and increases in muscle strength. However, recent research suggests that both training modalities have an impact on mitochondrial respiration.

Objective: To study the mitochondrial adaptations in skeletal muscle and peripheral blood mononuclear cells (PBMCs) after a resistance training program, both in a cohort of young women and in a cohort of older women.

METHODS: Methods: 18 healthy young women and 6 old women followed a strength training program based on 2 exercises that stimulated the quadriceps muscles: leg press and leg extension. Both exercises were performed 2 times a week for a total of 6 weeks. The maximum strength was evaluated for each exercise (test of 1 repetition maximum, 1RM) at the beginning and at the end of the program. Moreover, they were assessed clinically including their body composition and muscle quality. A muscle biopsy of the vastus lateralis muscle of the thigh was performed using the TSK Acecut biopsy needle (11G x 75 mm, 22 mm Type) before and after the training period. Mitochondrial respiratory function of skeletal muscle was measured with high-resolution respirometry (Oroboros O2k-FluoRespirometer) from isolated mitochondria and permeabilised fibres. In addition, mitochondrial respiratory function was measured in PBMCs. Independent and paired t-tests were conducted to compare means between and within groups, before and after the intervention. A value of $p<0.05$ was considered statistically significant.

RESULTS: Results: Here we report that 6 weeks of resistance training significantly improved the muscle strength as assessed by both the leg press and leg extension 1RM tests. Moreover, the mitochondrial respiratory function measured in skeletal muscle and peripheral blood mononuclear cells showed an improvement after training in Complex I, Complex I+II, Complex II, Maximal respiration, and Complex IV.

CONCLUSION: Conclusions: We provide evidence showing that 6 weeks of resistance exercise training results in quantitative changes in skeletal muscle strength and mitochondrial respiration, both locally (skeletal muscle) and peripherally (PBMCs). Thus, resistance exercise training appears to be a means to augment the respiratory capacity and intrinsic function of skeletal muscle mitochondria, even in older people who basally have poor mitochondrial function.

RELATIONSHIPS BETWEEN LOWER BODY STRENGTH CHARACTERISTICS AND INITIAL ACCELERATION COORDINATION IN HIGHLY TRAINED TO WORLD CLASS SPRINTERS

DONALDSON, B., BEZODIS, N.E., BAYNE, H.

UNIVERSITY OF PRETORIA

INTRODUCTION: Inter- and intra-limb coordination has recently been described in initial sprint acceleration [1]. From a dynamical systems perspective, coordination patterns emerge from interacting individual, task and environmental constraints [2]. Lower body strength is a key individual constraint in sprinting and influences sprint performance, but the interactions between strength characteristics and movement patterns are not yet known. This study aimed to assess the relationship between lower body strength and initial acceleration coordination in sprinters.

METHODS: Twelve male sprinters (100 m PB: 9.95–11.17 s) performed 30 m sprints on an outdoor track during training. 3D kinematics for the first four steps were recorded using IMUs (250 Hz; Noraxon, USA). Participants then performed countermovement jump (CMJ), isometric squat (ISQ) and repeated hop tests using force plates (1000 Hz; Bertec, USA) and eccentric hamstring tests (NordBord, Vald, Australia). Thigh-thigh and shank-foot coordination were quantified for step 1 and steps 2-4 using a vector coding and binning approach [1]. Relationships between strength measures and the proportion of the step spent in each coordination bin in step 1 and steps 2-4 were assessed using Spearman's (rho) correlations.

RESULTS: ISQ relative maximal force was negatively associated with the proportion of anti-phase leading (-) (rho=-0.67, p=0.02) and positively with anti-phase trailing (+) (rho=0.82, p<0.01) thigh-thigh coordination in step 1, as well as a negative association with in-phase trailing (-) in steps 2-4 (rho=-0.67, p=0.02). ISQ force was negatively associated with in-phase foot (+) (rho=-0.70, p=0.02) and positively with in-phase foot (-) (rho=0.62, p=0.03) shank-foot coordination in steps 2-4. CMJ height was negatively associated with in-phase shank (-) coordination in step 1 (rho=-0.81, p<0.01). Hop test RSI was negatively associated with in-phase leading (-) (rho=-0.58, p=0.05) thigh-thigh coordination and positively associated with anti-phase shank (+) (rho=0.60, p=0.04) and in-phase shank (-) (rho=-0.59, p=0.04) shank-foot coordination in step 1.

CONCLUSION: These findings suggest sprinters with larger maximal strength capacities have more trail leg dominant limb interchange in step 1 and exhibit a pattern indicative of more synchronous "scissoring" of the thighs. Moreover, greater maximal strength was associated with shank-foot coordination patterns exhibiting less in-phase forward rotation in early flight and potentially greater reliance on "shin block" to orientate the shank before touchdown in steps 2-4. Finally,

the current results suggest larger reactive strength capacities may be associated with coordination showing a sequential reversal of foot then shank rotation during "shin block" to prepare for touchdown, as well as reduced shank dominance during simultaneous forward rotation around dorsiflexion. These are novel findings for further understanding acceleration technique.

INFLUENCE OF FOOTWEAR ON F-V PROFILE IN SPRINT ACCELERATION

FAGUNDES, A.O.1, RIBAS, L.R.1, SILVA, E.S.1, LA TORRE, A.2, VARGAS, G.D.1, KRUEL, L.F.M.1, MORIN, J.B.3, PEYRÉ-TARTARUGA, L.A.1

1 EXERCISE R. LAB., UNIV. FED. DO RIO G. DO SUL, POA, BRAZIL; 2 DEP. BIOMED. SC. FOR HEALTH, UNIV. DEGLI STUDI DI MILANO, ITALY; 3 UNIV LYON, UJM-SAINT-ETIENNE, INTER-UNIV. LAB.HUM. MOV. BIOL., FRANCE

INTRODUCTION: The first steps of sprint demand a high propulsive force, playing a key role in performance. The use of different shoes can directly influence the application and orientation of the force applied onto the ground at the foot. We aimed to compare the force-velocity profile during sprint acceleration between wearing sprint spike shoes versus wearing conventional (marathon) shoes.

METHODS: For this study, 24 national and regional level male trained sprinters with age 22.0 ± 3.8 years, stature 178.0 ± 5.9 cm, body mass 73.3 ± 6.7 kg and 100 m time of 11.06 ± 0.40 s were evaluated. Ethics approval was obtained from the Universidade Federal do Rio Grande do Sul (Protocol: 73415817.5.0000.5347). After a 30 min warm-up (10 min of running, stretching and 5 accelerations of 30 m), the sprinters performed four 30-m sprints at their maximum intensity with a 5-min interval between attempts, 2 of them using spike shoes and 2 with conventional shoes in a randomized order. For data collection, a smartphone (iPhone 7+) was positioned on a tripod in the sagittal plane at 10 m from the running track (15 m from the start) and 1 m high. All tests were filmed at a sampling frequency of 120 Hz and the split times were determined at 5, 10, 15, 20, 25 and 30 m using the MySprint app (Apple Inc., USA) for further analysis of the variables: 30 m time (t30m), maximum speed, maximum theoretical speed, maximum theoretical horizontal force, maximum power, peak ratio of force and its decrease, and force-velocity profile slope. We quantify the magnitude of the difference between the two conditions using Glass's delta (Δ) and the following classifications: null (< 0.1), very small (0.1 to 0.19), small (0.2 to 0.49), medium (0.5 to 0.79), large (0.8 to 1.19), very large (1.2 to 1.9), and huge (over 2.0).

RESULTS: The sprinters improved the t30m (Δ = -1.15, large) using spike shoes (4.20 ± 0.10 s) in comparison to conventional shoes (4.35 ± 0.13 s). Similarly, the sprinters improved the physical qualities using spike shoes compared to conventional shoes, resulting in an improvement in maximum velocity (Δ = -0.24; small) of 0.11 m/s and maximum theoretical velocity (Δ = -0.16; very small) of 0.08 m/s, as well as maximum horizontal force (Δ = -1.75; very large) and maximum power (Δ = -1.67; very large). The slope of the force-velocity profile (Δ = 0.80; large) increased from spike shoes to conventional shoes by about 13%. Also, using spike shoes improved mechanical effectiveness with a peak and decreasing rate in the force ratio of 11% (Δ = - 2; huge) and 8% (Δ = 1.14, large), respectively.

CONCLUSION: We can conclude that spike shoes significantly influence sprint performance and mechanical effectiveness. Theoretical force and maximal power are the physical quality variables most relevant to these changes.

HAMSTRING MUSCLE ELECTROMYOGRAPHIC ACTIVITY IN VARIOUS SPRINT DRILLS

PRINCE, C.1, EDOUARD, P.2, CHAPON, J.2, DANDRIEUX, P.E.2, SAMOZINO, P.1

1 UNIV SAVOIE MONT BLANC, INTER-UNIVERSITY LABORATORY OF HUMAN MOVEMENT BIOLOGY, CHAMBÉRY, FRANCE; 2 UJM-SAINT-ETIENNE, INTER-UNIVERSITY LABORATORY OF HUMAN MOVEMENT BIOLOGY, SAINT-ETIENNE, FRANCE

INTRODUCTION: During sprinting, and specifically the swing phase of the leg, hamstring muscles are exposed to high levels of muscle activity as the muscle-tendon unit (MTU) is lengthening and the musculotendinous force is peaking a. These considerable mechanical loads could explain the high prevalence of hamstring muscle injury (HMI) specifically in sprint-related sports. Before maximum sprinting, part of the warm-up is devoted to carrying out sprint drills aiming at loading hamstring muscles' specifically to sprint b. Sprint drills are divided into 4 main categories (A, B, C and D drills), targeting key phases of the gait cycle (Swing phase: (A) early pre-activation and (B) pre-activation, (C) stance phase, (D) swing phase: recovery) c and are assumed to provide a specific mechanical stimulus, notably high hamstring muscles activity. As part of a more global project studying mechanical loads on hamstring muscles, this study aimed to character-ise hamstring muscles' electromyographic (EMG) activity during sprint drills compared to sprint maximal activity.

METHODS: Sixteen athletes, competing in track and field performed A, B, C and D sprint drills and two 40-meter sprints. Hamstring muscles (biceps femoris and semi-tendinosis) electromyographic activity was recorded with EMG (Delsys©, 1000Hz) electrodes. Raw EMG signals were filtered, rectified, and expressed as a percentage of a maximal voluntary isometric contraction (%MVIC). Comparison in maximal EMG activity between sprint and athletic drills was tested with repeated ANOVA.

RESULTS: During maximal sprinting, hamstring muscles were maximally activated at 247.5% ±139%MVIC for biceps femoris and 206% ±100% MVIC for semi-tendinosis. Biceps femoris overall activity level for sprint drills ranged from an average of 132.4%-146.9%, relative to MVIC. Semi-tendinosis overall activity level for sprint drills ranged from an average of 144.8%-177.5%, relative to MVIC. Biceps femoris activity was significantly greater during sprints than during A-Skip ($p < .05$; Cohen's $d = 1.29$); B-Skip ($p < .05$; $d=1.29$); C-Bound ($p < .01$; $d =1.47$), and ABCD-Run ($p < .01$; $d= 1.42$). However, no significant differences were reported between sprints and drills for semi-tendinosis EMG activity.

CONCLUSION: This preliminary analysis revealed that the exercises performed by track and field athletes during warm-up elicit lower levels of biceps femoris electromyographic activity than those reported during maximal sprinting. Further analysis of hamstring muscle-tendon unit lengthening and lengthening velocity is currently underway to draw more definitive conclusions about hamstring mechanical loading reported during sprint drills and to know whether hamstring muscles are prepared enough for sprinting.

LEG JOINT KINETIC DETERMINANTS OF MAXIMAL SPEED SPRINT RUNNING

NAGAHARA, R.

NATIONAL INSTITUTE OF FITNESS AND SPORTS IN KANOYA

INTRODUCTION: High-speed sprinting is achieved by force production onto the ground, which is generated through joint moment produced by muscle contraction. Differences in leg joint kinetics during the support phase at multiple running speeds have been demonstrated (1,2). However, there is limited information regarding what leg kinetic aspects can be determinants of maximal speed sprint performance. For example, although Bezodis et al. (3) indicated, using four sprinters, that the ankle plantarflexion during the support phase and hip extension during the early support phase can be important for better maximal speed sprint performance, there has been no cross-sectional study investigating the relationship of sprint performance with leg joint kinetics during maximal speed sprinting with enough number of participants. The purpose of this study was to investigate leg joint kinetic determinants of maximal speed sprinting performance using waveform analysis.

METHODS: Thirty-one male sprinters (mean ± SD: age, 21.3 ± 3.9 years; stature, 1.73 ± 0.06 m; body mass, 67.1 ± 5.0 kg; personal best 100-m time, 11.22 ± 0.42 s) ran 60-m with maximal effort, during which ground reaction forces and running motion in the maximal speed phase were recorded using force platforms (1000 Hz) and motion capture system (250 Hz). Joint torque and power at the hip, knee and ankle during the support phase of two steps during the maximal speed phase were calculated using a standard inverse dynamics analysis for both legs. For joint torque and power at each joint, an average of two signals from two support leg were calculated. Mean running speed for two steps during the maximal speed phase was computed. Then, one-dimension statistical parametric mapping for correlation analysis was used to examine relationships of mean running speed with joint torque and power signals during the support phase.

RESULTS: The average running speed for two steps during the maximal speed phase was 9.51 ± 0.29 m/s. The statistical parametric mapping revealed that the average running speed was significantly correlated with ankle plantarflexion torque from 38% to 52% of the support phase ($P = 0.03$) and with ankle negative power (plantarflexion torque with dorsiflexion angular velocity) from 21% to 34% of the support phase ($P = 0.01$).

CONCLUSION: The current results show that ankle plantarflexion torque and power production capability during the middle and early support phases could be important for achieving high sprinting speed during the maximal speed phase.

MUSCLE ACTIVITY TIMING AND AMPLITUDE IN THE EARLY ACCELERATION PHASE OF CURVE SPRINTING

MILLOT, B.1,2, PRADON, D.3, DINU, D.1, BLACHE, P.1, CECCHELLI, G.1, ARNOULD, A.1, HEGYI, A.4, SLAWINSKI, J.1

FRENCH INSTITUTE OF SPORT - FRENCH ATHLETICS FEDERATION

INTRODUCTION: Surface electromyography (sEMG) helps understand the muscular origin of sprinting technique. It has been shown that maximal hip flexion and maximal hip extension angles are reached later at maximal velocity in the curve than in the straight (1). The hip flexors and extensors activation timings were shown to influence the step frequency at maximal velocity (2). Since the inside leg step frequency is reduced within the curve (1), this could result from delayed inside leg activation timings. The aim of the present experimentation was to investigate the onset of muscle activity and the sEMG amplitude of hip flexors and hip extensors over the early acceleration phase in straight-line and curve sprinting.

METHODS: 9 (6 male and 3 female) experienced-to-elite curve sprinters (mean ± SD: age = 22.8 ± 3.0 years; body mass = 70.8 ± 5.7 kg; height = 177.3 ± 6.6 cm) volunteered to participate in this study. After a 45-min self managed warm-up, the participants performed 10 and 40-m sprints within two sprinting conditions in a randomized order: straight-line and curve on a reconstructed lane 5 (radius = 41.58 m) of a standard athletics track.

sEMG (Delsys Inc., 2148 Hz) were positioned on the Rectus Femoris (RF) and Biceps Femoris long head (BF) of both left (L) and right (R) legs (3). After full-wave rectification and band-pass filtering (20-500 Hz), the onset timings (% of stance duration) of muscle activity were identified using Teager-Kaiser energy operator (TKEO) and Approximated Generalized Likelihood Ratio (AGLR) (4). Mean sEMG amplitudes were normalised to the maximal activity of the corresponding muscle detected over the straight-line 40-m sprints. Two-way RM ANOVAs were performed.

RESULTS: There were no significant effects for condition or side neither for the onsets of muscle activity of RF ($p > 0.283$) and BF ($p > 0.412$); nor for the sEMG amplitude of RF ($p > 0.718$) and BF ($p > 0.111$).

CONCLUSION: The early acceleration phase of curve sprinting on a reconstructed lane 5 did not result in alterations of neither the onset timings nor the magnitudes of hip flexors and hip extensors muscular activity in comparison to the straight-line. Yet, this analysis only focussed on the first steps of a sprint. As already suggested by Judson et al. (5) regarding the ground reaction forces; the effect of the bend on the muscular activity during the acceleration phase could accumulate with the increasing velocity. Therefore, investigations should aim to investigate whether differences in muscular activity between straight-line and curve sprinting can be found in the later stages of the acceleration phase.

OP-MH09 Sedentary behaviour

ONLINE CIRCUIT TRAINING INCREASES ADHERENCE TO PHYSICAL ACTIVITY GUIDELINES: A RANDOMIZED CONTROLLED TRIAL OF MEN LIVING WITH OBESITY

BOUCHARD, D.R., KERSHAVARZ, M., SÉNÉCHAL, M.

UNIVERSITY OF NEW BRUNSWICK

INTRODUCTION: To examine adherence to the weekly physical activity guidelines (150 minutes of aerobic activities at moderate-to-vigorous intensity or more and two session of strength training or more, and health outcomes during the COVID-19 pandemic for men living with obesity, 46 weeks after being offered an online muscle strengthening circuit program for 12 weeks.

METHODS: Sixty men (age ≥ 18 years) living with obesity (body fat % ≥ 25) were randomly assigned to the intervention group (N=30) or the control condition (N=30) for 12 weeks. The intervention group was offered an online CIRCUIT training, three sessions per week, while the control group received a website helping them to reach the physical activity guidelines. Adherence to the weekly physical activity guidelines was evaluated 46 weeks after enrolling in the program using a heart rate tracker (Fitbit Charge 3) and an exercise log. Health outcomes (e.g., anthropometrics, body composition) were measured at baseline and after 12, 24, and 46 weeks.

RESULTS: More participants in the intervention group adhered to the physical activity guidelines compared to the control group at 46 weeks (intervention 36.8% vs control 5.3%; p=0.02). However, the intervention group did not surpass the health outcomes changes observed in the control group after 12, 24, and 46 weeks.

CONCLUSION: Increasing adherence to exercise in men living with obesity is a challenge. The proposed program increased adherence to the physical activity guidelines after about a year for men living with obesity; however, more studies are needed to understand how to improve health outcomes when following an online delivery exercise program in this population.

PHYSICAL ACTIVITY, SITTING TIME, AND GENERAL HEALTH STATUS: THE IMPACT OF COVID-19 INFECTION

SANTOS, A.1,2, OLIVEIRA, A.1, SILVA, L.1, TASINAFO, M.1, MAZZONETTO, L.1, GOMIDE, E.1,3, ABDALLA, P.1, VENTURINI, A.1, SEBASTIÃO, E.4, MACHADO, D.1,5, CORDEIRO, J.2, ANDRADE, D.1, BOHN, L.2, MOTA, J.1

1 UNIVERSITY OF SAO PAULO, BRAZIL; 2 UNIVERSITY OF PORTO, PORTUGAL; 3 CLARETIANO-UNIVERSITY CENTER, BRAZIL; 4 NORTHERN ILLINOIS UNIVERSITY, USA; 5 UNIVERSITY OF ALGARVE, PORTUGAL

INTRODUCTION: The covid-19 pandemic negatively impacted physical activity (PA), amount of sitting time (ST) and individual's perceptions of general health status (GHS). However, sex, age and nutritional status are factors that have not yet been considered to understand this impact. Thus, we aimed to examine the impact of covid-19 signals, symptoms, and clinical outcomes on perceptions of GHS and time spent in PA and ST in adults and older adults, considering sex, age groups and nutritional status as confounding variables.

METHODS: This cross-sectional study included adults (≥18 years old) from a northeastern region of São Paulo, Brazil, who received a positive diagnosis of covid-19 between March/2020 and February/2021. Participants were randomly selected according to their telephone information using an oficial list of covid-19 survivors provided by the Health Department of the city of Ribeirão Preto. Through telephone, the short version of the International Physical Activity Questionnaire (IPAQ) was used to collect information on PA and ST, and a questionnaire developed for the purpose of the study was used to gather information on sociodemographic characteristics, body mass index (BMI), GHS, covid-19 signals and symptoms, and

clinical outcomes. Participants were asked to answer the questionnaires considering the week before the covid-19 diagnosis (pre-diagnosis), and the week when the interview took place (post-diagnosis). The Wilcoxon test for paired samples was used to compare the total time of PA (minutes/week), ST (hours/day), and GHS in the covid-19 pre- and post-diagnosis. The Quade's ANCOVA test verified the influence of covid-19 signals, symptoms, and clinical outcomes on the PA, ST, and GHS, controlled for confounding variables (sex, age and nutritional status).

RESULTS: Of the 509 participants, 311 (61%) were female and 397 (78%) aged between 18 and 59 years old. The total time of PA decreased and the individuals perception of GHS worsening in the post-diagnosis for male (Δ%= 46.4; p<0.001; Δ%= 25.0; p<0.001) and female (Δ%= 35.1; p<0.001; Δ%= 0; p<0.001), respectively. ST increased in males (Δ%= 17.1; p=0.010). The signals and symptoms of sore throat for males (F= 4.402; p=0.037), and fatigue/tiredness for females (F= 8.373; p=0.004) influenced PA reduction. The number of days the individuals were intubated significantly contributed to increase ST in males (F= 4.485; p=0.035). Finally, fever, loss of taste, diarrhea for males, and headache, breathing dificulty, loss of smell, sore throat, and fatigue/tiredness negatively influenced GHS for females (p<0.050).

CONCLUSION: Covid-19 infection exerts a negative impact on PA, ST and GHS, even after controlling for age, sex, and nutritional status. Our findings reinforce the importance of interventions to implement PA time spent, reduce ST, and improve the GHS after a positive diagnosis of covid-19.

CEREBROVASCULAR IMPACTS OF BREAKING UP PROLONGED SITTING WITH WALKING AND RESISTANCE ACTIVITIES.

GRIFFITHS, T.D., RICHARDS, C.T., CRONE, D., STEMBRIDGE, M., LORD, R.N.

CARDIFF METROPOLITAN UNIVERSITY

INTRODUCTION: Prolonged sitting is a frequent behaviour in the workplace, despite the increased risk of developing cardiovascular disease. A decline in middle cerebral artery blood velocity (MCAv), a surrogate marker for cerebral blood flow, has been reported following a period of prolonged uninterrupted sitting; this may impact on cognitive and cerebrovascular health. Frequent walking breaks may attenuate this decline in MCAv, however it is currently unknown whether resistance based activities may better preserve MCAv. Therefore, the aim of this study was to investigate the cerebrovascular effects of breaking up prolonged sitting with walking and resistance-based activities.

METHODS: Desk based-workers (n=11, BMI=27.4kg/m2) were recruited to complete three 8-hour working day trials; 1) Uninterrupted sitting, 2) five-minute hourly self-paced walking breaks (Walk), and 3) five-minute hourly resistance activities (Resistance), incorporating 30 second rotations of squats, lunges and an upright plank. Transcranial Doppler (Spencer Technologies, PMD150 ST3, New England, USA) was used to measure MCAv and posterior cerebral artery blood velocity (PCAv). Resting cerebral blood velocities were measured at baseline and at the end of the day. Data was sampled and averaged across five minutes respectively. Absolute change from baseline was calculated for MCAv and PCAv at both time points. A two-way repeated measures ANOVA was used to determine differences in MCAv and PCAv across time and condition.

RESULTS: There were no baseline differences in MCAv (p=0.9622) or PCAv (P=0.9831). Uninterrupted sitting led to a 9.8cm/s and 5.6cm/s decline in MCAv (p=0.0012) and PCAv (p=0.0881) respectively. Both walking and resistance activity attenuated the sitting related decline in MCAv to a 0.5 and 1.1cm/s decline respectively. Both walking and resistance activity attenuated the sitting related decline in PCAv to a 1.1 and 1.9cm/s decline respectively. No differences between physical activity modalities on MCAv or PCAv was observed.

CONCLUSION: Avoiding sharp declines in cerebral blood velocity observed during prolonged sitting is important maintaining for cerebral health. Regular interruption of sitting using physical activity breaks affords an opportunity to attenuate this decline. Further research is required to develop the mechanistic relationship between alterations in cerebral blood flow velocity, cognitive performance and cerebrovascular health.

ACCELEROMETER-DETERMINED MOVEMENT BEHAVIOURS, SARCOPENIA AND SARCOPENIC OBESITY IN COMMUNITY-DWELLING OLDER ADULTS

WIEDMAIER-BARROS, J.1, HIGUERAS-FRESNILLO, S.1,2, SADARANGANI, K.P.3, MARTÍNEZ-GÓMEZ, D.1

1 AUTONOMOUS UNIVERSITY OF MADRID; 2 LINKÖPING UNIVERSITY ; 3 DIEGO PORTALES UNIVERSITY

INTRODUCTION: Sarcopenia is an age-related skeletal muscle condition characterized by muscle strength and muscle mass loss [3]. Sarcopenic obesity (SO) is a functional and clinical condition where an excess of fat mass and sarcopenia coexist [2]. Both conditions are considered risk factors for frailty, diverse comorbidities, and mortality [4]. Increasing physical activity (PA) is a relevant strategy for successful aging [5] but there is no consensus about which characteristics of PA might be beneficial to attenuate sarcopenia and SO progression [1]. The aim of this study was to analyse the associations between different intensity accelerometer-determined daily activities and sarcopenia and SO in a sample of older adults

METHODS: 200 high-functioning community-dwelling older adults wore the Intelligent Device for Energy Expenditure and Activity for two consecutive days. All activity types recorded were classified into three intensity categories: sedentary behaviour (SB), light PA (LPA) and moderate-to-vigorous PA (MVPA). For muscle strength measurements included hand grip dynamometer and chair-stand tests were used. Skeletal muscle mass (SMM) and fat mass were estimated by bioelectrical impedance. Associations of daily activities with the study variables were examined using linear regression models.

RESULTS: There were no significant associations between total time spent in SB, LPA, or MVPA and sarcopenia. Nevertheless, SO showed a negative association with total time spent in MVPA [ß (95%CI): -0.28 (-0.41, -0.16)]. Walk at a brisk pace and other MVPA activities were significatively associated with the following SO components: lower limb strength [ß

(95%CI): 1.15 (0.40, 1.91) for walking and 4.65 (0.55, 8.75) for other activities], SMMiweight [ß (95%CI): 1.45 (0.68, 2.22) for walking and 8.59 (4.51, 12.67) for other activities] and fat mass % [ß (95%CI): -2.63 (-4.12, -1.14) for walking and -13.98 (-21.96, -5.99) for other activities].

CONCLUSION: Only MVPA seems to be related to lower levels of SO. No accelerometer-determined movement behaviour was related with sarcopenia.

PRESCRIBING AN ADAPTED PHYSICAL ACTIVITY PROGRAM (MATCH) AS USUAL CARE TO PREVENT IATROGENIC DECLINE IN HOSPITALIZED OLDER ADULTS: IS IT POSSIBLE AND BENEFICIAL ?

PEYRUSQUE, E.

UNIVERSITÉ DU QUÉBEC À MONTRÉAL

INTRODUCTION: Hospitalization leads to iatrogenic declines due to bed rest which accelerates the spiral of loss of autonomy (high risk of falls and frailty) and healthcare needs (home care services; readmission). We observed in pilot study settings that implementing as usual care an adapted, unsupervised daily PA program (MATCH) seems feasible, acceptable and effective in geriatric assessment units (GAU) and in COVID-19+ units. However, the reasons for hospitalization of older adults are heterogeneous, and patients may be admitted to various geriatric units (GUs). Thus, we aimed to assess the feasibility, and acceptability of implementing PA (MATCH) as usual care into 2 other GUs (geriatric rehabilitation unit (GRU) & post-acute care unit (PACU)) and explore its health effects.

METHODS: Patients admitted to 2 GUs at the Institut Universitaire de Gériatrie de Montréal (Canada) were examined by the Physicians to evaluate their eligibility. Subsequently, the physiotherapist/kinesiologist assessed the mobility score via a decisional tree and taught one of 5 unsupervised adapted PA programs (the one related to their mobility score). Thereafter, patients should follow this PA prescription by themselves during their hospitalization. Eligibility rates, inclusion rates (care acceptance), time to implementation, adherence and patient & clinician acceptability were assessed and compared across GUs. Moreover, physical performance [handgrip strength (HS (kg)); normal 3-meter Timed Up & GO (TUGn, sec); 4-meter walking speed (WS; m/sec), muscle endurance (30sec Sit-to-Stand (30-STS), repetition number), SPPB (Short Physical Performance Battery; X/12)] and frailty status (SOF questionnaire; X/3) were assessed at admission (Ta) and at discharge (Td). T-test, paired t-tests and Chi-Squared were performed.

RESULTS: Eligibility rate (%: GRU=32.5; PACU=26.6; p=0.12) and length of stay (days: GRU=39.4; PACU=37.6; p=0.33), inclusion rate (%: GRU=80.9; PACU=75.6; p=0.32), implementation delay (days: GRU=5.91; PACU=5.88; p=0.48) and adherence to PA prescription (%: GRU=83.5; PACU=71.9; p=0.15) were similar. Regardless of GUs, acceptability was good for clinicians (%: GRU=78; PACU=76) and for patients (SUS:>75%). Finally, all participants independently of the Gus improved significantly (p<0.001) and clinically their HS (Ta: 19.7±7.4 vs. Td: 21.9±8.5 kg), TUGn (Ta: 36.7±18.5 vs. Td: 23.9±1.7 sec), WS (Ta: 0.44±0.2 vs. Td: 0.62±0.2 m/s), 30-STS (Ta: 6.1±2.8 vs. Td: 7.9±3.2 rep), SPPB (Ta: 4.8±1.8 vs. Td: 6.5±2.5 pts/12) and SOF (Ta: 1.9±0.9 vs. Td: 1.53±1.0/3).

CONCLUSION: Implementing PA as usual care appears feasible, acceptable and beneficial in PACU and GRU. Based on the present and previous findings, MATCH can be assessed in all GU settings. However, before generalizing, further RCT studies are needed to confirm our promising results.

OP-AP35 Basketball: Training and Testing

MOVEMENT CHARACTERISTICS OF MALE AND FEMALE 3-ON-3 BASKETBALL PLAYERS AT NATIONAL AND INTERNATIONAL TOURNAMENTS

SMITH, H.K., SPRIGGS, N., COSKUN, B., BIRD, S.P., ELLIOT, C.A., OLSEN, P., HAMLIN, M.J.

LINCOLN UNIVERSITY

INTRODUCTION: Despite the increased popularity and number of national and international competitions for 3-on-3 basketball, internal and external movement demands are not well described. Such information is important for coaches and trainers alike to ensure adequate training protocols are used to prepare athletes for competition demands. Therefore, the aim of this study was to quantify the internal and external movement demands of 3-on-3 basketball matches in both national and international competitions using indoor GPS technology (VX Sport, Omni, Wellington New Zealand) and an athlete monitoring system (Health and Sport Technologies Ltd., trading as Metrifit, Millgrange, Greenore, Co. Louth, Ireland).

METHODS: Twelve well trained representative basketball athletes (8 males; 20.8 ± 1.8 yr, 190.3 ± 5.5 cm, 92.4 ± 9.9 kg and 4 females; 20.3 ± 1.5 yr, 171.4 ± 2.3 cm, 72.2 ± 3.8 kg mean ± SD) competed in (n=12) national competition matches and (n=6) international competition matches on a FIBA-sized basketball half-court (15 m x 11 m) with VXSport Omni devices inserted into custom-made pockets in the back of VXSport Smart vests. Measures taken included total duration (mins) total distance (m), relative distance (m/min) covered during games, high intensity distance (m) travelled at ≥ 15 km/h, high intensity sprints (number) at ≥ 15 km/h, maximal speed (km/h), total number of sprints, total number of jumps, high-intensity accelerations, and decelerations (> 3m/s/s), maximum and average heart rate (bpm) and distance travelled at difference speed band zones (0 – 6 km/h, 6.1 – 12 km/h, 12.1 – 18 km/h and 18.1 - 24km/h). Post-game internal demands were recorded on the Metrifit athlete monitoring system on player's phones, which included rate of perceived exertion (RPE), perceived physical, technical, tactical, and psychological performance on a Likert scale ranging from 1 – 10 for RPE and 1 – 5 for the other measures.

RESULTS: When compared to national competition, male and female international competition variables were higher for total duration ($p = 0.008$), total distance ($p = 0.026$), high intensity HR duration ($p = 0.040$), mean HR ($p = 0.048$), maximum HR ($p = 0.040$), and distance at 6.1-12 km/h ($p = 0.003$). Interestingly, the same variables were substantially higher in females compared to males in both national and international competitions. In addition, all post-game psychological variables such as RPE, perceived physical, technical, tactical, and psychological performance were higher in international matches compared to national matches for both males and females.

CONCLUSION: The novel finding of this study was that international external and internal 3-on-3 basketball competition demands showed higher intensities in most variables. Significant differences between genders were also observed highlighting the importance of gender-specific training and coaching strategy prior to and during competitions.

FUNDAMENTAL AND SPECIFIC MOTOR SKILLS PROFICIENCY IN YOUTH BASKETBALL PLAYERS. THE ROLE OF SPECIFICITY AND COMPLEXITY

FONT-LLADÓ, R.1,3, PONS-OLIVER, M.2, JODAR, A.1, LÓPEZ-ROS, V.2,3, PRATS-PUIG, A.1,4

UNIVERSITY OF GIONA

INTRODUCTION: Introduction: The most proficiency level of motor development in sport is achieved by the combination and/or modification and mastery of the fundamental motor skills to the sport-specific context. Specificity consists of adapting some elements of FMS pattern to the specific sport context. Complexity depends on the interaction between various elements of motor skill patterns to determine muscle-specific synergy based on the task and the environment in which the task is. The main purpose was to study the relationship between fundamental motor skills (FMS) and sports-specific skills (SSS) in terms of specificity and complexity in youth basketball players.

METHODS: Sixty-two amateur basketball players aged from 6 to 15 years were included in the study (age, 10.8 ± 2.3yr; female,45,2%). Cross-sectional measurements of maturity offset, FMS [sprint (Sp) and change of direction (COD)] and SSS [sprint while dribbling (SpBk) and change of direction while dribbling (CODBk)] were performed in a large basketball indoor court. The tests used were: 25msprint (2Sp), Vcut (COD), 25mSp_BK (SpBk), and Vcut_BK (CODBk). The time of each test was recorded with timing gates (Microgate Witty Wireless Training Timer, Bolzano, Italy). Every test was performed twice with a rest period of 3 min between trials and 5 min between tests. The best trial of each test was used.

RESULTS: Pearson's correlation shows significant associations between skills paired by specificity criterion (from basic to specific): Sprint and Sprint while dribbling ($\beta=0.937$ $p=0.000$), and Change of direction and Change of direction while dribbling ($\beta=0,821$ $p=0.000$). Furthermore, between skills paired by complexity criterion (from simple to complex): Sprint and Change of direction ($\beta=0,937$ $p=0.000$), and Sprint while dribbling and Change of direction while dribbling with ($\beta=0,813$ $p=0.000$). The association also existed between Sprint (basic and simple) and Change of direction while dribbling (specific and complex) ($\beta=0,810$ $p=0.000$). However, the independent predictors of Change of direction while dribbling were: change of direction ($\beta=0.406$ $p=0.001$), maturity offset ($\beta=-0.185$ $p=0.032$), sex ($\beta=0.182$ $p=0.032$), and experience ($\beta=-0.206$ $p=0.005$) explaining 81.5% of its variability.

CONCLUSION: Taken together, these results demonstrate the relation between FMS (Sp and COD) and SSS (SpBK and CODBK) when considering FMS complexity and specificity. Also, FMS (COD), maturity offset, sex, and sport-specific experience (BK) have been taken into consideration to explain SSS (COD_BK) proficiency.

RELATIONSHIP BETWEEN SALIVARY BIOMARKERS AND EXTERNAL LOAD DURING A PROFESSIONAL MEN'S BASKETBALL GAME

CABARKAPA, D.V., CABARKAPA, D., ESERHAUT, D.A., PHILIPP, N.M., FRY, A.C.

UNIVERSITY OF KANSAS

INTRODUCTION: In sports science, external load (EL) refers to the amount of physical work completed by the athletes, while internal load represents an individual physiological response to the amount of work completed during a training session. In response to a single bout of strenuous exercise, testosterone (T), as a hormone associated with anabolic processes, is likely to experience a slight increase or decrease. Alternatively, cortisol (C), as a hormone that works antagonistically to T, is likely to experience a considerably greater increase. When expressed as a testosterone-to-cortisol ratio (T/C), these two hormones serve as a viable measure of the athlete's recovery status. Thus, the purpose of this study was to examine the relationship between EL experienced by basketball players during a game and T, C, and T/C.

METHODS: Six professional male basketball players (x̄±SD; hgt=191.8±11.9 cm, wgt=19.2±14.4 kg; age=28.3±2.2 yrs) volunteered to participate in the present study. After arrival at the gym (12:00h), each participant wore an EL monitoring system composed of compression shorts and a tri-axial accelerometer (StriveTech, Bothell, WA, USA) sampling at 1000 Hz. Upon completion of the warm-up procedure, consisting of a set of dynamic stretching exercises and 15 min of partner shooting, participants proceeded with playing a simulated 5x5 basketball game (4x10 min quarters with Elam Ending). By holding an oral swab (Salimetrics, State College, PA, USA) sublingually in their mouth for 2 min before releasing it into a centrifuge tube, all participants simultaneously provided salivary samples post first (P1Q), second (P2Q), third (P3Q), and fourth (P4Q) quarter. A separate enzyme-linked immunosorbent assay was used for each hormone and all samples were ran in duplicates. Intra- and inter-assay variances for T and C were 5.6% and 5.1%, and 6.2% and 6.9%, respectively. Pearson product-moment correlation coefficients were used to measure the strength of linear regression ($p<0.05$).

RESULTS: The average EL, T, C, and T/C values were 0.450±0.162 [arbitrary unit], 0.954±0.257 [nmol/L], 14.264±6.411 [nmol/L], and 0.076±0.006 [ratio], respectively. Statistically significant correlations were observed between EL and C ($r[22]=0.751$, $p<0.001$; $R2=0.564$), and EL and T/C ($r[22]=-0.729$, $p<0.001$, $R2=0.531$). Despite a tendency to display a weak positive association, the correlation between EL and T did not reach a significance level ($r[22]=0.371$, $p=0.075$, $R2=0.138$).

CONCLUSION: Overall, the findings of the present study reveal a strong positive relationship between EL and C, and a strong negative relationship between EL and T/C. Although further research pertaining to position-specific differences is warranted, we can conclude that as the amount of physical work completed by the athlete during a basketball game increases, the C tends to follow the same pattern. However, T/C, as an indicator of athletes' recovery status, tends to display an inverse trend and progressively decreases throughout a game span.

REPEATED JUMP TEST FOR CHILDREN AND ADOLESCENTS AT VARIOUS STAGES OF BASKETBALL GAMES, AND THEIR RELATIONSHIPS TO AEROBIC CAPACITY

MECKEL, Y., SEGEV, S., ELIAKIM, A.

THE LEVINSKY-WINGATE ACADEMIC COLLEGE, WINGATE CAMPUS

INTRODUCTION: In basketball, the vertical jump is an important type of activity that is performed as a single or repeated action during different stages of a basketball game (Ben Abdelkrim et al., 2007) Relationships between aerobic fitness and repeated jump test (RJT) performance indices have previously been examined among adolescent male basketball players (Segev & Meckel, 2020), but not among children. The aim of the study was to compare repeated jump tests (RJTs) performance indices of adolescent and prepubertal basketball players during different stages of basketball games, and to examine their relationships to aerobic capacity.

METHODS: The study included 34 male basketball players – 18 children (age 12.1±0.4 yrs) and 16 adolescents (age 17.2±0.4 yrs.) – who were asked to perform RJT (6 sets of 6 consecutive jumps), after a warm-up, at halftime, at the end of a game, and an aerobic capacity test (20m Shuttle Run Test). Performance indices for the RJT were: Ideal jump height (IJH), Total jump height (TJH) of all the jumps, and Performance decrement (PD) during the test.

RESULTS: A significant decrease in IJH between half-time and full-time was seen among the adolescents ($p<0.01$), yet not among the children. Moreover, while the TJH was significantly increased ($p<0.05$) among the children at the end of the game compared to at the warm-up, this significantly decreased among the adolescents ($p<0.01$). Significant correlations were found between the IJH at halftime and full-time and the aerobic fitness, and between the TJH at halftime and the aerobic fitness among the children's group. No significant correlations were found between aerobic fitness and any RJT performance indices in the adolescents' group.

CONCLUSION: The findings demonstrate that prepubertal children are superior in maintaining repeated jumping performance during basketball games compared to adolescents. The findings also suggest that the aerobic system is a significant energy contributor among children, but not among adolescent players, during repeated jump activity. Coaches of young basketball players may allow more breaks for recovery during training sessions that involve repeated jumps.

TRAINING ON SAND OR ON PARQUET: IMPACT OF A PRE-SEASON TRAINING ON SPEED AND JUMP PERFORMANCE IN PROFESSIONAL BASKETBALL PLAYERS

VUONG, J., HEIL, J., BREUER, N., THEODOROPOULOS, M., VOLK, N., EDEL, A., FERRAUTI, A.

RUHR UNIVERSITY BOCHUM

INTRODUCTION: The abilities to effectively decelerate, change direction (CoD), accelerate, and jump are crucial physical qualities in modern basketball [1]. Recently, sand as a training surface has received wide recognition in practice for improving these attributes, although scientific evidence is lacking. In particular, the effects of a specific CoD speed training on sand have not been studied so far. Therefore, the present study aims to investigate the effect of CoD speed training on sand compared to a parquet surface with regard to speed and jump performance.

METHODS: Twenty-five male professional basketball players (age: 24.1 ± 4.2 years; height: 192.5 ± 8.0 cm; body mass: 92.6 ± 11.6 kg), from three teams with an equal level of competition, participated in a systematic controlled pre-season intervention study over seven weeks, followed by a taper week. Two teams completed an identical speed training protocol

either on sand (S) or on a hard surface (H), while the third team served as control (C), with all following their pre-season training at the same total training volume. The training protocol was applied twice a week, consisted of CoD drills in combination with plyometrics and followed a weekly progression regarding training volume and intensity. Pre-intervention and post-tapering, subjects were tested for speed (5, 10, 20 m sprint (ST)) and jumping performance (countermovement jump (CMJ), pivot jump (PJ), repeated jumps (RJ), crossover triple hop (CH)).

RESULTS: A repeated-measures ANOVA showed significant interaction effects for the 10 and 20 m ST (10 m: $p = .05$, $\eta2 = .012$; 20 m: $p = .002$, $\eta2 = .028$), the CMJ ($p < .001$, $\eta2 = .079$), and the PJ ($p = .002$, $\eta2 = .025$). Post hoc pairwise comparisons showed differences only for S regarding 10 and 20 m ST (10m: -0.04 ± 0.05 s, pTukey = 0.018; 20 m -0.09 ± 0.08 s, pTukey = <.001) as well as for CMJ (4.88 ± 2.32 cm, pTukey = <.001) and PJ (3.93 ± 2.53 cm, pTukey = <.001). No differences were found for 5 m ST, RJ and CH.

CONCLUSION: The results support the effectiveness of sand as a training surface, primarily for speed and jumps with longer ground contact times that are determined by the concentric force development. This is likely due to the force-absorbing nature of the surface, resulting in increased muscle activation and longer ground contact times. However, the same characteristic leads to a deficiency in reactive force development out of the short stretch-shortening cycle, which is reflected by the lack of improvement in RJ and CH for S.

OP-SH06 Psychobiology

VARIATION OF BLINK RATE AFTER ACUTE VERY LIGHT EXERCISE PREDICTS PREFRONTAL COGNITIVE ENHANCEMENT LEVELS

KUWAMIZU, R., YAMAZAKI, Y., AOIKE, N., SOYA, H.

UNIVERSITY OF TSUKUBA

INTRODUCTION: Acute physical exercise, even very light exercise, elicits the activation of the dorsolateral prefrontal cortex (DLPFC) and improves executive function (EF) (Byun et al., 2014). However, the underlying neurobiological mechanisms of this are not fully understood. Accumulating evidence shows that resting-state spontaneous eye blink rate (rssEBR) is associated with brain states that are linked to arousal, especially modulation of the dopaminergic system (e.g., Jongkees & Colzato, 2016; Demiral et al., 2023). Our previous cross-sectional study demonstrated that higher baseline rssEBR mediates the association between aerobic fitness and prefrontal EF, which leads us to the hypothesis that rssEBR-linked neural substrates explain the neurobiological effects of physical exercise (Kuwamizu et al., 2021). The rssEBR-linked neural substrates may also be associated with the impact of acute exercise on EF, but whether EF enhancement with acute exercise depends on rssEBR upregulation changes remains unclear.

METHODS: Healthy young adults participated in two conditions: 10-minute very light-intensity cycle ergometer exercise (30% Vo2peak) and resting. Twenty-four participants (age = 22.2 ± 1.5) were analyzed. rssEBR was recorded for 3 minutes before and immediately after exercise and rest. To evaluate the EF, a color-word Stroop task was administered before and after exercise and rest. Prefrontal activation was measured using functional near-infrared spectroscopy while performing the Stroop task.

RESULTS: Very light exercise significantly improved Stroop task performance and task-related left-DLPFC activation (all $p < 0.01$). There were no significant differences between conditions in the change in rssEBR ($p = 0.44$). The correlation analyses, however, revealed significant association between the change in rssEBR and improved Stroop task performance ($r = 0.62$, $p = 0.001$).

DISCUSSION and CONCLUSION: Acute very light-intensity exercise does not elicit consistent rssEBR increase. This result does not support the hypothesis that upregulation of rssEBR-linked neural substrates contributes as the primary mechanism of the enhancement with very light-intensity exercise. However, increased rssEBR was associated with higher EF enhancement levels and vice versa. This suggests that rssEBR-linked neural substrates might work as modulators of cognitive enhancement levels following exercise; further study is needed. As a bonus, this finding indicates that blink measurements might provide a new contactless and clearly visible biomarker for predicting brain impact with exercise.

THE EFFECTS OF NEUROFEEDBACK TRAINING AND PSYCHOLOGICAL SKILLS TRAINING ON PUTTING PERFORMANCE IN EXPERT GOLFERS

HUNG, T.

NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: In recent studies, the effectiveness of neurofeedback training (NFT) and psychological skills training (PST) have been evaluated not only in the clinical population, but also for their enhancement of performance in general. The mechanism for the effect may differ based on different effective attention control derived from both trainings. Previous research suggests that Frontal Midline Theta (Fmθ) is an indicator of top-down sustained attention and Fmθ can be used to distinguish an individual's best and worst golf putting performances during the pre-putt period. Thus, this study investigated the effect of NFT and PST on golf putting performance and hypothesized that expert golfers would exhibit enhanced putting performance after both trainings.

METHODS: Twenty-eight expert golfers were recruited and assigned into the NFT group (N = 9), PST group (N = 8), or control group (N = 11). Participants were asked to perform golf putting while electroencephalogram (EEG) was recorded, both before and after intervention. The NFT group participated in eight 1.5-hr sessions of Fmθ NFT in a lab setting. During the Fmθ neurofeedback training, participants had to develop their own strategies for controlling Fmθ amplitude based on the visual or audio feedback in real-life putting. The PST group participated in eight 1.5-hr sessions of Mindfulness-Acceptance-Commitment (MAC) in a lab setting. During this time, the control group did not receive any type of intervention.

RESULTS:The one-way ANOVA showed a significant effect on putting accuracy ($F(2, 27) = 9.648$, $p = .001$). The post hoc analysis showed that the NFT group had better performance than control group ($p = .003$) and PST group ($p = .004$). Fmθ and attention-related cortical indicators did not differ between the three groups.

CONCLUSION:Despite its limitations, this study found that 8-session Fmθ NFT significantly improved putting performance in expert golfers while mindfulness based intervention did not. To the best of our knowledge, this is the first long-term interventional Fmθ NFT study on putting performance and EEG activity. The null finding in the PST group could be attributed to promotion of control over automation in acceptance-based mindfulness training, which may not match the attentional style of these participants. From a practical standpoint, although Fmθ NFT was ineffective in changing EEG-related cortical activities during putting, it is effective in improving putting performance. The mechanism of performance enhancement via NFT and PST still remains a question. Future research could focus on clarifying the underlying mechanism of the effect through NFT and PST.

AUTOMATED STRESS RECOGNITION AND EVALUATION VIA A SELF-DESIGNED INTERACTIVE VIRTUAL REALITY PLATFORM

TAO, K., HUANG, Y., SHEN, Y., SUN, L.

BEIJING SPORT UNIVERSITY

INTRODUCTION: Stress is commonly elicited through internal or external stimuli in physical activity, and is assessed using subjective and objective measurements. Traditionally, subjective methods determine the stress level of a person through questionnaires and answers rated on a stress scale. Due to the notable improvements in virtual reality (VR) techniques, virtual reality exposure therapy (VRET) is considered an efficient tool to overcome these weaknesses. VRET assumes the possibility that participants feel real-life stressful situations in a similar magnitude in VR, and succeeds in tracking physiological signals and recognize affective stress states, which provides a method of linking subjective and objective measures of stress recognition.

METHODS: fifty-seven adult athletes (19 males and 38 females) with an average age (±SD) of 20.9 (±1.9) years, were enrolled to participate in this study with written consent. Participants were asked to log in to the system and sit at ease in the chair for 3 min to exclude any other artificial distractions. Later, they entered the three independent VR contents in a random order to experience both low- and high-stress modes from all three scenes for nearly 2 minutes per mode. The whole experiment lasted for approximately 30 minutes (including nearly 12 minutes of virtual experiences) and finished with the completion of the retrospective survey on the Experience Evaluation of Virtual Reality Scene, which provided feedback on the psychometric quality of the self-designed VR platform.

RESULTS: Our findings demonstrate the concurrent variations between physiological data (heart rate, electrodermal activity and eye-blink rate) and self-reported stress ratings, and include the evaluations of the VR system by computing Cronbachs alpha (α=0.72) and Kaiser-Meyer-Olkin (KMO) coefficient (η=0.78) through a retrospective survey, which were subsequently confirmed as reliable on four aspects (sense of presence, sense of space, sense of immersion and sense of reality) via factor analysis. Additionally, we demonstrate the effectiveness of physiology-based stress level classification (no stress, low stress and high stress) and continuous SSAI score prediction, with accuracy (0.742), F1-score (0.709) and recall (0.774) by bagging ensemble learning model and goodness-of-fit reaching 0.44 via multivariate stepwise regression.

CONCLUSION: We have designed an interactive virtual reality platform for stress recognition based on Unity engine and possesses complex interactive functionalities that enable participants to experience stressful scenes. The main contributions are twofold. First, we realize the automation of stress recognition in physical activity using several supervised learning algorithms. Second, this study provides detailed insight regarding the effect of objective physiological measures on the validation of subjective self-ratings, which stimulates the further investigations of stress disorder treatment.

ASSOCIATION OF SCREEN TIME AND PHYSICAL ACTIVITY WITH SLEEP QUALITY IN COLLEGE STUDENTS DURING COVID-19 OUTBREAK

LIU, Y., SUN, Y., ZHENG, J., WANG, K., HUANG, T.
SHANGHAI JIAO TONG UNIVERSITY

Background: Sleep is important for physical and mental health. Some epidemiological studies found that excessive screen-based activity and lower physical activity were strongly associated with poorer performance in various aspects of sleep, especially reduced sleep quality. However, the associations between screen time and sleep quality may vary by different types of screen time. Evidence showed that college students had more screen time (ST) and less physical activity (PA) during the COVID-19 epidemic. The associations of specific types of screen time and physical activity with sleep quality remain to be clarified. Therefore, the study aims to elucidate the associations of different types of screen time and physical activity with sleep quality among university students during COVID-19 outbreak .

Methods: A total of 1550 students from universities in Shanghai, China, completed an online survey in May 2022. The data collected included basic information (gender, age, school), self-reported screen time (TV/movie viewing, recreational reading, video gaming, online social media), Pittsburgh Sleep Quality Index (PSQI) score, International Physical Activity Questionnaire (IPAQ) and sedentary time. The screen-based activities in the responses were categorized into three levels (ST < 1h, 1h < ST < 2h, ST > 2h). The moderate to vigorous physical activity was categorized into three levels as well (none of MVPA, MVPA < 150min/week, MVPA > 150min/week). Associations between various types of screen time and physical activity with sleep quality were examined by multiple linear regression.

Results: There were 1453 valid questionnaires received in total (response rate: 93.74%). The percentage of self-reported ST > 2 hours/day was the highest among all types of screen activities. Approximately, a half of the college students had less than 150 minutes of moderate to vigorous physical activity per week. The linear regression revealed that MVPA were not significantly associated with sleep quality during the epidemic. However, the linear regression revealed that TV/movie viewing > 2 h was associated with poorer sleep quality ($\beta = 0.37$, 95% CI: 0.04-0.70, $p = 0.028$) and recreational reading > 2 hours/day was also positively associated with poorer sleep quality ($\beta = 0.67$, 95% CI: 0.33-1.02, $p < 0.001$). However, there were no associations between video gaming and online social media and sleep quality.

Conclusion: The present study indicated that the associations between screen time and sleep quality varied by the types of screen activities. During the COVID-19 pandemic, excessive screen time has a negative impact on sleep quality, particularly the TV/movie viewing and recreational reading. However, physical activity level was not associated with sleep quality. Future interventions for improving sleep quality in college students should consider the types of screen activities and controlling screen exposure.

DEVELOPMENT AND EVALUATION OF THE PSYCHOMETRIC PROPERTIES OF A NEW MEASURE OF ATHLETE INSOMNIA: INSOMNIA IN RESPONSE TO SPORTS-RELATED STRESS TEST QUESTIONNAIRE

NEDELEC, M., CHAUVINEAU, M., MARTINENT, G.
INSEP

INTRODUCTION: INTRODUCTION: Impaired sleep is particularly frequent among elite athletes which has been linked to various negative consequences, including lower athletic performance and general health [1]. Several studies have examined potential acute and chronic factors placed on elite athletes resulting in compromised sleep, e.g. training and competition [1]. Candidate risk factors for compromised sleep in elite athletes also include many factors commonly considered to influence sleep in non-athletic individuals and particularly psychological stress and anxiety [2]. The aim of the present study was to develop and validate the Insomnia in Response to Sports-related Stress Test (IRSST) questionnaire, a new specific instrument with the goal of sensitively measuring vulnerability to sport-specific stressful situations among elite athletes.

METHODS: Five hundred and thirty-one competitive elite athletes (mean age = 17.6±4.4 years) completed the Ford Insomnia Response to Stress Test (FIRST) questionnaire, a standardized questionnaire assessing the likelihood of sleep disruption due to common stressful situations (e.g. before having to speak in public, before an important meeting the next day) [3], and the IRSST, a six-item questionnaire developed to assess the level of sleep disturbance in response to the commonly experienced sport-specific stressful situations, i.e. before competition, after daytime competition, after nighttime competition (20:00-21:00), after nighttime training (20:00-21:00), during training camp, after injury. A development and validation process including substantive, structural, and external stages was used in the present study [4].

RESULTS: One eigenvalue of the exploratory factor analyses was greater than 1.0 (i.e., 2.91, 48.52% of explained variance) whereas the scree test provided evidence for a one-factor solution, with all the six items achieving a loading of .40 or higher on the factor. The goodness-of-fit indices of the six-item one-factor confirmatory factor analyses model provided further evidence of the structural stage of IRSST score. The correlation between IRSST and FIRST scores was .47 ($p < .001$, moderate effect size).

CONCLUSION: These results provide strong evidence for construct validity, indicating that the IRSST is a promising scale for assessing the likelihood of sleep disruption due to sports-related stressful situations. The results of reliability and correlational analyses provided further evidence of the promising psychometric properties of the IRSST. We believe that the IRSST could provide to the sport and sleep science communities a sleep screening tool for use in this unique population.

OP-AP15 Coaching Strategies

TRAINING PRACTICES AND COACHING PHILOSOPHY OF SUCCESSFUL NORWEGIAN NATIONAL COACHES IN ENDURANCE SPORTS

BUCHER SANDBAKK, S., HAUGEN, T., TØNNESSEN, E., LOSNEGARD, T., SEILER, S., SANDBAKK, Ø.
NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY, TRONDHEIM, NORWAY

INTRODUCTION: While performance development in endurance sports typically is described by the interaction of loading factors such as training volume, frequency, and intensity distribution, practitioners themselves highlight indicators of training quality – the how and why – as the most important factors leading to success. In this context, successful coaches are highly systematic in collection of training data, and carefully experimental regarding training adjustments. Somewhat surprisingly, the practices, knowledge and experience of the very best coaches have received minimal systematic attention in research literature. The mysteries and secrets of the training process are challenging to quantify and require an integrative and multidisciplinary approach. Therefore, the aim of this study was to explore the training practices and coaching philosophy of successful coaches in endurance sports.

METHODS: Twelve male Norwegian coaches with a track record of coaching endurance world-class athletes (total of >320 Olympic, World and European Championship medals; mainly Norwegian athletes) in cross-country skiing, biathlon, speed skating, rowing, road cycling, swimming, long-distance running, and triathlon participated. Individual semi-structured interviews on planning, organization and periodization of training, competitive activity, training load and quality indicators, load monitoring, testing, and athlete follow-up provided approximately 180 min audio recording per respondent. The transcripts were approved by the respective coach, formally translated to English and analyzed thematically.

RESULTS: Preliminary analyses reveal a high-volume approach, with the majority of training at low-intensity and with training volume and intensity distribution periodized using a traditional model as common features among the coaches' training philosophies. This includes 2-3 days (2-5 sessions) weekly as the cornerstones of the training program and that other training sessions are built around these. The key sessions become gradually more competition-specific in all characteristics towards the competition period. There are clear sport-specific differences in the training content, driven by differences in competition demands, mechanical and muscular load during specific training sessions, as well as access to facilities and environmental conditions. All coaches described that a coach-driven and athlete-centered coaching philosophy was essential to create trust, mutual understanding, and provided the foundation for optimizing the training process and execution of sessions for each athlete. The factors involved in this process will be described and discussed in the presentation.

CONCLUSION: This study presents a holistic picture of "state-of-the-art" endurance training, including novel qualitative information about training and coaching philosophies from successful Norwegian coaches in endurance sports.

THE PERCEIVED VALUE OF ATHLETE MONITORING TO ELITE SPORT PRACTITIONERS

NEUPERT, E.
UNIVERSITY OF PORTSMOUTH

INTRODUCTION: Athlete monitoring systems (AMS) can aid performance optimisation and injury prevention, but recently their efficacy has been questioned. The perceived value of monitoring matters, because if practitioners lack confidence in their monitoring systems, their ability to positively influence training programming is diminished. To address this, researchers have primarily sought to improve AMS metric-related factors e.g. measure reliability. In comparison however, the impact of socio-environment factors e.g. stakeholder buy-in on AMS, has received less attention. This study explored the perceived value of athlete monitoring by elite sport practitioners focussing on socio-environment factors.

METHODS: Seventy-five elite sport practitioners (response rate: n= 30) who worked with tier 3-5 athletes (1) were invited to take part in an online survey about their athlete monitoring practices. The practitioners represented 14 different sports and 599 athletes. The survey took approximately 20 minutes to complete, with questions primarily answered by checkboxes, Likert scale responses or short answers. Spearman's correlation coefficient was used to test the strength of Likert relations and Bonferroni corrected to $p < 0.017$.

RESULTS: Fifty-two percent (n=13) respondents were confident in the sensitivity of their athlete self-report measures (ASRM) to detect meaningful change, with 64% (n=16) indicating their ASRM was underpinned by scientific studies. Such scientific evidence was linked with improved feedback to athletes ($r(23) = 0.487$, $p = 0.014$); and improved feedback correlated with better athlete monitoring adherence ($r(22) = 0.675$, $p < 0.001$). If athletes did not complete their monitoring, 52% (n= 13)

respondents felt the athletes' performance might be compromised. However, most respondents 56%, (n= 14) had worked with internationally successful athlete(s) who had reached the podium at major international events and did not complete their monitoring.

CONCLUSION: While AMS can be a useful tool for performance optimisation, its potential value isn't always realised. The difference between some practitioner's beliefs; (a lack of monitoring compromises performance) versus reality; (some internationally successful athletes do not complete monitoring) indicates that the efficacy of monitoring should be regularly reviewed to ensure it is providing value. Practitioners should also consider simultaneously addressing socio-environment and metric-related factors in order to improve AMS efficacy.

USE THE 'ARTISTIC LENS': EXPLORING YOUNG PEOPLE'S LEADERSHIP PERCEPTIONS

METTÄLÄ, M.

FACULTY OF EDUCATION AND SOCIETY

Introduction

There is a lack of theories that explain how young people can develop as leaders, and how existing theories can be applied to young adults and children. The purpose of this study is to explore how leadership skills are taught to potential young leaders.

Methods

Data consists of 7 observations and fieldnotes from two leadership programs for youth: one program in a sport-club context with 20 participants and the other in a higher education setting with 60 participants. Furthermore, 4 semi-structured interviews with leaders from sport-clubs and from the field of leadership was conducted. Questions focused on leadership, leaving out personal background or life-stories.

Results

The interviewees underline the importance of getting youth engaged in leadership trainings, in problem-solving, how to handle and cope challenges, the ability to reflect and learn from actions (instead of focusing on performance and results), creating, and developing relations. They also emphasize the importance of consciously affirming young participants in their learning processes, share experiences through dialogue and most importantly, listening. Yet, observations show that although the young participants attended the programs voluntarily, they were inactive during lectures and workshops. Participants explained: "not having the courage", "not understanding what leadership is", not knowing what to do", and "not knowing how to engage and speak in a group". Roleplay and improvisations engaged young participants more than for example discussions.

Discussion

There is a need for more knowledge on leadership training and young people and how to increase participation. One way to meet the challenge is to use the 'artistic lens', including flexibility and openness to discovery, as well as embracing the chaos which enters in the reflective process of exploration. This implies asking potential young leaders how they perceive leadership. There is also the need to understand how leaders and practitioners in the field of leadership uphold their leadership and training methods. Young people are valuable members in their communities and though they may not hold positions of authority, they possess the potential to exercise leadership in meaningful ways.

OP-PN23 Immobilization and Recovery

DOES HUMAN SKELETAL MUSCLE POSSESS A NEGATIVE MEMORY OF ATROPHY?

TURNER, D.C., RAASTAD, T., SEYNNES, O.R., ULLRICH, M., SHARPLES, A.P.
NORWEGIAN SCHOOL OF SPORT SCIENCES

INTRODUCTION: Skeletal muscle (SkM) size and function are compromised during prolonged periods of disuse. It is evident that SkM possesses a positive memory of exercise-induced hypertrophy. However, it is unknown whether human SkM has a negative memory of disuse atrophy. The present study therefore examined the physiological response to repeated atrophy in human SkM.

METHODS: Ten young healthy males (n=7) and females (n=3; 27 ± 4 yrs, BMI 26.4 ± 5) underwent 2 weeks of atrophy via unilateral limb immobilization followed by 7 weeks of recovery and another 2 weeks of repeated atrophy. Before and after each atrophy period, measures of leg lean mass (DXA), anatomical cross-sectional area (aCSA, ultrasound) of the vastus lateralis (VL) and rectus femoris (RF) muscles, alongside isometric knee extension torque (dynamometry) across 3 knee flexion angles (90-, 60- and 30-degrees) were assessed. SkM biopsies were obtained for future downstream molecular analyses. A one-way ANOVA with Tukey HSD post-hoc analysis enabled detection of significant changes ($p<0.05$). All data are presented as mean ± SD.

RESULTS: Firstly, there was no significant difference between baseline and recovery for any of the parameters assessed, suggestive of a full recovery following the initial period of disuse-induced atrophy. A significant loss of leg lean mass (-3.4 ± 2%, p=0.01) and VL aCSA (-9 ± 3.8%, p=0.0003) occurred after atrophy that was comparable to the reductions in lean leg mass (-2.9 ± 1.9%, p=0.003) and VL aCSA (-8.9 ± 4.5%, p=0.0003) experienced after repeated atrophy. Importantly, a significant reduction in RF aCSA only occurred following later repeated atrophy (-3.5 ± 2%, p=0.02) with no change after the earlier atrophy period (-0.5 ± 2.2%, p=0.6). In terms of muscle function, there was a similar reduction in knee extension torque at 90-degrees after atrophy (-14.3 ± 11.4%, p=0.02) and repeated atrophy (-13.8 ± 11.7%, p=0.02). However, loss of muscle strength at 60-degrees was exacerbated after later repeated atrophy (-14.3 ± 8.8%, p=0.002) relative to the loss observed after earlier atrophy (-12.5 ± 10.5%, p=0.02). There was also a trend towards a greater strength loss at 30-degrees after repeated atrophy (-9.6 ± 14.4%, p=0.1) versus earlier atrophy (-7.5 ± 18.7%, p=0.5), however this was not statistically significant.

CONCLUSION: Overall, both periods of atrophy evoked comparable reductions in parameters related to muscle size (leg lean mass and VL aCSA) and function (knee extension strength at 90-degrees knee flexion). However, a significant reduction in RF aCSA only occurred in response to later repeated atrophy even following full recovery from earlier atrophy. This was associated with a greater loss of muscle strength at 30- and 60-degrees after later repeated atrophy. To delineate the possible mechanisms underpinning these physiological responses to repeated atrophy, we will conduct unbiased genome-wide epigenetic and transcriptomic analyses on the muscle biopsies derived from this study.

UNEXPECTED HYPERTROPHIC, PHENOTYPICAL, AND OXIDATIVE METABOLISM TRANSCRIPTIONAL ADAPTATIONS IN RESPONSE TO RESISTANCE TRAINING FOLLOWING 10 DAYS OF MUSCLE DISUSE

FRANCHI, M., SARTO, F., SIRAGO, G., CANDIA, J., GIACOMELLO, E., HARTNELL, L., MONTI, E., NOGARA, L., TONIOLO, L., DE VITO, G., FERRUCCI, L., NARICI, M.
UNIVERSITY OF PADOVA

INTRODUCTION: Physical inactivity is a main curse of modern society, characterised by neuromuscular decline with progressive loss of muscle mass, strength, and power and by an increased risk of major chronic diseases. Exercise countermeasures seem to be highly beneficial for contrasting neuromuscular impairments; however, as most studies have employed nutritional or exercise during unloading periods, there is a paucity of data regarding recovery programs right after muscle disuse. We aimed to study the functional, structural, molecular and transcriptional responses to a 21-day active recovery program based on resistance training (RT) following 10 days of muscle unloading intervention.

METHODS: Eleven healthy males (22.1±2.9 y) underwent a 10-day unilateral lower limb suspension (ULLS) period, followed by 21-day of active recovery, consisting in a RT program for the knee extensors performed at 70% of the 1RM. The data collection was performed at baseline (BSL), at the end of the ULLS (LS10), and at the end of the exercise recovery period (AR21). Quadriceps femoris (QF) and vastus lateralis (VL) volume and isometric maximum voluntary contraction (MVC) were evaluated. VL muscle architecture and body composition were assessed by ultrasonography and BIA. Histological data (i.e., fibre CSA and type, glycogen content) were evaluated from VL biopsies and transcriptomic profile was investigated by RNA-seq.

RESULTS: Following ULLS, QF and VL volume decreased (-3.7% and -3.5%, $p<0.05$ and $p=0.05$, respectively) as did MVC (-29.3%, $p<0.001$) and pennation angle (-3.85%, $p<0.05$). After the 21-d AR period, MVC and pennation angle were fully restored (+42% and +4.4%, compared to LS10, respectively) whereas QF and VL volume showed a surprising overshoot (+18.6% and +24.2%, $p<0.001$, compared to LS10, respectively). These changes at whole muscle level were not matched by fibre CSA, as no such changes were observed for both fibre types. However, glycogen staining intensity increased after AR (+16.1%, $p<0.001$) as did whole body water content (+3.1%, $p<0.05$). Transcriptomics analyses showed that the most

differentially expressed genes, showing a dampened enrichment after ULLS and a strong re-enrichment following AR, were identified in the hallmarks and pathways related to oxidative phosphorylation, glucose and fatty acid metabolism. These data were accompanied by a reduction of fibre type II distribution at AR21 (-21%, p<0.05) and an increase in fibre type I (+34%, p<0.05).

CONCLUSION: RT successfully recovered functional and structural muscle properties after 10 days of disuse, but in contrast with what usually observed in response to RT, oxidative metabolism and slow fibre type were mostly affected by disuse and recovery, suggesting that muscle could enhance metabolic recovery before hypertrophy per se in response to RT following disuse. Further studies should clarify the responses of such exercise countermeasures after muscle disuse scenarios.

SHORT-TERM IMMOBILIZATION LOWERS MUSCLE CONNECTIVE PROTEIN SYNTHESIS RATES IN HEALTHY YOUNG ADULTS

HOLWERDA, A.M., WEIJZEN, M.E.G., ZORENC, A., JETTEN, G.H.J., HOUBEN, L.H.P., KERR, A., DAVIS, H., KEOGH, B., KHALDI, N., VERDIJK, L.B., VAN LOON, L.J.C.

MAASTRICHT UNIVERSITY MEDICAL CENTRE+

INTRODUCTION: Short periods of limb immobilization lower myofibrillar protein synthesis rates. Within skeletal muscle, the extracellular matrix of connective proteins is recognized as an important factor determining the capacity to transmit contractile force. Little is known with regards to the impact of immobilization and subsequent recovery on muscle connective protein synthesis rates. This study examined the impact of 7 days of leg immobilization and 14 days of subsequent ambulant recovery on daily muscle connective protein synthesis rates.

METHODS: Thirty healthy, young (24±5 y) men were subjected to 7 days of one-legged knee immobilization followed by 14 days of ambulant recovery. Deuterium oxide ingestion was applied over the entire period and muscle biopsy samples were collected before immobilization, after immobilization, and after recovery to measure muscle connective protein synthesis rates and mRNA expression of key extracellular matrix proteins (collagen I, collagen III), glycoproteins (fibronectin, tenascin-C), and proteoglycans (fibromodulin, and decorin). A two-way repeated measures (time x leg) ANOVA was used to compare changes in muscle protein synthesis rates during immobilization and recovery. Data represent mean±SD.

RESULTS: During immobilization, muscle connective protein synthesis rates were lower in the immobilized (1.07±0.30 %/d) compared with the control (1.48±0.43 %/d; P<0.01) leg. When compared to the immobilization period, connective protein synthesis rates in the immobilized leg increased during subsequent recovery (1.47±0.63 %/d; P<0.01). Following recovery, skeletal muscle collagen I, collagen III, fibronectin, fibromodulin, and decorin mRNA expression increased when compared to the post-immobilization timepoint (all P<0.001).

CONCLUSION: Short-term immobilization lowers muscle connective protein synthesis rates. Muscle connective protein synthesis rates increase during subsequent ambulant recovery, which is accompanied by increased mRNA expression of key extracellular matrix proteins.

CROSS-EDUCATION EFFECT BY ECCENTRIC VS CONCENTRIC RESISTANCE TRAINING OF THE ELBOW FLEXORS IMMOBILISED BY A CAST

NOSAKA, K.1, WU, S.H.2, CHEN, H.L.2, TSENG, W.C.3, TSENG, K.W.3, KANG, H.Y.4, CHEN, T.C.4

1 EDITH COWAN UNIVERSITY, 2 NATIONAL CHIAYI UNIVERSITY, 3 UNIVERSITY OF TAIPEI, 4 NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: Muscle strength gain conferred by a unilateral limb resistance training is transferred to a non-trained homologous muscle of the contralateral limb, which is referred to as the cross-education effect. The magnitude of increase in muscle strength of the contralateral limb was 35% (95% CI: 20.9%–49.3%) of that of the ipsilaterally trained limb (Munn et al. J Appl Physiol 2004). Interestingly, the magnitude of the cross-education effect appears to be greater after eccentric (ET) than concentric resistance training (CT). The magnitude of muscle damage induced by maximal eccentric exercise of the elbow flexors was reduced when the second bout of the same exercise was performed by the contralateral homologous muscle within 4 weeks (Chen et al. Med Sci Sports Exerc 2016). However, no previous study has compared the effects of ET versus CT of the non-immobilised arm on the immobilised arm for muscle strength, atrophy and damage. The present study tested the hypotheses that ET would attenuate decreases in muscle strength and cross-sectional area (CSA) of the immobilised arm greater than CT, and ET would provide greater protective effects against muscle damage induced by maximal eccentric exercise after immobilisation than CT.

METHODS: Sedentary young men were placed to ET, CT or control group (n=12/group), and their non-dominant arms were immobilised for 3 weeks. During the immobilisation period, the ET and CT groups performed 5 sets of 6 dumbbell curl eccentric-only and concentric-only contractions, respectively at 20-80% of maximal voluntary isometric contraction (MVCiso) strength over six sessions. MVCiso torque, root-mean square (RMS) of electromyographic activity during MVCiso, and bicep brachii muscle CSA were measured before and after immobilisation for both arms. All participants performed 30 maximal eccentric contractions of the elbow flexors (30EC) by the immobilised arm after the cast was removed. Several indirect muscle damage markers were measured before, immediately after, and for 5 days following 30EC.

RESULTS: ET increased MVCiso (17 ± 7%), RMS (24 ± 8%), and CSA (9 ± 2%) greater (P<0.05) than CT (6 ± 4%, 9 ± 4%, 3 ± 2%, respectively) for the trained arm. The control group showed decreases in MVCiso (-17 ± 2%), RMS (-26 ± 6%), and CSA (-12 ± 3%) for the immobilised arm, but these changes were attenuated greater (P<0.05) by ET (3 ± 3%, -0.1 ± 2%, 0.1 ±

0.3%, respectively) than CT (-4 ± 2%, -4 ± 2%, -1.3 ± 0.4%, respectively). Changes in all muscle damage markers after 30EC were smaller (P<0.05) for the ET and CT than control, and ET than CT group (e.g., peak plasma creatine kinase activity, ET: 860 ± 688 IU/L, CT: 2,390 ± 1104 IU/L, control: 7,819 ± 4,011 IU/L; peak muscle soreness, ET: 17 ± 16 mm, CT: 40 ± 14 mm, control: 60 ± 26 mm).

CONCLUSION: These results showed that ET of the non-immobilised arm was effective for eliminating the negative effects of immobilisation and attenuating muscle damage induced by eccentric exercise of the pre-immobilised arm.

HEAT THERAPY TO ACCELERATE MUSCLE REGENERATION

DABLAINVILLE, V.1,2, MORNAS, A.3, AL MULLA, M.4, BAYNES, F.5, CARDINALE, M.1, RACINAIS, S.1,2,3

1> ASPETAR ORTHOPAEDIC AND SPORTS MEDICINE HOSPITAL, DOHA - QATAR, 2> INRA MONTPELLIER - FRANCE, 3> INSEP, PARIS - FRANCE, 4> GLASGOW UNIVERSITY, GLASGOW-UK, 5> LONDON SOUTH BANK UNIVERSITY, LONDON

INTRODUCTION: Muscle injuries represent one of the most common type of injuries encountered by health professionals. Cold based therapies are considered the gold standard solution to treat muscle injuries. But no evidence has shown the efficacy of cold application in the regeneration of human skeletal muscle following soft tissue injuries. Animal studies showed that cold application delayed muscle regeneration and increased muscle fibrosis (1). In contrast, heat-based therapies applied on muscle injury have been shown to improve and shorten the regeneration in rats (2). The aim of this study was to investigate the effects of three distinct thermal therapies applied by water immersion on human skeletal muscle regeneration.

METHODS: Healthy males (n=36, age: 33.7 ± 3.5yrs) performed an electrically stimulated eccentric exercise of the right leg followed by 11 days of supervised recovery with daily legs water immersion. Immediately after the exercise, participants were distributed in a counterbalanced way in 3 groups of water immersion: 1) Cold with 15 min at 12°C, 2) Neutral (sham/control) with 30 min at 32°C and 3) Hot with 60 min at 42°C. First bath was initiated an hour after damaging exercise completion. Blood was collected on 3 occasions for Myoglobin and creatine kinase (CK) analysis. Maximal voluntary contraction (MVC), rate of force development (RFD), peak twitch (PT) and pain were monitored.

RESULTS: No significant differences in the level of work done during the exercise were found across the groups, suggesting a consistent damage creation across the groups. Muscle temperatures (3cm depth) reached respectively 33.2 ±2.3°C for Cold, 35 ±1°C for Neutral and 38.9 ±0.4°C for Hot group at the end of each bath.

Myoglobin was significantly lower in the hot group 4 days after the damages (Hot= 991±574 vs Cold= 2134±1123 and Neutral= 1823±972ng/mL) with a significant interaction between treatment and time (p<0.02, p-eta2= 0.217) but not after 8 days (hot= 91±32 vs cold= 130±50 and neutral= 132±57 ng/mL). CK was significantly lower in Hot compared to Cold 8 days after damages (Hot= 1928±924 vs Cold= 4667±3010 and Neutral= 3937±2447 U/L) (p<0.02, p-eta2= 0.224). No significant differences in myoglobin and CK results were found between Cold and Neutral groups. Although the interaction did not reached significance for MVC (p=0.073), post-hoc analyses showed significantly higher MVC for Hot than Cold at day 2 and 4 (p<0.05).

CONCLUSION: The lower values in blood markers of muscle damage measured for Hot group suggest a faster removal of intra-muscular damages with the Hot treatment. Furthermore, MVC appeared to recover faster with Hot treatment. In contrast, the cold treatment had no significant effect on the muscle recovery indices. Heat-based therapies could represent a novel therapy to accelerate muscle regeneration after an injury.

OP-SH26 Well-being and sport

WHY ARE YOU DOING THIS? THE RELATIONSHIP BETWEEN MALTREATMENT HISTORY AND SPORTS MOTIVATION USING THE SELF-DETERMINATION THEORY.

RODRIGUE, C., LALANDE, D., PAQUETTE, L., PARENT, S., HÉBERT, M., BLACKBURN, M.E., DION, J.

UNIVERSITÉ DU QUÉBEC À CHICOUTIMI

A regular sports practice is associated with many positive health effects, and this is even more true for adolescents (Gómez-Baya et al., 2020). Sports participation motivation is increasingly studied using the Self-Determination Theory (SDT). This theory displays motivation on a continuum, from extrinsic to intrinsic; suggesting that undertaking an activity with more self-determined motivation is associated with more positive outcomes, while less self-determined motivation is associated with more dropouts and negative outcomes. Another facet of the SDT suggests that three basic psychological needs (autonomy, competence, relatedness) must be fulfilled to be intrinsically motivated (Ryan & Deci, 2017). On a different note, a disturbing rate of the population reports a history of child maltreatment (i.e., neglect, sexual, physical, and psychological abuse), which is associated with serious health issues (WHO, 2019). A promising avenue to prevent its negative outcomes is by promoting sports participation in youth, which should ideally be intrinsically motivated. To our

knowledge, no study has focused on sports participation in adolescents with a history of maltreatment, through the lens of SDT. The present study aimed to 1) compare adolescents with and without a history of maltreatment, all involved in a sport, on SDT factors and psychological outcomes, and 2) test the mediating role of basic psychological need satisfaction in the context of sports on the relationship between cumulative experiences of maltreatment and intrinsic motivation. A sample of 1,384 adolescents (M=14.69, SD=0.81) was retrieved from a larger sample. Participants completed questionnaires on sports participation, SDT factors, psychological outcomes, and maltreatment. First, group comparisons showed that adolescents with a history of maltreatment reported significantly lower self-esteem, life and body satisfaction, and more internalized and externalized symptoms. They also reported similar amounts of time devoted to sports, but significantly lower intrinsic and higher extrinsic motivation, as well as a lower satisfaction of all three basic psychological needs (<.01). Then, results of a path analysis showed significant indirect effects for autonomy [B=-0.037, 95% C.I. (-0.056, -0.02), p<.05], competence [B=-0.027, 95% C.I. (-0.042, -0.014), p<.05], and relatedness [B=-0.017, 95% C.I. (-0.032, -0.004), p<.05]. These findings suggest that the negative relationship between maltreatment history and intrinsic motivation was partly explained by the level of satisfaction of basic psychological needs. The present results highlight the relevance of considering the satisfaction of autonomy, competence, and relatedness in sports programs, to increase youths' self-determined motivation, particularly among those who have experienced maltreatment and hopefully create an environment where they can experience its positive effects.

CONFLICTING OR ENRICHING? WEEKLY FOLLOW-UP OF THE RELATIONSHIPS BETWEEN STUDENT-ATHLETES' ROLE INTERACTIONS AND WELL-BEING

LEFEBVRE DU GROSRIEZ, S.1, ISOARD-GAUTHEUR, S.1, BALK, Y.2, SARRAZIN, P.1

<1> UNIVERSITÉ GRENOBLE ALPES, <2> UNIVERSITY OF AMSTERDAM

Introduction

Due to the multiple demands of each career, student-athletes are especially at risk of well-being impairment. By meeting the demands, resources consumed in one role (e.g., athlete) may not be available in the other role (e.g., student): this is role conflict (Greenhaus & Beutell, 1985). Alternatively, the experiences lived in one role could provide resources usable in the other role: this is role enrichment (Greenhaus & Powell, 2006). Role interactions (i.e. conflict and enrichment) are likely to influence student-athletes well-being. Thus, the purpose of the present study was to examine the within-subject relationships between resources (i.e., mental rest), contextual demands, role interactions and contextual well-being indicators among student-athletes.

Method

Participants were thirty-three French student-athletes (women = 15) who responded to a weekly online questionnaire across five months, assessing their perceived mental rest, role interactions, demands, stress, and satisfaction in academic and athletic contexts.

Results

Multilevel analyses showed that after controlling for contextual demands, mental rest, age and gender, both school and sport stress were predicted (β = [.11 to .14], p <.05) by sport-to-school and school-to-sport conflicts. In addition, sport-to-school enrichment was also negatively related to sport stress (β = -.18, p <.001). School satisfaction was negatively predicted by sport-to-school conflict (β = -.13, p = .011) and positively by school-to-sport enrichment (β = .26, p <.001). Finally, sport satisfaction was negatively predicted by school-to-sport conflict (β = -.12, p <.05) and positively by sport-to-school enrichment (β = .23, p < .001). The four models predicted between 16% and 38% of the within-subject variance in contextual well-being.

Discussion

The results of this study contribute to research on student-athlete well-being by showing (1) that contextual stress and satisfaction vary significantly across weeks at the within-subject level, and (2) that sport-school role interactions predict contextual well-being, just as work-family role interactions predict organizational and family well-being. From a practical perspective, evidence of the relationships between demands, role interactions, and well-being could help student-athlete supervisors become aware of the need for specific dual-career management and help student-athletes manage their dual careers more effectively.

IS A COACH INDUCED EMPOWERING CLIMATE A PROTECTIVE FACTOR AGAINST (PEER) INTERPERSONAL VIOLENCE IN SPORT GROUPS?

OHLERT, J., SCHÄFER-PELS, A., RAU, T., ALLROGGEN, M.

GERMAN SPORT UNIVERSITY COLOGNE

Introduction

Research shows that a coach induced empowering climate is helpful for fostering intrinsic motivation in athletes. On the other hand, persons affected by sexual violence often report power inequalities between themselves and their aggressors within qualitative studies. As a strong empowering climate created by the coach has the effect of reducing power inequalities by empowering the athletes, the question arises if a coach induced empowering climate can also be a protective factor against different forms of interpersonal violence in sport? Furthermore, a particular focus within this study was on interpersonal violence between peer athletes, as previous studies show that for example one third of all incidences of sexual violence were caused by peer athletes (Ohlert et al., 2018). The question was how an empowering climate generated by the coach would also affect violence among the athletes?

Method

In this manner, an online survey with 648 athletes from 58 different kinds of sport was conducted. Participants answered to the German version of the "Empowering and Disempowering Motivational Climate in Sport Questionnaire" (EDMCQ; Ohlert, 2018). Furthermore, their observations and experiences of physical, psychological, and sexual violence were assessed with the German Version of the "Interpersonal Violence in Sport Questionnaire" (IViS; Vertommen et al., 2016).

Results

Different MANOVAs revealed that for all forms of interpersonal violence, athletes who had observed or experienced any form of this violence reported lower empowering climate and higher disempowering climate scores on some subdimensions. The differences were most evident for psychological violence, but held also true for sexual violence by the coach and by peer athletes.

Discussion

Our results indicate that a coach induced empowering climate (and less disempowering climate) is a promising aspect when clubs are looking for protective factors against all forms of interpersonal violence. Therefore, educating coaches in inducing an empowering climate can not only promote intrinsic motivation, but also seems to prevent interpersonal violence, including violent behavior among the athletes.

ASSOCIATIONS BETWEEN BELIEFS REGARDING INSTRUMENTAL EFFECTS OF MALTREATMENT AND COACH PSYCHOLOGICAL MALTREATMENT AND NEGLECT BEHAVIORS

PARENT, S., RADZISZEWSKI, S., GILLARD, A., BÉLANGER-GRAVEL, A., GAGNÉ, M.H., VERTOMMEN, T., WOODBURN, A.

UNIVERSITÉ LAVAL

Purpose: Given the magnitude of maltreatment toward athletes, evidence-based coach education is necessary to prevent those behaviors. Some coaching practices that constitute maltreatment are seen as necessary to drive performance of athletes, deter failure, test resilience and so on. The present study aims to examine if those beliefs are associated with psychological maltreatment and neglect behaviors in coaches.

Method: The sample consists of 732 adult Canadian coaches involved in organized sport. They completed an online questionnaire assessing their beliefs regarding instrumental effects of maltreatment (Perceived Instrumental Effects of Maltreatment Scale - PIEMS) and their behaviors regarding maltreatment (adapted version for coaches of the Violence Toward Athlete Questionnaire - VTAQ). A multiple logistic regression was performed to ascertain the effects of age, sex at birth, years of coaching experience, level of athletes they are coaching and mean PIEMS score on the likelihood that participants committed psychological maltreatment or neglect towards athletes.

Results: The logistic regression model was statistically significant, $\chi 2(11) = 52.614$, $p < .001$. The model explained 9.2% (Nagelkerke R2) of the variance for psychological maltreatment and neglect behaviors. Of the five predictor variables, only two were statistically significant: increasing number of years of coaching experience and mean PIEMS score were associated with an increased likelihood of perpetrating psychological maltreatment or neglect towards athletes.

Conclusion: Our results show that beliefs regarding instrumental effects of maltreatment are linked with psychological maltreatment and neglect behaviors of coaches. Targeting those beliefs in coach education programs will contribute at preventing maltreatment toward athletes.

BULLYING IN SPORT: A CASE STUDY OF HUNGARIAN SWIMMING

SZEKERES, D.1, WHYTE, I.2, SOOS, I.1

1. HUNGARIAN UNIVERSITY OF SPORTS SCIENCE, BUDAPEST, HUNGARY 2. INTERNATIONAL NETWORK OF SPORT AND HEALTH SCIENCES, FRANCE

INTRODUCTION

Bullying is a hostile and deliberate behaviour. Recent work on 'black pedagogy' (Borosan et al., 2022) highlighted areas of concern in Hungarian schools, however, it also raised issues in sport. The literature evidences incidences of psychological, physical or sexual abuse across a variety of sports, from recreational to elite performers, and across the globe such as in the UK, USA and France, among other countries. Hungarian Swimming came under the spotlight as a result of the Túri case. Significant abuse against swimmers was proven. Apart from 'black pedagogy' research, there is little published work on this topic in Hungary. This paper aimed to kickstart the process by interrogating the international literature on one key area of abuse, namely bullying, and compare the findings with Hungarian swimmers' experiences.

METHOD

A search of the literature was conducted using key words of elite sport, bullying, and swimming,followed by comparison with transcripts of swimmers' statements. Theoretical models were applied for fit.

RESULTS

The literature showed that bullying in sport is a worldwide phenomenon, with coaches, parents, and peers being the protagonists. Performance demands were instrumental in bullying by coaches and parents. Bullying from peers seems more likely to reflect social interactions. In terms of Hungary's elite swimmers, bullying was mainly led by coaches, with verbal bullying being endemic. Critical comments about athletes' capacities or talents or for relatively poor training or competition performances predominated, often shouted at the athletes, regularly in public. At times, the verbal abuse was accompantied with physical punishment. Subsequently, Bronfenbrenner's Socio-ecological framework was identified as a sound model to explain the phenomenon.

DISCUSSION

A conclusion can be drawn that bullying may be existed in elite Hungarian swimming, mirroring in part the international literature. But, at this level and age of particpants, peer-based bullying was limited. These investigations led to changes with respect to safeguarding policies and operations. Progress is now needed. Bullying is one abusive behaviour and work is needed across the full spectrum. First, a full systematic review of the literature is required embracing all global sport, at all ages, levels and abilities, and including legal and grey literature from varying jurisdictions. Secondly, there is a need to identify what policies have been developed to safeguard children and vulnerable adults across sports and national boundaries. Finally, studies must be undertaken to investigate the efficacy of policy and strategy directives at all levels as new procedures, education, training, and accreditation opportunities are pointless unless they make a difference. Identifying whether this is happening should be the ultimate aim of future research.

IS-PN07 Mitigating the effects of heat stress during the 2024 Paris Olympics

PRACTICAL APPROACHES TO MINIMISE THE IMPACT OF DEHYDRATION ON ATHLETE PERFORMANCE

JAMES, L.

LOUGHBOROUGH UNIVERSITY

For athlete hydration, much debate centres on how (mainly laboratory-based) research is translated into drinking recommendations for athletes, with strategies mainly described as falling into two categories: 'planned' or 'thirst driven/ad libitum' drinking. Whilst a 'thirst driven/ad libitum' approach will likely suffice in many settings; some specific situations may require a deliberate plan.

With elite athletes undertaking prolonged high-intensity exercise, particularly in the warm/hot environments likely at Paris 2024, sweat rates will be high and often far greater than the volume of drink feasible to ingest during exercise. For example, an elite runner weighing 60 kg and sweating at an average of 3 L/h over a marathon taking 2 h 10 min, would need to consume ≥5 L of drink during the race to prevent dehydration equivalent to 2% body mass. This means dehydration (sometimes significant) can develop, and performance may be negatively impacted. In contrast, it is important to recognise that in some settings, sweat rate will be low and fluid availability plentiful, meaning over-drinking, and exercise-associated hyponatraemia may present a risk to athlete health/performance.

Randomised cross-over experiments consistently demonstrate the negative impact of dehydration on athletic performance, particularly endurance performance. The mechanisms underpinning these impairments are multifactorial, likely acting in combination depending on the individual athlete, the athletic endeavour, and various environmental factors. Situations where dehydration is likely to develop should be carefully considered and planed for to give the athlete the best chance of minimising performance deficits. Even if the plan is simply to drink to thirst/ad-libitum. It must also be recognised that it may not always be possible to fully replace sweat losses or even maintain dehydration below a certain threshold. As such, athletes/support staff may consider other strategies during the short- and long-term pre-event preparation to minimise dehydration-induced performance deficits.

This presentation will outline how athletes' performances at Paris 2024 may be impacted by dehydration and cover practical approaches to allow athletes/support staff to make decisions about when and when not to plan fluid intake during exercise. Other potential strategies for minimising dehydration-induced performance impairments and considerations for overlap between hydration and other fuelling/nutrition strategies will also be considered.

COOLING STRATEGIES FOR ELITE ATHLETES: BENEFICIAL EFFECTS ON EXERCISE PERFORMANCE AND PRACTICE CONSIDERATIONS

BONGERS, C.

RADBOUD UNIVERSITY MEDICAL CENTER

Cooling strategies prior to (pre-cooling) or during exercise (per-cooling) are known to improve exercise performance in the heat due to reductions in thermal strain and an increased heat storage capacity. Pre-cooling can be described as the rapid removal of heat from the body before exercise to create a larger heat storage capacity, whereas per-cooling is defined as any opportunity to reduce thermal stress during exercise by applying a cold stimulus. Possible cooling interventions include cold water immersion, cold water/ice slurry ingestion (also known as internal cooling), wearing a cooling/ice vest or cold packs, water spray or water dousing, and the application of menthol on the skin or by using a mouth rinse. Previous studies demonstrate that pre- and per-cooling improve exercise performance in the heat by 4.7% and 5.3%, respectively, with greater performance benefits for endurance exercise compared to intermittent sprint exercise protocols. Along with its effects on exercise performance, cooling reduces the risk of exertional heat-illness and may facilitate safer exercise performances during the Paris Olympics of 2024. Therefore, athletes and their coaches should focus on cooling interventions and practise different interventions in competitive settings to optimise performance and increase the chance of winning a gold medal! Sport-specific regulations, practical considerations and local environmental conditions are important determinants for the effectiveness and implementation of cooling interventions. For example, event-specific regulations do not always permit per-cooling strategies such as wearing a cooling vest or cooling packs. This suggests that athletes should adopt a customised cooling strategy that complies with the regulations, practical considerations and environmental conditions of their sport and event. This presentation will outline the effectiveness of different times (i.e. pre- or per-cooling) and types (i.e. internal and external) of cooling interventions on exercise performance and thermophysiological outcomes (i.e. core temperature, skin temperature, heart rate), and explain the different approaches that can be used by athletes during competition, while taking into account the effectiveness of the intervention and the practical feasibility. Physiologist, coaches, and athletes will benefit from this presentation by gaining a deeper understanding of the nuances associated with implementing cooling strategies into the pre-event preparation, warming-up and/or during competition of elite athletes.

HEAT ACCLIMATION AND THE ELITE ATHLETE: BENEFITS AND INTEGRATION INTO THE TRAINING PROGRAMME

PÉRIARD, J.

UNIVERSITY OF CANBERRA

Heat acclimation and the elite athlete: Benefits and integration into the training programme Abstract: Heat acclimation has been suggested to be the most important intervention one can adopt to reduce physiological strain and optimise performance in the heat. The adaptations stemming from regular exposure to heat stress enhance thermoregulatory capacity, improve fluid balance and increase cardiovascular stability. The functional benefits associated with heat adaptations lead to improvements in endurance performance and comfort in the heat, and reduce the risk of exertional heat illness and thermal injury. Although the benefits of heat acclimation are well established, a key question for elite athletes regarding the implementation of heat training is when to schedule it in the overall training programme. Prior to a major competition, most athletes will undertake a block of training in which volume and/or intensity are increased, followed by a period of taper. Supplementing the intensified training period with exercise-heat exposures may lead to suboptimal training adaptations due to fatigue accumulation and inadequate recovery, particularly when adopting more traditional and rigorous laboratory-based heat acclimation regimens (e.g. 10-14 consecutive days of exercise in the heat for 90 min). Moreover, while exercise-heat exposure during the taper may help maintain the benefits of heat acclimation, it may also interfere with the goal of reducing overall training load. As such, this presentation will outline the time course of human heat adaptation, detail the performance benefits conferred by acclimation when exercising in hot environmental conditions, and explain the different approaches that can be used to induce heat acclimation. These different approaches, including the controlled heart rate and post-exercise passive heat exposure approaches, will be contextualised to the different training periods leading up to a major competition. Examples of which approaches to use and when to implement these will be provided. The benefits of heat re-acclimation will also be outlined, along with timelines for its implementation for the re-induction of adaptations. The different heat acclimation approaches will also be discussed in relation to the availability of resources and arrival timeline of the athlete at the competition venue. Physiologist, coaches and athletes will benefit from this presentation by gaining a deeper understanding of the nuances associated with implementing heat acclimation into the training programme of elite athletes.

NIRS ASSESSMENT OF MICROVASCULAR FUNCTION AND MUSCLE OXIDATIVE CAPACITY IN PATIENTS WITH FRIEDREICH'S ATAXIA

NERI, M., VUKAJ, X., FICHERA, M., NANETTI, L., MARCHINI, G., MARZORATI, M., MARIOTTI, C., PORCELLI, S.

NATIONAL RESEARCH COUNCIL

INTRODUCTION: Friedreich's ataxia (FA) is an inherited autosomal recessive disorder caused by the reduction of frataxin protein and affecting central and peripheral nervous systems, skeletal muscle and myocardium. In FA patients, reduced levels of the frataxin protein cause iron overload, increased oxidative stress and impairment of mitochondrial function [1]. FA patients show progressive gait disturbances, limb ataxia, lower extremity weakness and early fatigue which have been correlated to mitochondrial disfunctions. Decreased oxygen delivery and microvascular impairments as secondary effect of muscle disuse may also contribute to exercise intolerance [2]. In this study we aimed to evaluate microvascular function and muscle oxidative capacity in FA patients by near infra-red spectroscopy (NIRS), a non-invasive technique which has been demonstrated effective in highlighting mechanistic insights into different diseases [3].

METHODS: Eighteen FA patients (26±8 years) and fourteen age-matched healthy subjects (CTRL) were recruited. All patients were able to walk either without support or with walker and had a mean total score at the SARA Scale of 17±6 points [4]. NIRS measures were performed on gastrocnemius medialis (GM) by a continuous-wave device. Adipose tissue thickness (ATT, mm) was measured by a skin caliber. Microvascular responsiveness was evaluated analysing tissue saturation index (TSI) changes during the first 30 s of reperfusion (Slope30) immediately following 3-min occlusion of popliteal artery [5]. Muscle oxidative capacity (mVO2) of GM was estimated by NIRS from recovery rate constant (k) of TSI changes during brief intermittent arterial occlusions [6]. Within-subject test-retest reproducibility of k was tested as intraclass correlation coefficient (ICC) and Pearson's coefficient.

RESULTS: ATT was 6.9±2.8mm for FA patients and 5.9±2.3mm for CTRL. During 3-min ischaemia, TSI difference between the minimum and maximum was similar between FA (19.2±9.8%) and CTRL (20.9±10.9%, p=0.66). Slope30 was significantly lower in FA (0.46±0.24%*s-1) compared to CTRL (0.74±0.43%*s-1, p=0.03). The individual test-retest reliability of k in both FA and CTRL was good (ICC=0.74; r=0.74). k was lower in FA (1.19±0.53 min-1) compared to CTRL (2.36±0.82min-1, p<0.001).

CONCLUSION: FA patients, compared to healthy controls, showed lower microvascular responsiveness and muscle oxidative capacity. Thus, FA patients may have muscular exercise impairment due to deficit of both O2 delivery and O2 uptake at skeletal muscle level. Present data also suggest that NIRS can represent a non-invasive tool to identify pathophysiological hallmark of FA, suggesting potential future applications for monitoring disease progression or response to rehabilitative interventions.

NEAR-INFRARED SPECTROSCOPY MUSCLE OXYGEN SATURATION AND HEART RATE IN MAXIMAL EXERCISE: COMPARISON BETWEEN TREADMILL, ELLIPTICAL TRAINER AND CYCLE ERGOMETRY

ABRANTES, C.1,2, MACHADO, I.1, SANTARÉM, D.1

1 RESEARCH CENTER IN SPORTS SCIENCES, HEALTH AND HUMAN DEVELOPMENT

INTRODUCTION: Maximal exercise intensity is widely used to assess physiological responses in a variety of populations. Determine muscle oxygen saturation (SmO2), using the emerging easy-to-use technique of near-infrared spectroscopy (NIRS), combined with the heart rate (HR) in response to different exercise modes (or ergometers), remains unclear. The aim is to compare the changes in SmO2 in the gastrocnemius medialis (GM) and vastus lateralis (VL) muscles, and the HR response at maximal exercise intensity performed on a treadmill, an elliptical trainer and a cycle ergometer.

METHODS: Fourteen healthy volunteers (age=34.9±9.1 years; height=169.4±8.6 cm; weight 69.7±9.8 Kg) performed three incremental tests to maximum intensity in a treadmill, an elliptical trainer and a cycle ergometer in different days and in a random order. During the incremental tests, the HR (Garmin, Soft Strap Premium, USA) and the SmO2 (Moxy 3, Fortiori Design LLC, Hutchinson, USA) of VL and GM were collected. The data of the last intensity level with one-minute duration was used to determine average HR (HRavg), peak HR (HRpeak), average SmO2 (SmO2avg) and minimum SmO2 (SmO2min) in VL and GM muscles.

RESULTS: Repeated measures ANOVA revealed an exercise mode effect on HRavg (F2,26=12.44, p=0.001, n2=0.150) and HRpeak (F2,26=13.15, p=0.001, n2=0.170). Higher values were found on HRavg on treadmill vs. cycle (177.2±7.5 vs. 167.5±13.4 bpm, p=0.005) and on elliptical (175.0±9.3 bpm, p=0.018) vs. cycle. A similar pattern was found on HRpeak with higher values on treadmill vs. cycle (183.9±2.1 vs. 172.9±3.7 bpm, p=0.004) and elliptical (180.5±2.5 bpm, p=0.017) vs. cycle. An exercise mode effect of SmO2min in VL (F2,20=5.24, p=0.015, n2=0.230) showed lower values on elliptical vs. cycle (15.0±10.7 vs. 37.6±18.2%, p=0.035). An exercise mode effect was also found in GM on SmO2avg (F2,24=27.19, p<0.001, n2=0.530) and on SmO2min (F2,24=18.35, p<0.001, n2=0.450). Lower values were found on SmO2avg on treadmill vs. cycle (27.3±9.4 vs. 57.6±14.9%, p<0.001) and on elliptical (33.0±12.1%, p<0.001) vs. cycle. Similarly, the SmO2min was lower on treadmill vs. cycle (21.8±9.0 vs. 48.3±15.2%, p<0.001) and on elliptical (25.3±13.2%, p=0.002) vs. cycle.

CONCLUSION: The treadmill and the elliptical trainer promoted an higher HR response at maximal intensity, probably justified by the amount of active muscle mass and for being body-weight support exercises. The SmO2, as a local variable, shows that the technique and body-position in the elliptical trainer requires more the VL, and the treadmill requests more of the GM. This exercise mode expertise is crucial for exercise prescription.

INFLUENCE OF EXERCISE DURATION AND TRAINING ON THE FUNCTIONAL RESERVE DURING SUPRAMAXIMAL EXERCISE TO EXHAUSTION

GARCÍA-GONZÁLEZ, E., GALVAN-ALVAREZ, V.1, GALLEGO-SELLES, A.1, MARTINEZ-CANTON, M.1, GARCIA-PEREZ, G.1, PEÑA-VEGA, P.1, IZQUIERDO-RUFINO, I.1, MARTIN-RINCON, M.1, CALBET, J.A.L.1

1 IUIBS AND ULPGC, SPAIN

INTRODUCTION: A partial recovery of exercise capacity is possible despite applying total ischaemia at the end of high-intensity exercise to exhaustion. Thus, some "functional reserve" (FR) or capacity to produce power at the same or higher level than at exhaustion exists at task failure. However, little is known about the factors that determine the FR. We aimed to determine if FR is higher when a given supramaximal exercise bout is stopped before task failure. Secondly, we aimed to determine the effects of sprint interval training (SIT) on the FR. We hypothesized that FR would depend on the level of fatigue at exhaustion and that SIT would increase the FR.

METHODS: After familiarization and VO2-relationship assessment, 29 healthy volunteers (22M/7F) performed 4 bouts of supramaximal exercise (120%VO2max) to exhaustion interspersed by 20s of ischaemia application (FRtest). On another visit, the duration of the 1st bout was limited to 40% of the time to exhaustion (TTE), followed by the 3 remaining bouts at 120%VO2max until exhaustion (shortened FR, SFR). A subgroup of 7 males followed SIT (4-6 30s sprints, 4min rest, 6 sessions in 2 wks). Leg lean mass (LLM, DEXA), performance (Lode Exc.) and cardiorespiratory variables (Vyntus) were assessed.

RESULTS: In FRtest, TTE during the 1st bout was 246±90 and 234±104 (P=0.72), work/kg LLM was 3.6±1.5 and 3.6±1.4 kJ/kg (P=0.974), O2deficit (df) was 3666±1388 and 2005±580 mL (P=0.001) in M and F, respectively. The FR (sum of 2nd and subsequent bouts) was 1.42±0.6 and 1.92±0.8 kJ/kg LLM (P=0.078), O2df was 1408±835 and 897±506 mL (P=0.14) during the FRtest, in M and F, respectively. In the SFR, FR was 3.3±1.6 and 3.4±1.8 kJ/kg LLM (P=0.91), O2df was 2656±1484 and 1476±474 mL (P=0.050) for M and F, respectively. The sum of O2df incurred in all 4 bouts was almost identical in FRtest and SFR in both sexes (4573±2111 and 4591±2192 mL, P=0.94). After training, performance in the 1st bout was largely improved (TTE by 33%, work/LLM by 33%, O2demand by 48% and O2df by 65%, all P<0.05), causing a remarkable performance enhancement during the whole supramaximal test (sum of all bouts). Training did not significantly alter the FR (P>0.05).

CONCLUSION: This research indicates that the FR is a limited and measurable variable in young, healthy males and females. These results show that the determination of the FR using repeated supramaximal bouts to exhaustion is robust, i.e., it is not influenced by a lower initial degree of fatigue in the first bout, provided that the subjects perform until task failure in the subsequent bouts. Two weeks of SIT do not augment the amount of FR, despite a marked performance enhancement during the supramaximal test. It remains to be determined whether differences in FR are present in elite athletes or modified by other training programs.

CARDIORESPIRATORY FITNESS MEDIATES ISOMETRIC AND ISOKINETIC STRENGTH EFFECTS IN MAXIMAL FAT OXIDATION IN TYPE 2 DIABETES.

OPAZO-DÍAZ, E.1,3, MARÍN-GALINDO, A.1,2, MONTES-DE-OCA-GARCÍA, A.1,2, PÉREZ-BEY, A.1,2, RAMIREZ-JIMENEZ, M.1,2,4, CORRAL-PÉREZ, J.1,2, CASALS, C.1,2, PONCE-GONZALEZ, J.1,2

1EXPHY RESEARCH GROUP, UNIVERSIDAD DE CÁDIZ, SPAIN; 2INSTITUTO DE INVESTIGACIÓN E INNOVACIÓN BIOMÉDICA DE CÁDIZ, SPAIN; 3UNIVERSIDAD DE CHILE, CHILE; 4UNIVERSIDAD DE VALLADOLID, SPAIN

INTRODUCTION: There is a loss of muscle mass in type 2 diabetes mellitus (T2DM) patients. Consequently, this population has decreased muscular strength and cardiorespiratory fitness (CRF). In addition, T2DM is associated with impaired fat

oxidation, a biomarker of metabolic flexibility related to muscle health. However, it remains unknown if this impairment in fat oxidation is more due to muscle strength or CRF loss. Hence, this study aimed to analyse the influence of muscular strength and CRF on maximal fat oxidation (MFO) capacity in T2DM.

METHODS: Sixty-six volunteers with T2DM (41 men, age 55±7) of the Edugution/Apetex study were evaluated in the same visit to the laboratory for testing. Body composition assessment by bioimpedance analysis was used to assess fat and lean mass. Indirect calorimetry during 30 min in a supine position at rest was used for the metabolic calculation of resting fat oxidation. Then, an incremental exercise protocol in a cycle ergometer with two consecutive phases was performed for MFO and VO2max. The first phase aimed to determine MFO, and it consisted of 3 min steps of 15W increments with a cadence of 60rpm. The test was stopped when RQ ≥1. After 5 min rest, the second phase to detect VO2max began with steps of 15W/min until exhaustion. Moreover, an Isometric knee extension test (Isom) for 6 seconds, three repetitions at 60° per second (Iso60), and 15 repetitions at 120° per second (Iso120) of knee concentric flex-ext were performed in an isokinetic dynamometer for peak and average torque. The maximal fat oxidation was estimated by interpolating the rest metabolic test, the incremental 3min step 15W test, and the VO2max test points. Linear stepwise regression and mediation analyses were performed to explain the relationship between muscular strength, CRF, and MFO with a significance of 95%.

RESULTS: The analysis by Baron and Kenny criteria shows that the Isom Peak Torque/Lean mass (Indirect Effect(I.E.): 0.189; C.I: 0.063-0.358), Iso60 Average Flexion Torque/Lean mass (I.E: 0.175; C.I: 0.073-0.313) and Iso120 Average Flexion Torque/Lean mass (I.E: 0.241; C.I: 0.110-0.409) have an indirect effect on MFO/Lean mass, and is mediated by VO2max/Lean mass. When the analysis considers only the legs for lean mass, Iso60 Average Flexion Torque/Legs lean mass (I.E: 0.193; C.I: 0.088-0.341) and Iso120 Average Flexion Torque/Legs lean mass (I.E:0.246; C.I: 0.112-0.421) have an indirect effect on MFO/Legs lean mass mediated by VO2max/Legs lean mass.

CONCLUSION: The Isom, Iso60, and Iso120 leg strength have an indirect effect on MFO and are mediated by VO2max when normalised by total and leg lean mass. CRF and lean mass are determinants of fat oxidation, and the results suggest that muscular strength needs to be considered as a complementary factor in the T2DM population. IS-BM02 Strategies for musculoskeletal loading modification to reduce injury risk in running

SELF-OPTIMIZED RUNNING STYLES: SHOULD WE CHANGE THE WAY WE RUN?

VANWANSEELE, B.

KU LEUVEN

Watching people run, it is evident that there is a substantial variability in how we move forward. Although the movement is very similar as everyone adopts a bipedal gait and puts one foot in front of the other to move forward, each runner runs with their own preferred running style including a self-selected speed, stride frequency and foot strike pattern. This preferred running style adapted by runners is metabolically optimal for them, i.e. the pattern that allows minimal energy consumption. Hence, energy minimization is often assumed to be one of the major neuromuscular mechanisms underlying the preferred gait. In addition, good exercise economy is beneficial for performance in endurance running. Changing to a forefoot strike pattern increases the gastrocnemius medialis muscle force, indicating larger metabolic cost. However as these muscles are working at a lower contraction velocity they do not consume more metabolic energy. In addition, preferred stride frequency reflects a trade-off between minimizing metabolic rate during stance by a high stride frequency, without excessively increasing the cost of leg swing or reducing the available time to produce the necessary forces.

In contrast, recommendation were made over the last decade to change the running pattern to reduce the musculoskeletal load on specific parts of the human body and reduce injury risk. A multitude of these retraining strategies can be founded in the literature (including changing foot strike pattern, increasing stride frequency and increasing duty factor) and have the ultimate goal to reduce the number of running injuries. However, as running injuries are a complex multifactorial interplay between intrinsic and extrinsic factors, a first step is to investigate what the effect of changing the running style is on musculoskeletal loading in the short-term term and to demonstrate that these changes can be learned and retained over time. There is conflicting and limited evidence for the short-term effect of gait retraining on the loading of the targeted joint. In addition, changing the load in one joint could affect the load in adjacent joints. In addition, if the metabolic energy is increased the runner might fatigue faster which could lead on itself to changes in running style and increased injury risk. It is therefore important to get a more holistic (load on the complete lower legs) overview of the effect of changes in running patterns and how these might change due to fatigue throughout a training session. This talk will present an overview of evidence on the short and long-term effects of gait retraining on reducing the loading on the targeted and the adjacent joints, and what evidence there is on potential changes during the training.

Trainers and sport medical staff could benefit from more holistic insight in the effects of running retraining.

EFFECT OF WEARABLE-BASED REAL-TIME FEEDBACK ON MUSCULOSKELETAL LOADING TO REDUCE INJURIES

VAN HOOREN, B.

MAASTRICHT UNIVERSITY

Repetitive tissue loading during the ground contact phase of running leads to microdamage. This microdamage can accumulate and eventually lead to a running-related injury when accompanied by insufficient time for remodelling and adaptation. Tools that can provide (real-time) feedback on the load applied to common injured tissues may therefore be helpful to reduce running injury risk.

Due to the importance of load in the development of running injuries, an increasing number of wearables is estimating biomechanical loading variables such as the ground reaction force or ground reaction force correlates (e.g. tibia shock, vertical loading rate) based on the assumption that these measures provide useful estimates of the forces experienced by tissues within the body such as bones and tendons. However, these surrogate measures do not always accurately reflect the force experienced by tissues within the body, and therefore, the use of these surrogate measures to predict or prevent injuries can be misleading. Further, since tissue load has a non-linear relationship with tissue damage, measures of tissue load also need to be translated to tissue damage to more accurately inform on potential adjustments to training.

The main purpose of this talk will be to discuss 1) research on quantifying loading and damage at common running injury locations using wearable technology and 2) the effect of wearable-based real-time feedback on this load to reduce injury risk in-field. The talk will finish with a discussion of the limitations to current approaches for quantifying load and damage at common injury locations and highlight some future research requirements to overcome such limitations.

Overall, the quantification of tissue loading with wearable technology and the provision of real-time feedback to reduce loading on certain tissues may be useful to reduce injury risk. However, further research is required to better individualize the load and damage estimations by incorporating individual-specific tissue characteristics such as tendon stiffness and/or bone cross-sectional area. Finally, feedback models should also incorporate the process of adaptation and re-modelling and be able to differentiate between different training levels to ensure appropriate recommendations.

The target audience includes individuals interested in running injury prevention, biomechanics and sports performance.

THE RUNNING SHOE AS A STRATEGY TO MODIFY MUSCULOSKELETAL LOADING AND PREVENT RUNNING-RELATED INJURIES

MALISOUX, L.

LUXEMBOURG INSTITUTE OF HEALTH

Running can be practiced almost everywhere and requires mainly a pair of "appropriate" running shoes. However, the term "appropriate" is ambiguous, and the properties of running shoes has always generated hot debates among clinicians, coaches and athletes, whatever the level of practice. Indeed, the main drawback of regular running practice is the high incidence of musculoskeletal injuries, which is considered a major barrier to continued participation. The running shoe may potentially play an important role in injury prevention as it represents the main interface between the foot and the ground. Consequently, some shoe features may influence the burden of repetitive external and internal mechanical load applied to the musculoskeletal system. Over the last decades, running shoes have been prescribed based on matching shoe features to foot morphology. Furthermore, shoe cushioning technology is expected to protect runners against repetitive loading of the musculoskeletal system. Conversely, some schools of thought have promoted the use minimalist footwear. Overall, it is a popular belief that footwear is one of the main extrinsic factors influencing running-related injury risk. Despite the constant progress in running shoe technology, injury rate seems to remain high. The main purposes of this talk will be 1) to clarify what scientific evidence is available for clinicians and coaches to provide the runners with advice for the choice of "appropriate" running shoes with the view to reducing injury risk, and 2) to explore the underlying mechanisms that may explain the possible protective effect of some shoe features.

Overall, it is still too early to formulate evidence-based prescriptions regarding the choice of running shoe features. Nevertheless, some results suggest that certain shoe features may be of benefit to specific subgroups of runners. The few randomised trials conducted so far still need to be confirmed before any shoe prescription guidelines are scientifically justified. Caution should be taken when generalizing these preliminary findings from research, as well as when facing simplistic explanations and common sense. The impact of the biomechanical modifications induced by shoes features on injury risk has also been poorly investigated. Furthermore, inappropriate biomechanical variables have been used, especially when investigating shoe cushioning. More studies investigating the effect of shoe features on both running biomechanics and subsequently on injury occurrence are needed. Indeed, the size of the effect of shoe features on running biomechanics may be small and considered not "clinically relevant", but the accumulated effect over the thousands of steps of each running session may represent a substantial difference in the cumulative load applied to the musculoskeletal system. The consequence on the health of the athlete can only be assessed through a prospective collection of complaints.

RUNNING ON ROAD OR TRAIL, WHAT IS THE DIFFERENCE IN ENERGY COSTS AND PERCEIVED EXERTION

LAMBERTS, R.P.1, BURGER, J.2, BOSCH, A.2, TAM, N.2, EKEN, M.M.3

1 STELLENBOSCH UNIVERSITY; 2 UNIVERISTY OF CAPE TOWN; 3 STELLENBOSCH UNIVERSITY

INTRODUCTION: Over the last decade trail running has become popular and more and more runners cross-train on both surfaces (1,2). Although several studies have described the differences between road and trail running, as well as the associated risk of injury (3), relatively little is known about the differences in physical demands and subjective perceptions during road and trail running and especially during running uphill and downhill running. Therefore, the aim of this study was to determine if physiological responses and ratings of perceived exertion differ between running on tar (road) or gravel (trail).

METHODS: An a priori sample size of twenty well-trained runners (25±5 yrs) who were accustomed to both trail and road running participated in the study. All participants completed a peak treadmill running speed (PTRS) test as well as 4 sub-maximal outdoor runs. All subjects performed 2 trail and 2 road runs, one at 50% add the other one at 60% of PTRS. The profile of the trail and road course were identical and existed of 500m of downhill running and 500m of running uphill (11%). Heart rate (HR) and oxygen consumption (VO2) were captured during the run, while a rating of perceived exertion for the uphill and downhill section was captured directly after each run. Data were analysed with a 3-way ANOVA (condition, speed, gradient), while a posthoc Tukey test was performed when significance was found.

RESULTS: No differences in any of the physiological responses or the ratings of perceived exertion were between running on trail or road. However, significant differences were found when running downhill, at both 50% and 60% of PTRS. Mean HR (10±6 bpm at 50%PTRS & 10±4 at 60%PTRS, p<.0001)) and VO2 consumption (3.9±1.6 ml·min-1·kg-1 at 50%PTRS & 3.8±1.2 ml·min-1·kg-1 at 60%PTRS, p<.0001) were higher and running economy was poorer(17.1±9.2 ml·min-1·km-1 at 50%PTRS & 16.0±8.0 ml·min-1·kg-1 at 60%PTRS, p<.0001) when running downhill on trail. Interestingly RPEs were similar for both the uphill and downhill sections between the road and trail condition at both speeds.

CONCLUSION: The costs of running downhill at the same speed on trail are significantly higher than on a road (Heart rate: 7 to 8%; VO2: 17 to18%, running economy: -17 to -18%). However, runners report similar ratings of perceived exertion when running on trail or on road. This mismatch of higher energy cost and similar subjective perceptions might result in trail runners over-pacing themselves while running downhill in trail running. In addition, this mismatch might increase the risk of injuries as runners might also not be aware of faster-rising levels of accumulated fatigue while running downhill on trails.

EFFECTS OF NIKE VAPORFLY NEXT% SHOES ON RUNNING ECONOMY, BLOOD LACTATE CONCENTRATION, AND ENERGY EXPENDITURE – A SINGLE CASE FIELD STUDY

TRISKA, C.1, SOUKUP, C.1, SCHARNER, M.1, ERNST, J.1, MATHY, A.1

LEISTUNGSSPORT AUSTRIA

INTRODUCTION: Since several years carbon plate shoes are commonly used in long distance races and also the fastest marathon ever was performed with these shoes. Recent works suggest that high-level runners notably benefit from wearing carbon plate shoes compared to traditional lightweight shoes [1], however, results for sub-elite and recreational runners are controversial [2]. The major limitation of recent studies is that the running tests were performed on a treadmill which clearly lacks ecological validity. Therefore, we performed a field test to assess running economy and metabolic response.

METHODS: A 40-year-old age-group triathlete (stature: 1.82 m, body mass: 74 kg, VO2max: 57 mL/min/kg) performed four 1,200 m runs on a 400-m outdoor athletics track. Two runs were performed at 3.33 m/s wearing either Nike Vaporfly Next% (NEO) or Asics DS Trainer (TRAD). After that two additional runs at 4.17 m/s were performed using NEO and TRAD. All runs were performed below critical speed in order to ensure steady state conditions in oxygen uptake. Passive rest periods between the 1,200-m runs were 15 min. During all runs respiratory gases and ventilation were measured breath-by-breath using a mobile gas analyser (MetaMax-3B, Cortex Biophysik GmbH, Germany). After each run a blood sample from the earlobe was obtained to assess blood lactate concentration. Samples were analysed subsequently using an automated lactate analyser (Biosen_C, EKF diagnostics, Germany).

RESULTS: Respiratory exchange ratio was below 1.00 in all runs (range: 0.83 to 0.95). Running economy at 3.33 m/s was 219 and 207 mL/kg/km (-5.5%) for TRAD and NEO, respectively and at 4.17 m/s was 212 and 197 mL/kg/min (-7.0%) for TRAD and NEO, respectively. Similar to running economy, blood lactate concentration was lower in NEO at 3.33 m/s (2.0 vs. 2.1 mmol/L; -5.0%) and also lower for NEO at 4.17 m/s (5.8 vs. 6.2 mmol/L; -6.9%) compared to TRAD. Total energy

expenditure at 3.33 m/s was 1066 J/s and 1036 J/s (-2.8%) for TRAD and NEO, respectively. At 4.17 m/s total energy expenditure was 1274 J/s and 1197 J/s (-6.0%) for TRAD and NEO, respectively.

CONCLUSION: The results of this single-case overground running study suggest that amateur athletes can benefit from wearing carbon plate shoes to a greater degree at higher speeds. Independent of running speed, running economy was notably superior when wearing the carbon plate shoe compared to the traditional lightweight shoe. Furthermore, muscle metabolic stress (i.e., blood lactate concentration) and total energy expenditure (i.e., oxidation of fat and carbohydrates) were considerably lower when using the carbon plate shoe. The findings of this field study are in accordance with recent findings obtained from treadmill running tests which recommend the use of carbon plate running shoes when aiming to elevate running performance by enhancing running economy and lowering muscle metabolic stress.

BRIDGING THE GAP BETWEEN CRITICAL VELOCITY AND MAXIMAL LACTATE STEADY-STATE

QUITTMANN, O.J., GEHLERT, G., SCHWARZ, Y.M., NOLTE, S., FUCHS, M., SCHIFFER, A., SLOWIG, Y., FOITSCHIK, T., ABEL, T.

GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: The ability to sustain a high metabolic rate for an extended period of time is essential for endurance performance and reflects the interplay between the aerobic and anaerobic metabolism [1]. The most frequently used parameters in that regard are the onset of blood lactate accumulation (OBLA), maximal lactate steady-state (MLSS) and critical velocity (CV). These concepts have been discussed extensively in recent reviews [2,3]. Despite the overwhelming general observation that CV overestimates MLSS, the origin of this discrepancy is still unknown [3]. This study examines the CV-MLSS difference and analyses whether physiological parameters may help to bridge the gap between concepts.

METHODS: A total of n=19 well-trained runners/triathletes performed several lab tests to determine maximal lactate accumulation rate (ċLamax), maximal oxygen uptake (V̇O2max), fractional utilization (%V̇O2max), running economy (RE), maximal fat oxidation rate (MFO), OBLA and MLSS. Furthermore, time trials (TTs) over 1, 2 and 3 km were performed on an outdoor track to determine CV and D' by the linear t(d) model [4]. Post-exercise lactate concentration was recorded immediately after the TTs as well as 3 and 6 min afterwards. Repeated measures ANOVA and Bland-Altman plots were used to analyse differences between OBLA, MLSS and CV. The absolute difference between CV and MLSS was correlated with several physiological parameters.

RESULTS: TTs were performed in 174±10, 385±25 and 607±47 s, respectively. The corresponding maximal post-exercise lactate concentrations were 14.8±2.8, 13.8±2.9 and 12.3±2.28 mmol/L, respectively. OBLA (4.25±0.49 m/s), MLSS (4.15±0.49 m/s) and CV (4.66±0.42) differed significantly among each other. Limits of agreement for CV-MLSS ranged between +0.13 and +0.88 m/s, while the mean relative difference was 12.5±5.6%. CV and MLSS shared ~85% of their variance. The only physiological parameters that significantly correlated with the CV-MLSS difference were maximal post-exercise lactate concentrations following the 2 km (r=0.558, p=0.013) and 3 km (r=0.645, p=0.002) TTs. RE demonstrated a positive tendency (r=0.409, p=0.082).

CONCLUSION: Our findings show that individuals with higher post-exercise lactate concentrations after the 2 and 3 km TTs demonstrate larger CV-MLSS differences. High concentrations might reflect the participants' effort during the TTs which result in a higher estimation of CV. Previous research in soccer players found no significant difference between OBLA and MLSS and a lower mean relative CV-MLSS difference of ~10% [5]. This might be due to the applied TTs (1.5 and 3 km) and/or their lower performance levels in terms of MLSS (3.64±0.36 m/s). Future research should expand the selection of physiological parameters and perform such analyses for the relative CV-MLSS differences.

PERSPECTIVES OF DETRENDED FLUCTUATION ANALYSIS (DFA) OF HEART RATE VARIABILITY (HRV) FOR EXERCISE PRESCRIPTION AT THE BOUNDARY OF MODERATE TO HEAVY INTENSITY

GRONWALD, T.1, KAUFMANN, S.2, HORN, L.2, BERBERICH, L.2, WAGENHAUSER, M.2, HOOS, O.2

1 MSH MEDICAL SCHOOL HAMBURG, 2 JULIUS-MAXIMILIANS-UNIVERSITY WÜRZBURG

INTRODUCTION: The non-linear index alpha 1 of DFA (a1) of HRV has been shown to be a promising biomarker especially for the transition between moderate to heavy intensity domain and for real-time exercise intensity feedback [1,2,3]. However, since validation data on prescribed prolonged exercise bouts are still scarce the true significance for exercise prescription remains to be fully elucidated. Therefore, the present pilot study aims to evaluate its ability to prescribe and monitor exercise intensity at the transition between moderate and heavy domain during a continuous running bout.

METHODS: 21 moderately trained endurance athletes (9w, 12m; age: 25.9±3.6years, height: 178.4±9.9cm, body weight: 70.8±8.7kg, body fat: 12.2±4.4%, maximum heart rate: 198.4±7.9bpm, maximum oxygen consumption (VO2peak): 59.0±8.3 ml/kg/min) performed an exhausting ramp test in which running speed (RS) at first ventilatory threshold (RSVT1)

and at DFAa1=0.75 (RSa1) were determined. Afterwards, a 20-min continuous running bout at RSa1 (20minRSa1) was administered. Blood lactate concentration (BLC) was assessed after 20minRSa1 and VO2, HR and DFAa1 (window width: 120s, grid interval: 10s) were continuously recorded and statistically evaluated.

RESULTS: The prescribed external load of RSa1 (10.6±2.0km/h) was similar to RSVT1 (10.8±1.7km/h; p=0.209) and yielded mean HR of 154.6±12.3bpm, mean VO2 of 38.1±6.0ml/kg/min, mean DFAa1 of 0.84±0.24 and BLC of 1.56±0.59mmol/l at the end of 20minRSa1. In comparison of start and end of 20minRSa1 HR showed a significant increase from 152.2±12.2 to 158.4±13.0bpm (p<0.001, d=0.51), while VO2 and DFAa1 remained rather stable with 37.9±5.7 vs. 38.5±6.3ml/kg/min (p=0.06, d=0.10) and 0.85±0.29 vs. 0.78±0.23 (p=0.112, d=0.24), respectively. Linear regression slopes supported these results with 0.0724±0.0447 for HR, 0.0083±0.0130 for VO2, and -0.0009±0.0028 for DFAa1, respectively.

CONCLUSION: Our data in endurance running supports the general notion that DFAa1 of 0.75 is promising for internal load-based exercise prescription at the boundary of the moderate to heavy intensity domain [3]. Inter-individual differences and the fact that RSa1 target led to reduced values of DFAa1<0.75 in some participants (n=5) implies the need for internal load-based real-time monitoring and intra-individual internal-to-external load analysis as a regular biological calibration procedure. Furthermore, future studies should compare continuous exercise bouts of different exercise intensity domains to elucidate possible decoupling mechanisms of DFA a1 and other internal load measures in relation to external load, as this may also bear potential for durability assessment of endurance exercise performance.

INDIVIDUALIZED LOW-INTENSITY JOGGING WITHIN RECOVERY ZONE 1 INCREASES THE ABILITY OF ENERGETIC RECOVERY IN PROFESSIONAL SOCCER PLAYERS

PARK, S.

CHA UNIV.

INTRODUCTION: This study aimed to investigate whether individualized low-intensity jogging (ILIJ) within the recovery zone 1 (RZ1) before lactate threshold 1 (LT 1) increases energetic recovery and general endurance capacity (zones 1, 2, and 3) in Korean professional soccer players.

METHODS: Twenty-four professional soccer players in the Korea professional Football League (n = 24, age: 24.53 ± 4.85 years, height: 180 ± 6.30 cm, body mass: 75.86 ± 8.01 kg, body fat: 12.19 ± 2.69%) participated in the study. During a free season, the 1-h ILIJ intervention involved 27 sessions spanning nine weeks and jogging speed corresponding to 72% of LT 1 (7.15 ± 0.95 km·h−1). Pre- and post-LT testing parameters determined within 9 weeks included blood lactate concentrations (La−) and heart rate (HR) at certain exercise intensities during LT test. The jogging/running speeds (S), delta (Δ) S, HR, and ΔHR were analyzed at 1.5, 2.0, 3.0, and 4.0 mmol·L−1 La−, respectively.

RESULTS: Levels of La− and HR at the same exercise intensities (5.4–16.2 km·h−1) in the post-LT test compared with pre-LT test were significantly reduced ($P < 0.05$ and $P < 0.01$, respectively). Moreover, S at all specific La− levels (1.5, 2.0, 3.0, and 4.0) were significantly increased, while HR at 2.0, 3.0, and 4.0 La− decreased significantly ($P < 0.05$ and $P < 0.01$, respectively). Low to moderate positive associations were found between ΔS and ΔHR at 1.5 and 2.0 La− ($r = 0.52$; $R2 = 0.27$ and $r = 0.40$; $R2 = 0.16$, respectively).

CONCLUSION: The nine-week ILIJ within RZ1 increased energetic recovery and general lactate exponential curve (rightward shift) in professional soccer players. This effect relates to repeated high-intensity intermittent sprints during the 90-min soccer game.

PERIPHERAL ALTERATIONS AND INCREASED PERCEIVED FATIGUE CONTRIBUTE TO ACUTE CROSSOVER FATIGUE AFTER A UNILATERAL SUBMAXIMAL ECCENTRIC KNEE FLEXOR EXERCISE

GIODA, J., DA SILVA, F., CORCELLE, B., MONJO, F., BREDIN, J., PIPONNIER, E., COLSON, S.S.

UNIVERSITÉ CÔTE DAZUR- LAMHESS UPR 6312

INTRODUCTION: After a unilateral muscle exercise, the performance of the non-exercised muscle of the contralateral limb may also be impaired. Although previously evidenced, this phenomenon known as "crossover fatigue" [1] is still debated in the literature. The variability of the study designs (e.g., age, sex, training status, upper vs lower body muscles…) participates to this debate [2]. While often used in resistance training and/or rehabilitation programs, only four studies have investigated the influence of eccentric contractions (ECC) on crossover fatigue and have reported discrepant outcomes. Therefore, this study was designed to assess the etiology of crossover fatigue of the non-exercised contralateral knee flexor muscles after a unilateral submaximal ECC fatiguing exercise of the ipsilateral muscles.

METHODS: Seventeen healthy young men were evaluated before (PRE), immediately after a unilateral submaximal ECC knee flexor exercise (POST) and 24 hours later (POST24). ECC exercise was performed in the exercised limb (EL) until a 20% decrease in maximal voluntary isometric contraction (MVIC) was reached. Neuromuscular function (i.e., MVIC, voluntary activation and electrically muscle contractions evoked at high and low frequency [Dt100Hz and Dt10Hz, respectively]) were measured in both the EL and non-exercised limb (NEL). Perceived muscle soreness was measured in both the EL and the NEL and global perceived fatigue was also assessed.

RESULTS: At POST, the reduction in maximal voluntary isometric contraction observed in the EL was -28.1 ± 6.5% ($p < 0.001$) and a crossover fatigue occurred in the NEL (i.e., maximal voluntary isometric contraction decrease of -8.5 ± 16.2%; $p < 0.05$). At POST, voluntary activation decreased in the EL only (-6.0 ± 8.2%; $p < 0.05$) while electrically muscle contractions evoked at high and low frequency were impaired in both limbs (i.e., -11.6 ± 17.9% and -8.07 ± 24.2%, respectively; $p < 0.05$). Global perceived fatigue was significantly increased at POST ($p < 0.001$). Although the maximal voluntary isometric contraction of both limbs had returned to PRE values at POST24, perceived muscle soreness scores were higher than PRE values in the EL ($p < 0.05$) whereas perceived muscle soreness did not change in the NEL.

CONCLUSION: This study is the first to highlight the occurrence of crossover fatigue on the knee flexors (-9%). In the EL, both central (i.e., reduced VA) and peripheral (i.e., impaired muscle evoked contractions) alterations accounted for the observed reduction in maximal voluntary isometric contraction. In contrast, given the significant reductions in muscle evoked contractions in the NEL, only peripheral alterations possibly involving systemic adaptations participated to the crossover fatigue observed at POST. Finally, increased global perceived fatigue could be involved in the impairment of maximal voluntary isometric contraction in both limbs.

REPEATED EXPLOSIVE CONTRACTIONS OF DORSIFLEXOR MUSCLES AFFECT THE MAXIMAL VOLUNTARY FORCE, RATE OF FORCE DEVELOPMENT AT MAXIMAL AND SUBMAXIMAL LEVELS, MAGNITUDE AND COMPLEXITY OF FORCE FLUCTUATIONS

D'EMANUELE, S., ANGIUS, L., HAYMAN, O., GOODALL, S., SCHENA, F., TARPERI, C., BOCCIA, G.

UNIVERSITY OF VERONA

INTRODUCTION: The loss of maximal voluntary contraction (MVC) is considered the most valid and widespread approach to measuring muscle fatigue. However, in many daily and sporting activities, the time required to develop maximal or submaximal force is longer than the time available to develop it. The rate of force development (RFD) is considered a valid indicator of neuromuscular fatigue (1) measured in explosive contractions targeting both maximal and submaximal force levels. Moreover, the changes in the magnitude and complexity of force fluctuations may have important functional consequences, given that the accuracy of voluntary movements is often more important for successful performance than maximal force-generating capacity (2). Considering the relevance of daily life and sports gestures to quickly produce maximal and submaximal forces, the aim is to understand fatigues effect on quick contractions targeting submaximal forces and the magnitude and complexity of force fluctuations.

METHODS: 14 male adults (32±6 yrs) visited the laboratory for familiarization and assessment. The participants were seated with the ankle inserted in the dynamometer with 64-channel HDsEMG placed over the tibialis anterior. PRE and POST fatiguing task an MVC and 12 ballistic isometric contractions at 30, 50, and 70% of MVC were performed. The fatiguing task consisted of a series of explosive contractions, interspersed by 4s, with a holding phase of 6s at 70% of MVC until failure. We considered the submaximal explosive contractions assessed PRE and POST and the first three and last three contractions of the fatiguing task for analyses.

RESULTS: PRE vs. POST fatiguing task the MVC, peak force and RFDpeak decreased respectively by 37, 21 and 40%. Time to peak force and time to peak RFD increased respectively by 43 and 18%. RFD assessed at 50, 100, and 150 ms decreased respectively by 36, 47 and 46% (all $p \leq .05$). RMS at 50, 100 and 150 ms assessed PRE and POST showed no statistically significant changes. The coefficient of variation changed from 1,6 to 2,7% and the mean force changed from 267,8 to 226,3 N·m. Approximate entropy decreased from 0.174 to 0.132 and the detrended fluctuation analysis changed from 1.57 to 1.73 (all $p \leq .05$). ANCOVA showed after the fatiguing task an RFD decreased at 50, 100 and 150ms during contractions at all submaximal levels.

CONCLUSION: The fatiguing task worsened the force production capacity and control overall which was evidenced by a decreased MVF, a longer time to peak force, a lower RFD, greater force fluctuations and lower force complexity. Of note, RFD, and time to peak force were evidenced also in explosive contractions targeting submaximal force levels. Overall, these results showed that fatigue reduces the neuromuscular systems adaptability over various dimensions.

NEUROMUSCULAR FATIGUE IMPROVEMENTS AND HEAT ADAPTATIONS CAN BE PRESERVED 20 DAYS AFTER HEAT-ACCLIMATION.

DI DOMENICO, H.1, GOUGH, A.2, NORTON, B.2, HINTZY, F.1, MAXWELL, N.2, RUPP, T.1, HAYES, M.2

1 - LIBM, UNIV SAVOIE MONT-BLANC, EA 7424, CHAMBÉRY, FRANCE; 2 - ENVIRONMENTAL EXTREMES LABORATORY, SCHOOL OF SPORT AND HEALTH SCIENCES, UNIVERSITY OF BRIGHTON, EASTBOURNE, UK

INTRODUCTION: Adaptations to short-term (<7 exposures) heat-acclimation (HA) decay rapidly and are lost within 2 weeks, likely compromising pre-competition/deployment training [1]. 6-days of post-exercise hot water immersion (HWI) has been suggested to retain heat adaptations for 2 weeks [2]. However, the effects of this method on overall fatigue (e.g. neuromuscular, cognitive and perceived) remains unknown and may compromise training. This study aimed to i) investigate the effect of 6-days post-exercise HWI on neuromuscular, cognitive and perceived fatigue pre and post exercise in a hot environment; ii) examine the effect of one maintenance session of post-exercise HWI per week on overall fatigue during 20 days of HA decay.

METHODS: 10 healthy males (22±3 yrs, 78±18 kg) completed HA: 6-days of post-exercise (running at 65% VO2max for 40min, 22°C) HWI (40min, 40°C). A Heat Tolerance Test (HTT = running 30min at 9km.h-1 2% slope at 40°C, 40% humidity) [3] was performed pre and post HA. Every 6 days post HA, a maintenance post-exercise HWI session was performed and a HTT was completed post10 and 20 days. Maximum voluntary contraction of the quadriceps (MVC), central [voluntary activation (VA)] and peripheral alterations [high-frequency doublet (Db100), twitch (Pt)] were evaluated pre and post each HTT. Cognitive performances (accuracy, reaction time, omission) to response inhibition (Stroop) and working memory (3back-letter) were performed pre and post each HTT. Perceived fatigue (ROF scale) was evaluated each day. Two-way repeated measure ANOVAs and Holm correction for post-hoc tests were performed.

RESULTS: Increase in rectal temperature and heart rate at rest and during the HTT were lower post HA compared to pre and sustained post20 (all $p<0.001$). Expansion in plasma volume and sweat rate, observed post HA, were not sustained post10 (respectively, $p=0.02$ and $p=0.04$). VA pre-post HTT was better preserved post HA and sustained post20 ($p=0.002$). Decrease in MVC, Db100 and Pt due to HTT was not different pre and post HA (respectively, $p=0.3$, $p=0.3$ and $p=0.2$). Accuracy to cognitive tasks was not impacted by HTT ($p=0.7$) but reaction time was faster post HTT compared to pre ($p=0.002$). All cognitive performances were improved after HA and post20. Perceived fatigue was stable during HA to post20 ($p=0.4$).

CONCLUSION: HA of 6 days post exercise HWI induced beneficial HA related adaptations (lower rectal temperature and heart rate, higher plasma volume and sweat rate); re-trained once a week, some of these adaptations were sustained for 20 days. HTT alterations on central component were limited by HA, and it was preserved for 20 days, while peripheral alterations were not. This simple, practical and effective HA strategy does not induce additional fatigue, and may preserve central function, during an exercise in a hot environment.

ACCELERATED RECOVERY OF NEUROMUSCULAR FUNCTION FOLLOWING LOW-LOAD CONTINUOUS BLOOD FLOW RESTRICTION EXERCISE COMPARED TO HIGH-LOAD RESISTANCE TRAINING

DAVIDS, C.J.1, GENEAU, M.C.1, LICHTWARK, G.2, COOMBES, J.S.2, PEAKE, J.3, RAASTAD, T.4, ROBERTS, L.A.5

1 LA TROBE UNIVERSITY, MELBOURNE 2 THE UNIVERSITY OF QUEENSLAND, BRISBANE 3 QUEENSLAND UNIVERSITY OF TECHNOLOGY, BRISBANE 4 NORWEGIAN SCHOOL OF SPORTS SCIENCE, OSLO 5 GRIFFITH UNIVERSITY, GOLD COAST

INTRODUCTION: Low-load resistance training with blood flow restriction (BFR) can elicit skeletal muscle adaptations that are similar in magnitude to high-load (HL) training, albeit with much less mechanical loading (1). However, there is limited understanding of the acute fatigue and recovery timelines with BFR exercise, and how these compare to typical HL training practices. Such insight would inform practitioners and coaches in successfully implementing BFR exercise in athletic cohorts.

METHODS: Twelve strength-trained males (22.3 +/- 3.2 years; height: 182.1 +/- 6.3 cm; body mass: 84.1 +/- 9.0 kg) performed four sets of squat-based exercise under four different conditions: (a) low-load resistance exercise (LL, 30%1RM); (b) high-load resistance exercise (HL, 70%1RM); (c) LL with intermittent blood flow restriction (BFR-I); and (d) LL with continuous blood flow restriction (BFR-C). LL conditions performed four sets of 30, 15, 15 ,15 repetitions, whereas HL performed four sets of 10 repetitions. Neuromuscular fatigue was evaluated by quantifying repetition velocity during exercise, and changes in isometric strength and jumping performance following exercise. The twitch interpolation technique was utilised during isometric contractions to investigate the origin of fatigue. Perceptions of effort were recorded before and after each set of exercise using a modified Borg exertion scale (CR-10).

RESULTS: Peak and average repetition velocities progressively slowed across the four sets with HL and BFR-C (~−5-8%) and this was significantly different to LL and BFR-I (~+4-7%; $p<0.05$). Perceptions of effort increased with exercise in all trials (all $p<0.01$), however this increase was greatest with BFR-C and HL equally (all $p<0.01$). At 60 minutes post-exercise, peak voluntary torque (PVT) and peak twitch torque (PTT) remained significantly below baseline levels with HL only ($p<0.05$). Jump height was also significantly impaired only following HL (~−15%; $p<0.01$) post-exercise. Rate of force devel-

opment (RFD) during the isometric and jumping tasks were similarly impaired in HL and BFR-C (~−18%; p<0.01). Voluntary activation (VA) did not change following any of the exercise trials (all p>0.05).

CONCLUSION: In conclusion, both BFR-C and HL squat exercise appears to induce significant neuromuscular fatigue during exercise, which resulted in slowed repetition velocities and greater perceptions of effort. However, unlike HL, it appears that several markers of neuromuscular fatigue are diminished within 60 minutes following continuous BFR exercise with LL. In particular, the PTT responses suggest that fatigue of peripheral origin may persist at 60 minutes post-exercise with HL but not BFR-C. The outcomes of this investigation may provide benefit to coaches within the competitive season, when caution is taken to balance the effects of fitness and fatigue on athletic performance.

INTRODUCTION: The effects of fatigue on neuromuscular function in adolescence are poorly researched, despite the potential impact on managing training loads and recovery in maturing children 1. Impaired sprint performance is commonly used as an indicator of fatigue but does not provide information on underlying biomechanical parameters of theoretical maximal force and velocity (F0 and v0) which are also impacted by growth and maturation. Only a few studies have investigated the effect of physical fatigue on force-velocity-power qualities of sprinting in rugby players 2,3. Furthermore, neuromuscular fatigue differs according to maturation. This study aimed to assess the effect of maturation on the impact of physical fatigue on F-v profile and sprint performance.

METHODS: This study involved 15 prepubertal (Pre) (155 ± 8 cm; 46.2 ± 8.6 kg) and 17 post-pubertal (Post) (179 ± 7 cm; 75.3 ± 8.9 kg) rugby players, who underwent 2 experimental sessions separated by at least 24 hours. Anthropometric characteristics and maturity status were assessed in the first session. In the second session and after a standardised 15-minute warm-up, subjects performed 7 blocks consisting of a 30m sprint and 5 minutes of high-intensity exercise (accelerations, decelerations, etc.) with one minute of passive recovery. Raw speed-time data for 7 maximal 30m sprints were measured with a radar (Stalker ATS II). The decrement in performance was assessed through a fatigue index (FI) computed from 30m times4. To analyse the effect of physical fatigue on the F–v profile, technical parameters, and sprint performance according to maturation and block (B1 to B7), a mixed two-way repeated measures analysis of variance was performed.

RESULTS: Significant main effects of block were found for Pmax, v0, 30m time, RFmax, and DRF ($p < 0.0001$ for all) with no significant differences between groups. For Pre and Post, deltas (Δ %) between B1 and B7 for Pmax, v0, 30m time, RFmax and DRF were -15% and -20%; -11% and -10%; +10% and +11%; -5% and -9%; +8% and +5%, respectively. They were all non-significant. Only F0 showed a significant main effect of block ($p < 0.0001$) and maturation ($p = 0.02$). Deltas were -5% and -12% for Pre and Post without significance. The intensity of the fatiguing task was controlled using the rate of perceived exertion and FI for which there was no significant effect between groups.

CONCLUSION: The results showed a decrease in all parameters for both groups due to the fatiguing protocol, with no significant differences between Pre and Post (except for F0). However, none of the deltas was significantly different. The differences in F0 did not impact Pmax and sprint performance. Finally, both groups experienced similar fatigue kinetics, regardless of maturation (similar FI).

OP-AP23 Interval Sprint Training

EFFECT OF DIFFERENT EXERCISE-TO-REST RATIOS DURING REPEATED-SPRINT TRAINING IN HYPOXIA INCLUDED IN A CLASSICAL ALTITUDE CAMP

BOUTEN, J., BRICK, M., SABOUA, A., HADJAJ, J.L., PISCIONE, J., MARGOT, C., DOUCENDE, G., BOURREL, N., MILLET, G.P., BROCHERIE, F.

INSEP

INTRODUCTION: Repeated-sprint training in hypoxia (RSH) is a popular and effective way of improving physical performance compared to similar training in normoxia. Repeated sprint training consists of "all-out" efforts of short duration (<

30 s) interspersed with short incomplete recoveries (<60 s) [1]. RSH efficiency relies on hypoxia severity, but also on effort duration and exercise-to-rest ratio [2,3]. However, the responses to RSH when combined with prolonged altitude exposure remain scarce. The aim of this study was therefore to assess the effect of two RSH training protocols with different exercise-to-rest ratios during a classical altitude camp.

METHODS: 16 players from the French national female rugby sevens team completed a 3-week natural "live high-train high" altitude camp at Font Romeu (1800 m asl) in preparation of the 2022 Rugby World Cup sevens. This camp included 5 RSH sessions performed on a bicycle ergometer in a hypoxic room (simulated altitude of 3000 m asl) with varying exercise-to-rest ratios of 1:2 to 1:3 (velocity-based group, n = 7) or 1:2 to 1:5 (aerobic-dominant group, n = 9) based on players' physical profile. Heart rate, peripheral oxygen saturation (SpO2) and rating of perceived exertion (RPE) were monitored during the first and last RSH session, as well as peak power output (PPO), mean power output (MPO) and sprint decrement score (Sdec).

RESULTS: PPO and MPO significantly improved from the first to the last training session (main effect, PPO: from 895 ± 104 to 977 ± 127 W, $p < 0.001$, Cohen's d = 0.70; MPO: from 690 ± 74 to 744 ± 93 W, $p < 0.001$, Cohen's d = 0.63), irrespective of the training protocol (interaction effect: $p > 0.05$). Sdec remained unchanged from the first to the last session (22.5 ± 5.7 vs 23.4 ± 7.6%, main effect: $p > 0.05$, Cohen's d = 0.13). The acute decrease in SpO2 remained similar throughout the training period despite a large effect size (82 ± 4 vs. 79 ± 5%, $p > 0.05$, Cohen's d = 0.75), without any group nor interaction effects (both $p > 0.05$). Interestingly, the velocity-dominant group perceived RSH training as harder than the aerobic-dominant group (RPE: 18.1 ± 0.8 vs. 16.6 ± 1.8 AU, $p < 0.01$, Cohen's d = 1.12), without any evolution over the training period ($p > 0.05$).

CONCLUSION: Adding five sessions of repeated-sprint training in hypoxia results in performance improvements during a classical altitude camp, independently of the imposed exercise-to-rest ratios. Whether manipulating exercise and recovery duration results in different beneficial effects of the metabolic pathways under hypoxic stress needs further investigations, as well as their combination with chronic hypoxia-induced haematological adaptations.

IMPROVEMENTS IN MAXIMAL OXYGEN UPTAKE PLATEAU AFTER TWO WEEKS OF SPRINT INTERVAL TRAINING.

LLORIA-VARELLA, J., KORAL, J., RAVEL, A., MURIAS, J.M., FÉASSON, L., BUSSO, T.
UNIVERSITÉ JEAN MONNET SAINT-ETIENNE

INTRODUCTION: Previous interventional studies ranging from 2 to 12 weeks of sprint interval training (SIT) have reported significant and consistent improvements in maximal oxygen uptake (VO2max) (1). The physiological adaptations behind these improvements tend to occur early within the training program and involve principally peripheral-related changes such as increased oxidative capacity due to a better muscle capillarization, and/or upregulation of enzymatic activities (2). However, although exercise intensity seems to be a key factor for mediating most of the improvements (2), no clear relationship between the length of the training programs and the magnitude of improvements has been identified for SIT (1). This study aimed to determine whether a positive association exists between total training time and the gains in VO2max induced by a SIT program.

METHODS: 13 non-active and healthy individuals performed three all-out training sessions per week involving 15 s sprints interspersed with 2 minutes of recovery on a cycle ergometer. The 6-week training program was divided into three 2-weeks blocks in which training volume was increased from 10 to 14 repetitions over the first four sessions and was reduced to 8 in the last session of each block. The power output (PO) during the sprints was recorded in every session. Isometric maximal voluntary contraction of the knee extensors (iMVC), power-force-velocity profile (PFVP), and VO2max were assessed every two weeks from the baseline to examine the time-course of training-induced changes (Pre, Week2, Week4, Week6). An additional evaluation was performed one week after the end of the training period (Week7).

RESULTS: A significant increase in VO2max (8.7 ± 4.2%; $p<0.001$) was observed at Week2 compared to Pre with no further differences observed at the subsequent time points. The iMVC and the maximal power output obtained from the PFVP did not change throughout the training program ($p=0.21$ and $p=0.68$, respectively). The maximal theoretical force obtained from the PFVP was significantly increased at Week2, Week6 and Week7 compared to Pre. In contrast, the maximal theoretical speed decreased at Week7 compared to Pre. The mean PO per sprint increased significantly with training.

CONCLUSION: These results suggest that five sessions of SIT might be enough for upregulating the physiological mechanisms mediating the adaptations behind the increases in VO2max. Moreover, and even though the training program lasted four more weeks after Week2, no additional gains were observed suggesting that there is not a positive association between longer training all-out programs and improvements in VO2max for a given training frequency. In contrast, the gains observed for the parameters of the PFVP and the mean PO per sprint showed that, despite the aerobic function tended to a plateau, other functions can still be further developed with additional training.

SEMITENDINOSUS HYPERTROPHY IS LINKED TO IMPROVEMENT IN SPRINT PERFORMANCE AFTER ONE YEAR OF SPRINT-BASED TRAINING: AN OBSERVATIONAL STUDY

KAWAMA, R.1,2, TAKAHASHI, K.2,3, TOZAWA, H.1, FUJII, N.4, ARAI, A.4, HOJO, T.1,4, WAKAHARA, T.4
1, 4 DOSHISHA UNIVERSITY; 2 RESEARCH FELLOW OF JAPAN SOCIETY FOR THE PROMOTION OF SCIENCE; 3 WASEDA UNIVERSITY

INTRODUCTION: It is still questionable as to which muscles are most important for achieving fast sprint running velocity in sports and academic fields. Researchers have demonstrated that sprinters with large sizes of the rectus femoris (1), se-

mitendinosus (2), gluteus maximus (3), and psoas major (4) showed high sprint performance in cross-sectional studies. However, little is known about the impacts of hypertrophy of these muscles on intra-individual changes in sprint performance. This study aimed to examine the impacts of the hypertrophy of each trunk and thigh muscle on the intra-individual changes in sprint performances during one year of sprint-based training.

METHODS: Twenty-three male sprinters (the personal best record for the 100-m race: 11.36 s ± 0.44 s) at a university's athletics club participated in this study. They continued their sprint-based training for one year without our intervention. Before and after the one-year observation period, the participants performed two 100-m sprints with their maximal effort on a synthetic track. Mean sprint velocities at 0–100 m and 50–60 m intervals and spatiotemporal variables (e.g., step frequency and step length) at 50–60 m interval were measured with timing gates and a high-speed camera, respectively. The volumes of 14 trunk and thigh muscles were also measured by magnetic resonance imaging. Muscle volumes were normalized to their body mass at each time point.

RESULTS: Sprint velocities at 0–100 m ($p < 0.001$) and 50–60 m ($p = 0.018$) intervals, stance time ($p = 0.015$), and flight distance ($p = 0.013$) at 50–60 m interval were significantly increased after the observation period. Additionally, the absolute and relative volumes of the tensor fasciae latae, sartorius, biceps femoris long head, biceps femoris short head, semitendinosus, and iliacus were significantly increased (all $p < 0.05$). Among the above six muscles, the changes in the absolute and relative volumes of the semitendinosus were positively correlated with the change in sprint velocity at 50–60 m interval ($p = 0.013$ to 0.015), but not with the changes in any spatiotemporal variables ($p = 0.119$ to 0.898).

CONCLUSION: The present result is in line with that in the previous cross-sectional study showing a positive correlation between the semitendinosus volume and the sprint velocity at 50–60 m (2). The semitendinosus was reported to be highly activated at the late swing phase during high-speed running (5). Thus, the semitendinosus hypertrophy may increase the angular velocity of the hip extension, and thereby might contribute to the increase in sprint velocity. The present finding suggests that semitendinosus hypertrophy has an important role to enhance sprint performance within individuals.

SHOULD I REST OR SHOULD I GO NOW? A COMPARISON BETWEEN FIXED AND SELF-SELECTED REST DURATIONS IN HIGH-INTENSITY INTERVAL TRAINING CYCLING SESSIONS

COLORNI, E., OHAYON, E., CÔTÉ, N.J., OBLOSKI, U., HALPERIN, I.

TEL AVIV UNIVERSITY, TEL AVIV, ISRAEL AND MCGILL UNIVERSITY, MONTREAL, QUEBEC, CANADA;

INTRODUCTION: In high-intensity interval training (HIIT), the rest durations between intervals are commonly prescribed using a fixed approach (e.g., 30 seconds between intervals). An alternative is the self-selected (SS) approach, in which trainees select their resting durations. Studies comparing the two approaches report mixed results. However, in these studies, trainees in the SS condition rested for as little or as long as they wished, leading to dissimilar total rest durations between conditions. Here, for the first time, we compare the two approaches while controlling for total rest duration.

METHODS: Twenty-four amateur adult male cyclists completed a familiarization session, followed by two counterbalanced cycling HIIT sessions. Each session was composed of nine, 30-second intervals, in which the goal was to accumulate as many watts as possible on an SRM ergometer. In the fixed condition, cyclists rested for 90 seconds between intervals. In the SS condition, cyclists had 720 seconds (i.e., 8x90 seconds) of rest to allocate in any way they wished. We measured and compared watts, heart rate, electromyography of the knee flexors and extensors, rating of perceived effort and fatigue, perception of autonomy and enjoyment. Additionally, a subsample of ten cyclists completed a retest of the SS condition.

RESULTS: With the exception of perception of autonomy, which was higher in the SS condition, both aggregated and across-interval outcomes were highly similar in both conditions. For example, the average aggregated differences were: 0.57 (95% CI -8.94, 10.09) for watts; -0.85 (95% CI -2.89, 1.18) for heart rate; and 0.01 (95% CI -0.29, 0.30) for rating of perceived effort (on a 0-10 scale). Additionally, the retest of the SS condition resulted in a similar rest allocation pattern across the intervals and in similar outcomes.

CONCLUSION: Given the similarities between the fixed and SS conditions, both can be equally utilized based on coaches' and cyclists' preferences and training goals.

THE EFFECT OF OVERSPEED TRAINING ON MAXIMUM VELOCITY IN TRAINED INDIVIDUALS- A PILOT STUDY

INGLIMA, S., LUBIAK, S., RIDDELL, S., GOTLA, T., THOMPSON, B., MAY, J., WALTERS, J.

THE UNIVERSITY OF TAMPA

INTRODUCTION: Maximum velocity is among the most critical performance attributes for many athletes [1]. This performance measure is often quantified in field or laboratory-based settings using sprint assessments. Past research investigated resisted and assisted sprint training to improve velocity in trained individuals [2]. However, there is limited evidence

investigating the effects of overspeed treadmill training (OTT) on maximum velocity. The purpose of this pilot study was to investigate the effects of OTT on maximum velocity in trained individuals.

METHODS: Two college-aged participants (control: 21 y/o, 79.1 kg, 171.5cm; OTT: 23 y/o, 67.3 kg, 165 cm) completed OTT. The duration of this study lasted seven weeks. Week one included familiarization with the treadmill protocol. Pre and post-measurements on the treadmill (TRE) and track (TRA) occurred at weeks two and seven. All TRE sessions were completed using the h/p/cosmos locomotion treadmill system, which allowed subjects to sprint at 80% of their body weight. TRE testing measured the peak velocity that the participant was able to maintain for five seconds. TRA testing measured 40m time using timing gates (Brower), peak velocity, and average velocity using a radar gun (Stalker ATS II). TRE and TRA testing sessions were separated by at least 48 hours. During the protocol, subjects trained twice per week. The control group trained at the average velocity from their best 40m time trial (100%), while the OTT group trained slightly above the average velocity of their best 40m time trial (105%). The number of sprints increased from three (weeks three and four) to four (week five) to five (week six), while the velocity remained constant. Post-testing mirrored pre-testing measurements taken at week two. Percent changes from pre to post for each subject were analyzed using Excel.

RESULTS: For the OTT subject, peak velocity increased by 1.42% (29.4 to 29.8 Km/h), average velocity decreased by 2.49% (28.3 to 27.6 Km/h), and 40m time increased by 2.55% (5.09 to 5.22s). For the control subject, peak velocity increased by 3.02% (34.6 to 35.7 Km/h), average velocity decreased by 0.46% (33.2 to 33.0 Km/h), and 40m time increased by 0.46% (4.34 to 4.36s).

CONCLUSION: Both subjects showed improvements in peak velocity. However, OTT showed no effect on average velocity or 40m time. These findings suggest that training at or above average 40m velocity could potentially improve peak velocity. Additionally, declines in average velocity and 40m time performance may have been due to a lack of acceleration training. Further research is needed to investigate different magnitudes of assistance, as well as the effects of OTT with acceleration training on sprint performance.

SPORTS INFLUENCE ON MANUAL DEXTERITY DEVELOPMENT: AN OBSERVATIONAL STUDY ON A YOUNG HEALTHY POPULATION

AMATO, A., PATTI, A., PAOLI, A., NORDSTROM, A., PROIA, P., BIANCO, A.

UNIVERSITY OF PALERMO

INTRODUCTION: Manual dexterity allows us to manipulate objects, perform activities of daily living and achieve good motor function development1,2. At the basis of this skill, there are neuromotor processes involving the coordination of the central and peripheral nervous systems. Alternated manual dexterity is associated with learning or attention disorders in the developmental age. Understanding which sports activity is most effective in stimulating this skill could be useful in ensuring its normal development and accompanying the rehabilitation of pathological subjects in an inclusive context: interventions aimed at restoring adequate manual dexterity have the characteristics of some sports activities such as Basketball but are carried out in isolated settings where disability is enhanced3. However, there are no studies to date investigating the effect of specific sports on manual dexterity development in youth 8-15 years old, so this is the purpose of our study.

METHODS: 78 subjects were recruited and divided into a basketball group (BG), a dexterity sports group (DG), and a no-sports group (NG). Manual dexterity was assessed by three methods all administered on the same day and on both dominant (D) and non-dominant (ND) hands: grooved pegboard test (GP), coin rotation task (CRT), and handgrip test (HG).

RESULTS: MANCOVA analysis, performed considering age as a covariate, showed a significant difference between BG, DG, and CG groups in the GP and HG performance, with no significant and significant covariate for age. The Scheffé post-hoc comparison highlights that the BG scored significantly higher than NG on GPD ($p:0.01$) and GPND ($p:0.02$) but no significant difference was found between NG and DG for GPD ($p>0.05$) and GPND ($p>0.05$). In addition, BG showed a better performance than NG and DG in both HGD (NG $p:0.01$; DG $p:0.01$) and HGND (NG $p:0.02$; DG $p:0.03$). No groups effect on CRTD and CRTND performance ($p>0.05$) was found. However, age was significantly correlated with performance on the CRTD ($r:0.27$; $p:0.17$) or CRTND ($r:0.36$ $p:0.00$). The correlation analysis showed a negative correlation between both CRTD and CRTND and GPD (CRTD $r:-0.43$, $p<0.001$; CRTND $r:-0.45$, $p<0.001$); between CRTD and CRTND and GPND (CRTD $r:-0.43$, $p<0.001$; CRTND $r:-0.44$, $p<0.001$); between HGD and HGND and GPD (HGD $r:-0.35$, $p:0.00$, HGND $r:-0.33$, $p:0.00$). A positive correlation was found between CRTD and CRTND and HGD (CRTD $r:0.27$, $p:0.02$; CRTND $r:0.38$, $p<0.001$) and between CRTD and CRTND and HGND (CRTD $r:0.27$, $p:0.02$; CRTND $r:0.37$, $p<0.001$).

CONCLUSION: All variables of manual dexterity correlate with each other; age does not influence GP performance, which is instead influenced by playing a sport. BG has better absolute values in all scores. Specifically, significantly higher than the NS group in all tests. In contrast, there are no statistically significant differences between DG and NG. Playing basketball might be more helpful in improving manual dexterity deficits than other sports and a sedentary lifestyle

PUTTING YIPS IN GOLF NOVICES. PREVALENCE AND TASK DEPENDENCY

HAGGENMÜLLER, K.1, URBANO, J.1, RIVERO, J.1, MARQUARDT, C.2, HERMSDÖRFER, J.1

TECHNICAL UNIVERSITY OF MUNICH

INTRODUCTION: Yips in golf are involuntary muscle contractions that typically occur during short distance putts and that result in target misses. About 40 % of professional golfers experience yips that are a very significant threat for the career. The causes for yips are still unknown with focal dystonia, anxiety, stress and behavioral peculiarities being considered to contribute. We and others have recently observed that yips may also occur in golf novices. In the present study, we investigated putts in a larger sample of golf novices to determine the prevalence of yips and how different modes of putting modulate the yips.

METHODS: 73 golf novices got a short introduction into putting and were requested to perform 2.5 m putts with a one-handed grip (1H) and with both hands under normal conditions (2H), with closed eyes (2HnoFB) and without a ball (2HnoBall). Ten trials were performed per condition and kinematics of the golf club movement was determined using the SAM PuttLab device (Science and Motion GmbH). Yips was measured as changes of the acceleration of the club head angle around the moment of impact (200 ms window).

RESULTS: During the one-handed condition (1H), nine novices (12.3 %) yielded yips beyond a threshold of 4000 °/s² (> mean + 2 SD of normal distribution). With the exception of one novice with extraordinary strong yips, modifying the conditions of playing the putts abolished the yips (2H, 2HnoFB, 2HnoBall: yips affected players vs. non-affected players: Mann-Whitney-U Test $p > 0.05$). Kinematic variables that characterized the putt before hitting the ball such as club maximum velocity and backswing time did not differ between affected and non-affected players (1H and all other conditions: Mann-Whitney-U Test $p > 0.05$).

CONCLUSION: Yips were detected in 12.3 % of golf novices. Playing with one hand was the most sensitive condition, while the phenomenon was massively reduced when two hands were used, irrespectively from the exact characteristics. Interestingly, the kinematics of the putt before the impact was not responsible for the yips, suggesting that movement execution was normal until shortly before the impact and only the condition was responsible for the occurrence of the yips. One-handed putts may be particularly vulnerable due to the instability of the hand-arm complex. It remains unclear whether a feeling of instability is critical or the two-handed grip mechanically dampened any muscle jerks. This could be resolved by EMG recordings. The fact that yips in professional players are typically reported in normal two-handed grips could indicate that the type of yips differs or that one-handed symptoms may expand to two-handed symptoms during extensive practice.

THE RETENTION OF EXPLICIT BUT NOT IMPLICIT MOTOR MEMORY CAN BE IMPAIRED BY CARDIOVASCULAR EXERCISE: THE MODERATING EFFECT OF FITNESS LEVEL

KRAFT, V.S.1, CRISTINI, J.2,3, DE LAS HERAS, B.2,3, RODRIGUES, L.2,3, PARWANTA, Z.2,3, HERMSDÖRFER, J.1, STEIB, S.4, ROIG, M.2,3

**EQUAL CONTRIBUTION, 1 TECHNICAL UNIVERSITY OF MUNICH, GERMANY, 2 CRIR, CANADA, 3 MCGILL UNIVERSITY, CANADA, 4 UNIVERSITY OF HEIDELBERG, GERMANY*

INTRODUCTION: Cardiovascular exercise (CE) can influence the consolidation of procedural memory, especially when performed immediately after motor practice [1]. Changes in corticospinal excitability (CSE) are discussed as a physiological mechanism signaling or suppressing consolidation, and thus retention [2]. This study examines the effects of CE on the retention of explicitly and implicitly learned motor sequences, CSE changes in response to exercise and their interaction.

METHODS: 56 participants (24.1±3.3, 32 female) practiced a sequence learning task – the Serial Reaction Time Task (SRTT) – either with explicit or implicit awareness of an underlying sequence [3]. Following motor practice, participants either performed a 16 min CE protocol – 3 times 3 min at 90% of individual peak power output (PPO) interspersed with 2 min at 25% PPO – or rested (randomized parallel group design). Retention was quantified as the change in SRTT performance from the end of practice to a 24 h retention test. Before and after learning and 15, 30, 45, and 60 min after CE or rest, CSE was measured by applying transcranial magnetic stimulation over the primary motor cortex (M1).

RESULTS: An ANOVA showed no effects of CE on retention ($F(2,31)=0.56$, $p=0.577$). Exploratory analyses with group assignment based on acquired awareness of the practiced sequence suggested that CE specifically impaired explicit memory content in participants with lower fitness ($R2=0.27$, $F(1,16)=6.03$, $p=0.026$). A global measure of CSE change (Area under the Curve) was associated with retention across participants ($R2=0.58$, $p=0.0014$) with no observed effect of CE on CSE.

CONCLUSION: CE did not show significant effects on retention regardless of whether the SRTT was encoded implicitly or explicitly. Yet, considering the degree of acquired awareness of the sequence, CE appeared to impair consolidation in participants with explicit awareness and lower fitness. This is consistend with the idea of the reticular-activating hypofrontality model [4], extending it to motor practice right before and not only during CE. The observed CSE changes between CSE and memory align with previous literature and emphasize that M1 is crucial in consolidating procedural memories [3].

INTERNAL PROCESSES OF OUTCOME PREDICTION IN BASKETBALL – AN EEG STUDY

MAURER, L.K., HINNEBERG, B.M., JUNGE-BORNHOLT, L.E., WACHSMANN, F.D., MAURER, H., HEGELE, M., MÜLLER, H.

JUSUS LIEBIG UNIVERSITY GIESSEN

INTRODUCTION: Internal models in the motor system constantly predict effects of motor actions (McNamee & Wolpert, 2019). Behavioral studies show that motor experts can report outcomes of their own actions above chance (e.g. Cañal-Bruland et al., 2015; Maurer et al., 2022), indicating that they have access to these internal processes. The present study aims to confirm this by the example of basketball shooting. It is examined whether verbal predictions of basketball free throws correlate with the neural activity of internal prediction processes, by means of event-related potentials in the EEG (i.e., the error-related negativity, ERN).

METHODS: 20 experienced basketball players (6w, 14m; 24.21 ±4.18 years) verbally predicted their throwing result (hit/miss) in 500 free throws in every second throw without receiving feedback about the ball flight. For this purpose, they wore liquid crystal glass goggles occluding their vision after ball release, and headphones playing white noise. The EEG was recorded with a mobile 64-active electrode system (LiveAmp, BrainProducts, Germany). Muscle and eye movement artefacts were corrected with a combined dipole and cluster analysis via ICA and the ERN was determined synchronized to ball release for the mean difference curves between hits and misses. Prediction accuracy was calculated as the percentage of correct predictions above an individual chance level and normalized with respect to a perfect prediction.

RESULTS: On average, prediction accuracy was 13.54 % (SD = 9.74%) above chance level ($t(19) = 6.22$, $p < .001$, $d = 1.39$). EEG activity of the misses were more negative compared to the hits in the time window 100-200 ms after release ($t(19) = -2.2$, $p = .02$, $d = -.50$), meaning that outcome prediction was internally represented by the ERN.

CONCLUSION: Discussion

As expected, experienced basketball players can verbally predict the outcome of their own free throws above chance. In the EEG, a clear ERN signal of internal prediction processes was observed. Indicating players have access to their predictive internal motor processes.

IS-MH04 Exercise for skeletal muscle ageing: mechanisms and mitigation

EXERCISE REJUVENATES THE MOLECULAR PROFILE OF AGEING IN SKELETAL MUSCLE

EYNON, N.

VICTORIA UNIVERSITY

Ageing represents an important health and economic burden on society. Approximately 15% of the world population are over 65, a proportion expected to rise to 22.5% by 2050. Sedentary behaviour and lack of physical activity accelerate the widespread cellular and molecular changes induced by ageing, resulting in the increased prevalence of many chronic diseases.

Epigenetics (particularly DNA methylation) is one of the hallmarks of ageing. The epigenome is effecting gene expression, and is particularly sensitive to exercise, and exercise training programs caused widespread DNA methylation shifts in genes that are relevant for skeletal muscle health, and ageing.

My research group focuses on the development of novel, cross-tissue molecular approaches to identify sex-specific healthy ageing and exercise-related marks in humans. This approach will provide a greater understanding of the multiplicity and complexity of the cellular networks involved in exercise responses and strong translational path. The Gene SMART study, led by our group, is the first of its kind to comprehensively assess genetic and epigenetic markers that contribute to muscle health pre-and-post intense exercise (total of ~1200 human muscle & blood samples at various exercise points). Using data mining, and bioinformatics approaches we combined the Gene SMART cohort, data sets from international collaborators and open access datasets to perform a powerful molecular analyses to uncover robust marks of

ageing in males and females. In my presentation, I will discuss some of the recent research coming from my group on how exercise mitigate the ageing molecular responses.

HIIT TO GET FIT? NOVEL AND TRADITIONAL EXERCISE MODES TO IMPROVE MUSCLE HEALTH IN OLDER ADULTS AND PATIENT COHORTS

MACDONALD, M.

MCMASTER UNIVERSITY

The traditional focus of most exercise programs for older adults and patient cohorts has been on a combination of moderate intensity continuous and resistance exercise training. Generally, this exercise prescription includes 30 minutes per day of moderate intensity aerobic exercise, performed 5 days per week with the addition of resistance exercise training as the program progresses. It has been shown that adherence to the training program is often more important than exercise type and intensity for prediction of survival, and that the physiological benefits of exercise training are not sustained if exercise habits are not maintained. Recent research has suggested that high intensity interval training (HIIT), might be an alternative exercise prescription for older individuals and patient cohorts and might address some barriers to exercise adoption and adherence. This talk will explore the growing literature examining both novel and traditional exercise modes to improve muscle health in older adults and patient cohorts.

NOT SARCOPENIC! SKELETAL MUSCLE IN OLDER EXERCISERS AND MASTERS ATHLETES

HARRIDGE, S.

KINGS COLLEGE LONDON

As we get older, we lose skeletal muscle mass and function. When this process reaches a critical threshold, a disease termed "sarcopenia" can be defined. The underlying cause of this decline is likely to be multifactorial. Factors such as loss of motor units, anabolic resistance to feeding and exercise, impaired recovery from exercise induced damage (relating to stem cell dysfunction), inflammation and cellular senescence have all been associated with tissue loss and declines in strength and power. However, a confounding factor of studies investigating muscle ageing is physical (in)activity. In addition to ageing processes, skeletal muscle is highly sensitive to both mechanical and metabolic signals. Thus, for many older people a resulting aged muscle phenotype is a product of ageing processes interacting with the negative effects of inactivity.

When very active older people are studied muscle mass and function are also lost. The loss of function is clearly even in the most highly trained on individuals as demonstrated by a decline in athletic performance. In masters or veterans' sports there is progressive decline (which accelerates during the eighth decade) in world records in every discipline. These records and performances tell us two things. The first is that there is no denying that an ageing process is taking place. Whilst the second tells us that there is a large potential for exercise to ameliorate the decline in mass and function. The physical capabilities of older athletes relative to age matched non-active counterparts are far superior. Here such active individuals are far removed from being classified as sarcopenic.

This lecture will focus on exploring concepts surrounding ageing muscle phenotypes in the light of what lessons we might learn from older exercisers and masters' athletes.

Oral presentations

OP-AP13 Virtual Reality Training

A COMPARISON OF THE INTENSITY AND PLEASURE EXPERIENCE DURING VIRTUAL REALITY BOXING AND PUNCHING BAG BOXING.

AERENHOUTS, D., MERTENS, L., ADAM, A., SARENS, M., ZINZEN, E.

VRIJE UNIVERSITEIT BRUSSEL

INTRODUCTION: Virtual Reality (VR) exergames are potentially a fun and attractive alternative for traditional sports in contributing to young adults' physical activity, provided that the exercise intensity is comparable. Therefore, the aim of this study was to compare the exercise intensity of VR boxing with punching bag (PB) boxing, in healthy young adults. A secondary aim was to compare the pleasure experience during VR and PB boxing.

METHODS: Using a cross over design, 24 young adults (aged 21.7 ± 1.2 years ; 25% women) participated in a PB boxing session or played the 'KO league – heavy bag DLC' in VR, using an Oculus quest 2 head mounted display. Each trial took 15 minutes each with standardized punching combinations and hitting frequency. Exercise intensity was evaluated through heart rate peak percentage (HRpeak%), difference in blood lactate concentration pre and post exercise (ΔBLa) and rate of perceived exertion (RPE) on a 6-20 Borg scale. Pleasure experience was examined using a 0-10 VAS scale. A one-way repeated measures ANCOVA, with fat free mass percentage as a covariate, was used to compare HRpeak%, RPE scores and pleasure experience, while a Wilcoxon signed rank test was used to investigate the difference in ΔBLa, due to non-normality.

RESULTS: Fat free mass percentage was not a significant covariate (p = 0.06). No significant differences (all p>0.05) were found between both conditions for the intensity parameters HRpeak% (VR: 75.7 ± 12.2%; PB: 78.6 ± 14.9 %), ΔBLa (VR: -0.10 ± 0.09 mmol/l; PB: 0.05 ± 0.26 mmol/l) and RPE (VR: 11.4 ± 2.4; PB: 13.0 ± 1.8). For both conditions a high range in HRpeak% and RPE was observed, indicating intensities from light to vigorous. In addition, no difference in pleasure experience was found (VR: 7.0 ± 2.1; PB: 6.7 ± 2.0; p = 0.42).

CONCLUSION: According to the results of this study, VR boxing is an equally intensive and fun alternative for PB boxing in young adults. Interestingly, exercise intensity showed a high inter-individual variation. Therefore, regardless of using a punching bag or a VR game, boxing can contribute to a more or less extent to young adults their physical activity level.

SENSITIVE EXPERIENCE OF THE HIGH-LEVEL GYMNAST: 3D IMMERSION AND TRAINING IN VIRTUAL REALITY

PAINTENDRE, A., FROISSART, T.

UNIVERSITÉ DE REIMS CHAMPAGNE ARDENNE

Introduction

For the 2024 Olympic Games, the gymnastics federation is trying to answer the dilemma concerning the "dose" of training that is conducive to winning medals. This one reaches up to 30 hours per week questioning the physical load and the risk of injuries. The REVEA project (ANR 20-STHP-0004) aims to optimize the performance of the mens group by supplementing the real training time with Virtual Reality (VR) training. The virtual embodiment and the 3D immersive experience is essential to optimize the transfer between what is seen and what is practiced in real life: the self-generated movement would promote the liveliness of the action simulation during the observation of the action (Baudry et al., 2005), while promoting an adaptation to the environment. From the body experience lived in real training, this research aims to model a 3D tool to immerse French gymnasts during training in VR.

Methods

Enaction "places interaction and its dynamics at the center of the knowledge construction phenomenon" (De Loor & Tisseau, 2011). In VR, interaction relies on "the scalability of the coupling between the virtual reality system and the user" (Ibid., 2011), promoting the gymnasts corporeal presence. Eight self-confrontation interviews with INSEP gymnasts in international competition conditions were conducted. The course of experience of the gymnasts was reconstructed using the EAC and the traces of the observatory. More precisely, the components of the hexadic sign (Theureau, 2015) were processed in order to identify similarities and singularities between the gymnasts experiences.

Results

The sensory register of the gymnasts experience is central. Plural and singular, the sensations represent information supporting the mobilized knowledge and stimuli incorporated during their performances: respiratory, visual, auditory, muscular, haptic and kinesthetic.

Discussion/Conclusion

These results contribute to the configuration of the 3D modeling to target the immersion of the gymnast and the optimization of the VR training:

1. Two modes of practice: one competition, the other training (influence the auditory and visual stimuli)

2. Body sensations to be highlighted according to the needs of the training to guide the gymnasts body adjustments (muscular, respiratory, kinesthetic)

3. Time management methods: from the call to the apparatus to the end of the routine, and to optimize the connections between the elements.

THE USE OF 360° VIDEO IN SWIMMING EDUCATION

ROCHE, L., CUNNINGHAM, I., ROLLAND, C., FAYAUBOST, R., MAIRE, S.

UNIVERSITÉ DU QUÉBEC À MONTRÉAL

Introduction

Drowning is a serious public health problem threat claiming the lives of 372,000 people each year worldwide that can be linked to an individual's ability to swim. Learning to swim requires limited fear of water (Peden & Franklin, 2020). Our exploratory study investigated the potential interests of 360° video use for reducing fear of water to foster learning how to swim. This study is the first stage of a larger funded project.

Methods and participants

The study is situated in the theoretical lens of the Course of Action research approach (Theureau, 2010) used in cognitive anthropology and is part of the enaction paradigm and embodied cognition perspective. This lens aims to consider hu-

man activity according to a double logic of, activity as enaction (Varela et al., 1991) and experience (Poizat et al., 2016). The object of analysis of this program is the activity, accomplished in a real situation that is, in a given physical and social environment. For this exploratory study, we conducted a multiple case study (Stake, 2005) with two volunteer students (non swimmers) from a group of students aged 11–12 years during a PE lesson for learning to swim. At the beginning of the lesson, students viewed 360° videos taken in the swimming pool at different depths. They viewed (with a headset and a smartphone) progressively deeper and deeper 360° videos during viewing situations that were filmed in the swimming pool without pupils in the water. Students' activity with the headset was recorded and this video was used for a self-confrontation interview (Theureau, 2010) that helped elicit their feelings during the viewing experience.

Results

Three main results can be underlined. First, the use of 360° video viewed in an HMD led students to live an original corporeal immersive experience, a kind of immersion in the pool but experienced outside the water. Second, students felt a strong emotional engagement between anxiety and curiosity from exploring the aquatic environment. Third, during the viewing situation, students developed and acquired accurate perceptive cues and knowledge related to the aquatic environment.

Discussion

These preliminary results provide insight into the feelings of swimming students when viewing 360° video and inform us about a decreased fear of water after viewing such videos. These results are in line with Botella et al. (2017) based on virtual reality use. In order to obtain a higher degree of generalization of the findings, we are presently corroborating this data in relation to quantitative data collected (by questionnaires).

ANTICIPATION PERFORMANCE IN VIRTUAL REALITY BOXING: IMPACT OF GAZE-CONTINGENT BLUR ON ELITE BOXERS.

LIMBALLE, A., KULPA, R., VERHULST, E., LEDOUIT, S., BENNETT, S.

UNIV RENNES, INRIA, M2S - EA 7470, RENNES, FRANCE

INTRODUCTION: Perceptual-motor skills are essential to performance in combat sports but remain poorly trained (Romeas et al., 2022), often with a focus on reaction time. Therefore, we studied how the properties of VR (standardization, reproducibility, and perception-action coupling) can facilitate the development of new tools that assess perceptual-motor skills underlying performance. Particularly, we are interested in the impact of a visual blur on anticipation in boxing. The introduction of blur inhibits visual perception of fine details that can act as distractors but preserves essential information such as the kinematics of the opponents limbs. To date, blur has been applied in real word settings using lenses (Mann et al. 2010) or 2D computer blurred displays (Ryu et al. 2015). Using 2D video display and gaze-contingent blur, Ryu et al. reported that novices, but not experts, decision making benefited when a moderate level of blur was applied in peripheral vision. However, these studies did not manipulate the location of blur in a realistic 3D visual task, where normal perception-action coupling was preserved.

METHODS: To overcome these limitations, we used a gaze-contingent gaussian blur within a VR environment. 11 French elite athletes faced a virtual opponent, standing 1 m away in a virtual ring, who launched successive attacks of 20 sequences (10 of 1 punch and 10 of 2 punches). Each participant completed 3 blocks of 60 trials, in a random-blocked order separated by a 2-minute break. In each block, participants performed the task in one of 3 Viewing Conditions. In the control condition, participants were presented with normal vision of the visual display. For the other 2 Viewing Conditions, a gaze-contingent blur manipulation was made relative to the point of fixation, such that participants were presented with a peripheral or a central blur. Participants had to avoid by dodging the incoming punches and counterattack to touch the opponent.

RESULTS: Linear mixed modelling revealed no significant effect of blur on performance but a significant main effect of the sequence type ($p<.0001$). Post-Hoc indicated that performance was better when facing sequences of one punch compared to sequences of two punches ($p<.0001$). The rating mean probabilities revealed that the number of dodges and counterattacks was similar when facing one punch sequences, but the number of counterattacks decreased more when facing a two punch sequences (0.144) compared to dodging response (0.198).

CONCLUSION: Overall, the results showed expert boxers were resilient to blur in this VR anticipation task. Interestingly, however, observation of the individual response data showed individual variability depending on the blur condition. It is envisaged that this new method will enable more consideration of the how blur can be used in the investigation of perceptual-motor learning.

This work is part of REVEA and DIGISPORT projects supported by the ANR in the "France 2030" program (20-STHP-0004 and ANR-18-EURE-0022).

THE EFFECT OF STATIC QIGONG PRACTICE IN TWO TYPES OF CONDITIONS - STANDARD AND USING VIRTUAL REALITY

ANGELOV, V.

NATIONAL SPORTS ACADEMY

INTRODUCTION: The benefits of Qigong exercises practicing have been known since ancient times. The effect of their performance has been studied by numerous specialists [1-4]. The main idea of this paper was combining the ancient qigong practice with modern technological advances. An object of the study is the effect of static qigong practicing. The aim is to compare the psycho-physiological response of the body after performing the same static qigong exercises in

two types of conditions - normal and using virtual reality. According to the research hypothesis, the application of virtual reality during qigong practice will stimulate psychophysical relaxation, which will create conditions for increasing the effect of qigong exercises.

METHODS: Thirty-eight athletes, of which 15 females and 23 males, aged 20-25 years participated in the study. A set of static standing qigong exercises performed by the help of a wall with 20 min duration was prepared. For its performance with VR glasses, a video with natural sights and relaxing music was selected. The indicators studied were heart rate variability, energy expenditure, fingertip temperature, balance abilities, hip joint flexibility, reaction time, movement frequency, accuracy, time perception, attention concentration, etc. Tests like Stand and reach test, Flamingo Balance Test, CPS Test, Reaction Time Test, Time Perception Test, Aim Test, Schulte Test, etc. have been used. The parameters studied before and after the static qigong set practicing under two types of conditions were measured.

RESULTS: The collected data was statistically processed using Descriptive Statistics, Shapiro-Wilk Test and Paired Samples T Test. Significance was set at $p<0.05$. Most of the results were statistically significant. The effect size for 10 indicators using Cohens formula was determined. Several types of comparisons to prove the effect of static qigong exercises in both types of conditions were performed. The study found that the energy expenditure, average and maximum heart rate during the exercise in normal conditions were 58.9 ± 16.5 kcal, 86.2 ± 6.9 bps, 102.5 ± 10.9 bps, respectively. Using virtual reality glasses, these indicators were 54.7 ± 20.9 kcal, 83.8 ± 6.1 bps, 100.0 ± 7.3 bps, respectively. The effect size found under normal conditions was small for 7 parameters, medium for 2 and large for 1 parameter. In virtual reality conditions, a small effect size was achieved for 1 parameter, medium for 6 and large for 3 parameters.

CONCLUSION: The study proved that the use of virtual reality during static qigong practice increases the relaxation effect of these exercises. As a result, a greater growth was found in the most of metrics examined in this type of workout. Nevertheless, we recommend that the use of virtual reality during qigong performance should be moderated and used as a tool providing specialized variety, rather than replacing impacts in normal conditions entirely.

OP-MH25 Physical activity/Inactivity

THE EFFECTS OF REDUCING SEDENTARY TIME ON SKELETAL MUSCLE INSULIN SENSITIVITY – A RANDOMIZED CONTROLLED TRIAL

SJÖROS, T., LAINE, S., GARTHWAITE, T., VÄHÄ-YPYÄ, H., KOIVUMÄKI, M., ESKOLA, O., LÖYTTYNIEMI, E., HOUTTU, N., LAITINEN, K., KALLIOKOSKI, K.K., SIEVÄNEN, H., VASANKARI, T., KNUUTI, J., HEINONEN, I.H.A.

1: TURKU PET CENTRE, UNIVERSITY OF TURKU, ÅBO AKADEMI UNIV., AND TURKU UNIVERSITY HOSPITAL, TURKU, FINLAND. 2: THE UKK INSTITUTE, TAMPERE, FINLAND. 3: UNIVERSITY OF TURKU, TURKU, FINLAND.

INTRODUCTION: Sedentary behaviour (SB) and physical inactivity are known to associate with impaired insulin sensitivity. The exercise–induced improvement in whole-body insulin sensitivity rely mainly on the changes in skeletal muscles, but the effectiveness of reducing daily SB in improving skeletal muscle insulin sensitivity remains unknown.

METHODS: Forty-four sedentary inactive adults [mean age 58 (SD 7) years; 43% men] with the metabolic syndrome were randomized into intervention and control groups. The 6-month individualized behavioural intervention supported by an interactive accelerometer and a mobile application aimed at reducing daily SB by 1h compared to the baseline. SB and physical activity were measured with hip-worn accelerometers throughout the 6-month intervention. Skeletal muscle insulin sensitivity in the thigh area (quadriceps femoris and hamstrings) was measured with hyperinsulinemic euglycemic clamp combined with [18F]fluoro-deoxy-glucose positron emission tomography before and after the intervention. The differences between intervention and control groups (group*time interaction) were tested with linear mixed models; and additionally between participants that, according to accelerometry, successfully reduced SB compared to participants that continued to be sedentary during the intervention.

RESULTS: Quadriceps femoris and hamstring muscle insulin sensitivity did not significantly change during the intervention in either group. However, the change in hamstring insulin sensitivity correlated inversely with the change in accelerometer-measured SB ($r=-0.40$, $p=0.024$) and positively with the changes in moderate-to-vigorous physical activity ($r=0.37$, $p=0.036$) and daily steps ($r=0.37$, $p=0.038$). Moreover, insulin sensitivity increased in the hamstrings among the more active participants ($\gtrsim$ 27 min decrease in measured daily SB) compared to the continuously sedentary participants (time*group $p=0.020$).

CONCLUSION: Hamstrings are postural muscles that are activated during standing and light activities, whereas the quadriceps femoris is thoroughly activated during more strenuous and strength-demanding activities. Therefore, reducing SB has potential in improving insulin sensitivity in postural muscles, even if this intervention did not induce any significant changes in muscle insulin sensitivity. However, behavioural interventions targeted to reduce SB may increase insulin sensitivity in the postural hamstring muscles, if the desired behaviour change is accomplished.

ASSOCIATIONS OF DOMAIN-SPECIFIC PHYSICAL ACTIVITY AND SEDENTARY BEHAVIOR WITH BLOOD LIPID PROFILE AMONG JAPANESE CHILDREN: A COMPOSITIONAL DATA ANALYSIS

KIDOKORO, T., KITANO, N., LANG, J.J., TOMKINSON, G.R., MAGNUSSEN, C.G.

NIPPON SPORT SCIENCE UNIVERSITY

INTRODUCTION: Optimizing childhood domain-specific physical activity (PA) and sedentary behavior (SB) for blood lipid profile is not well understood. We aimed to 1) determine the associations between accelerometer-measured PA and SB for each domain (school time and out-of-school time) with blood lipid profile and 2) estimate predicted changes in blood lipid profile with hypothetical time-reallocation between domain-specific SB and PA among Japanese children using compositional data analysis (CoDA).

METHODS: This cross-sectional study included 284 children (147 boys and 137 girls) aged 9–12 years. The times spent in SB, light-intensity PA (LPA), moderate-intensity PA (MPA), and vigorous-intensity PA (VPA) were assessed using accelerometers. Fasting lipid profile was assayed for triglycerides (TG), high-density lipoprotein cholesterol (HDL-C), and non-HDL-C levels.

RESULTS: Time spent in out-of-school VPA relative to the other behaviors was inversely associated with non-HDL-C (boys: βilr1 = -0.096, 95% confidence interval [CI] = -0.184 to -0.008), TG (boys: βilr1 = -0.469, 95% CI = -0.699 to -0.238), and positively associated with HDL-C (girls: βilr1 = 0.087, 95% CI = 0.016–0.158) levels after adjusting for age, body mass index, and time spent in other SB or PA domain. During the out-of-school period, replacement of just 1 minute from the remaining behaviors for VPA was associated with a more favorable lipid profile. In contrast, the associations of SB, LPA, and MPA with blood lipid profile were weak or null.

CONCLUSION: The present study examined the associations of domain-specific PA and SB with blood lipid profile among children using CoDA. We found that the time spent in VPA (particularly out-of-school VPA) was favorably associated with the blood lipid profile, whereas the associations for SB, LPA, and MPA were weak or null. Additionally, our isotemporal substitution analyses suggested that replacing 1 min/day of out-of-school SB and/or lower-intensity PA (LPA and MPA) with out-of-school VPA was favorably associated with non-HDL-C (for boys), TG (for boys), and HDL-C levels (for girls). Our results suggest that increasing VPA levels, particularly during out-of-school time, is important for improving blood lipid profile results among children.

EFFECT OF PHYSICAL ACTIVITY PROGRAM ON SLEEP AND SLEEP-RELATED VARIABLES: A RANDOMIZED CONTROLLED TRIAL

BARON, P.

UNIVERSITÉ DU LITTORAL COTE DOPALE

INTRODUCTION: Chronic exercise is recognized as an effective approach to improve sleep in people suffering from insomnia. However, the underlying mechanisms of interaction between sleep and physical activity are still poorly understood. Therefore, this study investigates the effects of a physical activity program on sleep and sleep-related physiological variables.

METHODS: 24 inactive women (49 ± 6.2 yrs) suffering from insomnia were randomly assigned to either a control group or a physical activity (PA) program. The PA program consisted in a 12-week program with three 1h15 sessions of moderate to vigorous aerobic exercise per week. Sleep was assessed using the Insomnia Severity Index (ISI) and accelerometers. Epworth sleepiness scale, Perceived Stress Scale (PSS), Hospital Anxiety and Depression scale (HAD), hair cortisol, nocturnal heart rate variability (HRV), 24-hour continuous core temperature were also assessed before (T0) and after (T1) 12 weeks in each group.

RESULTS: at T1, PA group showed a lower ISI score ($p<0.001$) and a longer total sleep time ($p<0.05$). Moreover, sleep efficiency tends to be higher ($p=0.058$). PSS score decreased ($p<0.01$). For HR, there is an increase in the RR interval ($p<0.05$). For HRV, in the time domain, there is an increase in SDNN ($p<0.05$). No change was observed in frequency domains. There was no difference for hair cortisol levels and core temperatures, although the amplitude of core temperature tends to be increased ($p=0.087$). At T1, the PA group showed a lower ISI score than the control group ($p<0.01$). When analyzed as score changes (T1 - T0), there was a positive correlation between changes in insomnia severity symptoms and changes in Epworth sleepiness scale ($r=0.794$; $p<0.05$) and PSS score ($r=0.777$; $p<0.05$) and a negative correlation between changes in insomnia severity symptoms and changes in core temperature amplitude ($r=-0.687$; $p<0.05$)

CONCLUSION: Our results suggest that moderate to vigorous aerobic exercise improves subjective sleep quality, objective sleep quantity, heart rate variability and decrease perceived stress in inactive middle-aged women suffering from insomnia. The data provide evidence indicating that changes in insomnia severity have associated to changes in thermoregulation, perceived stress and sleepiness.

TOWARDS A MORE HOLISTIC APPROACH TO DESCRIBE THE DIFFERENCE BETWEEN MEN AND WOMEN IN PHYSICAL ACTIVITY AND SEDENTARY BEHAVIOUR: DATA FROM A NATIONAL SAMPLE IN LUXEMBOURG

BACKES, A., COLLINGS, P., MALISOUX, L.

LUXEMBOURG INSTITUTE OF HEALTH

INTRODUCTION: Physical activity (PA) and sedentariness are complex and multidimensional behaviours with many-faceted accumulation patterns. The understanding of an individual's movement behaviour profile requires a holistic ap-

proach that goes beyond the use of standard measures such as time spent in moderate to vigorous PA (MVPA). Our first objective was to identify wearable-specific indicators and their analytical methods used to assess PA and sedentary behaviour. In a second step, we illustrated the potential benefits of these indicators over standard measures through a descriptive analysis of a specific population and the comparison between men and women.

METHODS: A scoping review was conducted to search for articles published in English between 2010 and 2020 by screening three databases. Only indicators that assessed PA and sedentary behaviour using data from triaxial accelerometers were retained. The identified methods to calculate these indicators were applied using data from an observational study (2016-18) that included Luxembourg residents aged 18-79 years and who each provided ≥4 valid days of accelerometry data (n=1122, including 599 women and 523 men).

RESULTS: In total, 24 articles describing 13 indicators were included in the scoping review. These indicators can be classified into three categories related to (1) the activity intensity distribution, (2) the activity accumulation, and (3) the temporal correlation and regularity of the acceleration signal. Most of these indicators were applied on a population of Luxembourg residents that spent 51% of daily time sedentary, 11% in light PA, 6% in MVPA and 32% asleep. Although, time spent in MVPA did not differ between women and men (76.9 and 79.8 min/day in men and women, respectively, p=0.22), the average 24h acceleration was higher (p<0.05), time spent in light PA was higher (p<0.001) and the intensity gradient was steeper (p<0.001) in women compared to men. These differences align with a lower average acceleration observed across the most active 30 and 15 minutes of the day in women (p<0.05). In total, more than a quarter (26.4%) of all sedentary time was spent in bouts lasting 60 minutes or longer. Women spent less time in sedentary behaviour (p<0.001), had shorter bout lengths (p<0.05) and fewer sedentary bouts of prolonged length (>30 min, p<0.001) compared to men.

CONCLUSION: Standard measures may not reflect differences between groups in PA and sedentary behaviour. The indicators identified in this study provide a more in-depth understanding of an individual's habitual movement behaviour profile. Surprisingly, few studies have investigated accumulation patterns of PA, time in light PA and especially sedentary time, even though there is evidence that extended periods of inactivity may have a harmful impact on health. The advantage of the identified indicators is that they cover the entire intensity range and provide additional information on their accumulation pattern.

COLLAGEN PEPTIDE SUPPLEMENTATION BEFORE BEDTIME REDUCES SLEEP FRAGMENTATION AND IMPROVES COGNITIVE FUNCTION IN MEN WITH SLEEP COMPLAINTS

CLIFFORD, T., THOMAS, C., ŠKARABOT, J., KINGSHOTT, R.N., VIRGILIO, N., PRAWITT, J.

LOUGHBOROUGH UNIVERSITY

INTRODUCTION: Sleep quality is worse in athletes compared to the general population. As several nutrients interact with neurotransmitters that help regulate the sleep-wake cycle, there is a growing interest in dietary strategies that promote sleep. The non-essential amino acid, glycine, may improve sleep by activating N-methyl-D-aspartate (NMDA) receptors in the suprachiasmatic nucleus (SCN) (Kawai et al., 2015). Collagen peptides (CP) are rich in glycine and have also been shown to increase brain derived neurotrophic factor, which is diminished in poor sleepers (Flores et al., 2020) and after sleep restriction. Thus, the aim of this study was to examine if CP, which are increasingly used by athletic populations, can promote sleep quality in poor sleepers.

METHODS: In a randomized, crossover design, 13 athletic males (age: 24 ± 4 years; training volume; 7 ± 3 h·wk1) with sleep complaints (Athens Insomnia Scale, 9 ± 2) consumed CP (15 g·day1) or a placebo control (CON) 1 h before bed for 7 nights. Sleep quality was measured with subjective sleep diaries and actigraphy for 7 nights; polysomnographic sleep and core temperature were recorded on night 7. Cognition, inflammation, and endocrine function were measured on night 7 and the following morning. Subjective sleepiness and fatigue were measured on all 7 nights. The intervention trials were separated by ≥7 days and preceded by a 7-night familiarization trial.

RESULTS: Polysomnography showed less awakenings with CP than CON (21.3±9.7 vs. 29.3±13.8 counts, respectively; P=0.028). The 7-day average for subjective awakenings were less with CP vs. CON (1.3±1.5 vs. 1.9±0.6 counts, respectively; P=0.023). The proportion of correct responses on the baseline Stroop cognitive test were higher with CP than CON (1.00±0.00 vs. 0.97±0.05 AU, respectively; P=0.009) the morning after night 7. There were no trial differences in core temperature, endocrine function, inflammation, subjective sleepiness, fatigue and subjective sleep quality, or other measures of cognitive function or sleep (P>0.05).

CONCLUSION: Seven days of CP supplementation reduced awakenings and improved Stroop test cognitive performance and may therefore serve as a useful strategy to mitigate the potentially deleterious effects of poor sleep on exercise and cognitive performance in male athletes with sleep complaints.

OP-BM17 Coordination

RELIABILITY OF EVENT-RELATED SPECTRAL PERTURBATIONS IN TARGET-DIRECTED KICKING IN SOCCER

PISKIN, D., BÜCHEL, D., LEHMANN, T., BAUMEISTER, J.

UNIVERSITY OF PADERBORN

INTRODUCTION: An accurate kick requires sensorimotor processing of visuospatial information and its translation into a motor output. Although distinctive cortical activity has been shown to be linked with superior accuracy in other target-directed sport actions (e.g. basketball throws), little is known about the cortical dynamics underlying precise kicking. This knowledge may help to optimize and specialize interventions to improve accuracy in applied scenarios such as penalty and pass-kicks. To explore relevant effects of e.g. expertise, fatigue or injury on kicking accuracy, it is important to extract reliable neurophysiological measures. Based on this background, the purpose of this study was to describe the reliability of event-related spectral perturbations (ERSP) underlying target-directed kicking in healthy novices.

METHODS: Eleven participants performed pass-kicks towards a target placed at three meters distance. Cortical activity was recorded using a 64-channel mobile EEG system. The experiment was repeated after one week. The EEG data was preprocessed and epoched based on kick-onset. Cortical sources of the EEG signal were identified through the application of independent component analysis (ICA). Functional sources were clustered according to k-means algorithm and the clusters including the majority of the sample at both time points were considered for further analysis. The ERSPs were extracted and intraclass correlation coefficients (ICC) were computed to quantify week-to-week reliability of kick-related ERSPs. To acknowledge comparable motor behavior, the anatomical motion range of the kicking leg was recorded through inertial-measurement-units and analyzed for week-to-week reliability.

RESULTS: The results revealed reliable activity of parieto-occipital and frontal regions upon kick onset. In the occipital brain regions, an alpha desynchronization was observed during the swing and follow-through phases with moderate to excellent reliability scores (ICCs between 0.57-0.9). In the frontal region, there was an evident theta synchronization prior to ball contact with moderate to good reliability scores (averaged ICC: 0.63) and an alpha desynchronization upon ball contact with moderate to excellent reliability scores (ICCs between 0.59-0.86). The anatomical motion ranges for hip flexion, knee flexion and foot external rotation showed moderate reliability (ICCs between 0.62-0.74).

CONCLUSION: This study aimed to assess the reliability of kick-related ERSPs for the first time. Under comparable motor behavior during kicking, the parieto-occipital and frontal brain regions demonstrated reliable activity. Particularly after kick-onset, the observed cortical phenomena demonstrated moderate to excellent reliability. These reliability findings provide the opportunity to explore deeper insights of cognitive and sensorimotor mechanisms which are involved in the planning, execution and different contexts of a target-directed kick.

INCREASE IN SULCAL DEPTH AFTER 12 WEEKS OF A PHYSICAL ACTIVITY BREAK WITH COORDINATIVE EXERCISES

SCHARF, C., KOSCHUTNIG, K., ZUSSNER, T., FINK, A., TILP, M.

UNIVERSITY OF GRAZ

INTRODUCTION: Although there are some studies which investigated the effects of coordinative exercises on the brain structure, only a few studies investigated the effects on surface-based brain metrics [1, 2, 3] in adults. Furthermore, the current state of research on the effects of physical activity on brain outcomes is insufficient for young and middle-aged adults [4]. Therefore, a physical activity break (PAB) with coordinative exercises was offered to university office workers. The project aimed to evaluate the effects of the PAB on cortical thickness and folding.

METHODS: Nineteen women and six men participated in the randomized controlled study. They were allocated to an intervention (IG: n=16, 42.8±10.2 years) and a control (CG: n=9, 44.2±12.3 years) group. The IG performed a PAB for 15-20 minutes with coordinative exercises, mainly juggling tasks, two times per week for 12 weeks. Before (week 0), six (week 6), and twelve weeks (week 12) after the start of the intervention, we assessed changes of surface-based metrics of the brain with MRI (3T Magnetom Vida scanner, Siemens Healthineers Erlangen, Germany). Additionally, juggling performance was assessed by measuring the time of performing a three-ball-cascade. The surface-based brain metrics were evaluated using the fully automated pipeline in CAT12. For the estimation of the cortical thickness and central surface, the project-based thickness approach was used. All results were FWE-corrected. We used analysis of variance, t-tests, and non-parametric tests with a significance level of 0.05 to analyze the data.

RESULTS: Cortical depth increased in right inferior parietal regions at week 6 and 12 ($p < 0.001$) in the IG. No changes were found in cortical thickness. In addition, the juggling performance improved from week 0 (0.3±1.0 s) to week 6 (1.9±1.6 s; $p<.002$), from week 0 to week 12 (4.4±4.4, $p<.001$) and was different compared to the CG at week 6 (1.9±1.6 vs 0.0±0.0 s; $p<.001$), and week 12 (4.4±4.4 vs 0.0±0.0 s, $p<.001$). No significant changes for the brain and juggling parameters were found in the CG.

CONCLUSION: The regular engagement in the three-month PAB with coordinative exercises was associated with an increase in vertex-wise cortical depth in a cluster comprising the right inferior parietal lobe and improvements in juggling performance. There is evidence, that the identified sulcal cluster is implicated in tactile and visual object processing [5].

Furthermore, this cluster appears to display some overlap with areas of the intraparietal sulcus, which have been referred to as "interfaces between the perceptive and motor systems for controlling arm and eye movements in space" [5]. Therefore, this study shows evidence, that changes in surface-based metrics in this area can be related to regular engagement in exercise training with visuo-coordinative demands.

BALANCE BIKE: AN EVIDENCED SOLUTION FOR LEARNING TO CYCLE INDEPENDENTLY IN HEALTHY ADULTS

CHOW, G.C.C.

THE EDUCATION UNIVERSITY OF HONG KONG

INTRODUCTION: Undoubtedly, adults find it difficult to ride with children if they have not learned to ride a bicycle themselves unless they would like to ride on a bicycle with training wheels. Unfortunately, previous studies showed that an average of 9.7% of the total population in 10 countries does not know how to cycle and is unable to self-launch and cycle on a conventional bike. Therefore, this multiphase project was conducted to determine whether healthy adults could be educated to learn to cycle independently: Phase 1) a case-control observational study and Phase 2) a one-arm 8-session intervention pre- and post-test study.

METHODS: In Phase 1, a total of 13 cyclists (6M and 7F; age: 22.62 ± 2.14 y; height: 167.12 ± 10.97 cm; weight: 62.49 ± 12.21 kg) and 8 non-cyclists (3M and 5F; age: 22.13 ± 1.36 y; height: 164.00 ± 5.45 cm; weight: 56.30 ± 3.49 kg) completed a battery of balance bike tests and a jump test. Based on these data, eight 20-minute balance bike training sessions specific to cycling postural stability and control were developed. In Phase 2, another 11 non-cyclists (2M and 9F; age: 36.73 ± 15.74 y; height: 160.68 ± 9.12 cm; weight: 57.50 ± 12.57 kg) completed the balance bike training that was formulated in Phase 1 to evaluate whether healthy adults without cycling experience could develop essential cycling stability on a balance bike and transfer the skills to a conventional bike. The study was approved by the Human Research Ethics Committee of The Education University of Hong Kong.

RESULTS: Bayes factor analyses revealed extreme evidence supporting the alternative hypothesis that the cyclists in Phase 1 were able to ride faster on a balance bike in a 15m sprint test (4.90 s vs 6.79 s, $BF01 = 0.228$, $p = 0.013$, $d = 1.89$) and a two-turn curved sprint test (6.35 s vs 9.66 s, $BF01 = 0.138$, $p = 0.037$, $d = 3.31$) than the non-cyclists. Besides, the Bayes factor for the time of completion in the two balance bike tests in the repeated measures in Phase 2 provided extreme evidence for the alternative hypothesis that the novel balance bike training improved non-cyclists riding performance on a balance bike (15m sprint: -1.68 s, $BF01 < 0.001$, $p < 0.001$, $d = 1.66$; two-turn curved sprint: -2.60 s, $BF01 < 0.001$, $p < 0.001$, $d = 2.29$). Jump height was also improved by 2.27 cm ($BF01 = 0.019$, $p < 0.001$, $d = 1.42$).

CONCLUSION: This study revealed that the balance bike manoeuvres could divide adults with and without the ability to cycle while jumping performance did not seem to be effective. Regardless of the participant's age (19–63 y), all non-cyclists learned to ride a conventional bike independently after completing eight 20-minute sessions of our novel balance bike programme. This study provided evidence of positive riding skill transfer from a balance bike to a two-wheel bike and building confidence for every adult to learn how to cycle with dignity.

A STUDY ON THE EFFECT OF COLOR VISION STIMULATION BY COLORED GLASSES LENSES ON MOTOR CONTROL ABILITY

ZHANG, W., NÉGYESI, J., TAKADA, H., NAGATOMI, R.

1. TOHOKU UNIVERSITY OF MEDICINE AND SCIENCE IN SPORTS AND EXERCISE, 2. HUNGARIAN UNIVERSITY OF SPORTS SCIENCE. ZHANG, W.1, NÉGYESI, J.1,2, TAKADA, H.1, NAGATOMI, R.1

INTRODUCTION: The use of individually preferred colored glasses has gained popularity with the expectation that it may improve balance control and sports performance, however, the results of previous studies remain inconclusive. In the present study, we aimed to determine the association between participants' subjective preference and balance performance when wearing different colored glasses.

METHODS: The experiment was divided into two studies. In study 1, 13 participants stood on dominant-leg or two legs on a pair of synchronized force plates for 30 seconds with 60 seconds rest between the five-five randomized stance trials, while wearing red, blue, yellow, green, or transparent colored glasses. And subjects were asked to subjectively evaluate the balance performance under different colored glasses. In addition to 5 center of pressure related variables, we analyzed five features of electromyography data from three lower limb muscles (medial gastrocnemius, biceps femoris, tibialis anterior) on both legs. In study 2, the experiment was divided into experimental conditions and control conditions. In the experimental condition, 3 subjects were asked to wear the determined best and worst colored glasses based on each subjects balance performance during the single-leg stand task (Innochi test) among 26 colored glasses to complete the single-leg, side-hop, front-hop task and in control condition, wore without lenses-glasses to complete the same task. Center of pressure data was recorded during the keeping balance.

RESULTS: In study 1, no significant effect of colored glasses was found, however, rankwise analyses of the data consistently revealed that participants performed the stances with different balancing strategies when wearing different colored glasses, regardless of the color itself. However, changes in standing stability when wearing different colored glasses could not be determined by the participants' subjective preference. In study 2, we used one-way ANOVA analysis to compare the data from the center of pressure in the three conditions. And we found that in the front-hop task, differences in center of pressure were observed between wearing different colored glasses when doing front-hop task under non-dominant leg (Environmental area: P=0.007, Root-mean-square area: P=0.016). The balance performance of wearing the best colored glasses is more stable compared to the worst colored glasses (Environmental area: Best-worst: p=0.03, Root-mean-square area: Best-worst: p=0.016).

CONCLUSION: Overall, our experiment confirmed that subjects subjective evaluations cannot be used to judge their balance performance with their preferred colored glasses. Different subjects will have different motor strategies with different preferred colors. Then we demonstrated that wearing different colored glasses could affect our balance task performance when doing a front-hop task. Our experimental results provide support and benefit for the future development of colored glasses to improve athletic performance.

CONCURRENT ACTIVATION POTENTIATION IMPROVES LOWER-LIMB MAXIMAL STRENGTH BUT NOT DYNAMIC BALANCE IN RUGBY PLAYERS

RIZZATO, A., DALLA COSTA, V.G., PAOLI, A., MARCOLIN, G.

UNIVERSITÀ OF PADOVA

INTRODUCTION: Concurrent activation potentiation (CAP) is the phenomenon that increases athletic performance by activating muscles not directly involved in the performed activity (1). Among the CAP strategies, the effect of mouthguard jaw clenching on strength and power has been exhaustively studied (2, 3). Conversely, its influence in dynamic balance control has been poorly investigated. Rugby players need high levels of strength and balance to cope tackling events and are familiar with mouthguard to protect their teeth from injuries. Therefore, this study aimed to understand whether mouthguard jaw-clenching could acutely improve rugby players' dynamic balance and strength performance.

METHODS: Thirteen rugby players were involved in a cross-sectional design to test their dynamic balance and lower-limb maximal strength in maximal bite (MB) and no-bite (NB) conditions. Balance tests were performed over a force platform (AMTI BP6040, Watertown, MA, USA) placed on a servo-controlled electrically driven movable platform (EnginLAB srl, Padua, Italy). Subjects underwent five trials wearing a boil-and-bite mouthguard for MB and NB with an anterior-posterior perturbation of the base of support (displacement: 100mm; ramp rate: 400mm/s). In the first 2.5 seconds after the perturbation, we calculated the following center-of pressure (CoP) parameters: the Area95 (the area of the 95th percentile ellipse), the Unit Path (the mean velocity), the first displacement after the perturbation point (First Peak), and the displacement between the maximum and minimum peak of the CoP trajectory (Δ Max). The dominant-limb maximal strength was tested isometrically on a custom-built chair with a load cell. Maximal strength and rate of force development (RFD) in the 0 to 50, 50 to 100, and 100 to 150 ms time windows were calculated.

RESULTS: The t-test analysis did not show any statistically significant difference between the MB and NB conditions for the dynamic balance parameters calculated. Maximal strength was higher ($p<0.05$) in the MB (817.81 ± 186.94) than NB (770.66 ± 190.43) condition. For all the time windows considered, RFD values were higher in the MB condition (RFD0-50: 1324.19 ± 276.94; RFD50-100: 749.76 ± 158.31; RFD100-150: 502.15 ± 122.40) than NB condition (RFD0-50: 1228.06 ± 230.28; RFD50-100: 638.54 ± 144.84; RFD100-150: 467.33 ±114.14).

CONCLUSION: Our results provide the first evidence that jaw-clenching-induced CAP did not improve dynamic balance performance. Moreover, mouthguard jaw clenching alone acutely increased maximal isometric strength and RFD. This finding agrees with previous literature (4) that showed how the combined effect of CAP strategies (hand gripping, jaw clenching, and Valsalva maneuver) improved knee-extensor strength compared to no CAP condition.

OP-MH11 Resistance training in cancer patients

NO ADVERSE EFFECTS ON THE ARMS VOLUME DIFFERENCE AND SHOULDER-ARM DISABILITIES AFTER A 12-WEEKS RESISTANCE TRAINING PROGRAM IN FEMALE BREAST CANCER SURVIVORS: EFICAN STUDY.

ESTEBAN-SIMÓN, A., DÍEZ-FERNÁNDEZ, D.M., RODRÍGUEZ-PÉREZ, M.A., ARTÉS-RODRÍGUEZ, E., CASIMIRO-ANDÚJAR, A.J., SORIANO-MALDONADO, A.

UNIVERSITY OF ALMERÍA

INTRODUCTION: Shoulder-arm disabilities and lymphedema are two of the most prevalent breast cancer-related side effects. These side effects induce a reduced ability to perform daily life activities, which is of major clinical and public health concern. Several factors such as surgery type, lymph node resection and treatment type might influence the appearance of shoulder-arm disabilities and lymphedema after breast cancer. However, it remains unknown if these factors may also influence the effects of a resistance training program. The aims of these secondary analyses of the EFICAN study were i) to assess the effects of a 12-weeks resistance training program on arms volume difference and shoulder-arm disabilities in breast cancer survivors, and ii) to evaluate whether the main risk factors for developing cancer-related lymphedema and shoulder-arm disabilities were associated with the effects of the training program.

METHODS: 60 female breast cancer survivors participated in this clinical trial and were randomized to an exercise group (12-weeks resistance training program) or a control group. Eligibility criteria were to be a breast cancer survivor, and to have completed surgery, chemotherapy, and/or radiotherapy up to 10 years before recruitment. Exclusion criteria were to have metastatic breast cancer, to have a breast reconstruction intervention planned within 6 months, to have any absolute contraindication for exercise, to perform more than 300 minutes/week of structured exercise. The participants underwent baseline and 12-weeks assessments where the arms volume difference, shoulder-arm disabilities and upper-limb muscular strength were evaluated. The treatment-related information was registered through the medical history.

RESULTS: No between-group differences were observed on arms volume difference (1.207; 95% CI -0.964 , 3.377; P=0.270) or shoulder-arm disabilities (2.070; 95% CI -4.362 , 8.501; P=0.521) after the training program. Likewise, there was no association of the surgery type, presence of lymph node resection, chemotherapy, radiotherapy, and hormone therapy with the changes in arms volume and perceived shoulder-arm disabilities after the intervention. However, a higher change in upper limb muscular strength was associated with a reduced shoulder-arm disabilities (-0.426; P=0.020).

CONCLUSION: The findings of this study indicate that resistance training does not affect arms volume difference and shoulder-arm disabilities in female breast cancer survivors. The main risk factors for developing lymphedema were not associated with the effects of the intervention, although higher increase in upper-limb muscular strength was associated with reduced shoulder-arm disabilities.

FEASIBILITY OF PROGRESSIVE RESISTANCE TRAINING IN BREAST CANCER SURVIVORS SUFFERING FROM PERSISTENT PAIN

MADELEINE, P., RASMUSSEN, G.H.F., KRISTIANSEN, M.

AALBORG UNIVERSITY

INTRODUCTION: The current knowledge on the feasibility of performing progressive resistance training in female breast cancer survivors (BCS) suffering from persistent pain is lacking. The aim of this study was therefore to conduct a summative process evaluation of the analgesic effect of a resistance training trial (ANTRAC), delivered to female breast cancer survivors (BCS) with persistent pain > 1.5 years after treatment to evaluate the feasibility of this type of training intervention.

METHODS: Twenty BCS with self-reported pain intensity ≥ 3 on a 0-10 numeric rating scale participated in the ANTRAC trial and were randomized to either an experimental group (EXP) or a control group (CON). The EXP completed a 12-week supervised resistance training program, resulting in a significant decrease in pain sensitivity, but not pain intensity. Following the intervention, EXP performed a summative process evaluation examining three domains: Fidelity, Participants & Response and Context. Fidelity referred to participant compliance and the extent to which the intervention was delivered as intended. Participants & response referred to the participants interaction and satisfaction with the intervention within four topics: Structure, Character, Effect and Concerns and side effects. Context referred to environmental and organizational factors. A 5-point Likert scale was used for the responses.

RESULTS: Mean participant compliance was 91% with 72-99% of the sessions delivered as intended, indicating that fidelity was high. Most participants (90 % on average) agreed or strongly agreed with all statements regarding structure, character, and effect, and disagreed or strongly disagreed with experiencing concerns and adverse effects. Finally, 90% of the participants were satisfied with the training facilities, equipment, and location, indicating that the context was appropriate.

CONCLUSION: The summative process evaluation indicated that participants were satisfied with the structure and content of the RT intervention. This study and the associated clinical findings underline that progressive resistance training could be offered to BCS reporting persistent pain.

METHODS: RESULTS: CONCLUSION: EFFECTS OF ECCENTRIC VERSUS CONCENTRIC CYCLING EXERCISE ON NEUROMUSCULAR FATIGUE AND MUSCLE DAMAGE IN PATIENTS WITH BREAST CANCER

HUCTEAU, E., MALLARD, J., BARBI, C., VENTURELLI, M., SCHOTT, R., PIVOT, X., FAVRET, F., DUCROCQ, G.P., DUFOUR, S.P., PAGANO, A.F., HUREAU, T.J.

INSTITUT DE CANCÉROLOGIE STRASBOURG EUROPE / UR3072

INTRODUCTION: Patients with breast cancer treated with chemotherapy experience substantial fatigue and skeletal muscle deconditioning (1). Eccentric cycling might be an interesting exercise modality to provide a strong neuromuscular stimulus (i.e., neuromuscular fatigue) in order to alleviate these symptoms, while minimizing the impaired and limiting contribution of the cardiopulmonary system. However, the neuromuscular consequences of eccentric cycling remain unclear. This study aimed to investigate the magnitude and etiology of neuromuscular fatigue induced by eccentric cycling, compared to conventional concentric cycling performed at either similar power output or VO2 , in patients with breast cancer.

METHODS: After familiarizations to eccentric cycling, nine patients with breast cancer performed 3 cycling sessions (3x6min) in eccentric or concentric mode. Eccentric cycling session (ECC) was compared to a concentric session matched for power output (CONpower, 80% of concentric peak power output, 95±23W) and another one matched for VO2 (CONVO2, ~10 mL/min/kg). Central and peripheral fatigue were quantified via changes in pre- to postexercise voluntary activation (VA) and quadriceps potentiated twitch force (Qtw) evoked by supramaximal femoral nerve stimulation, respectively. Rate of perceived exertion (RPE) was assessed using the Borg CR-10 scale after each cycling session. Muscle damage was quantified in the blood pre- and 24h postexercise using creatine kinase (CK) and lactate dehydrogenase (LDH) activities. Muscle soreness was quantified 24h and 48h postexercise using a visual analogue scale.

RESULTS: ECC resulted in a greater decrease in MVC (-25±12%) compared to CONpower (-11±9%) and CONvo2 (-5±5%) post-exercise (P<0.001). VA decreased only in ECC (-9±6% postexercise, P<0.001). The decrease in Qtw was similar between ECC and CONpower post-exercise (-39±21% and -40±16%, P>0.99) but was lower in CONVO2 (-17±9%, P<0.001). CONpower resulted in a twofold higher oxygen consumption compared to ECC and CONVO2 (P<0.001). No change in CK or LDH activities were reported from pre- to 24h post-exercise. RPE was higher in ECC compared to CONpower (P=0.042), but lower compared to CONVO2 (P<0.001). Thigh muscle soreness was greater in ECC compared to CONpower and CONVO2 24h and 48h post-exercise (P<0.01).

CONCLUSION: This study demonstrated that eccentric cycling induced greater neuromuscular fatigue than concentric cycling performed either at similar power output or VO2, without inducing harmful muscle damage. While matched for power output, the metabolic demand was 44% lower in eccentric than concentric cycling. Taken together, eccentric cycling might be an interesting exercise modality to provide a strong neuromuscular stimulus while minimizing the impaired and limiting contribution of the cardiopulmonary system.

EFFECTS OF HIGH VS. MODERATE INTENSITY COMBINED STRENGTH AND ENDURANCE TRAINING DURING CHEMOTHERAPY ON CARDIORESPIRATORY FITNESS, MUSCLE STRENGTH AND ENDURANCE IN WOMEN WITH BREAST CANCER

WIESTAD, T.H.1,2, VIKMOEN, O.3, RANES, M.1, THORMODSEN, I.1, FLUGE, Ø.1,2, MELLA, O.1,2, BERNTSEN, S.4,5, NORDIN, K.4, RAASTAD, T.3,5

1 HAUKELAND UNIVERSITY HOSPITAL, 2 UNIVERSITY OF BERGEN, 3 NORWEGIAN SCHOOL OF SPORT SCIENCES, 4 UPPSALA UNIVERSITY, 5 UNIVERSITY OF AGDER

INTRODUCTION: (Neo-)adjuvant chemotherapy for breast cancer has the potential to reduce recurrence and mortality but are often accompanied by significant adverse effects. Both aerobic and resistance exercise has been shown to be beneficial for individuals with adjuvant therapy-related side effects, but few studies has investigated the optimal intensity, and timing of an exercise intervention (1). High intensity exercise has previously shown promising results on muscle strength and maintenance of cardiorespiratory fitness in patients with breast cancer (2, 3). The aim of the current study was to to compare the effect of high-intensity (HIT) vs. moderate-intensity (MIT) combined strength and endurance training on cardiorespiratory fitness (VO2max), muscular endurance and muscle strength measured as 1 repetition maximum (1RM) in patients with breast cancer during chemotherapy.

METHODS: Women diagnosed with stage I-III breast cancer was randomized to 12 weeks of HIT (n=29) or MIT (n=36). Both groups performed home-based endurance training and supervised strength training twice a week. The HIT group trained at an intensity of 80-90% of the heart rate reserve (HRR) and 1RM and the MIT group at 40-50% of the HRR and 1RM. The aerobic exercise consisted of 5x2 minutes intervals in the HIT group, and as continuous work in the MIT group. Testing of VO2max, muscle strength and muscular endurance was performed between the first and second cycle of chemotherapy (T0) and after chemotherapy (T1).

RESULTS: At baseline, VO2max was 33±7 ml/kg/min and was reduced in both groups by 7±12% (p<0.05) in HIT and by 9±9% (p<0.05) in MIT with no significant difference between groups (p=0.569). Chest press 1RM at baseline was 27±7 kg and increased in the HIT group by 8±14% (p=0.02) and tended to increase in the MIT group with 6±15% (p=0.06). There was no significant difference between groups (p=0.536). Leg press 1RM at baseline was 41±18 kg and increased in the HIT group by 11±18% (p<0.005). There was no change in the MIT group (2±19% (p<0.74)) and no significant difference between groups (p=0.08). There were no significant change in leg extension 1RM from baseline (37±9 kg) in either group, or in muscular endurance (baseline 33±15 repetitions There were no significant differences between groups for neither leg extension (p=0.48) nor muscular endurance (p=0.21).

CONCLUSION: Neither HIT nor MIT counteracted the decline in VO2max in breast cancer patients during the chemotherapy treatment. However, the decline was slightly lower in the HIT group and HIT also increased muscle strength in chest press and leg press, which correspond with previous findings (3).

EFFECTS OF HEAVY-LOAD STRENGTH TRAINING DURING (NEO-)ADJUVANT CHEMOTHERAPY ON CARDIORESPIRATORY FITNESS, MITOCHONDRIAL ENZYMES AND CAPILLARIES IN WOMEN WITH BREAST CANCER

VIKMOEN, O.1, STRANDBERG, E.1,2, DEMMELMAIER, I.2,3, BERNTSEN, S.2,3, NORDIN, K.2, RAASTAD, T.1,3

1. NORWEGIAN SCHOOL OF SPORT SCIENCES, OSLO, NORWAY, 2. UPPSALA UNIVERSITY, UPPSALA, SWEDEN, 3. UNIVERSITY OF AGDER, KRISTIANSAND, NORWAY

INTRODUCTION: (Neo-)adjuvant chemotherapy for breast cancer has deleterious effects on maximal oxygen uptake (VO2max), mitochondrial function and capillary content in muscles (1,2). Physical exercise during treatment may counteract some of these negative effects. However, the effects of strength training (ST) alone are not well documented. The aim of this study was to investigate if heavy-load ST can counteract the deleterious effects of chemotherapy treatment on VO2max and muscle content of mitochondrial enzymes and capillaries in women diagnosed with breast cancer.

METHODS: Women diagnosed with stage I-III breast cancer were randomized either to a ST intervention group (INT, n=23) or a usual care control group (CON, n=17). The INT group performed supervised heavy-load ST twice a week over the course of chemotherapy (approximately 16 weeks) whereas the CON group was encouraged to continue with their usual activities. Measures of VO2max and collection of muscle biopsies from m. vastus lateralis was performed before the first cycle of chemotherapy (T0) and after chemotherapy (T1). Biopsies were analyzed for mitochondrial enzymes (Citrate Synthase [CS], COX4 and HADH) in western blots and capillaries per fiber area (CAFA) by immunohistochemistry. Unpaired and paired t-test were used to test for differences between groups and within-groups respectively.

RESULTS: VO2max decreased from 28.3±7.2 to 26.5±5.8 ml•kg-1•min-1 (-6±11%, $p<0.001$) in the INT group and from 29.1±7.7 to 26.8±7.4 ml•kg-1•min-1 (-11±9%, $p<0.001$) in the CON group from T0 to T1 with no differences between the groups ($p=0.13$).

CS levels were reduced in the control group (14.9±14.8%, $p=0.004$) and COX4 tended to be reduced (-11±23%, $p=0.073$) from T0 to T1. No changes were observed in the INT group and the change from T0 to T1 was different between the groups ($p=0.04$). No significant changes occurred in HADH. For all three enzymes combined, there was a decrease in the CON group with no change in the INT group and a difference ($p<0.001$) between the groups in change from T0 to T1.

CAFA was reduced in the CON group from T0 to T1 with 19±25% ($p=0.02$) in the type 2 fibers and non-significantly in the type 1 fibers (-9±23%, $p = 0.14$). There were no changes in the INT group and the percent change from T0 to T1 was different between the groups in type 2 fibers ($p=0.03$) and in type 1 fibers ($p=0.05$). There was a positive correlation between the percent change in VO2max and the percent change in CAFA in the type 2 fibers ($r=0.55$, $p=0.01$).

CONCLUSION: The ST program did not counteract the decline in VO2max in breast cancer patients during the chemotherapy treatment. However, ST prevented the decline in muscle mitochondrial enzymes and capillaries which was observed with usual care chemotherapy. Our data suggest that ST alone can preserve aerobic properties of the muscle cells in breast cancer patients during chemotherapy treatment.

RESIDENTS' PERCEIVED QUALITY OF LIFE TOWARDS SPORTS EVENTS: SYSTEMATIC LITERATURE REVIEW AND META-ANALYSIS

CHEN, H.W., CHEN, I.C., CHEN, F.C., CHEN, M.Y., CHENG, T.C.

NATIONAL TAIWAN NORMAL UNIVERSITY

Introduction

Sports events have numerous impacts on the host city such as economic and cultural impacts (Gursoy & Kendall, 2006; Kaplanidou et al., 2013). Among the potential benefits, a positive impact on host residents was one reason why cities bid to host sports events. When an event is held, residents' interactions with participants directly or indirectly affect their QoL (Quality of Life). Previous studies argued that the host residents who perceived higher QoL are more likely to support recurring sports events or recommend them to others. However, systematic reviews and comprehensive quantitative analysis

of the accumulated data are still lacking between residents' perceived impacts of sports events and QoL. The aim of this study is to identify the determinants of perceived QoL of the host population, to access the effect between different impact perceptions and QoL, and to examine whether host residents who perceive higher QoL have more support toward sports events.

Methods

The present study followed Preferred Reporting Items for Systematic Review and Meta-Analysis Protocols (PRISMA-P), and the SPIDER framework was utilized to formulate the search strategy. EBSCO, Scopus, T&F, Emerald, and WOS databases were searched in January 2023. The search in 5 databases returned 1306 articles. Ultimately, 9 studies of QoL outcomes were included in the assessment and synthesis process.

Results

The meta-analysis results revealed a correlation between overall impact perceptions and QoL with r =0.23 (95%CI= 0.06-0.39). The r value for the correlation between economic impacts, sociocultural impacts, psychological impacts and QoL respectively: 0.28 (95%CI=0.03-0.49,k=3,n=3,189, Q=87.83,p<.001), 0.44(95%CI=0.26-0.59,k=3,n=3,189, Q=59.94,p<.001), 0.260 (95%CI=0.23-0.29, k=3, n=3,196, Q=0.07,p=0.97). The findings suggested a positive correlation between residents perceived overall QoL and their support for the sports event (r=0.27, 95%CI=0.17-0.36). Results showed that residents perceived higher overall QoL in their support for non-mega events than for mega-events. Besides, Residents in Asia are more sensitive to overall QoL when deciding on event support compared to North America. The present study also found no significant difference in perceived QoL during different phases of the sports event (95%CI=-0.01-0.31, k=4, n=7,984).

Discussion

The study found a significant positive impact of economic, sociocultural, and psychological factors on host residents QoL, with sociocultural impacts having the largest effect. The perceived overall QoL had a small effect on residents support for the event. Hence, we suggested that governments or event organizers could enhance host residents' support when bidding on sports events by emphasizing the potential sociocultural benefits, especially for mega sports events. Findings clearly suggest that a closer examination of different time points of sports events used to assess the QoL perceptions is needed.

CAN THE CREDIBILITY OF GLOBAL SPORT ORGANIZATIONS BE RESTORED? A CASE STUDY OF THE ATHLETICS INTEGRITY UNIT (AIU)

FABIEN, O., VERSCHUUREN, P.

UNIVERSITY OF LAUSANNE, UNIVERSITY OF RENNES

This paper explores how the credibility of global sport organizations can be renegotiated in a post-scandal context. Many large-scale governance and integrity scandals have marked the recent history of sports organizations. In some cases, and under external pressure, this has led Global Sports Organizations (GSOs) to set up regulatory entities, such as the WADA.

Theoretical Frame

The paper draws on Goffman's frame analysis to understand how the AIU has managed to produce a framing that allows it to cope with and even overcome the discredit linked to the athletics doping scandals. We analysed three key factors □frame consistency, empirical credibility, and credibility of the frame articulators□, to understand "why some framings seem to be effective or 'resonate' while others do not" (Benford and Snow, 2000: 619).

Methods

1. A media analysis: in total, 14 outlets were included in the analysis, covering a total of 1111 articles from both news media and specialized analytical journalism on GSOs or athletics.

2. Social media analysis was conducted in a third step to identify and analyze messages expressed through Twitter.

3. Data on how IAAF/WA, AIU and representatives framed the AIU in their public communication.

4. Interviews with international antidoping specialists

Results

The frame consistency, empirical credibility and the credibility of the frame articulators contributed to the construction of credibility. Besides, transparency and accountability helped to align the athletics authorities' strategic self-framing with the frames used by external stakeholders. Through the social production of its own performance, the Unit could escape the reputation stigma that has discredited other federations and sport organizations.

The absence of structural criticism, the praise emanating from leading media or industry representatives around both the governance and the effectiveness frames and the trend for naming the AIU as a good –if not best– practice in the sport sector, provide indication of this success and show that AIU's frame consistency, empirical credibility, and credibility as articulators have so far been effective and 'resonate' within the audience (Benford and Snow, 2000). The AIU case study proves instructive as it represents renewed practice for the sector. Through the social production of its own performance, the AIU could appear to escape the reputation stigma that has condemned other federations and sport organizations. AIU's case shows that the traditional mode of sport governance, based on a front stage of celebration and self-

congratulation, a lack of transparency, sweeping the dust under the carpet, and decisions taken behind the scenes, is no longer accepted, at least in the democratic countries.

THE ROLE OF RURAL SPORTS PROGRAMS IN POVERTY ALLEVIATION AND THE PREVENTION OF POVERTY RETURNING IN CHINA

ZHANG, S.G.
CHINA SPORT INFORMATION CENTER

Introduction

Through eight years of sustained work, China has lifted all rural poor population under the current standard out of poverty. Rural sports programs have played an important role in poverty alleviation and the prevention of poverty returning in China. Sports programs can reduce poverty by promoting health, education and diplomacy in developing countries. To provide references for the development of sport in the developing countries, it is important to make an intensive study of the role of rural sports programs in poverty alleviation and the prevention of poverty returning in China.

Methods

This study analyzes the history, the policies, the theories, and the governance system of poverty alleviation through rural sports programs in China, which will be examined by incorporating a literature review and comparative analysis into this paper.

Results

Based on the in-depth analysis of social functions of sport and rural poor people, Chinese sport administrators and sport management departments have formulated well-defined policies to guide the operation of poverty alleviation through rural sports programs, among which Opinions on the Implementation of Poverty alleviation through Sport Project released in 2018 by General Administration of Sport of China make a huge difference. In view of local conditions, different modes are used to shake off poverty and prevent poverty returning, including "sport plus tourism", "sport plus facilities", "sport plus health", "sport plus culture", "sport plus education", and "sport plus events".

Discussion

Through events and sport tourism, the underdeveloped areas have got investment from public institutions and private capitals. Through physical education and sport culture activities, rural poor people have got skills and willpower to eliminate poverty. Especially for those who fell into poverty due to illness, sport is an effective means of helping people to improve health and shake off poverty. Besides being a means of eliminating poverty, sports programs have also played an important role in preventing poverty returning.

BENEFICIAL EFFECTS OF A PERSONALIZED E-TRAINING PROGRAM IN MARFAN PATIENTS: THE FIRST RANDOMIZED CONTROLLED STUDY

JOUINI, S., MILLERON, O., ELIAHOU, L., JONDEAU, G., VITTIELLO, D.
UNIVERSITÉ PARIS CITÉ

INTRODUCTION: Marfan syndrome (MFS) is a rare genetic disorder primarily affecting the vascular system. This randomized controlled trial aimed at characterizing the physical abilities and quality of life (QoL) of MFS patients and designing and proposing a 3-month personalized e-training program. To demonstrate that a personalized e-training program improves the QoL of patients with MFS. Secondary objectives: 1/ To determine the beneficial effects of the e-training program on the physical capacities of patients. 2/ To demonstrate the safe nature of the management of MFS patients through a personalized e-training.

METHODS: 82 Marfan patients and 35 healthy subjects (H-S) were included in this study. MFS patients were randomly divided into 2 groups (control and trained) and compared with 35 healthy subjects. Different parameters (e.g., V˙O2peak, aortic diameter, 1RM, pulse wave velocity (PWV) and QoL (MOS SF-36) were assessed pre and post training.

RESULTS: The MFS significantly decreased the V˙O2peak (-25%; $p<0.001$) and the QoL of patients compared to H-S. The e-training increased the V˙O2peak (+3 mL/min/kg in average) and improved the scores of all MOS SF-36's dimensions. It also improved arterial pressure during exercise and had no adverse effect on aortic diameter (pre vs. post training: aortic root: 39±5 vs. 38±5 mm; $p= 0.71$) in our young MFS population.

CONCLUSION: Our e-training produced beneficial effects on MFS patients and maintained stable the aortic diameter. This work supports the feasibility and safety of personalized training for the management of MFS patients without severe symptoms.

THE EFFECT OF AEROBIC TRAINING ON EXERCISE-INDUCED HYPERTENSION IN ADULTS WITH PERSISTENT OR PERMANENT ATRIAL FIBRILLATION: A SECONDARY ANALYSIS OF THE OPPORTUNITY TRIAL.

WAY, K.L., TERADA, T., VIDAL-ALMELA, S., THOMAS, H.J., PARKER, L., KESKE, M.A., REED, J.L.
UNIVERSITY OF OTTAWA HEART INSTITUTE

INTRODUCTION: Exercise-induced hypertension (EIH), defined as a systolic blood pressure (BP) of ≥175 mmHg and/or diastolic BP of ≥110mmHg at low-to-moderate exercise intensity, leads to a 36% increase in cardiovascular events independent of resting BP. Up to 80% of adults with atrial fibrillation (AF) suffer from hypertension which is an independent risk factor for ischemic or haemorrhagic strokes. EIH may be a useful prognostic tool for screening hypertension control in people with AF and an important treatment target. Aerobic training is an effective strategy for improving resting BP, however the effect of aerobic training on EIH in adults with AF has yet to be explored. The aim of this study was to determine if aerobic training is effective for reducing the burden of EIH in adults with persistent or permanent AF.

METHODS: Secondary analysis of a randomised controlled trial. Adults with persistent and permanent AF were randomised to 12-weeks of twice weekly aerobic training of: (i) high-intensity interval training (HIIT): 2 sets of 8 x 30-second high-intensity intervals at 80-150% peak power output interspersed with 30-second recoveries. A 4-minute recovery between sets was provided; or (ii) moderate-to-vigorous continuous training (MICT; standard-care control): 30 minutes at 67-95% heart rate peak or 12 to 16 on the Borg's Rating of Perceived Exertion Scale. EIH was assessed using peak systolic and diastolic BP recordings completed immediately following a six-minute walk test (6MWT); tests were completed at baseline- and 12-week follow-up. Two-proportion Z-test and chi-squared analyses were performed to determine differences in baseline vs. 12-week follow-up proportions in EIH (BP: ≥170/110mmHg) and differences between HIIT vs. MICT and EIH proportions, respectively.

RESULTS: Eighty-six adults with AF (age: 69±8 years, 32% females, resting systolic BP: 126±17mmHg, resting diastolic BP: 78±10 mmHg) were randomised into HIIT (n=43) or MICT (n=43). Most patients were taking anti-hypertensive medications (64% beta-blockers; 24% ACE-inhibitors; 20% angiotensin-receptor blockers). Overall, 11% of patients were categorized with EIH at baseline. Following 12-weeks of either HIIT or MICT, only 4% of patients had EIH; this reduction in EIH burden was not significant (p=0.07). A total of 35 out of the 69 (51%) patients who completed the intervention experienced a reduction in peak systolic BP across both the HIIT and MICE groups. No significant differences were observed between HIIT or MICT for changes in EIH or peak BP (mean: 144/84±16/11mmHg).

CONCLUSION: EIH was present in 1 in 10 patients with AF in our cohort, despite most patients taking anti-hypertensive medications. Monitoring EIH following a 6MWT or exercise stress test may be a cost-effective tool for screening BP control in this population. Our data also suggests 12-week, twice weekly HIIT or MICT may potentially be effective for mitigating EIH in adults with AF.

EVENING BUT NOT MORNING AEROBIC-TRAINING IMPROVES SYMPATHETIC ACTIVITY AND PERIPHERAL BAROREFLEX SENSITIVITY IN TREATED HYPERTENSIVE ELDERLY PATIENTS: A RANDOMIZED CLINICAL TRIAL

FORJAZ, C.1, AZEVÊDO, L.1, AMARO-VICENTE, G.1, COSTA, L.1, HALLIWILL, J.2, RONDON, M.1, BRITO, L.1,3
1. UNIVERSITY OF SÃO PAULO, BRAZIL; 2. UNIVERSITY OF OREGON, USA; 3. OREGON HEALTH & SCIENCE UNIVERSITY, USA.

INTRODUCTION: In a previous study with middle-aged treated hypertensive men, we observed that aerobic training conducted in the evening induces greater blood pressure (BP) decrease than when conducted in the morning (1). Additionally, this greater BP reduction was accompanied by a greater reduction in the low frequency component of BP variability, suggesting a greater effect of evening training on peripheral sympathetic autonomic system, which needs to be tested using direct measures. Therefore, this study was designed to compare the effects of aerobic training conducted in the morning (MT) and in the evening (ET) on muscle sympathetic nerve activity (MSNA) and peripheral baroreflex sensitivity (BRS) in treated hypertensive elderly patients.

METHODS: The study was conducted in a single-center with a parallel-group design. Twenty-three patients with treated hypertension were randomly allocated into two training groups: MT (n=12, 5 men, 69±7 yr) and ET (n=11, 7 men, 65±5 yr). Training protocols were identical in both groups (cycling, 3 times/week, for 45 min at moderate intensity), but MT was conducted between 7 and 10 a.m., while ET occurred between 5 and 8 p.m. Before and after 10 weeks of training, beat-to-beat BP (finger photoplethysmography), heart rate (electrocardiography), and muscle sympathetic nerve activity (MSNA, fibular nerve microneurography) were assessed. Additionally, peripheral BRS was evaluated by the modified-Oxford technique using bolus injection of nitroprusside followed by phenylephrine. Peripheral BRS was quantified by the slope of the weighted negative linear regression between diastolic BP and MSNA burst incidence. Two-way mixed ANOVAs were employed, and significance level was set as P≤0.05.

RESULTS: From pre- to post-training, systolic BP decreased in ET, but did not change in MT (149±9 vs. 136±16 and 146±10 vs. 145±15 mmHg, respectively, P interaction =0.04), while diastolic BP decreased similarly in both groups (ET = 80±7 vs. 76±13 and MT=78±13 vs. 76±11 mmHg, P phase =0.05). MSNA presented a greater decrease after ET than MT (42±3 vs. 33±4 and 40±5 vs. 37±4 bursts/100bpm, respectively, P interaction=0.04). Peripheral BRS improved in ET and did not change in MT (-1.44±0.63 vs. -2.20±0.58 and -1.63±0.68 vs. -1.62±0.86 bursts.100 heartbeats-1.mmHg-1, respectively, P interaction=0.05).

CONCLUSION: In hypertensive elderly patients receiving anti-hypertensive medication, 10 weeks of aerobic training conducted in the morning as well as in the evening decreases diastolic BP, while only aerobic training conducted in the evening improves systolic BP, MSNA, and peripheral BRS.

EFFECTS OF DIFFERENT MODES OF ISOMETRIC RESISTANCE TRAINING ON AMBULATORY BLOOD PRESSURE VARIABILITY IN HEALTHY NORMOTENSIVES

BAROSS, A.W.1, WRIGHT, B.H.1, BAXTER, B.L.1, KAY, A.D.1

UNIVERSITY OF NORTHAMPTON

INTRODUCTION: One third of deaths globally each year are associated with hypertension, a modifiable risk factor for cardiovascular disease. Diurnal blood pressure (BP) variability including morning blood pressure surge (MBPS) and average real variability (ARV) of ambulatory BP, are associated with increased risk of stroke, heart failure and end-organ damage. Laboratory isometric resistance training (IRT) protocols have identified reductions in ambulatory BP MBPS and ARV following 8-10 weeks of training, however no research has investigated the effects of short-term IRT on ambulatory measures in normotensives. Therefore, the purpose of this study was to determine the effects of a novel home-based IRT device on ambulatory BP, MBPS and ARV in normotensives following 4 weeks of IRT.

METHODS: Thirty-eight normotensives (20 men, age = 33 ± 14 yr; 18 women, age = 28 ± 13 yr) were randomly assigned to an isometric handgrip training (IHG, n = 13), isometric training band (ITB, n = 12) or control (CON, n = 13) group. Before and after the 4-week laboratory-based training programme, resting and ambulatory BP, MBPS (mean systolic BP 2 hours after waking, minus the lowest sleeping 1-hour mean systolic BP) and ARV (calculated as previously reported [1]) were measured. IRT consisted of 4 x 2-minute contractions at 30% MVC (IHG) or at a perceived rate of exercise exertion equivalent to 30% MVC (IBT), with 2-minute rest periods, 3 days per week. A two-way repeated measures ANOVA was used to assess the within and between groups changes in resting, ambulatory BP MBPS and ARV.

RESULTS: Significant ($P < 0.05$) reductions were detected in resting systolic BP for both training modes (IHG = -5 ± 4mmHg; ITB = -5 ± 3mmHg) with no further reductions in resting BP measures. Additionally, no significant reductions were seen in 24-h (IHG = -1 ± 6mmHg; ITB = 2 ± 7mmHg), daytime (IHG = 0 ± 6mmHg; ITB = 1 ± 7mmHg) or night-time systolic ambulatory BP (IHG = -4 ± 7mmHg; ITB = -4 ± 8mmHg). Furthermore, no significant changes were observed in the MBPS (IHG = -1 ± 15mmHg; ITB = 1 ± 10mmHg), 24-h (IHG = 1 ± 3mmHg; ITB = 1 ± 2mmHg) or daytime (IHG = -1 ± 2mmHg; ITB = 0 ± 2mmHg) ambulatory ARV systolic BP.

CONCLUSION: These results support the unpublished data establishing the novel training device as a valid tool for lowering resting systolic BP and provides further evidence that IRT is effective for lowering resting BP in normotensives. However, the lack of significant reductions in ambulatory BP, MBPS and ARV following a four-week IRT programme may indicate that for diurnal BP reductions to occur a longer training stimulus may be needed. Further, the absence of any ambulatory reductions may be associated with the proposed biphasic pattern to vascular adaptations.

THE EFFECTS OF COCOA FLAVANOLS ON UPPER AND LOWER LIMBS DURING UNINTERRUPTED SITTING: INSIGHTS INTO MACRO- AND MICROVASCULAR FUNCTION

DANIELE, A., LUCAS, S.J., RENDEIRO, C.

UNIVERSITY OF BIRMINGHAM

INTRODUCTION: Prolonged sitting affects endothelial function in peripheral conduit arteries. Nutritional strategies might play an important role in counteracting these negative effects. Consumption of cocoa flavanols enhances peripheral vascular function, as measured in the brachial artery via flow-mediated dilation (FMD); however, whether this positive outcome is also present in the superficial femoral artery is not known. The objective of this study is to investigate whether acute ingestion of cocoa flavanols can prevent sitting-induced impairments in macrovascular and microvascular function in both the upper and lower body vasculature in young healthy adults.

METHODS: In a randomized, double-blind (the two cocoa beverages remain blinded as 523, and 947), cross-over trial, 13 young healthy men (age: 23 ± 3 years) completed two, 2-hour sitting conditions with consumption of either a high or low flavanol cocoa beverage. FMD and shear rate of the femoral and brachial artery, microvascular function (i.e., reperfusion slope) of the calf (assessed via near-infrared spectroscopy), and blood pressure, were collected before and after the 2-hour sitting intervention.

RESULTS: In these initial 13 participants (recruitment target n=36; complete set of data will be available at the time of the presentation), sitting significantly reduced femoral FMD (pooled data: 4% vs. 2.7%, p=0.011). However, this detrimental decline in vascular function was prevented in response to only one of the two cocoa beverages (i.e., 523). Reperfusion slope was not affected by sitting; however, our preliminary data suggests that cocoa beverage 523 may have a positive impact on reperfusion slope (although not statistically significant). In regard to brachial FMD, no significant changes were observed neither in response to sitting nor cocoa ingestion. Furthermore, these preliminary data suggest that sitting may have a negative impact on brachial FMD (pooled data: 5.5% vs. 4.8%, p=0.28; interaction: p=0.09), but this is only observed following cocoa beverage 947. In addition, positive shear rate declined in both the femoral (p<0.01) and brachial

artery (p<0.01) following sitting, although this was not differentially affected by flavanol content (interaction: p>0.1). No significant changes in blood pressure were observed neither in response to sitting nor cocoa ingestion. Finally, the impact of individual's cardiorespiratory fitness on vascular function in response to cocoa ingestion and sitting will be available at the time of the presentation.

CONCLUSION: Preliminary observations highlight the potential impact of cocoa consumption in ameliorating macrovascular and microvascular function following uninterrupted prolonged sitting, specifically in the lower limbs. Hence, cocoa consumption may be effective in attenuating sitting-induced vascular dysfunction in lower limb conduit arteries.

OP-SH07 Physical activity promotion

STRENGTHENING COMPETENCES OF FUTURE HEALTH PROFESSIONALS IN PHYSICAL ACTIVITY PROMOTION: THE DEVELOPMENT OF AN INTERPROFESSIONAL PEDAGOGICAL TOOL ON THE EXAMPLE OF THE COMMUNITY-BASED PROGRAM: "MOVE Y

WEGRZYK, J.1, LOTFY, H.1,2, SCHLÄPPY, F.1, SANTOS-ROCHA, R.3, DE LABRUSSE, C.1, HYVÄRINEN, M.1

SCHOOL OF HEALTH SCIENCES, UNIVERSITY OF APPLIED SCIENCES WESTERN SWITZERLAND

Introduction: Health professionals play a crucial role in promoting active lifestyles thereby increasing well-being and lowering the rate of noncommunicable diseases. Yet, university students (including future health professionals) do not meet guidelines on physical activity (PA) and sedentary behaviour [1, 2]. Meaningful and innovative learning environments could sensibilize and empower them to increase control over their own health and to promote PA in the community [3]. On the basis of the perinatal program "Move your Baby (MYB)" [4], as part of the BSc curriculum at HESAV, we developed a theory-based pedagogical tool to support evidence-based practice in PA promotion.

Methods: An online survey on PA and sedentary behavior was developed for the students including the study courses: physiotherapy, nursing, midwifery, radiologic medical imaging technology. Subsequently, a transversal pedagogical device for PA promotion for interprofessional and community-based settings was developed based on previously identified barriers to promote PA according to the Behavioral Change Wheel [5] and experience from the MYB program in which more than 200 BSc students participated since 2018. A self-administered questionnaire based on Gérard's method [6] is used to rate the tool's pedagogical effectiveness.

Results: 73% of the students (HESAV, n=193) reported sitting activities of >6h, and dissatisfaction (> 50%) with regards to access opportunities to be more active in and around the campus. The evidence-based, transversal pedagogical device has been implemented in the BSc curriculum of physiotherapy (n=70/year) and midwifery (n=60/year). Evaluation grids allowed to standardize interventions and evaluation processes. Students are currently rating improvement in their knowledge, skills and confidence to promote PA in order to rate the tool's effectiveness.

Discussion: Offers to increase the students' level of PA as well as meaningful learning environments through community-oriented educational programs can support identifying with the role as future health promoters, understanding social determinants of health, and providing personalized counseling in PA. We present a generic framework that guide behavioral change intervention and can be adapted and implemented for (future) exercise professionals while addressing different target groups (e.g., children, seniors).

NEGOTIATING A PHYSICALLY ACTIVE LIFE DURING THE SCHOOL DAY –– AN ETHNOGRAPHIC MULTIPLE CASE STUDY IN SWEDISH SECONDARY SCHOOLS

HOY, S., THEDIN JAKOBSSON, B., LUNDE, C., LARSSON, H.

THE SWEDISH SCHOOL OF SPORT AND HEALTH SCIENCES

Introduction

A national policy for physical activity in Swedish compulsory school can be found in the general curriculum, where it states that "the school should also strive to provide all students with daily physical activity within the framework of the entire school day" (SNAE, 2019). Yet, many schools seem to struggle to meet this task. The aspiration to provide all students with daily physical activity in school settings are far more paradoxical than at a first glance. Educational settings are often

defined as 'the solution', because it gathers all adolescents during a third of the day. And, whilst the health benefits of physical activity are well documented, the reasons for choosing these behaviors or not are complex, related to social, cultural, and gender structures of the school and its individuals.

The objectives of this study are to explore secondary schools (i) understandings and practices connected to the physical activity policy embedded in the general curriculum, and (ii) what the perceived barriers and facilitators towards implementation of the policy are.

Methods

This ethnographic multiple-case study was performed by a team of four researchers over the course of a year in four Swedish secondary schools. The fieldwork involved participant observations, informal conversations, and semi-structured interviews (72 interviews with 86 respondents) with school management, staff responsible for secondary students and for student health or/and are engaged in physical activity, physical education teachers, as well as secondary school students (13-14 years old). All phases of data analysis were performed using reflexive thematic analysis.

Results and Discussion

Preliminary results show that the structure of the school and its environments clearly influence the opportunities and conditions for physical activity during a school day. At the same time, the age of adolescence is a period in life when we go from being children to becoming adults, where independence increases and thence the free choice of being active or inactive. Students own influence and participation in how they want to be active or not should reasonably increase with their development in autonomy. With this autonomy, physical activity behaviors also work as a social marker that is informed by gendered and socio-cultural structures. It appears to create tension between the ideas of agency and structure, both at the individual level but also at the school organisational level. Conflicting ideas between the public good and private rights often seem to arise in this endeavour.

CORPORATE WELLNESS: INTERVENTION TO PROMOTE PHYSICAL ACTIVITY, ERGONOMICS, HEALTH AND ACTIVE LIFESTYLE WITH ONE YEAR FOLLOW-UP

FRACCA, I.

STUDIO PREVENZIONE E SALUTE DI FRACCA DOTT.SSA ILENIA

Introduction. The promotion of health in the workplace plays a role of increasing importance at European level, worthy of note is the "European Network Workplace Health Promotion" (ENWHP) program. Industry leading company in the production of machines for tanneries and equipped with a gym, hosted us to conduct our study.

Aims. This study evaluated the effectiveness of an informative workplace wellness program in increasing physical activity levels, reducing sedentary behaviour and musculoskeletal disorders in staff.

Methods. In the beginning, 89 Employees (E) (average age=45.2 years, 8.9% female (F) divided in 50 Operational Staff (OS) and 39 Offices Employees (OE), completed three questionnaires: International Physical Activity Questionnaire (IPAQ short form),Occupational Sitting and Physical Activity Questionnaire (OSPAQ), Nordic Musculoskeletal Questionnaire (NMQ). At the same time, postures during work were observed, photographed and analysed. These observations were followed by 3 information bimonthly phases: company training meeting for E, distribution of an information brochure on the physical activity benefits and distribution of different protocols of adapted physical exercise for OS and OE.

At the 1-year FOLLOW-UP, 73 E, (average age=45 years, 7.3% F, OS = 38, OE = 35), compiled the questionnaires IPAQ, OSPAQ, NMQ and Client Satisfaction Questionnaire-8 (CSQ-8) which contained a space for suggestions. Data were examined with chi-Quadro and ANOVA for repeated tests.

Results. In initial data it was observed that only 15% of E used the company gym, and 69.66% could be considered very active (IPAQ). Many of the E suffer or have suffered in the last 12 months from musculoskeletal disorders (NMQ): lumbar area E=51,69%, OS=60%, OE=41,03%; cervical area E=49,44%, OS=44%, OE=56,41%.

In the follow-up (dropout 17.98%), there were significant changes in OSPAQ: in the OS a reduction in time spent standing ($P = 0.004$) and an increase in time spent walking ($P = 0.008$) in one day, in E the time spent standing is reduced ($P < 0.05$) which goes from 40.57% to 30.41% of the total time.

No significant differences were observed in physical activity levels (MET-min/wk), working day sitting time and musculoskeletal disorders by anatomical district (NMQ) although a tendency to decrease in general is noted.

Conclusions. This workplace wellness was much appreciated, the ergonomic recommendations were followed, however it did not affect the use of the company gym and in the reduction of musculoskeletal pain by anatomical district (NMQ) although there is a tendency towards lack in general, did not improve the already high levels of physical activity. Considering the average age and that many E suffer or have suffered from musculoskeletal disorders further and different proposals are needed.

PS-PL02 The development of sports champions: applied perspectives on the nature vs nurture conundrum

HOW SPORTS CHAMPIONS DEVELOP MAY NOT BE HOW YOU THINK

MACNAMARA, B.
CASE WESTERN RESERVE UNIVERSITY

What makes a champion? Two popular theories, one from psychology and one from sports science, have emerged offering countering claims. According to the deliberate practice view, athletes who specialize early and engage in maximal amounts of coach-led practice will prevail. In contrast, according to the deliberate play view, athletes who play multiple sports for fun at young ages will prevail.

Which is correct? To an extent, the answer depends on the age of the athletes: When examining youth athletes, meta-analyses reveal results aligned with the deliberate practice view: Compared with their national-class counterparts, international-class athletes specialized earlier and had accumulated more coach-led practice in their main sport. However, when examining adult athletes, the pattern is the opposite: Compared with their national-class counterparts, world-class athletes specialized later and had accumulated more coach-led practice in other sports, but less overall practice in their main sport.

These results tell us that the oft-regaled tales of Tiger Woods and Serena Williams starting at a young age and focusing on their sport to become great champions are the exception, not the rule. In fact, these tales are often false: Both Tiger Woods and Serena Williams played multiple sports before specializing in their main sport.

Nonetheless, several questions often emerge after hearing these findings. Did the results differ by type of sport played? They did not. Were world-class athletes simply more talented athletes, better at multiple sports? World-class athletes reached sports-specific milestones later than their national-class counterparts, indicating they were not outperforming the competition when they were younger. Does the deliberate play view explain these differences? Amount of peer-led play had little on performance at any age or level of competition.

These results align with other, more recent meta-analyses indicating that the top junior athletes do not become the top adult athletes (and that the top adult athletes were not top junior athletes). Junior performance explains less than 2% of the variance in performance as an adult. At the oldest junior age category, only 1 out of 4 international-level performers reach the international stage as adults. At one age category younger, the number drops to 1 out of 11. One age category younger, 1 out of 17. This suggests that talent identification based on a young athlete's current performance is misguided.

Why is youth performance such a poor predictor of later performance? Along with dropout due to burnout, injury, or other reasons, various predictors may develop at different times and speeds across individuals, such as biological maturation. My plenary partner, Craig Harrison, will continue this discussion, addressing various physiological issues in the context of developing sports champions.

BIOLOGY TO BEHAVIOUR: ADVANCES IN TALENT DEVELOPMENT

HARRISON, C.
AUCKLAND UNIVERSITY OF TECHNOLOGY

How do we keep potential champions in sport long enough to prevail? Since youth sports began in the early 20th century, kids have competed based on chronological age. Twelve-year-olds against other 12-year-olds. Fifteen-year-olds against other 15-year-olds. Yet while chronological age increases at the same rate for everyone, biological age does not. Kids develop at different rates. Some earlier. Some later. Thus, athletes with the same birth date can differ considerably in their biology. How does this affect talent identification? While skill plays an obvious role in top junior performance, an increasing body of research shows the significant impact of biological maturation.

Studies examining selection in youth sports indicate a distinct bias towards early developing athletes. Simply put, bigger, faster, stronger kids are more likely to make the team. Why is this true? In junior cricket, biologically older players bowl faster, throw further, hit harder, and perform better in tests of body strength, increasing cricket performance. In football and basketball, advantages in strength, power and speed give the early-maturing player the edge in competition. Crucially, such physical advantages show up in the evaluations of coaches during selection. A bias that, in some cases, is not lost until the transition from junior to senior sport.

The fact that potentially skilled but later-maturing athletes are less likely to make the team, and/or more likely to be deselected, is a failure of our talent system. Because short-term outcomes trump long-term development, kids with promise but who can't yet compete physically, are overlooked. However, new approaches that assess individual growth rates are starting to appear, with exciting implications for athlete development. New research in swimming shows, for instance, how maturation-based corrective adjustments may start levelling the playing field for young athletes.

Changes in biology not only influence who makes the team but a young athlete's development trajectory once they get there. Most noteworthy is how they cope with training volume and intensity. Rapid increases in height and weight common during the adolescent growth spurt change the way an individual experiences sport. Coordination can be lost. Skill can digress. Bones and tendons become more sensitive to stress. And all at a time when for a talented young athlete, demand typically goes up!

The adolescent growth spurt is a crucial stage of development. Major physical and physiological changes lead to fluctuations in performance and a heightened risk of injury. Importantly, new research investigating methods to control load exposure and stabilise the stress response amongst developing athletes is encouraging for healthy athlete development.

What is youth sport for? How we identify potential sport champions, as well how we develop them once they appear, starts with answering this question.

IS-AP05 Repeated Sprint in Hypoxia – What now? what next?

HAPPY BIRTHDAY RSH - 10 YEARS OF INNOVATION - AN UPDATE

MILLET, G.

UNIVERSITY OF LAUSANNE

The first publication on RSH is dated 2013. After 10 years, more than 50 publications have been published in a large range of sports from badminton to rugby or cross-country skiing. RSH effectiveness seems due to large recruitment of fast-twitch (FT) fibers combined to a compensatory vasodilation (with an increase in blood flow) mechanism; overall benefiting more FT fibers due to their great fractional O2 extraction (when highly perfused). The oxidative-glycolytic balance during RSH sessions and the minimal hypoxic dose are also important points to be considered. Many areas remain non investigated; e.g. induced fatigue? optimal conditions? potential adaptation and translation to clinical patients (PAD, elderly, ...)? Is it limited to team or racket-sports players?

In this session, we will also discuss the limitations of RSH and why it may not work for you.

RSH AND DIETARY NITRATE SUPPLEMENTATION: IS IT THE WHOLE GREATER THAN THE SUM OF ITS PARTS?

SOUSA, A.

UNIVERSITY OF TRÁS-OS-MONTES E ALTO DOURO

High-intensity interval training (HIIT) and repeated sprint training in hypoxia are gaining attractiveness and are based on different mechanisms. Combining nutritional strategies while performing RSH may result in more favourable outcomes on performance. One nutrient is of particular interest: inorganic nitrate (NO3-), a precursor of nitric oxide (NO), which is normally ingested by athletes in the form of beetroot juice. NO production, via NO3- supplementation, is accelerated in both acidic and hypoxic environments, seeming to be one of the primary vasodilatory candidates for the enhanced RSHs hyperemia. Collectively, dietary NO3- has the potential to improve training adaptation under hypoxic conditions as could be particularly effective to ameliorate the adverse impact of hypoxia. Studies performed within lighter exercise intensities and/ or during short period of supplementation, suggest that dietary NO3- reduces muscle metabolic perturbation and that muscle oxygenation status and exercise tolerance are improved. However, recent acute and chronic interventions have shown that dietary NO3- supplementation could be interpreted as unnecessary to improve performance or training adaptation when RSH is conducted. This session will assist athletes and coaches, to consider the recommended supplementation protocols to improve performance or training adaptation in hypoxic conditions, particularly when RSH is performed.

COMBINING ENVIRONMENTAL STRESSORS WITH REPEATED-SPRINT TRAINING IN HYPOXIA: WHAT TO EXPECT, WHERE TO GO?

BROCHERIE, F.

FRENCH INSTITUTE OF SPORT

Repeated-sprint training in hypoxia (RSH) has been demonstrated to provide putative physiological and performance benefits. Recently, repeated-sprint training in the heat was also shown to enhance fitness level, thereby conferring a substantial interest in the combination of both environmental stressors to maximize the physiological adaptations and performance gains. Contrasting findings question whether the addition of heat during RSH confers a greater physiological and/or mechanical strain and induced larger performance alteration, which may depend on the environmental dosage and training characteristics. This presentation will summarize the last evidences on RSH-based training combined with other environmental stressors and discuss future perspectives.

OP-PN16 Muscle Metabolism II

UNDERLYING SKELETAL MUSCLE DETERMINANTS OF THE FORCE-VELOCITY-ENDURANCE PROFILE OF ELITE ENDURANCE ATHLETES

BLERVAQUE, L.1, DELHAYE, C.1, MERLET, A.2, MOREL, B.1, BOWEN, M.1, DIRY, A.3, FÉASSON, L.2, SAMOZINO, P.1, MESSONNIER, L.A.1

1.LABORATOIRE INTERUNIVERSITAIRE DE BIOLOGIE DE LA MOTRICITÉ (LIBM), UNIVERSITÉ SAVOIE MONT BLANC, CHAMBÉRY, FRANCE.

INTRODUCTION: Athlete's force-velocity-endurance (FVE) profile is an important factor of rowing performance (1, 2), but its underlying skeletal muscle determinants remains unknown in this population. In endurance-trained athletes, the critical power (CP), a major component of the FVE profile, is strongly related to muscle O2 supply (i.e. capillarization) (3) but could also in theory be influenced by changes in O2 consumption capacities (4). Interestingly, elite rowers display high maximal oxygen uptake and elevated CP (2). Therefore, it can be hypothesized that elite rowers display exceptional both O2 supply and consumption which are determinant of their elevated CP. CP can result from different combinations of critical force (F0c) and velocity (V0c). Although different physiological and muscle characteristics determinants can intervene on the dimensions of force and velocity of CP, they have never been investigated. Therefore, the aim of the present study was to investigate the relationship between skeletal muscle features and parameters of the FVE profile in elite rowers.

METHODS: Eleven elite rowers performed i) a 3-min all-out test (3AO), ii) a 2000 m trial, both on a rowing ergometer, and iii) a muscle biopsy (vastus lateralis). Before the 3AO, six strokes in different velocity conditions were performed and these force/velocity data were analysed to assess maximal power (Pmax), maximal force at null velocity (F0i) and maximal velocity at null force (V0i). The same procedure was replicated at the end of the 3AO to obtain F0c, V0c and CP. Biopsy cryosections were used for immunofluorescent staining to obtain fibre-type specific capillary-to-fibre ratio (C/Fi), fibre cross-sectional area (CSA) as well as fibre typology. Histo-enzymatic staining of the sections was used to quantify relative activity of cytochrome C oxidase into the fibres (COx).

RESULTS: Pmax and CP were positively related to the 2000m trial performance ($r=0.86$; $p<0.001$ and $r=0.74$; $p<0.01$). CSA was positively correlated to Pmax and F0i ($r=0.70$; $p<0.02$ and $r=0.71$; $p<0.01$) but not V0i ($r=0.44$; $p=0.15$). C/Fi and CSA ($r=0.72$; $p<0.02$ and $r=0.73$; $p<0.02$) but not COx ($r=0.30$; $p<0.37$) were related to CP. The correlation with C/Fi was also significant with F0c ($r=0.63$; $p<0.05$). V0c did not correlate with any of the muscle characteristics.

CONCLUSION: The present study demonstrated the importance of skeletal muscle capillarisation in CP in elite endurance athletes. Surprisingly, even in these highly endurance-trained and oxidative athletes, fibre oxidative capacity did not seem to determine CP. As expected, Pmax was mainly determined by CSA. Interestingly, the muscle characteristics determined only the force component of the initial and critical power, i.e. F0i and F0c.

A PHYSIOLOGICAL REDUCTION IN PH PROVIDES A POTENTIAL MECHANISM FOR THE PREFERENTIAL INHIBITION OF LIPID METABOLISM WITH INCREASING EXERCISE INTENSITY

FRANGOS, S.M., DESORMEAUX, G.J., HOLLOWAY, G.P.

UNIVERSITY OF GUELPH

INTRODUCTION: A transient reduction in intramuscular pH (acidosis) occurs with increasing exercise intensity alongside a shift in fuel preference from lipids to carbohydrates. In vitro, even mild acidosis (pH 7.2 to 6.8) can reduce the maximal activity of the rate-limiting enzyme for lipid oxidation, carnitine palmitoyltransferase-I (CPT-I), indicating CPT-I may be a key control point for the acidotic attenuation of lipid metabolism. However, the mechanisms underlying this effect are not well-characterized and it remains unknown whether the aerobic metabolism of carbohydrates and/or mitochondrial metabolism common to both substrates is also affected by pH. Therefore, we utilized mitochondrial respiration to assess the influence of pH on single and mixed substrate responses in murine skeletal muscle at rest and following a single bout of intense exercise.

METHODS: Mitochondria were isolated from resting hindlimb skeletal muscles of wild type C57BL/6N female mice and permeabilized skeletal muscle fibers were prepared from the red gastrocnemius at rest or following a single bout of intense exercise (20 m/min, 15% grade, to exhaustion). Mitochondrial respiration was performed in buffers at pH 7.2 or 6.8. Substrates were titrated individually (CPT-I-dependent and independent substrates, pyruvate, lactate, glutamate, succinate, and ADP), or combined titrations were performed. Data was analyzed using a paired Students t-test and expressed as mean + SD.

RESULTS: Despite no difference in mitochondrial coupling, oxygen affinity or ADP respiratory responses between pH values, oxidative phosphorylation (OXPHOS) was generally attenuated by acidosis, as respiration with CPT-I-dependent

substrates, pyruvate, lactate, glutamate, and succinate were attenuated at pH 6.8 compared to pH 7.2. However, providing more pyruvate and ADP at pH 6.8 to model increases in glycolytic/glycogenolytic flux and ATP turnover with intense exercise, overcame the acidotic attenuation of carbohydrate-linked OXPHOS, supporting literature indicating that glycolytic/glycogenolytic flux increases with exercise intensity despite reductions in intramuscular pH [1]. Alternatively, we suggest lipid metabolism may be particularly sensitive to acidosis, considering CPT-I-dependent respiration was attenuated and malonyl-CoA (M-CoA) inhibition of CPT-I was enhanced, which together would limit the contribution of lipids to ATP provision. This potent effect of acidosis to enhance M-CoA inhibition of CPT-I in sedentary muscle persisted following a single bout of intense exercise, providing a possible mechanism whereby lipid metabolism may be preferentially inhibited at higher exercise intensities.

CONCLUSION: Combined, these data support transient acidosis as a mechanism preferentially attenuating lipid metabolism, and therefore a possible regulator of intensity-dependent shifts in skeletal muscle fuel use.

RESISTANCE-ONLY AND CONCURRENT EXERCISE INDUCE SIMILAR MYOFIBRILLAR PROTEIN SYNTHESIS AND ASSOCIATED MOLECULAR RESPONSES IN MODERATELY ACTIVE MEN

LEE, M.J., CARUANA, N.J., SANER, N.J., KUANG, J., STOKES, T., MCLEOD, J.C., OIKAWA, S., BISHOP, D.J., BARTLETT, J.D., PHILLIPS, S.M.

VICTORIA UNIVERSITY

INTRODUCTION: The molecular responses to aerobic and resistance exercise are divergent and may be antagonistic if performed concurrently. Concurrent exercise is hypothesised to compromise the anabolic response to resistance-only exercise. The potential for molecular incompatibility may depend on concurrent exercise order and participant training status; however, the influence of these variables is understudied. Therefore, we examined myofibrillar protein synthesis (MyoPS) rates, and associated molecular responses, to resistance-only and concurrent exercise (with different exercise orders), before and after 10 weeks of training.

METHODS: Healthy, moderately active males were allocated to one of three groups, which were matched for age, baseline strength, body composition, and aerobic capacity: (1) resistance-only exercise (RE, n = 8), (2) RE followed by high-intensity interval exercise (RE+HIIE, n = 8), or (3) HIIE followed by RE (HIIE+RE, n = 9). Participants trained 3 days/week for 10 weeks. Concurrent sessions were performed on the same day, separated by 3 h. On the first day of weeks 1 and 10, muscle biopsies were sampled immediately before, after, and 3 hours after each exercise mode and analysed for changes in molecular markers of MyoPS (via western blot and PCR), and muscle glycogen. Additional muscle was sampled at the end of both weeks to determine MyoPS using orally administered deuterium oxide.

RESULTS: In both weeks, absolute MyoPS rates and relative changes from pre-training were similar between all groups ($P > 0.05$). MyoPS increased from pre-training levels in Week 1 (FSR%/day [fold-change] RE: 2.02 ± 0.27% [~1.4-fold]; RE+HIIE: 1.86 ± 0.22% [~1.4-fold]; HIIE+RE: 1.81 ± 0.36% [~1.4-fold]), but not Week 10 (RE: 1.43 ± 0.24% [~1.0-fold]; RE+HIIE: 1.59 ± 0.26% [~1.1-fold]; HIIE+RE: 1.49 ± 0.25% [~1.1-fold]). Post-exercise changes in many proteins reflective of MyoPS (e.g., mTORC1, eEF2, rpS6) were also similar between groups. MuRF1 and MAFbx mRNA exhibited order-dependent responses; MAFbx mRNA decreased during recovery from prior RE, while MuRF1 mRNA increased after HIIE (irrespective of exercise order) and decreased after subsequent RE. Exercise-induced changes in MyoPS and some genes were also dampened from Week 1 to Week 10 (e.g., PGC-1α mRNA, ~6 to 7-fold vs ~2 to 3-fold).

CONCLUSION: Concurrent exercise did not compromise the anabolic response to resistance-only exercise, irrespective of exercise order or training status. Our findings challenge the idea that concurrent aerobic and resistance exercises are incompatible at a molecular level. Our data also suggest that molecular responses are dampened after training when exercise is performed at the same relative intensity. These findings provide unique data that could inform programming of exercise variables for athletes and individuals who engage in concurrent training.

HIGH-VOLUME STRENGTH TRAINING DECREASES MITOCHONDRIAL RESPIRATORY CAPACITY IN SKELETAL MUSCLE OF YOUNG WELL-TRAINED ROWERS

PETERSEN, E., MAZZA, O., ØRTENBLAD, N., NIELSEN, J., LUNDBY, C., GEJL, K., LARSEN, S.

UNIVERSITY OF COPENHAGEN

INTRODUCTION: Strength training of moderate volume has performance-enhancing benefits for elite rowers with effects primarily attributed to an increased muscle mass and maximal- and explosive muscle strength. Mitochondria are organelles within cells and are vital for the energy metabolism. The function of the mitochondria is related to endurance performance and can be improved by aerobic training and moderate volume strength training. In periods, the Danish National Rowing Team practice strength training of a high volume; however, the impact of this type of strength training on the mitochondrial function has yet to be clarified. In this study, we investigated the effects of high-volume strength training on mitochondrial respiratory capacity (MRC) in well-trained rowers.

METHODS: Twenty Danish male (n = 12) and female (n = 8) rowers with a mean (± SEM) age of 22.2 ± 0.76 years and a maximal oxygen consumption (VO_2max) of 54.1 ± 1.7 ml/kg/min were enrolled in the study. Based on body weight, sex, training history, and performance level the participants were matched and randomized to either a group performing high-volume strength training (HV-ST) (n = 10), or a control group assigned to strength training of moderate volume (MV-ST) (n = 10). The intervention period was eight weeks with a recovery week after week three and seven. The strength train-

ing program involved three exercises (leg press, trap-bar deadlift, and bench pull) and was performed three times per week. In HV-ST the volume was gradually increased from three to 10 sets of 10 repetitions during the initial three weeks and maintained at 10 sets in week four to seven. Load adjustments were made throughout the training period to ensure that no repetitions were in reserve during the last three sets of each exercise. MV-ST completed three sets of 10 RM/exercise throughout the training period. Before and after the eight-week intervention period, the participants performed a VO2max test and had a muscle biopsy obtained from m. vastus lateralis. MRC was measured in permeabilized muscle fibers using high resolution respirometry after the addition of substrates, ADP and an uncoupler to stimulate complex I (CIp) and II (CI+IIp) respiration and to test maximum capacity of the electron transfer system (ETS).

RESULTS: The results showed a decrease in MRC (p = 0.002) after HV-ST when assessing CI+IIp linked respiration, whereas a decline was detected in both groups for CIp stimulated respiration and ETS. No changes were observed in body weight or VO2max after the intervention period in neither of the two groups.

CONCLUSION: These findings indicate that HV-ST and, at varying degree, MV-ST cause a decrease in mitochondrial function. It could be speculated whether the observed mitochondrial respiratory impairment is an artefact of overtraining rather than a chronic physiological adaptation to HV-ST, as the measurements were performed five to seven days after the last training session.

THE IMPACT OF MUSCLE MITOCHONDRIAL UNCOUPLING AND CARDIAC OUTPUT ON VO2PEAK IN SINGLE-LEG KNEE EXTENSION EXERCISE

GIURIATO, G.

UNIVERSITY OF VERONA

INTRODUCTION: The dynamic single-leg knee extensor ergometer (SLKE) is a model used to isolate the quadriceps exercising muscle. The O2 peak uptake (VO2peak) during exercise is represented by the Fick principle, which accounts for both the convective and diffusive transport of O2. However, it is widely believed that the muscle mitochondrial oxidative capacity exceeds the delivery of O2 at VO2max (1, 2), resulting in the peripheral oxygen diffusion being ignored. In the SLKE, due to the difficulty in reaching maximum cardiac responses, the peripheral components, specifically muscle mitochondrial oxygen extraction, play a crucial role in determining VO2peak. This study aims to comprehend the relative influence of cardiac output (CO) and muscle mitochondrial respiration on VO2peak during maximal SLKE exercise. It is hypothesized that the peripheral components will have a predominant impact on VO2peak during SLKE exercise.

METHODS: During a maximal incremental test (+10W/min) at a SLKE, VO2peak of 20 young healthy subjects (10 M + 10 F) was assessed using a metabolic cart. Moreover, a muscle biopsy sample from the vastus lateralis was taken from each participant, and mitochondrial respiration was analyzed by high-resolution respirometry. CO, and mitochondrial Electron Transport Coupling Efficiency (ETCE), Net Oxphos Capacity (NOC), Electron Transport Excess Capacity (EC) were calculated.

RESULTS: A multiple linear regression was calculated to predict VO2peak based on CO, ETCE, NOC, and EC. A significant regression equation was found ($F(4,13)=64.26$, $p<0.001$), with an $R2$ of 0.9519. Participants' predicted VO2peak is equal to 3.308 + 0.1034(CO) - 4.02(ETCE) + 0.01226(NOC) - 0.0001476(EC), where CO is expressed in L/min. CO ($p<0.001$), ETCE ($p=0.001$), and NOC ($p=0.027$) were significant predictors of VO2peak.

CONCLUSION: During SLKE, the VO2peak is highly influenced by CO and muscle mitochondria O2 extraction capacity. Indeed, the increase in VO2 is linearly associated with increases in CO and mitochondrial respiration in the OXPHOS/ET state. Most importantly, we assessed that VO2peak is inversely associated with the mitochondrial coupling efficiency, usually influenced by ROS accumulation, protein secretion, leak/slip partial coupling. The last point confirms in vivo studies and suggests that mitochondrial uncoupling, as well as CO, play a key role in VO2 consumption during maximal SLKE exercise.

OP-AP16 Force Velocity Profiling and Training

WEIGHTLIFTING PERFORMANCE IS CORRELATED WITH SQUAT JUMP MAXIMAL POWER, BUT NOT WITH VERTICAL FORCE VELOCITY IMBALANCE

LANTERI, T., MORIN, J.B., YAGODKIN, K., BROUSSAL-DERVAL, A., PIPONNIER, E.

UNIVERSITÉ CÔTE DAZUR

INTRODUCTION: Weightlifting performance is defined by the ability to vertically lift the heaviest load using two movements – the Snatch (Sn) and the Clean & Jerk (C&J). Power output is the one of the key performance factors (1). Previous studies show some kinematic movement similarity, i.e., triple extension, and kinetic variables similarity, i.e., power output or force

production during weightlifting and vertical jump movements (2). In addition, jumping performances are related to vertical force-velocity profile parameters, especially to maximal power output (PMAX) and force-velocity imbalance (F-vIMB) i.e., magnitude of the difference between actual and optimal force-velocity profile. Then, it could be hypothesized that vertical force-velocity profile parameters may also be related to weightlifting performance. The aim of the present study was to test correlations between weightlifting performances in Sn and C&J, and vertical force-velocity profile parameters.

METHODS: Forty-one trained weightlifters (20 males and 21 females; age: 20 ± 5.5 years; height: 1.72 ± 0.35 m; body mass: 68.64 ± 12.72 kg) performed vertical jumps with four different additional loads (0%, 25%, 50% and 75% of their body mass). Parameters of their vertical force-velocity profile were calculated using system mass, push-off distance, and jump height. The analysis of the force-velocity profile was focused on several parameters, including theorical maximal force (F0), velocity (V0), PMAX, slope of force-velocity profile (Sf-v) and F-vIMB. The participants were required to provide their personal record in Sn and C&J, which had to be achieved within two weeks of the test session. All data were analysed with multiple correlations to determine the magnitude of association between weightlifting performance and force-velocity profile parameters.

RESULTS: Subjects' performances were 80.9 ± 27.4 kg (40-163kg) for Sn and 100.8 ± 33.7 kg (50-200kg) for C&J. Very high correlations were observed between weightlifting performances and PMAX (Sn: $r = 0.85$, $p < 0.001$; C&J: $r = 0.86$, $p < 0.001$) as well as F0 (Sn: $r = 0.79$, $p < 0.001$; C&J: $r = 0.76$, $p < 0.001$). In addition, moderate correlations between weightlifting performances and V0 (Sn: $r = 0.40$, $p < 0.001$; C&J: $r = 0.42$, $p < 0.001$) were found. However, no significant correlation was observed between weightlifting performances and SF-v (Sn: $r = -0.09$; C&J: $r = -0.06$) or F-vIMB (Sn: $r = 0.19$; C&J: $r = 0.15$).

CONCLUSION: Participants with higher F0, V0 and PMAX also had better weightlifting performances. Therefore, these parameters of the vertical force-velocity profile can be considered as factors associated with performance in weightlifting. However, unlike jumping performance, the slope and imbalance of the force-velocity profile were not related to weightlifting performance. Thus, it seems that the concept of an optimal vertical force-velocity profile may not be relevant for weightlifting.

CAN SET CONFIGURATION MODULATE FORCE-VELOCITY PROFILES IN UNTRAINED LIMB? THE CROSS EDUCATION PHENOMENON.

FARIÑAS, J.1, RIAL-VÁZQUEZ, J.1,2, RÚA-ALONSO, M.1,3,4, NINE, I.1, IGLESIAS-SOLER, E.1

1-PERFORMANCE AND HEALTH GROUP, UNIVERSITY OF A CORUNA . 2-CENTRE FOR SPORT STUDIES,REY JUAN CARLOS UNIVERSITY . 3-POLYTECHNIC INSTITUTE OF GUARDA, 4- CIDESD

INTRODUCTION: Cross education phenomenon (CE) consists in strength transfer from trained to untrained limb after an unilateral strength training program (1). Neuromuscular strength training adaptations may be evaluated analysing the force-velocity relationship (FV) changes (2). It is known that traditional training programs (TT) close to muscular failure result in CE regarding the one repetition maximum load (1RM), in contrast with Cluster training programs (CT) (3). The objective of this study was to evaluate the FV changes after two strength training protocols for lower limb with different set configuration.

METHODS: After 1RM (pre and post intervention) and 10RM evaluation for knee extension exercise, 35 subjects were randomly assigned to control (CON) TT and CT groups. 10 sessions were performed with dominant limb using the 10RM load. TT performed 4 sets of 8 repetitions with 3min rest between sets. CT performed 32 sets of 1 repetition wit 17.5s rest between each set. Parameters derived from FV linear equation were: force and velocity axis intercept (F0, V0), slope (SFV) and estimated power (Pmax= F0 ·V0 /4). Additionally, we obtained the percentage of F0 and V0 represented by optimal force and velocity respectively r (%Fpower; %Vpower) in both trained and untrained limbs.

RESULTS: For dominant limb, main effect of time was observed regarding F0 and V0 (postest > pretest), and for the SFV (steeper slopes in postest). Time × group interaction was observed only for Pmax ($p=0.002$), showing increments in CT and TT. No main effects or interaction was observed neither for %Fpower nor %Vpower. Regarding nondominant limb, main effect was observed for time with higher F0, and Pmax, and steeper SFV. Time × group interaction ($p=0.048$) was observed in V0, with significant decreases in CON. No main effect nor interaction was observed for %Fpower nor %Vpower.

CONCLUSION: These results suggest changes to strength-oriented force profiles in both segments. Although set configuration can modulate CE regarding 1RM (3,4), it seems that this factor does not influence on non-trained limb changes of FV nor of %Fpower and %Vpower.

EFFECT OF VELOCITY ON POWER-DURATION RELATIONSHIP IN JUMPING: TOWARDS AN INDIVIDUAL FORCE-VELOCITY-ENDURANCE PROFILE

SAMOZINO, P.1, MOREL, B.1, RIVIÈRE, J.R.1,2, PEYROT, N.2, BOWEN, M.1, GRANGE, T.1

<1> UNIVERSITY SAVOIE MONT BLANC, INTER-UNIVERSITY LABORATORY OF HUMAN MOVEMENT BIOLOGY

INTRODUCTION: The ability of lower limbs to produce and maintain high levels of power output depends on both the Power-Velocity (PV) relationship and ii) the power-duration (PD) relationship. While these two relationships have been mostly studied separately [1,2], the interaction between both remains less explored, notably the effect of velocity (independently from the movement frequency) on the PD relationship parameters: the critical power (CP, asymptote of the PD relationship) and the total amount of work that can be performed above CP (W'). Moreover, PD relationship has been widely studied through locomotion movements (e.g. pedalling, 2) but less during movements used in strength training (e.g. jumping). This study aimed at i) testing the feasibility of determination of PD relationship in jumping, ii) testing the effect of velocity on CP and W', and iii) exploring the likely associated interindividual variability.

METHODS: The PD relationship (CP and W') of 14 subjects were determined (via linear work-time model) in two velocity conditions (V1: 0.70±0.02 m/s and V2: 0.95±0.09 m/s) during repeated jump (a jump every 2s) tests to exhaustion performed at four power outputs (set via different loads) for each velocity (set via jump height) [3]. The goodness of fit of the PD relationship, the effect of velocity on CP and W' and the correlation in CP and W' between the two velocities were tested. From CP at the two velocities, the individual velocity maximising CP (critical optimal velocity, CVopt) was estimated.

RESULTS: The median R2 (linear work-time model) was 0.99. CP values (247± 44 W for V1 and 225± 43 W for V2) were moderately (d=0.509, P=0.006) lower at V2 than V1. W' was not different between V1 (1597±1254 J) and V2 (1629±891 J). CP (r=0.830) and W (r=0.532) were correlated between the two velocities. The difference in CP between V1 and V2 was positively correlated with the difference between CVopt and the average of V1 and V2 (r=0.905, p<0.001). The difference in W' between V1 and V2 was negatively correlated with the difference between CVopt and the average of V1 and V2 (r=-0.815, p<0.001).

CONCLUSION: The PD relationships, as well as CP and W', i) can be accurately determined during jumping and ii) are affected by velocity, but with iii) high interindividual variability and iv) moderate to high correlations between velocities. The interindividual variabilities in the differences in CP and W' between the two velocities can be partly explained by the positioning of V1 and V2 with respect to the individual estimated CVopt. This would suggest different individual Force-Velocity-Endurance profiles: some athletes present higher endurance capacities in high force-low velocity conditions than in low force-high velocity conditions, and vice versa for other athletes.

FORCE-VELOCITY-ENDURANCE PROFILING APPLIED TO ROWING PERFORMANCE

DELHAYE, C.1, MOREL, B.1, BLERVAQUE, L.1, BOWEN, M.1, DIRY, A.2, DOREL, S.3, MESSONNIER, L.1, SAMOZINO, P.1

[1] UNIVERSITÉ SAVOIE MONT BLANC. [2] FÉDÉRATION FRANÇAISE D'AVIRON. [3] NANTES UNIVERSITÉ

INTRODUCTION: The power output achieved in rowing, is contingent upon the ability to product and sustain elevated levels of power [1]. The two mains' power capacities determining performance are the maximal (Pmax) and the critical (Pc) power, the latter is defined as the asymptote of the power-duration relationship and represents the intensity threshold above which fatigue develops drastically, i.e. severe domain.

It is widely accepted that Pmax and Pc are both determinants of performance in 2000m rowing [2], although the precise extent of their contributions has yet to be fully established. Force-Velocity-Power (FVP) relationships define Pmax and Pc as the combination of maximal force (F0max and F0c) and velocity (V0max and V0c) qualities. During the 2000m rowing, the same level of power can be achieved with different FV combinations. Although the role of F0max and V0max in explosive performance has been thoroughly studied, their contributions, to performance in power endurance sports as well as the role of F0c and V0c remain unexplored.

The purpose of this study was to establish the interaction between rowing performance and Force-Velocity-Endurance (FVE) profile by determining the contribution of i) initial (Pmax) and critical (Pc) power, and ii) their respective force and velocity components, on rowing 2000-m ergometer performance.

METHODS: 11 high level-to-elite rowers performed a 3min All-out ergometer test, preceded and followed by 6 maximal strokes to establish initial and critical FVP profiles. Pmax and Pc are the apex of the PV relationship. FVE parameters (F0max, V0max, F0c and V0c) are the associated extremum parameters of FVP before and after the all-out exercise. Stepwise regression analyses were performed to quantify the contribution of theses variables on the mean power during the 2000-m ergometer test (P2000). Relative Weight Analyses is performed to gain a better understanding of the respective role played by each predictor in the linear regression [3].

RESULTS: The first model showed that 75% of the P2000 variance was explained by both Pmax and Pc (relative weight respectively 44.2% and 55.8%). The second model including FVE parameters showed that 72% of P2000 variance was explained by F0max and F0c (relative weight respectively 48.3% and 51.7%), without any significant contribution of V0max and V0c.

CONCLUSION: The results of this study showed as expected the important and balance contribution of Pmax and Pc in rowing performance during a 2000m test. Within the power, it appears that force qualities seem more predictive of the variance in P2000 than velocity ones. The best rowers presented here force oriented FVE profiles, meaning that it can be of great of interest to orient training to preferentially improve force and force endurance to maximise power production capacities.

OP-AP38 Fatigue

THE INTERACTIONS OF EXERCISE INTENSITY, MODALITY, AND DURATION ON CONCURRENT EXECUTIVE FUNCTION PERFORMANCE AMONG HIGHLY TRAINED ATHLETES

DONG, L.1,2, ROMEAS, T.2,3, VINCENT, T.4, BHERER, L.4,5,6, BERRYMAN, N.1,2,6

1UQAM, 2INSTITUT NATIONAL DU SPORT DU QUÉBEC, 3UNIVERSITÉ DE MONTRÉAL, 4INSTITUT DE CARDIOLOGIE DE MONTRÉAL, 5UNIVERSITÉ DE MONTRÉAL, 6CRIUGM

INTRODUCTION: High-intensity exercise is often associated with decreases in concurrent executive functioning (EF) performance, but it's less clear if this also applies to athletes whose sport requires EF under intense physical loads. Furthermore, little is known about EF during high-intensity interval exercise or about how exercise duration may interact with intensity. This study aimed to assess the effects of exercise intensity and modality on EF, and to explore temporal patterns of EF during exercise. We predicted that athletes would maintain performance across conditions, and that within conditions, performance would decrease over time.

METHODS: Six female (22.91±4.68 y) and 12 male (20.10±1.55 y) water polo players performed a 4-colour Stroop task during three cycling exercise conditions: constant-load moderate intensity (60% of maximal aerobic power [MAP]; CL60), constant-load high intensity (80% of MAP; CL80), and high-intensity interval (alternating 110% and 50% of MAP; HIIE). Conditions were work-matched, with exercise durations of 8 min 16 s (CL60) or 6 min 12 s (CL80 and HIIE). The Stroop task consisted of colour-naming trials; incongruent trials, which required participants to press the button of the same colour as the font; and switch trials, where participants instead had to identify the colour spelled by the word. Friedman tests for each trial type compared accuracy between conditions, and a linear mixed model was used to compare reaction time (RT) based on Condition and Trial type. To explore the effects of exercise duration on EF, in each condition, Stroop performance was divided into early, middle, and late thirds, and a second linear mixed model including Condition, Trial type, and Thirds as fixed effects was conducted for RT.

RESULTS: While there was no difference in accuracy between the conditions, RT was faster in CL60 compared to HIIE (diff=38.27 ms, $p<0.01$). There was no difference between the CL80 and HIIE conditions. RT for switch trials was slower than for both incongruent (diff=67.7 ms, $p<0.0001$) and naming (diff=249.5 ms, $p<0.0001$) trials, and incongruent trials were slower than naming trials (diff=181.8 ms, $p<0.0001$). The model considering exercise duration revealed interactions of Third with Condition ($p<0.001$) and Trial type ($p=0.02$). Stroop performance decreased in CL80 and HIIE – but not CL60 – after the first third. Consequently, though RT was similar across conditions in the first third, it was worse during CL80 and HIIE compared to CL60 during the middle and/or late thirds. Moreover, in all conditions, switch trial RT was slower during the late compared to the early third (diff=50.23 ms, $p=0.005$).

CONCLUSION: Our study suggests that high-level athletes also experience impairments to EF during high-intensity exercise, be it constant load or in intervals. Critically, it seemed that performance was initially similar across conditions, degrading at high intensity as a function of exercise duration, as well as depending on the complexity of the task.

CHANGES IN ELECTRICAL IMPEDANCE MYOGRAPHY (EIM) INDUCED BY FATIGUING CONTRACTIONS AND THE TIME-COURSE OF RECOVERY

LONGO, S., CÈ, E., RIZZI, D., TONINELLI, N., BORRELLI, M., RAMPICHINI, S., DORIA, C., LIMONTA, E., CORATELLA, G., ESPOSITO, F.

UNIVERSITÀ DEGLI STUDI DI MILANO

INTRODUCTION: Electrical impedance myography (EIM) is a technique deriving from the classical bioelectrical impedance analysis. In EIM, the electrodes are applied locally over a body segment to describe its bioelectrical tissue properties by resistance, reactance, and phase angle analysis. EIM, which is painless and quick to perform, has been demonstrated to change in response to different level of muscle contractions and fatiguing tasks. However, there is still little evidence about

its potential use to assess muscle fatigue and monitor fatigue recovery. Therefore, the aim of this study was to measure changes in EIM components induced by fatiguing contractions and the time-course of recovery.

METHODS: Fifteen healthy men (mean±SD; age=21.6±1.2 years; body mass=73.4±10.3 kg; height=176.0±7.4 cm) were recruited. Participants underwent a fatiguing and a control session (CTRL) in random order, separated by one week. During the fatiguing session, knee extensors maximum voluntary isometric contraction (MVC) and EIM components (i.e., resistance, reactance, and phase angle) over the anterior thigh were assessed PRE, POST, POST 5 min (POST5), POST 10 min (POST10), and every 10 min until the 90th min of recovery after a fatiguing exercise. The latter consisted in cycles of 5-s MVC/5-s rest until MVC reached 50% of PRE-value. The same procedures and time-course of evaluations were performed in CTRL with 10-min rest instead of the fatiguing task. Data were analysed by repeated-measure ANOVA with $p<0.05$.

RESULTS: After fatiguing contractions, MVC recovered within POST40 compared to PRE ($p>0.05$). Resistance decreased peaking at POST20 (-6.5%, $p<0.01$) and recovered within POST50 compared to PRE ($p>0.05$). Reactance decreased peaking at POST20 (-20.6%, $p<0.01$) and recovered within POST50 compared to PRE ($p>0.05$). Phase angle decreased peaking at POST20 (-15.5%, $p<0.01$) and recovered within POST50 compared to PRE ($p>0.05$). Some inter-individual differences in recovery time were present, particularly for MVC. No significant changes occurred during CTRL at any time points in any variable ($p>0.05$).

CONCLUSION: These preliminary results show that fatiguing contractions induced alterations in the EIM components. MVC and EIM alterations returned to PRE-values within 60 min from the cessation of the fatiguing task. These results indicate that EIM may have the potential to monitor recovery after a fatiguing exercise. However, further experiments are needed to confirm these preliminary results and investigate inter-individual variability.

EFFECT OF THE PRE-TAPER LEVEL OF FATIGUE ON THE TAPER-INDUCED CHANGE IN PERFORMANCE IN ELITE SWIMMERS

BRETONNEAU, Q.1, MORALES-ARTACHO, A.2, PLA, R.3, BOSQUET, L.1

UNIVERSITÉ DE POITIERS, FACULTÉ DES SCIENCES DU SPORT

INTRODUCTION: In swimming, a taper period is usually planned before major competitions to reach a peak performance. The pre-taper level of fatigue is a key factor to consider in the individualization of taper strategy. If parameters that condition the pre-taper level of fatigue are little known, sleep appears to play a key role due to the recovery processes activated during this phase. Thus, the aims of this study were 1) to assess the effect of taper on performance according to the pre-taper level of fatigue in elite swimmers and 2) to evaluate the role of sleep on the pre-taper level of fatigue.

METHODS: Physiological, psychological, biomechanical and sleep profiles were evaluated in 26 elite swimmers on 2 occasions: T0 and T1, scheduled respectively 10 and 3 weeks before their major competition. External training load was assessed on a daily basis. Race time was assessed during three official competitions (at T0 and T1 during intermediate competitions, and at the end of the protocol during the major competition).

RESULTS: Considering changes in physiological, psychological and biomechanical profiles between T0 and T1, 14 swimmers (17±2y; 1.8±0.1m; 63±11kg; best performance in % world record: 88±3%) were allocated to acute fatigue group (AF) and 12 swimmers (18±2y; 1.7±0.1m; 67±10kg; best performance: 89.5±2.6%) to functional overreaching group (F-OR). External training load before and during the taper was not different between groups, as well as the change in race time from T0 to T1. In contrast, the race time was lower in competition than at T1 in AF (-1.80±1.36%), while it was higher in F-OR (+0.49±1.58%, $p<0.05$ vs AF). Before taper, total sleep time was lower in F-OR, as compared to AF. Conversely, the fragmentation index was higher in F-OR ($p=.06$). From wakefulness to sleep, the internal temperature decreased in AF but not in F-OR. The minimum temperature during sleep was significantly lower in AF than in F-OR.

CONCLUSION: As compared to swimmers with acute fatigue, pre-taper sleep was poorer in overreached swimmers, which could contribute to their different response to the same training load. This poorer sleep could be linked to a lower regulation of the internal temperature before and during sleep. Moreover, the decrease in training load during the taper was not high enough to observe a gain in performance in overreached swimmers, probably due to excessive cumulated fatigue.

Thus, it could be interesting to evaluate and improve, if necessary, the sleep of swimmers before the overload period, in order to prevent overreaching. In this way, techniques that aim to improve sleep by acting on body temperature, such as cryostimulation, cold water immersion or specific mattresses, could be relevant. Also, it could be interesting for overreached swimmers to extend the use of these techniques during the taper period to further reduce their level of fatigue and, a fortiori, to observe a gain in performance during the competition.

PREDICTION OF SOCCER PLAYERS' FATIGUE: A MACHINE LEARNING APPROACH

SIMONELLI, C., ROSSI, A., MARCORA, S.M.

UNIVERSITÀ DI BOLOGNA

INTRODUCTION: Predicting the state of fatigue in soccer players is useful to design training and optimize performance on match day. Therefore, the aim of this study was to explore, using a framework of big data analytics, the most important predictors of fatigue in a group of sub-elite soccer players using inexpensive and practical data monitoring tools.

METHODS: Four sub-elite professional soccer teams took part in this study. Team 1 and 3 competed in the Italian professional third division (Serie C), while Team 2 and 4 competed in the fourth semi-professional Italian division (Serie D). Within an hour after the end of each training session or match, the players provided their session ratings of perceived exertion (sRPE) to quantify, together with training or match duration, the internal training load of the previous day, week (acute) and month (chronic). Moreover, every morning, the players filled the Wellness Questionnaire which includes subjective measures of fatigue, sleep quality, muscle soreness, stress and mood. Finally, some contextual factors, i.e. next match difficulty, score difference of the previous match, distance to previous match, and distance to next game, were also recorded. Machine learning models were trained and tested in order to assess their ability to predict the players' fatigue status of the next day.

RESULTS: Machine learning models can accurately predict the players' fatigue (accuracy 79-84%) using practical and inexpensive training monitoring tools. Specifically, muscle soreness, sleep quality, mood, and stress predict ~48% of the fatigue state with training load variables accounting for ~10%. Contextual factors related to matches add a further ~15% to the prediction of the fatigue state.

CONCLUSION: Sport scientists and coaches can use this framework of big data analytics to simulate the effects of different training programs in order to maximize players' readiness and reduce the potential drops in performance associated with fatigue.

IS-SH04 Winning at all costs? Current approaches to preventing doping in sport and exercise

KNOWLEDGE IS NOT ENOUGH! WHY VALUES-BASED DOPING PREVENTION COULD COMPLEMENT TRADITIONAL INFORMATION-BASED APPROACHES

ELBE, A.M.

LEIPZIG UNIVERSITY

As doping has tremendous negative consequences for athletes and the integrity of sports, the need for effective prevention programs is obvious. Primary prevention through education at an early age is key; however, educating young athletes about doping-related knowledge is deemed to be not sufficiently effective to minimize doping (Backhouse, 2015). Therefore, a focus on a values-based educational approach is emphasized by WADA (2021) and has become increasingly present in anti-doping efforts. Values-based education means "delivering activities that emphasize the development of an individual's personal values and principles. It builds the learner's capacity to make decisions to behave ethically". (WADA, 2021, p.10). As such, values-based anti-doping education can address emotions, motives, attitudes and values and often incorporates the fostering of moral competencies. This seems plausible since a person's morality, defined as his or her beliefs and practices about what is right or wrong, is presumed to be shapeable/trainable (e.g., Blatt and Kohlberg, 1975; Lind, 2009). Moreover, research indicates that especially moral variables, both personal and environmental, play an essential role in predicting doping proxies (i.e., likelihood, intention, attitudes). For example, variables like anticipated guilt, empathy, moral disengagement, moral identity, self-regulatory efficacy, and collective moral norms/moral atmosphere have been strongly and consistently linked to doping proxies in numerous studies (e.g., Boardley et al., 2018; Kavussanu et al., 2020; Ntoumanis et al., 2014) and, recently, also have been addressed in anti-doping efforts. Bandura's (1991) social cognitive theory of moral thought and action has served as foundation for most of this research. For instance, Kavussanu et al.'s (2021, 2022) research showed that intervening on athletes' moral identity and disengagement, their anticipated guilt and self-regulatory efficacy as well as on the team's moral atmosphere can reduce doping likelihood in athletes. Based on this evidence and on the method of ethical decision making training (Elbe & Brand, 2016) we present the evaluation of a recent values-based doping intervention for young athletes that aimed at affecting their anticipated guilt, empathy, moral disengagement and collective moral norms through six 45-min sessions. Within a cluster randomized controlled trial 30 teams (321 athletes) were assigned to one of the three conditions: values-based (VB), information-based, and no-intervention control and data were collected at pre, post, and follow up. Results showed that, for the VB condition moral disengagement sustainably (i.e., at follow up) decreased, whereas anticipated guilt at posttest and empathy at follow up increased. As a conclusion, specific elements from this intervention could potentially be a useful addition to traditional anti-doping education (i.e., information provision).

ANTI-DOPING EDUCATION: EXISTING EVIDENCE AND FUTURE TRENDS

BARKOUKIS, V.

ARISTOTLE UNIVERSITY OF THESSALONIKI

Doping use constitutes one of the most important threats of sport integrity. Education has been proliferated as the most important prevention approach (Barkoukis, 2015). In this respect, several interventions have been developed (Barkoukis et al, 2016; Codella et al., 2019; Duncan & Hallward, 2019; Kavussanu et al., 2022; Nicholls et al., 2020; Ntoumanis et al., 2021). Still recent evidence suggested that the majority of athletes reported low willingness to receive anti-doping education; especially males and young players (Skoufa et al., 2022). A possible explanation may lie on that anti-doping education is currently at an early stage and traditional learning pedagogies are used, e.g., traditional, lecture-like, one-way

communication approaches, are largely used. To address this issue learning pedagogies, such as problem-based learning (PBL), enable the learners to actively engage with the learning content (e.g., anti-doping education), set their own learning objectives, and accordingly engage in self-directed and independent learning are suggested (Wood, 2003). The use of new technologies, such as serious games and virtual reality, can address shortcomings in existing anti-doping education as evidence suggests that they can produce behavior change (Botella et al., 2017; Maples-Keller et al., 2017). The present study describes the evaluation of the application of a serious game and a virtual reality program against doping. The evaluation of the serious game has been conducted with 36 adolescents (Mage =16.36 years SD = 0.59, 21 males - 15 females). Participants completed a questionnaire based on Lund's (2001) questionnaire to measure the serious game's usability. It measures Usefulness, Ease of use, Ease of Learning, and Satisfaction. In addition, the EGameFlow questionnaire (Fu et al., 2009) was used to measure participants' enjoyment. This questionnaire measures Concentration, Clear Goal, Feedback, Challenge, Autonomy, Immersion, Social Interaction, and Knowledge Improvement. Responses are provided on a 7-point Likert ranging from 1 (strongly disagree), to 7 (strongly agree). The results of the analyses indicated that participants scored high on all dimensions of enjoyment except immersion and social interaction. With respect to usability the analyses indicated that participants found the game simple, easy and useful. Still, these data do not provide evidence on the effectiveness of new technologies on changing doping related mindsets. To address this question, we present an ongoing study on the implementation of a virtual reality game on important risk and protective factors of doping use. Up to fifty exercisers who will view a virtual reality game will respond to measures of doping willingness, attitudes, and anticipated regret prior and after their exposure to the virtual reality game. A sub sample of up to eight participants will participate in semi-structured interviews on the impact of the virtual reality game on their doping mindset.

A POSITIVE APPROACH TO TACKLING DOPING IN RECREATIONAL SPORT: EVIDENCE FROM THE MINDFUL MUSCLES PROJECT

LAZURAS, L.

SHEFFIELD HALLAM UNIVERSITY

Once thought to be an issue confined to elite competitive sport, doping is becoming more prevalent in recreational sport and exercise settings across Europe. According to UK Anti-Doping (2021) there are approximately one million users of anabolic steroids in the UK, and approximately 1 out of 5 exercises across different European countries self-reported the use of steroids and other doping substances, at least once in their lifetime (Lazuras et al., 2017). A growing body of research has shown that doping use in recreational sport is associated by body image concerns, such as drive for muscularity and muscle dysmorphia (Greenway & Price 2018; Goldman et al., 2019). Third-wave psychological interventions focus on positive psychological traits, such as self-compassion, self-acceptance, and mindfulness. Such interventions have been found effective in alleviating body image-related concerns and anxiety, and in the treatment of substance misuse (Linardon et al., 2018; Spijkerman et al., 2016). Project Mindful Muscles utilised principles and constructs of third wave psychological interventions (i.e., self-compassion, self-acceptance, and mindfulness) to address body image concerns and the use of image and performance enhancement drugs (e.g., anabolic steroids) among exercisers in seven European countries. Mindful Muscles developed a series of evidence-informed, self-administered modules targeting exercisers, as well as a guide for practitioners, in order to further promote the integration of self-compassion, self-acceptance, and mindfulness as key components of doping prevention in recreational sport.

The present paper will discuss the key findings of the Mindful Muscles project. This includes a rapid literature review that helped in developing the Mindful Muscles resources for exercisers and practitioners (Study 1); one-to-one interviews with practitioners in anti-doping, sport, and other professions with a doping prevention remit in 7 countries (Study 2); and the findings for a survey-based feasibility study that assessed exercisers' satisfaction and perceptions towards using the Mindful Muscles resources in 7 countries (Study 3). The paper will also discuss the theoretical implications of project Mindful Muscles, as well as the recommendations for policy and practice for doping prevention in recreational sport.

Oral presentations

OP-BM18 Muscle function

CHARACTERIZING THE LIGAND-BINDING BEHAVIOR BEHIND MUSCLE SYNERGISM BY ELASTOGRAPHY

GRINSPAN, G.1, FERNANDES DE OLIVEIRA, L.2, BRANDAO, M.2, BENECH, N.1

1-FACULTAD DE CIENCIAS, UNIVERSIDAD DE LA REPÚBLICA, URUGUAY. 2-PROGRAMA DE ENGENHARIA BIOMEDICA, UNIVERSIDADE FEDERAL DO RIO DE JANEIRO, BRAZIL.

INTRODUCTION: Ultrasound elastography is a widely accepted methodology to assess the mechanical properties of soft tissues. In biomechanics, this methodology allows to measure the shear elastic modulus (C44) of skeletal muscle in vivo and non-invasively. Most of the previous works have studied the relationship between C44 and different muscular variables related to muscle contraction. However, the link between muscle elasticity, force generation, and the binding dynamics among the contractile filaments during load sharing is currently poorly understood. Thus, the present work aims to apply elastography and the ligand-binding framework to explain the possible molecular basis behind muscle synergism.

METHODS: Thirteen healthy volunteers were asked to perform linear torque (T) ramps of isometric elbow flexion from 0-30% of MVC over 15 s (elbow flexed at 90°, wrist supinated) by using a research isokinetic dynamometer. The C44 map of the biceps brachial (BB), brachioradial (BR), and brachial (BB) muscles were measured during tasks through an Aixplorer ultrasonic scanner with a linear transducer array (4-15 MHz) in SSI mode. For each i-muscle, we calculated the Ci coefficient as Ci=1-(C44(0)/C44(T)), and applied conventional methods typically used in molecular receptors to characterize the kinetic behavior of each muscle. Specifically, if the Ci vs. T plot described a rectangular hyperbolic-like behavior, and the fits of 1/Ci vs. 1/T (Lineaweaber-Burk (LB) plot), T/Ci vs. T (Langmuir-Hines (LH) plot), and Ci vs. Ci/T (Scatchard plot) were linear with a determination coefficient (R2) ≥ 0.9, the binding dynamics was hyperbolic (H). On the other hand, if Ci vs. T showed a sigmoid curve and the fit of Ln(Ci/(1-Ci)) vs. Ln(T) (Hill plot) was linear with R2 ≥ 0.9, the binding dynamics was cooperative (positive (C+) if slope >1, negative (C-) if slope <1) or non-cooperative (slope=1).

RESULTS: The Ci coefficients of BB, BR, and BA muscles displayed different dynamics regarding the joint torque level. Beyond some individual variation, a general trend was observed. Thus, on average, the BR and BB muscles showed a C+ dynamic in the range of 4+-2% to 22+-5% MVC and 11+-4% to 30+-0% MVC, respectively. On the other hand, the Ci of the BA behaved differently between subjects, showing either C+, C-, or H dynamics between 1+-1% to 14+-4% MVC.

CONCLUSION: In this work, we studied a synergistic muscle system by applying the molecular ligand-binding framework in a biomechanical study elastography-driven. The Ci coefficients, calculated directly from C44, are suggested to be a good indicator of the amount of the attached actin-myosin cross-bridges. In this way, the results showed that the kinetics of cross-bridge formation could be accelerated (C+), decelerated (C-), or maintained at a constant speed (H), depending on muscle and the level of joint torque. This could be the underlying mechanism (at the molecular level) of the torque-dependent changes in load sharing between the elbow synergist flexors muscles.

CONTROLLING THE STRENGTH OF MAMMALIAN SKELETAL MUSCLE CONTRACTION BY THE THICK AND THIN FILAMENTS

HILL, C.1, KALAKOUTIS, M.1, ARCIDIACONO, A.1, PARADINE CULLUP, F.1, WANG, Y.1, FUKUTANI, A.1, NARAYANAN, T.2, BRUNELLO, E.1, FUSI, L.1, IRVING, M.1

1 KING'S COLLEGE LONDON, LONDON, UNITED KINGDOM; 2 EUROPEAN SYNCHROTRON RADIATION FACILITY, 38043 GRENOBLE, FRANCE

INTRODUCTION: Strategies for improving skeletal muscle contractile function via pharma- and nutraceuticals in athletic populations have been limited by our current understanding of regulatory mechanisms of contraction in mammalian muscle. Recent evidence from frog muscle (1) has shown that the thick filament plays a key regulatory role in contraction, where thick filament stress is a key determinant for the release of myosin motors from the helical folded OFF state to the actin attached ON state by modulating load in accordance with the force-velocity relationship. Here, we test this mechanosensing paradigm in mammalian skeletal muscle by coupling X-ray diffraction with unloaded shortening at maximal force generation.

METHODS: Small-angle X-ray diffraction patterns were collected in 2ms frames on an Eiger 2X-4M detector at the ID02 beamline at the ESRF, Grenoble, France, at a range of camera lengths to view both the low-angle X-ray reflections or the sarcomere reflections. Intact mouse extensor digitorum longus at 27°C were set to a sarcomere length (SL) of 2.85μm in resting muscle and electrically stimulated for 120ms. 60ms after the first stimulus under fixed-end conditions (SL 2.7μm), unloaded shortening was allowed for 15ms (SL 2.3μm), after which force redeveloped at the new fixed muscle length (SL 2.2μm). ~30 sets of 220ms X-ray records were collected per muscle (n=7).

RESULTS: Imposition of rapid shortening at the tetanus plateau caused a rapid abolition of force associated with concomitant changes in actin- and myosin-based X-ray reflections. The spacing of the M3 reflection, associated with the ~14.34nm axial repeat of myosin motors at rest, rapidly decreased to 14.28nm at the end of shortening. The first order myosin layer line reflection, associated with the ~43nm helical repeat of myosin motors, recovered to ~30% of its resting value, indicating partial recovery of the helical order of the myosin motors into the folded OFF state. However, the thick filament backbone, signalled by the M6 reflection with an axial spacing of ~7.17nm at rest, remained partially elongated (~7.20nm) at the end of shortening, indicating that the filament backbone – a key determinant of thick filament regulation – remained extended, despite the abolition of force. The second actin-based layer line, signalling the azimuthal position of tropomyosin, also decreased during unloaded shortening, indicating cooperativity between thin filament activation and myosin motor attachment.

CONCLUSION: These results indicate that activation of both the thick and thin filaments decreases during unloaded shortening at the tetanus plateau, though the thick filament is still strained at zero load. These results are consistent with the mechanosensing paradigm in the thick filaments (2,3), activation of the thin filaments by myosin motors, and positive coupling between the regulatory states of the thick and thin filaments.

DISTINCT MUSCLE FIBER TYPE DISTRIBUTIONS AFFECT WHOLE-BODY ENERGY RATE OF ISOLATED PLANTAR FLEXOR CONTRACTIONS AND THE ENERGY COST OF LOCOMOTION NEAR THE WALK-TO-RUN TRANSITION SPEED

SWINNEN, W., LIEVENS, E., HOOGKAMER, W., DE GROOTE, F., DERAVE, W., VANWANSEELE, B.

KU LEUVEN

INTRODUCTION: Single muscle fiber studies demonstrated that fast twitch fibers consume substantially more energy during isometric contractions than slow fibers, yet, the relative increase in energy rate with faster contractions appears smaller in fast compared to slow fibers [1]. Such observations introduced the idea that inter-individual muscle fiber type distributions may explain observed variability in whole-body (WB) energy rate during exercise. However, existing literature on the relationship between muscle fiber typology and WB energy rate is inconclusive, potentially due to the clear gap between a single muscle fiber and full-body exercise. Here, we first assessed the effect of isolated triceps surae muscle contraction velocities on WB energy rate in subjects with distinct muscle fiber type distributions and then related these results to the WB energy rate of walking and running at 2 m/s, exercises with comparable energy costs but distinct triceps surae muscle contraction velocities [2].

METHODS: We used H-MRS to non-invasively measure the muscle fiber type distributions of 29 subjects from which we selected the subjects exhibiting a rather slow (SLOW, n=10) or fast (FAST, n=8) muscle fiber typology. Next, these subjects performed cyclic plantarflexion contractions at three different ankle angular velocity conditions (isometric, 30°/s and 60°/s) while target torque (25% MVC), cycle frequency (1 Hz) and duty factor (1/3s activation, 2/3s relaxation) were kept constant. All angular velocity conditions as well as the treadmill walking and running trials at 2.0 m/s were sustained for 6 minutes during which we collected WB energy rate and triceps surae muscle activations.

RESULTS: With increasing ankle angular velocity, triceps surae muscle activations and WB energy rate increased in both groups ($p < 0.02$). However, during the isometric condition, net WB energy rate was lower in the SLOW compared to the FAST group ($p = 0.04$) whereas at faster ankle angular velocities, this between-group difference disappeared ($p > 0.39$). When walking at 2 m/s, an exercise associated with higher triceps surae contraction velocities but lower muscle force demands compared to running [2], WB energy rate was similar between groups with a trend towards the FAST group being characterized as more economical walkers than the SLOW group ($p = 0.10$). In contrast, when running at 2 m/s the SLOW group's WB energy rate was significantly lower compared to the FAST group ($p = 0.04$; interaction effect < 0.01).

CONCLUSION: For the first time, we demonstrated that distinct muscle fiber type distributions translate to different WB energy rate responses during isolated muscle contractions at different velocities. Additionally, we showed that muscle fiber type distributions may relate to observed difference in WB energy cost while walking or running near the preferred walk-to-run transition speed.

THREE-DIMENSIONAL SHAPE OF SKELETAL MUSCLE CONTRIBUTES TO MUSCLE STRENGTH EXERTION

UMEHARA, J.1,2, TANIGUCHI, M.2, YAGI, M.2, LI, G.3, SOUFI, M.3, OTAKE, Y.3, SATO, Y.3, FUKUMOTO, Y.1,2, HIRONO, T.2,4,5, YAMAGATA, M.1,2, NAKAI, R.2, ICHIHASHI, N.2

1 KANSAI MEDICAL UNIVERSITY; 2 KYOTO UNIVERSITY; 3 NARA INSTITUTE OF SCIENCE AND TECHNOLOGY; 4 CHUKYO UNIVERSITY; 5 RESEARCH FELLOW OF JSPS

INTRODUCTION: A skeletal muscle presents a variety of sizes and shapes across human individuals. A large body of literature has shown that the muscle size (i.e., volume or cross-sectional areas) determines the capacity of its force exertion. However, whether the variation of muscle shape impacts its function is one of the outstanding questions in the muscle biomechanics area. Herein, to address this issue, we generated the statistical shape model of skeletal muscle to represent the individual variation of three-dimensional shape and analyzed the association of the muscle shape with its strength exertion.

METHODS: The T1-weighted images of the right lower limb were acquired from 33 healthy young adults using a 3.0-T magnetic resonance imaging system. The heads of the quadriceps femoris muscle were labeled based on the automatic segmentation. Their volumes and maximum cross-sectional areas were calculated from the images. After given the shape correspondence among all images using a non-rigid registration, we constructed the statistical shape models of the quadriceps femoris and its heads, which consist of the mean shape and the shape vectors encoding most of the shape variations that was computed by principal component analysis. The muscle shape of each subject was defined as the representation in the shape vector space (i.e., principal component score). For muscle strength, isometric knee extensor torque was measured using a dynamometer. To probe the association of the muscle shape with its strength, stepwise regression was used specifying the muscle strength as a dependent variable and the principal component scores and the muscle volume or the cross-sectional area as independent variables in each muscle.

RESULTS: The shape variation could be represented by a small number of shape vectors in each muscle. Specifically, each of first three shape vectors possessed more than 10% explanation rate of shape variation and those three vectors explained approximately 70% of the total variance for each muscle. The stepwise regression showed that the muscle volume was the independent variable of muscle strength for the quadriceps, the rectus femoris, and the vastus lateralis and intermedius muscles. However, for the vastus medialis, both the principal component score in the second shape vector space and the muscle volume were identified as the independent variables of muscle strength. The second shape vector

explained 23% of shape variation and contributed to the deformation of the distal part of muscle, the so-called vastus medialis oblique. Comparable results were also obtained when the maximum cross-sectional area was used as the independent variable instead of the muscle volume.

CONCLUSION: Our findings demonstrated that the three-dimensional shape of vastus medialis could be one of the determinants of knee extensor strength, as the muscle size of the quadriceps femoris is. In addition, this study provided a new framework for understanding skeletal muscle geometry and its function.

OP-AP14 Coaching: Talent Development

CONTEMPORARY CROSS-CULTURAL VARIATIONS OF TALENT CONSTRUCTIONS IN A WESTERN-EUROPEAN CONTEXT

MONSEES, L.

MALMÖ UNIVERSITET: MALMO UNIVERSITET

Introduction

Talent has extensively been researched throughout a widespread of fields and by various scholars (e.g. Aggerholm, 2015), but especially within football (Christensen, 2011). Despite the abundance of scholarship, critics point to the persisting absence of a common definition for the notion of talent (e.g. Gray & Plucker, 2010). This raises the question of why it is so challenging to grasp the concept of talent, especially since many individuals, including coaches and talent scouts, engage with it regularly on a professional level. However, and although talent being a global and frequently used concept, it struggles to establish meaning. Culture is one of the main influences of human behavior and sensemaking (Sreen et al., 2018). However, and thus far, there is a lack of research investigating how cultural differences may impact sensemaking processes surrounding talent.

Theory/Method

The first part of the analysis been conducted using a discourse-theoretical approach based on Laclau and Mouffe (1985) which can be considered a method and theory at the same time. In the second part, Hofstedes cultural framework has been applied to get a better understanding of cross-cultural differences of the variations of constructions of talent (e.g. Hofstede, 2001)

Results

This research reveals significant disparities regarding how talent in football is constructed within Swedish and German media. The discourse-theoretical analysis reveals that talent is a floating signifier. Additionally, the results show that articulations of 'talent' are more non-linear and heterogenous in German media discourses compared to Swedish media. When articulating 'talent', Swedes and Germans both utilize comparable themes, yet, when contrasting the two countries, we observe a variation in which themes are emphasized. Applying Hofstedes model to these results, the analysis confirms a connection between cultural factors - such as the level of tolerance for uncertainty within a culture or whether a country is more masculine or feminine - and understandings of talent in football.

DETECTING INTERESTS AND THUS TALENTS: ELEMENTARY SCHOOL CHILDREN AND THEIR PROFILES OUT OF SPORTING ABILITIES AND PREFERENCES

SPIES, F., SCHAUER, L., PFEIFFER, M.

JOHANNES GUTENBERG-UNIVERSITY MAINZ

Introduction

Current efforts to design an effective, goal-oriented method of detecting talent are now focused on the differing interests of children (their preferences) and not just their sports-related motor skills (their ability) (e.g., Pion, 2015). When a person-oriented approach is used, it is of central importance to create profiles of different types in order to design movement

offers that effectively target the relevant groups and prevent dropouts. The aim of this study was to investigate in the elementary school context what types it is possible to identify in terms of both interests and ability.

Methods

A total of 159 children (8-11.5 years of age) were assessed to determine their interests and their ability using a sequential design approach. Affective interests were equated with the children's "preferences" for forms of exercise; these were scored on a seven-point Likert scale with smiley symbols during a video-assisted interview. "Ability" was assessed using seven sports-related motor skills tests. The mixed methods approach consisted of a quantitative step 1, a cluster analysis using SPSS27 (Ward's method; squared Euclidean distance). Based on the clusters, in-depth qualitative interviews were conducted in step 2; the results were subsequently evaluated using a content analysis process.

Results

Analysis revealed five clusters of children that exhibited significant differences in terms of ability and interests. In addition to the emotional-affective component (fun), the qualitative interviews also served to classify the interest aspects in terms of their cognitive and value-based components. They are indicative of the personality characteristics of the five types. For example, Cluster 4 showed situational interest in almost all sports on offer (fun score > 4 each). Their interest is associated with positive emotions, although their sport-related motor skills were rather below average.

Discussion

The data indicates that children at the age of 8 to 11.5 years are for the most part not yet committed to one type of sport. Their interests are determined by positive experiences and prior knowledge. Since athletic careers do not follow a straight line, and especially since multidisciplinarity in childhood is considered a favorable foundation for a successful career in sport (DiSanti & Erickson, 2019), schools, sports practice and sports science are faced with the task of responding suitably to children with different combinations of ability and preferences in the early phase of talent detection. The mixed method approach makes it possible to obtain differentiated insights.

TALENT DEVELOPMENT ENVIRONMENTS IN NORWEGIAN AGE-SPECIFIC NATIONAL TEAMS IN HANDBALL AND ICE HOCKEY

MEHUS, I., ASPVIK, N.P., SÆTHER, S.A.

NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY

INTRODUCTION: The Talent Development Environment Questionnaire (TDEQ-5) (1), has been used in the Norwegian context to investigate the TDE of male players in soccer academies (2). However, the Norwegian version of the TDEQ-5 has not been tested for factorial validity. Furthermore, to the best of our knowledge, no previous studies have compared how female and male athletes experience their TDE across national teams in separate team sports. This study aims to test the Norwegian version of the TDEQ-5 through confirmatory factor analysis (CFA) for a five-factor structure, (a) long-term development focus (LTD), (b) communication (COM), (c) alignment of expectations (AOE), (d) holistic quality preparation (HQP), and (e) support network (SN). We also aim to compare how female and male athletes experience the TDE across different team sports.

METHODS: Athletes of age-specific national teams (N=216, 42.59% female), between ages of 15-18 (M=16.28, SD=.88), from handball (44.91%) and ice hockey (55.09%) were included in this study. Questionnaires were administered by hand on location of national team gatherings.

RESULTS: The initial model of the CFA met most of the thresholds of the fit indices; $X2(265)=479.99$ ($p<.001$), $X2/df(1.8)$, RMSEA=.06 .05-.07, SRMR=.06. However, the CFI (.87) and the TLI (.86) were slightly below the acceptable reference value. Checking the modification indices suggested to add two covariate links between SN1 and SN4, and between AOE1 and LTD4. This improved the model fit; $X2(263)=437.38$ ($p<.001$), $X2/df(1.7)$, RMSEA=.06 .05-.07, SRMR=.06, and CFI=.90. Leaving only TLI (.88) slightly off the reference value. Cronbach´s alpha was calculated to test scale reliability; LTD (a=.76), AOE (a=.64), COM (a=.84), HQP (a=.80), SN (a=.66). To test for sport- and gender differences a series of two-way ANOVAs were performed. For LTD handball scored higher ($p<.05$). For AOE there were no significant differences between sports or gender. For COM men scored higher ($p<.01$). For HQP handball scored higher ($p<.01$). For SN there were gender- and sport differences, in addition to an interaction effect. Men scored higher compared to women ($p<.01$), handball scored higher compared to ice hockey ($p<.05$), and the interaction effect implied a larger difference between male and female athletes in ice hockey compared to handball ($p<.05$).

CONCLUSION: The Norwegian version of the TDEQ-5 appears to be an applicable tool for research and can be used to compare the TDE across gender and different team sports on a high level of competition.

IS-MH06 New targets for exercise in cardiac rehabilitation

EXERCISE IN PEOPLE BORN WITH A CONGENITAL HEART CONDITION

MAIORANA, A.
CURTIN UNIVERSITY

Congenital heart disease is one of the most frequently diagnosed congenital disorders, afflicting approximately 1% of live births worldwide. Congenital heart conditions range from minor septal defects to complex cardiac anatomy that requires urgent surgical intervention to sustain life, and many patients live with a cardiac anatomy that compromises cardiorespiratory function for the rest of their lives. Congenital heart disease (CHD) is a unique cardiovascular condition because it impacts people of all ages, from young babies to older adults, highlighting the importance of diverse approaches for prescribing exercise and physical activity across the lifespan.

The population of people living with CHD has grown rapidly in recent decades due to major advances in surgical and medical care. Although the benefits of physical activity and exercise are well recognised in the management of chronic diseases, the therapeutic role of exercise for the CHD population has been under-studied and under-recognised. In fact, people living with complex CHD have traditionally been advised against participation in sport and moderate or vigorous physical activity due to safety concerns. However, a evolving body of literature has demonstrated that physical activity and exercise are safe and beneficial for the vast majority of people with CHD following appropriate screening and that exercise training exercise training is a potent therapy to improve well-being and cardiorespiratory fitness in patients with CHD, which likely has important implications for prognosis. This has led to exercise training becoming an increasingly important adjunct to medical therapy in the management of patients with CHD. This presentation will describe the impact of different forms of congenital heart condition on the exercise response, summarise exercise training studies from the scientific literature and provide evidence-based guidance regarding appropriate exercise prescription in children and adults with diverse CHD.

EXERCISE IN THE PREVENTION AND MANAGEMENT OF ATRIAL FIBRILLATION

THIJSSEN, D.
RADBOUD UNIVERSITY NIJMEGEN MEDICAL CENTRE

Atrial fibrillation (AF) is the most common cardiac arrhythmia, characterized by irregular atrial activity. AF is related to increased risk of thromboembolic events, heart failure, and premature mortality. This highlights the need to treat AF and to prevent its potentially life-threatening complications. Regular physical activity and exercise training are integral for the secondary prevention of cardiovascular disease. Despite recent advances in more holistic care pathways for people with atrial fibrillation (AF), exercise rehabilitation is not provided as part of routine care.

The most recent European Society of Cardiology report for AF management states that patients should be encouraged to undertake moderate-intensity exercise and remain physically active to prevent AF incidence or recurrence. Indeed, emerging research has demonstrated beneficial effects of exercise on AF prevalence and AF-specific outcomes, including AF recurrence post-ablation. For example, meeting the international guidelines for physical activity, corresponding to ~150 min of exercise per week at moderate-to-vigorous intensity, seems an evidence-based recommendation for patients with AF to improve AF-specific outcomes and quality of life. Finally, studies reported a counterintuitively higher prevalence of AF in veteran endurance athletes compared with the general population. During this lecture, a state-of-the-art overview will be provided pertaining to the evidence and underlying mechanisms underpinning the role of exercise as medicine in the development and management of AF, but also the counterintuitive detrimental role of excessive endurance exercise.

EXERCISE IN CARDIO-ONCOLOGY

NAYLOR, L.
UNIVERSITY OF WESTERN AUSTRALIA

Worldwide there are an estimated 400,000 children and adolescents every year that develop cancer. In high income countries, ~85% of children diagnosed with cancer are expected to survive. Unfortunately, survivorship comes at the cost of ongoing health concerns, as a direct result of the initial cancer and/or its treatment. Of particular concern, is the heavy burden of cardiovascular disease; childhood cancer survivors are eight times more likely than the general population to die as a result of cardiovascular disease. Data from the St Judes' study indicates that over 50% of survivors develop injury to the heart. Cardiac abnormalities occurring in survivors of childhood cancer are difficult to detect as there is often an extended latency period where there may not be any apparent symptoms for several years after the completion of therapy. As a result, abnormalities are often not detected until the process is advanced, and aggressive therapy is required. Once cardiac disease and eventual heart failure manifests, the 2-year mortality can be as high as 60%, emphasizing the importance of early recognition of cardiac injury and cardiovascular disease (CVD) in an effort to prevent progression of cardiovascular injury in cancer survivors. This presentation will share data from our lab which shows exercise stress testing can be used to detect early, pre-clinical stages of cardiovascular disease in young adult survivors of childhood cancer.

Efficient intervention is crucial for optimal management of potentially modifiable risk factors to reduce lifelong disease and early mortality. Numerous studies have determined that childhood cancer survivors are not reaching recommended physical activity guidelines and are less likely to be physically active than their healthy peers. Exercise is therefore widely promoted as a cornerstone strategy to maintain health and prevent the development of late effects following childhood cancer, and current guidelines encourage survivors to participate in regular aerobic exercise, while caution that intense isometric or strenuous loads should be avoided. This presentation will explore the latest Cardio-Oncology Rehabilitation (CORE) guidelines and current evidence covering safety, screening and individualised prescription of exercise and the implementation of CORE into clinical practice.

Oral presentations

OP-MH14 Sarcopenia

HOME BASED, APP-MONITORED PHYSICAL EXERCISE INTERVENTION FOR OLDER PEOPLE WITH SARCOPENIA. PRELIMINARY RESULTS OF THE GROW YOUR MUSCLE (GYM) STUDY.

BONATO, M., MARMONDI, F., GALLI, L., INZAGHI, C., PENNACCHI, M., CERIZZA, C., LA TORRE, A., BANFI, G., CINQUE, C.
UNIVERSITÀ DEGLI STUDI DI MILANO

INTRODUCTION: Sarcopenia is a pathophysiological process of aging, caused by reduction of muscle strength, mass and function and it is associated with an increased risk of falls, fractures and physical disability. To date no longitudinal intervention studies have assessed physical activity as a primary outcome for treatment of sarcopenia. The aim of this study was to investigate the effects of a home-based, app-monitored body-weight resistance training program in improving muscle health in elderly and people living with HIV (PLWH) with sarcopenia. We here present measures of muscle mass, strength, and function of enrolled participants at baseline (BL) and after 12 weeks (W12).

METHODS: This is a monocentric, 48-week, randomized, parallel-group, superiority trial. Inclusion criteria are being sedentary; >60-year-old in the elderly or >50-year-old in the PLWH group and sarcopenia, as defined by low appendicular skeletal muscle mass index (ASMMI) by bioimpedentiometry (BIA) and/or low muscle strength by handgrip. Participants are randomized 1:1, separately in each group (elderly and PLWH), to: 1) Exercise group (EG), where participants perform a home-based, app-monitored resistance-training program; 2) Control group (CG), without exercise prescription. At BL, W12 and end of study (W48) participants are tested for muscle strength (handgrip, chair-stand-test, right thigh extensors), balance (Mini-BESTest), physical function (6MWT), and blood lipids. Correlation between variables were assessed by the Spearman correlation test, changes between BL and W12 by Wilcoxon matched pairs signed rank test and percent change differences between groups by Mann-Whitney test.

RESULTS: Fifty-six participants [41 elderly, age: 71 (63-75) and 15 PLWH, age: 59 (57-66), median (IQR)] have been screened so far and 44 (78%) have been enrolled in the study: 22 in EG and 22 in CG. At BL, there was a significant relationship between ASMMI and BMI (P=0.003; R=0.4), right thigh extensors (P<0.0001; R=0.6), handgrip (P<0.0001; R=0.8). The association between ASMMI and BMI was also maintained in men (N=21, P=0.018; R=0.5) and women (N=23, P=0.018; R=0.5). Seventeen participants (7 EG and 10 CG) completed the first 12 weeks of study and 7 dropped-out (5 EG and 2 CG). At W12 we did not observe significant percentage differences between EG and CG. However, a trend difference between EG and CG at W12 were observed in BMI [-0.3% (-2.8-1.7%) vs 1.2% (-0.1-3.1%)], ASMMI [1.8% (-2.7-4.1%) vs -0.8% (-2.2-3.0%)], handgrip [6.3% (-6.7-9.7%) vs -2.7% (-3.7-7.6%)], chair-stand-test [24% (0-40%) vs -6% (-12-8%)], Mini-BESTest [12% (0-16%) vs 9% (-5-24%)] and right leg extension [1.9% (-5.7-32.3%) vs -3.8% (-11.7-3.7%)] were observed.

CONCLUSION: Preliminary data show that BMI can be used as a potential tool for screening of sarcopenic participants. We expect that continuation of the study with enrolment of more participants will show an increase of strength, muscle mass and functional measures.

ASSOCIATIONS BETWEEN PHYSICAL ACTIVITY VOLUME AND INTENSITY AND KEY COMPONENTS OF SARCOPENIA: FINDINGS FROM THE MASS_LIFECOURSE STUDY

HURST, C., HILLMAN, S.J., WITHAM, M.D., GRANIC, A., SUETTERLIN, K., BUNN, J.G., DODDS, R.M., COOPER, R., SAYER, A.A.
NEWCASTLE UNIVERSITY

INTRODUCTION: The Muscle Ageing and Sarcopenia Studies Lifecourse (MASS_Lifecourse) study aims to investigate age-related changes in skeletal muscle across mid-life and old age. The study involves detailed phenotyping of skeletal muscle with a comprehensive assessment of lifestyle factors including physical activity (PA). While PA confers a range of health benefits into old age, the relationship between PA and skeletal muscle structure and function remains unclear. This may be related to the methods used for quantifying PA via accelerometry, which typically reports time spent in specific intensity categories. This approach relies on population specific cut-points and ignores a substantial proportion of the data from the 24-h profile. An alternative approach to describe PA involves two population-independent metrics: the average acceleration (indicative of the volume of activity; ACC) and the intensity gradient (indicative of the intensity distribution of activity; IG). We aimed to examine associations between ACC and IG with key components of sarcopenia in the MASS_Lifecourse study.

METHODS: Participants aged 45-85 years were recruited via primary care in Newcastle, UK. Grip strength, time taken to complete 5 chair stands (converted to speed (stands/sec) so that higher values indicate better performance), and appendicular lean mass index (ALMI; kg/m2) were measured. Participants were asked to wear a wrist-worn triaxial accelerometer (GENEActiv) for 7 days with PA quantified via ACC (volume of activity) and IG (intensity distribution). Data were processed and analysed using the R-package GGIR. We used linear regression to examine sex-specific associations of ACC and IG with grip strength, chair stand speed and ALMI. Data are mean [SD].

RESULTS: A total of 63 men (67 [10] years) and 81 women (63 [10] years) were included in analyses (grip strength: men 41.0 [11.0] kg, women 25.0 [6.1] kg; chair stand speed: men 0.46 [0.15] stands/sec, women 0.48 [0.17] stands/sec; ALMI: men 8.24 [0.91] kg/m2, women 6.35 [0.76] kg/m2). Participants achieved reasonably high volumes of activity (mean ACC: men 28.4 [7.3] mg; women 29.2 [7.9] mg) but were generally accumulating more time in low-to-mid range intensities (IG: men -2.52 [0.19]; women -2.58 [0.19]). There was no evidence of associations between either ACC or IG and grip strength or ALMI in either sex. There was weak evidence of a modest association between IG and chair stand speed in women (difference in mean chair stand speed per 1SD increase in IG = 0.04 stands/s; 95% CI 0.00-0.08, p = 0.04).

CONCLUSION: In MASS_Lifecourse, evidence for associations between PA volume and intensity with key components of sarcopenia was limited. Even though these participants were generally achieving high levels of PA, they may not be engaging in PA behaviours which benefit skeletal muscle structure and function. Further work should explore associations between specific PA behaviours and components of sarcopenia across mid-life and old age.

EFFECT OF RESISTANCE TRAINING AT MODERATE ALTITUDE ON SERUM MUSCLE DAMAGE BIOMARKERS

PEREZ REGALADO, S., LEON, J., BENAVENTE, C., BONITCH-GÓNGORA, J., ALMEIDA, F., PADIAL, P., PETRER, I., DE LA FUENTE, B., FERICHE, B.

UNIVERSITY OF GRANADA

INTRODUCTION: Hypoxia exposure is becoming increasingly useful as a complementary method in recovery processes after exercise-induced muscle damage due to its potential link with protein and satellite cell turnover activity when combined with resistance exercise (1). However, beyond the fact that most research studies have been conducted under simulated hypoxia conditions, the literature is very scarce regarding underlying molecular mechanisms during resistance training (RT) programs performed in terrestrial hypobaric hypoxia (HH). The present study aims to analyze the influence of HH exposure on exercise-induced muscle damage biomarkers after an 8-week RT program.

METHODS: Twenty men (22.75±3.73 years; 176.4±5.93 cm; 73.01±10.97 kg) participated in an 8-week program (3 sessions/week) of a traditional hypertrophy training under intermittent terrestrial HH (2320 m; CAR Sierra Nevada) or normoxia (690 m). Seventy-two hours before and after weeks 6 and 8 of the program, blood samples were taken to analyze inflammatory cytokines, such as tumor necrosis factor-alpha (TNF-α) by immunology multiplex assay (Sigma-Aldrich; Darmstadt, Germany) and creatine kinase (CK) activity by a COBAS kit from Roche (Indianapolis, USA).

RESULTS: Maximal strength increased in both groups after the training period ($p<0.05$), displaying large differences in favor of HH (13.95 % vs 27.49 % in N and HH; p= 0.018 [($\eta 2p= 0.27$]). Compared with PRE values, only the HH group displayed a moderate to large decrease in circulating TNF-α along the period (-5.29% vs -25.08% in N and HH; $p<0.05$ [($\eta 2p= 0.25$]). CK values did not reveal changes of interest between both conditions at any time ($p>0.05$).

CONCLUSION: The results of this research reveal that a RT period conducted under HH conditions improved strength and reduced the inflammatory muscle response concerning the same training in N. This could be attributed to physiological adaptations induced by the stress of the hypoxia exposure towards an M2 macrophage anti-inflammatory profile, partially inhibiting the TNF-α release into the bloodstream (2). Interestingly, CK values were maintained within the accepted range in the HH condition. This circumstance joined to a more decreased inflammatory response than in N, could suggest that the stressors factors linked to RT in HH may play a key role in the muscle adaptation process without compromising performance.

SARCOPENIA EXACERBATES MUSCLE FATIGABILITY DURING KNEE-EXTENSOR DYNAMIC CONTRACTIONS IN OLD ADULTS

GATTI, M.1, COLOSIO, M.1,2, SARTO, F.3, PASTORIO, E.1, ANSALDO, M.1, PELLEGRINO, M.A.1, FRANCHI, M.3, BOTTINELLI, R.1, NARICI, M.3, PORCELLI, S.1

INTRODUCTION: Aging is associated with structural and functional changes at skeletal muscle level (1). Along with alterations of the neuromuscular junction and muscle atrophy, old and very-old adults show lower knee extensors (KE) isometric

torque and greater muscle fatigability, compared to young subjects [2, 3]. Sarcopenia, a condition leading to reduced mobility, increased risk of falls and loss of independence [4], worsens age-related loss of strength and power in non-fatiguing conditions [5]. The aim of this study was to compare the loss of exercise-induced KE isometric torque and power, during KE dynamic contractions in healthy and sarcopenic old adults and investigate the potential mechanisms involved at voluntary activation and muscle level.

METHODS: Old (n=71, 37 women; age=76±5yr) and young adults (Y; n=21, 11 women; age=24±4yr) were recruited. Hand grip strength, chair-to-stand, and appendicular lean mass from DEXA were used to divide old adults into healthy (HO; n=54) or sarcopenic (SO; n=17) [6]. Each participant performed 80 maximal-velocity concentric KE contractions (1 every 3s) with a load equivalent to 20% of the maximal voluntary isometric contraction (MVIC) torque. Mechanical power output (Pw) of each contraction was calculated as the product of the measured torque and angular velocity. Before (PRE) and immediately after (POST) the dynamic fatiguing exercise, voluntary activation (VA) was evaluated by interpolated twitch technique during 5-s MVIC. High-frequency doublets (Db100) and single (St) transcutaneous electrical stimulations were also delivered through the femoral nerve on relaxed muscle.

RESULTS: Baseline MVIC torque showed a main effect of group ($p<.001$), and it was lower in SO (106±41Nm, compared to HO (148±50Nm, $P=.02$), being in both groups lower than Y (196±64Nm, all $p<.003$). At POST, relative MVIC torque reduction was not different among groups (about 20%). Baseline Pw showed a main effect of group ($p<.001$) and it was lower in SO (66±24W) than in both HO (88±31W, $p=.04$) and Y (145±36W, $p<.001$). The Pw reduction during exercise showed a main effect of group ($p<.01$), with a power loss of about 18% in Y, 22% in HO and 31% in SO. VA was not different among groups at any time point. In POST, St decrease was lower in Y (-12±88%) compared to SO (-27±17%; $p<.05$).

CONCLUSION: In old adults, sarcopenia was associated with a reduction in KE isometric torque and power. Exercise-induced loss of isometric torque was not different between healthy and sarcopenic adults whereas reduction in power after dynamic contractions resulted higher in the latter, suggesting that the age-related changes in fatigability are contraction-specific. Since no differences were observed for voluntary activation, the greater power reduction during exercise in sarcopenic adults may be due to intrinsic muscle impairment of contractile and/or metabolic nature.

INTRODUCTION: Chronic kidney disease (CKD) is a pathological condition characterized by several comorbidities, including uremic sarcopenia (US), which affects the quality of life and increases the risk of cardiovascular mortality [1]. Literature data suggest that regular and adapted physical activity (APA), combined with dietetic-nutritional treatments are effective to counteract the CKD progression and its comorbidities [2]. This pilot study evaluates the potential effects of 12-week online APA protocol combined with functional bars on the prevention of US and other related-CKD comorbidities.

METHODS: 21 CKD patients, aged 62.7±5 years, were randomized into 4 groups: A) online APA protocol (3 sessions per week, lasting 1 hour each) combined with a daily intake of 2 antioxidant and anti-inflammatory bars, based on natural bioactive compounds; B) only online APA protocol; C) only consumption of the functional bars; D) usual care. Physical capacity (6-minute walking test), muscle strength (handgrip strength test), body composition (bioelectric impedance analysis - BIA), quadriceps femoris muscle thickness (ultrasonography) and laboratory parameters were evaluated at baseline (T0) and after 12 weeks (T1).

RESULTS: At T1, 6-minute walking test reported an increase of walking distance, in groups A (9.4%) and C (11.5 %), while handgrip strength test decrease in group D for the right (-6.3%) and left limb (-6.0%). After the intervention, BIA showed an improvement in fat free mass and fat mass in groups A (7.2%) and B (-12.5%), where APA was included. The thickness of quadriceps femoris increased in groups A (12.6%), B (13.4%) and C (9.7%). We also observed an improving trend in total cholesterol in groups A (-7.6 %) and B (-15.4 %), however, all study groups showed a reduction of creatinine levels.

CONCLUSION: These preliminary data seem to confirm the effectiveness of APA and the additive role of the natural bioactive compounds in countering the US and other CKD comorbidities. Further studies are needed to confirm these preliminary data.

INTRODUCTION: Aging causes structural and functional changes in skeletal muscle and it is associated with decreased individual quality of life. The aim of this study is to evaluate the effect of a 24-weeks home-based resistance training program and amino acids supplementation on physical performance and muscle health in older subjects.

METHODS: This is a three-arms randomized-controlled study conducted at the IRCCS Ospedale Galeazzi-Sant'Ambrogio (Milan, Italy) enrolling 35 healthy and sedentary older participants (age: between 60 and 80 years) that have been randomly allocated into an experimental group performing a 24-weeks resistance exercise intervention (EXE; n=11), or an experimental group performing a 24-weeks resistance exercise intervention plus an intake of amino acids for the first 12-weeks (SUPPL; n=12), or a control group (CON; n=12). At the beginning (PRE), and after 24-weeks (POST), participants were assessed for muscle strength (Chair Stand Test, Handgrip Test, Maximum Isometric Strength of knee extensors and flexors, and One Repetition Maximum (1RM) by Leg-Press), balance and gait capacity (Mini-BESTest), body composition by Gold Standard assessments (dual energy X-ray absorptiometry: to obtain Appendicular Skeletal Muscle Mass Index (ASMMI); magnetic resonance imaging of thigh: to evaluate Intra Muscular Adipose Tissue (IMAT) and muscle Cross Sectional Area (CSA)).

RESULTS: Two-way ANOVA was used to test the effect of time, the effect of group and the effect of interaction. Intra- and inter-group differences for all variables were tested by Bonferroni post-hoc test. Results showed that EXE and SUPPL significantly improved the Chair Stand Test (EXE: PRE=12.36±3.11; POST=16.00±3.13; p=0.0003. SUPPL: PRE=12.08±2.84; POST=15.25±4.29; p=0.0009. Effect of Time: p<0.0001, Group: n.s., Interaction: n.s.) whereas no significant differences were observed in CON. In addition, SUPPL improved 1RM (PRE=145.46±35.60kg; POST=167.27±52.17kg; p=0.041. Effect of Time: p=0.016, Group: n.s., Interaction: n.s.) and Handgrip Test (PRE=21.73±9.48kg; POST=27.25±9.92kg; p=0.005. Effect of Time: p=0.002, Group: n.s., Interaction: n.s.). No significant differences were found on IMAT and CSA, but a difference was detected in CON group for ASMMI (PRE=7.31±1.61kg/m2; POST=6.91±1.44kg/m2; p=0.037. Effect of Time: n.s., Group: n.s., Interaction: 0.041).

CONCLUSION: It is well known that exercise and amino acids supplementation play a crucial role in maintaining good physical health and muscle mass. Data of this study demonstrated that home-based exercise could be an alternative method from traditional training practices, as it increases the maximal and submaximal strength of the lower and upper limbs. Furthermore, the two intervention groups maintained the baseline muscle mass while the CON group decrease the ASMMI.

LONG-TERM PARTICIPATION AFTER SEVERE BURN INJURY: IS PHYSICAL FITNESS, FATIGUE, AND PHYSICAL ACTIVITY LEVEL ASSOCIATED WITH SOCIAL PARTICIPATION? PRELIMINARY RESULTS OF A CROSS-SECTIONAL STUDY

PRENT, J.M., SPRONK, I., KIEBOOM, E.A.M., NIEMEIJER, A.S., SCHOLTEN-JAEGERS, S., HOUDIJK, H., NIEUWENHUIS, M.K., MOUTON, L.J.

ASSOCIATION OF DUTCH BURN CENTRES; UNIVERSITY MEDICAL CENTRE GRONINGEN, DEPT. OF HUMAN MOVEMENT SCIENCES; HANZE UNIVERSITY OF APPLIED SCIENCES GRONINGEN; UMC ROTTERDAM, DEPT. OF PUBLIC HEALTH

INTRODUCTION: Advances in treatment of acute burn injuries have resulted in improved survival rates, leading to an increased number of burn survivors that have to live with physical and/or psychological sequelae. Returning to daily activities and social participation is an important aspect of burn care rehabilitation. Exercise-based interventions have been shown to be effective in improving the social participation in other patient groups. However, in burn survivors it is unclear whether exercise-based interventions may improve their participation. In this study, we examined whether factors modifiable by exercise, i.e. fatigue, physical activity level, muscle strength, and aerobic capacity are associated with long-term social participation in burn survivors with severe burns. If so, these factors could be target of intervention to enhance social participation in burn survivors.

METHODS: A cross-sectional study was conducted in the three dedicated Dutch burn centers. Eligible were patients 18 years and older with severe burns (total body surface area (TBSA) burned >20% if 50 years or older, or TBSA burned >10% if >50 years, or TBSA full thickness >5% [1]). Five to seven years post burn, their social participation was assessed with the Work Productivity and Activity Impairment General Health questionnaire (question 6). Fatigue was assessed with the Brief Fatigue Inventory, and physical activity levels with the Baecke Physical Activity Questionnaire. Furthermore, grip strength was used as a measure of overall muscle strength and aerobic capacity was assessed with the Steep Ramp Test. Logistic regression was used to examine whether social participation (no limitations (score 0) vs limitations (score 1-10)) was associated with an individual's level of fatigue, physical activity level, muscle strength or aerobic capacity.

RESULTS: Forty-seven burn survivors participated (response rate: 33.6%), of which 68.1% was male. Their mean age was 52.7 years old (SD 15.8) and their median %TBSA burned was 18.0% (IQR: 12.0-34.0). Fifty-one percent reported to be limited in social participation. Their limited social participation was not associated with their level of fatigue (OR: 1.23; 95%CI: 0.92-1.65; p=0.16), physical activity level (OR: 0.66; 95%CI: 0.32-1.37; p=0.26), muscle strength (OR: 0.21; 95%CI: 0.02-2.80; p=0.24), or aerobic capacity (OR: 0.90; 95%CI: 0.57-1.41, p=0.64).

CONCLUSION: Many burn survivors experienced limitations in social participation. Their social participation could, however, not be explained by factors that can be modified by exercise. More research is necessary to identify modifiable factors for long-term social participation after severe burns. Such factors may support the design of tailor-made rehabilitation programs for burn survivors restricted in social participation.

PHYSICAL ACTIVITY BEHAVIOR OF AN IN-PATIENT POPULATION WITH ANOREXIA NERVOSA: A COMPARISON WITH HEALTHY CONTROLS

RAUSCH, L.K., SANDNER, T., HEIMBECK, A., FRÜHAUF, A., BICHLER, C., KOPP, M.

UNIVERSITÄT INNSBRUCK

INTRODUCTION: Physical activity (PA) behavior of patients with anorexia nervosa (AN) is commonly associated with abnormally high PA levels, often caused by a drive for fitness in order to initiate weight loss [1]. In an in-patient rehabilitation setting, the PA behavior of AN patients is usually limited due to PA restrictions within the daily routine. Yet, AN in-patients reported higher frequencies of PA if measured subjectively when compared with healthy controls [2]. The aim of this study was to objectively measure the PA behavior of an in-patient AN population and compare it with healthy controls. We hypothesized that PA characteristics, such as walking time and step count, would be enhanced in AN in-patients, despite PA restrictions.

METHODS: PA behavior of 30 female AN in-patients and 30 sex and age-matched healthy controls (18-39 years) was measured using accelerometers (Move4, MoviSense) on 2 weekdays and 2 days at the weekend. AN in-patients were assessed within the clinical routine of their rehabilitation stay at the Schön Clinic Roseneck, Germany. Compulsive Exercise Test (CET) and Commitment to Exercise Scale (CES) were used in order to determine obsessive-compulsive PA behavior risk in both groups.

RESULTS: Active PA parameters (walking, step count, running, cycling) differed significantly between groups, whereas passive PA parameters (sitting/standing, lying) did not. In average, AN in-patients showed longer daily walking times (185 ±44.6 min, vs. 121 ±43.1 min; p< .001), a higher step count (20498 ±2224 vs. 13106 ±4043; p< .001) and longer running times (22 ±31.2 min vs. 7 ±8.9 min; p= .078), whereas healthy controls spent more time during cycling (15 ±11.8 min vs. 1.8 ±2.3 min, p< .001). Daily time spent during sitting/standing (p= .511) or laying (p=.081) did not differ significantly between groups. High CET and CES scores correlated with low BMI rates (r (59) = .442, p< .001) and high step counts per day (r(59) = .362, p=.013). PA behavior did not differ significantly on weekdays compared with weekends in the two groups (p >.05).

CONCLUSION: Even in a rehabilitation setting when AN in-patients underlie PA restrictions, walking time and step count seem to be enhanced in AN in-patients compared to healthy controls. These results could be used by exercise therapy staff in rehabilitation to further monitor these specific PA parameters and adapt or form specific PA recommendations.

ASSOCIATION OF MUSCULAR ENDURANCE/STRENGTH WITH MOVEMENT-EVOKED PAIN IN PATIENTS WITH NON-SPECIFIC CHRONIC LOW BACK PAIN: THE BACKFIT PROJECT.

SEGURA-JIMÉNEZ, V.1,2, TSIARLESTON, G.3, DONOSO-PÉREZ, B.4, GIL-GUTIÉRREZ, Y.M.2, DELGADO-FERNÁNDEZ, M.3

1.INSTITUTO DE INVESTIGACIÓN BIOSANITARIA IBS.GRANADA, 2.UNIVERSITY OF CÁDIZ, 3.UNIVERSITY OF GRANADA, 4.UNIVERSITY OF CÓRDOBA

INTRODUCTION: Individuals with chronic pain might evade certain movements to prevent their experience of pain(1). A recent call for the transformation from studying pain and movement, to studying pain with movement has raised(2). Knowledge about potential MEP and factors associated with it in patients with non-specific chronic low back pain (NSCLBP) might lead to improve the knowledge on the disease and help in the development of future recommendations for this population. The aims of the current study were: (i) To examine the presence of movement-evoked pain (MEP) after muscular fitness tests completion; (ii) To test the association of muscular endurance/strength with MEP in patients with non-specific chronic low back pain (NSCLBP).

METHODS: A total of 104 (69 women) patients with NSCLBP aged 51.0±10.3 years old participated. To measure back extensor, back flexor, upper-body, and lower-body muscular endurance, the Biering-Sørensen, prone bridging, handgrip and the 30-sec chair stand tests were used, respectively. A visual analogue scale (VAS) was used to measure subjective changes in back pain intensity and unpleasantness. Testing was performed at arrival while participant was at rest sitting (VAS-pain at baseline) and immediately after performing each muscular fitness test during assessment (MEP). Global

muscular endurance was calculated with a weighted average of normalized index (z-score = (value – mean) / standard deviation) of each muscular strength/endurance test. To test the differences between VAS-pain after performing each muscular fitness test and VAS-pain at baseline, a paired t-test was performed. To assess the magnitude of the difference (effect size) Cohen's d coefficient was used. To test the association of muscular fitness with MEP, multivariate linear regression analysis was used controlling for VAS-pain at baseline, age, sex, time since diagnosis, marital status, education, fat percentage using the 'stepwise' method. Since no clear differences between sex were observed, all analyses were performed across the whole sample.

RESULTS: Patients showed greater pain after the Biering-Sørensen (mean difference=0.56; 95% confidence interval (CI)=0.02, 1.11; P=0.044) and the prone bridging tests (0.68; 0.15, 1.21; P=0.013) and lower pain after the handgrip (-0.99; -1.46, -0.52, P<0.001) tests completion. Greater global muscular fitness was associated with lower MEP after the Biering-Sørensen (b=-1.41; -2.29, -0.53, P=0.002), the 30-sec chair stand (-1.32; -2.10, -0.53, P=0.001), and the prone bridging (-0.81; -1.53, -0.09, P=0.028) tests completion.

CONCLUSION: Patients with NSCLPB presented MEP after the completion of back extensors and flexors muscular strength tests, whereas pain diminished after the completion of upper-body muscular strength. Greater muscular strength was overall associated with lower MEP. Motivating patients with NSCLBP to improve their muscular fitness seems advisable but needs confirmation with intervention studies.

NO CONTRIBUTION OF PRESYNAPTIC INHIBITION PATHWAYS TO IA AFFERENT DEPRESSION IN THE SOLEUS MUSCLE DURING DROP LANDINGS

SOTER, K.1, HAHN, D.1, GROSPRÊTRE, S.2

1: RUHR UNIVERSITY BOCHUM, GERMANY; 2: UNIVERSITÉ DE FRANCHE-COMTÉ, FRANCE

INTRODUCTION: Type Ia sensory fibers have been found to be phase dependently modulated during drop landings (DL) [1]. This modulation results in depressed soleus (SOL) H-reflex amplitudes shortly after ground contact (GC) during DL, which is thought to adjust the muscle-tendon stiffness in order to avoid injury [1, 2]. Since descending pathways from supraspinal centers can affect presynaptic inhibition (PSI), this study aimed to examine PSI during the flight and landing phases of DLs.

METHODS: Fifteen participants (3 females; 25.8y ± 7.0) received peripheral nerve stimulations during quiet stance (QS), 40cm DLs pre (PRE) and post (POST) GC. SOL H-reflexes elicited by tibial nerve stimulations were timed to occur 30 to 0ms PRE, 30 to 60ms POST landings and during QS. Ia presynaptic inhibition was assessed by conditioning the SOL H-reflex with femoral nerve stimulations, eliciting H-reflex heteronymous facilitation (HHF) and common fibular nerve stimulations, eliciting H-reflex D1 presynaptic inhibition (HD1) [3]. The conditioned SOL H-reflex amplitudes were then compared to the unconditioned test reflexes (HTEST) during QS, PRE and POST. Furthermore, EMG of SOL, medial gastrocnemius (MG), tibialis anterior (TA) and vastus medialis (VM) as well as hip, knee and ankle joint angles in unstimulated and stimulated trials were measured throughout DL tasks and QS. Two-way repeated measures ANOVAs for the factors time (QS, PRE, POST) and conditioning (HTEST, HHF, HD1) were performed.

RESULTS: HTEST amplitudes POST were significantly lower than PRE (-8.5% of Mmax, 95% CI[-1.9, -15.2], p = .011). Even though facilitation and inhibition could be observed in QS (HHF-HTEST: +6.7% of Mmax, 95% CI[-11.4, -2.0], p < .001 & HD1-HTEST: -6.9% of Mmax, 95% CI[-0.7, -13.1], p = .020), HHF and HD1 amplitudes exhibited no difference to HTEST (p = 1.000) PRE and POST. EMG recordings revealed significant differences in muscle activity just prior to stimulation between DL conditions (p < .045). Additionally, background EMG in unstimulated trials demonstrated increased EMG activity in DL conditions compared to QS and increases in MG activity during PRE and VM activity during POST (p < .007). No statistical differences were found for HTEST/HMAX responses (QS, PRE & POST), ankle angle and dorsiflexion angular velocity at GC (PRE & POST), M-wave amplitudes in TA and VM during HHF and HD1 conditions (QS, PRE & POST) and fatigue prior to post experiment (p > .074).

CONCLUSION: Differences in muscle activity during landing conditions might indicate altered behavior between the conditions. The differences in behavior might originate from the different nerve stimulations and lead to changed H-reflexes. Nevertheless, these results provide first evidence to suggest no influence of presynaptic inhibition on the modulation of H-reflex depression in drop landings.

LANDING FROM A COUNTER-MOVEMENT JUMP IN ALTERED GRAVITY CONDITIONS. CURRENT KNOWLEDGE AND FUTURE DIRECTIONS

GAMBELLI, C.N., PYPAERT, J.M., SCHEPENS, B.

NORTH-WEST UNIVERSITY

INTRODUCTION: Landing from a jump is a complex pre-planned motor action requiring the central nervous system (CNS) to predict the instant of contact with the ground (touchdown, TD). In this study, the human motor control of landing from a counter-movement jump was assessed in different conditions of simulated gravity (i.e., microgravity and hypergravity) and of sensory input environment (i.e., 1g, 0g or hypergravity). The objective is to provide a summary of our findings and shed light into the understanding of the biomechanics and human motor control of landing.

METHODS: Eight participants were asked to perform counter-movement jumps. Microgravity conditions (0.2g0, 0.4g0, 0.6g0 and 1g0) were simulated in a weightlessness environment (0g), during parabolic flight manoeuvres, by means of a Subject Loading System (SLS), providing a pull-down force. Hypergravity conditions (1.2g, 1.4g and 1.6g) were simulated on Earth with the SLS or by turn manoeuvres, generating centrifugal forces. Kinematics, kinetics and lower limb muscle activity (EMG) were recorded. A mixed-model ANOVA, with gravity level (0.2g-1.6g) and sensory input environment (1g, 0g, hypergravity) as fixed factors, and participant as a random factor, was performed.

RESULTS: In every condition, there is a pre-landing EMG of about 100 ms prior to TD. With increased gravity level in both hypergravity sensory input environments, angles at TD of the hip, knee and ankle joints are significantly decreased [1]. In hypergravity conditions simulated by centrifugal forces, angles at TD of the hip, knee and ankle joints are significantly decreased compared to hypergravity simulated by the SLS [1]. With increased gravity level in microgravity conditions, angles at TD of the hip, knee and ankle joints are significantly decreased [2]. In 1g0, angles at TD of the knee and ankle joints are significantly decreased compared to 1g on Earth [2].

CONCLUSION: The presence of pre-landing EMG about 100 ms prior to TD and the adaptation of body configuration at TD according to the gravity level suggest that participants were able to predict TD in altered gravity conditions. The increased "crouched" body configuration at TD with increased gravity levels or in unusual sensory input environments with the same gravity level (i.e., 1g0 and hypergravity simulated by centrifugal forces) may be a natural protective mechanism: increased ankle dorsiflexion at TD may increase stability [3] and increased knee flexion at TD may reduce the risk of anterior cruciate ligament injury [4, 5]. This natural protective mechanism deserves further investigations in injury prevention. Future research aims at assessing the landing coordination using intersegmental covariation of elevation angles [6].

BIOMECHANICAL PARAMETERS OF THE LOWER LIMBS WHEN LANDING FROM A JUMP DURING CHILDHOOD

TOUSSAINT, T., SCHEPENS, B.

UCLOUVAIN

INTRODUCTION: In sports, such as volleyball, basketball, gymnastics, parkour, jumping is a common task, and the control of landing is essential to perform as well as to avoid injury. Although this skill seems simple, it requests the integration of sensory information to predict the instant of touchdown (TD) and the characteristics of the forthcoming impact force, to finely adjust the biomechanical properties of the lower limbs to land softly.

In the present study, we aim to investigate the control of landing from a jump throughout childhood.

METHODS: 59 children from 3 to 12yo performed double-leg landings from a box of 30cm (n=275). No instruction was provided about the manner, speed, or arm movement. The vertical component of the ground reaction force (Fv) was measured using instrumented force plates and then the vertical acceleration (av), velocity (Vv) and displacement (Sv) of the center of mass of the body were calculated. A model was used to characterise the control of landing and was divided into two phases: 1) from TD to the peak of Fv, the lower limb behavior was modeled by a spring whose stiffness–k1 was determined as the slope of the linear relationship of the av-Sv curve; 2) from the peak of Fv to the end of landing, where the behavior was modeled as a spring associated with a damper and a stiffness–k2 and the damping coefficient–c2 were determined by iteration of av-Vv-Sv [1].

Statistics: A Principal Component Analysis (PCA) with Varimax rotation was used to identify the relationship between the age and the biomechanical parameters (k1, k2, c2).

RESULTS: The biomechanical model fits with the experimental data during both phases; R-squared equals 0.91±0.08 during the 1st phase and 0.85±0.09 during the 2nd. The PCA indicates that two components explain 85% of the total variance. The 1st component explains 49% and the loadings for the age, k1, k2 and c2 are respectively 0.92, -0.90, 0.11 and 0.29, while the loadings for the 2nd component are respectively 0.03, 0.10, 0.93 and 0.88. So, the PCA indicates that the stiffness–k1 decreases with the increase of age (from 1135±410 s-2 at 3-4yo to 328±138 s-2 at 11-12yo, mean±S.D.), while k2 and c2 do not change.

CONCLUSION: Our results show a decrease of the stiffness–k1 throughout childhood but no modification of the parameters k2-c2. As the motor development of children follows a cephalo-caudal direction involving an increased number of degrees of freedom [2], one explanation of the stiffer behavior observed in young children compared to older children could be a poor control of the ankle joint. This assumption is consistent with observations on the role of the ankle in the control of landing [3]. In the future, sports instructors should consider the stiff strategy in young children and develop adapted training programs to reduce the risk of injury.

HOW BIOMECHANICAL STABILITY DEFICITS DURING UNPLANNED SINGLE-LEG LANDINGS RELATE TO SELECTED MARKERS OF PURE COGNITIVE AND COGNITIVE-MOTOR FUNCTION?

GIESCHE, F.1, FRIEBE, D.1, BOTH, H.1, HÜLSDÜNKER, T.2, VOGT, L.1, BANZER, W.1

1 GOETHE-UNIVERSITY, 2 LUNEX INTERNATIONAL UNIVERSITY

INTRODUCTION: Cognitive skills such as visuomotor processing speed and executive function (e.g., cognitive flexibility or inhibitory control) are suggested to have an impact on injury risk during time-constrained athletic movements. It can be speculated that cognitive-motor performances are even more strongly related to injury risk than performances in classical pure cognitive assessments due to its higher ecologigal validity. Thus, the aim of this study was to gain further insights into the cognitive-motor processes associated with biomechanical stability during unplanned jump-landings.

METHODS: Twenty healthy amateur football players (27±5years, all males) performed 24 countermovement jumps with single-leg landings on a pressure plate. Equally balanced and randomly ordered, these needed to be performed either preplanned (landing leg indicated before take-off on screen) or unplanned (visual cue automatically shown approx. 400 ms before landing). Both conditions involved a visual distraction component that was briefly shown during the jump (moving players). Participats were asked to recall the movement directions of the players after landig. Biomechanical stability was meassured by means of peak ground reaction force (pGRF; [N]) and center of pressure path length (COP [mm]). In addition, decision-making was assessed as the amount of landing errors (wrong/both feet) in the unplanned condition. Selected cognitive-motor performances (responses to visual stimulus with lower limb) were assessed in standing position using the SKILLCOURT® System. The same cognitive tests (i.e., visuomotor reaction time; RT, cognitive flexibility, inhibitory control) were meassured via conventional computerized testing in sitting position requiring a minimal motor involvement (i.e., pressing button on the keyboard).

RESULTS: According to dependent t-Tests, unplanned landings produced higher COP values upon landing than the preplanned condition (+13%, p=0.034, d=0.6), but not sigificantly higher pGRF (p>.05). The increases of the COP (i.e., unplanned landing costs) were positively related to specific markers of cognitive-motor function (slower simple RT: r=0.55, p=0.015, and choice RT: r=0.47, p=0.04), but not to the pure cognitive test results (p>.05). No significant relationships could be found in terms of cognitive flexibiliy (switching test) and inhibitory control (Go no go test).

CONCLUSION: Cognitive-motor testing may be a promising, but still little researched moderator of unplanned jump-landing safety. Further research should elucidate the potential additional value of such novel test approaches to identify team sport athletes who are at risk of sustaining an injury during challenging athletic movement tasks that involve divided attention and time-constrained decision-making components.

MUSCLE ACTIVITY PRE AND POST DROP JUMP LANDING IN CHRONIC ANKLE INSTABILITY DURING REHABILITATION

FENNEN, L., WAHLBRINK, K., MILSTREY, A., OCHMANN, S., WAGNER, H., DUBBELDAM, R.

WESTFÄLISCHE WILHELMS-UNIVERSITÄT MÜNSTER

INTRODUCTION: In chronic ankle instability (CAI), among others, decreased peroneus longus and increased tibialis anterior muscle activity has been reported 200 ms prior to drop jump landing compared to healthy controls [1,2,3]. This study aims to analyse the recovery of lower extremity muscle activity during drop jump landings of chronic patients during their rehabilitation process and compare them to healthy controls.

METHODS: Eight CAI patients (26 ± 6 years) were evaluated over 3 months. The patients received individual physiotherapy focusing on e.g., muscle strengthening, coordination, and or joint mobility. The patients and 10 age-matched healthy controls performed a 2-limb stance trial and 5 drop jumps, which were recorded using Qualisys 3D motion analysis system. Muscle activity was recorded using surface EMG sensors (Noraxon). The tasks were repeated in weeks 0, 3, 6 and 12. The EMG data of the drop jumps were normalised using the 2-limb stance. The area under the curve was assessed for the phases 200 ms pre and 200 ms post landing. A pre- vs post-landing ratio was calculated. A repeated measures

statistical analysis was performed in SPSS for non-normally distributed data. The FAAM and CAIT were used to monitor daily life performance subjectively.

RESULTS: The CAI group had a significant higher pre-post ratio for all measurement times for the Peroneus longus, the Gastrocnemius medialis and lateralis, and Biceps femoris activity compared to the controls. The post-landing activity of the Abductor hallucis was lower for the CAI (not significantly). The patients reported a significant improvement in daily activities (FAAM-ADL), sports (FAAM-S), and instability score (CAIT) over time.

CONCLUSION: The observed abnormal muscle activity in CAI during drop jump landings did not recover during the rehabilitation process, while the patients reported improved daily and sport functions.

THE EFFECT OF TRUNK INCLINATION ON CENTER OF MASS DYNAMICS AND STEP-TO-STEP TRANSITION

NUNEZ-LISBOA, M.1,2, DEWOLF, A.H.2

1. UNIVERSIDAD FINIS TERRAE, CHILE 2. INSTITUTE OF NEUROSCIENCE, UCLOUVAIN LOUVAIN-LA-NEUVE, BELGIUM

INTRODUCTION: The anterior inclination of the trunk elicits a change in the position and projection of the center of mass (CoM) relative to the ground (1). Alterations in the sagittal alignment of the CoM and ankle joint positions are associated with a modification of the velocity and acceleration of the CoM relative to normal walking (2). In turn, it could result in a delayed timing of CoM redirection from downward to upward, modifying the step-to-step transition (3). In older adults, a delayed redirection of the CoM velocity has been observed and associated with a lack of propulsion at the end of the stance (4). Older adults also display greater trunk flexion (3), but its effect on step-to-step transition is unknown. To investigate the modification induced by trunk inclination, we compared the step-to-step transition in healthy young adults walking normally and walking with 4 different imposed trunk inclinations.

METHODS: Ten healthy young men walked at 1.1 m s-1 on an instrumental treadmill. They walked with a natural trunk position and with an imposed 10°, 20°, 30° and 40° of trunk flexion. The angles were controlled on the sagittal plane by OnForm app. For each condition, participants walked 3 minutes and the last 10 seconds of each session were recorded. The vertical ground reaction force (Fv) under each foot was recorded. The ratio between the maximal force of the front and the back leg (Ff/Fb) during the step-to-step transition was measured. From Fv, we computed the vertical velocity of the CoM, to determine the beginning (Vv,min) of the transition. A one-way ANOVA and Bonferroni post hoc were used to compare our variables.

RESULTS: No differences in step length were observed between conditions (ANOVA, $p=0.532$). The timing of Vv,min relative to the foot contact and Ff/Fb were different between conditions (ANOVA, $p<0.001$): the greater the increase in trunk flexion, the later Vv,min occurred relative to FC ($p<0.05$). Also, as compared to natural walking, Ff/Fb was higher in the 20°, 30°, and 40° trunk flexion conditions ($p<0.05$). No differences were founded in Ff/Fb between 10° and normal ($p = 1.00$).

CONCLUSION: Our results suggest that the trunk inclination modifies the transfer from one leg to the other. Therefore, the gait modification in older adults may partly be due to trunk flexion. Indeed, older adults have been reported with 9° of trunk inclination. However, in older adults, this inclination has been related to a significant change in Ff/Fb and a much greater modification of Vv,min than what we observed with a similar trunk angle (4). This suggests that trunk inclination alone cannot explain the alterations observed with age, but should be considered as a confounding factor since the step-to-step transition is a major determinant of the overall cost of walking (5).

DIFFERENCES IN EEG DELTA FREQUENCY BAND BETWEEN TREADMILL AND OVERGROUND WALKING

THARAWADEEPIMUK, K.

MAHIDOL UNIVERSITY

INTRODUCTION: For several decades, low-frequency cortical activity and electroencephalogram (EEG) delta bands (0.5-4 Hz) have been associated with sleep (1). Recently, various studies have suggested the use of low-frequency cortical activity in analyzing sensorimotor-related information. Human EEG delta activities were decoded to investigate kinematic parameters (2-4) and muscle activities (5) among different tasks and experimental. In treadmill and overground walking, the similarity of gait parameters and kinematic patterns were exhibited, while the disparity muscle activation patterns, joint moments and joint powers were frequently observed (6). We hypothesized that a significant difference in EEG delta frequency band would be presented between treadmill and overground walking during walking gait cycle. Therefore, the goal of this study was to compare EEG delta activities between gait cycles of human passive treadmill and overground walking.

METHODS: The electroencephalogram (32-channel EEG: eegoTMmylab ANT Neuro) and inertial measurement unit data (IMU: NORAXON Ultium Motion) were recorded from 10 healthy (5 men and 5 women) participants. The participants performed 3 minutes of passive treadmill and overground walking. Raw EEG and IMU data were analyzed using MATLAB software. The stride cycle of human walking was identified based on thigh angle (Noraxon MyoMotion-Segments Thigh RT-orientation-y), in which the maximum angle was demonstrated at initial contact. Then, the EEG delta frequency band was selected from peak locations (location vector at the peak indices) of thigh angle. The processed EEG data yielded a matrix of 30 rows (regarding 30 observing EEG active electrode placements) and 100 columns (regarding 100 time points/percentage of gait cycle). Statistical parametric mapping (SPM) analyses were performed to investigate the difference in continuous EEG delta frequency band of human walking gait cycle between passive treadmill and overground walking.

RESULTS: The average participant's stride cycle was 98. EEG delta frequency band of the walking gait cycle demonstrated a significant difference at Cz position within the 16.8% to 18.1% ($p=0.031$), and within the 65.8% to 66.3% of gait cycle ($p=0.031$). The duration of sub-phase of human gait cycle at Cz revealed mid-stance and initial swing phases respectively. At 17.5% to 19.8% of gait cycle, P3 position was significantly different ($p=0.002$). The duration of sub-phase of human gait cycle at P3 exhibited the mid-stance phase.

CONCLUSION: The results demonstrated brain activities responded at the Cz and P3 positions across the mid-stance and initial swing sub-phases of gait cycle supporting the role of sensorimotor integration (lower extremity) and sensations. Brain activities at Cz position relevant with motor task, and P3 associate with sensory input. Thus, this neural activation pattern observed during walking gait cycle potentially light up the knowledge for developing effective neuroprostheses for walking rehabilitation.

DIFFERENCES IN SQUAT AND STAIR DESCENT LOWER LIMB KINEMATICS BETWEEN HEALTHY CONTROLS AND PATIENTS WITH PATELLOFEMORAL PAIN

PAPADOPOULOS, K., BAMPOURAS, T.M.

*^UNIVERSITY OF WORCESTER, *LIVERPOOL JOHN MOORES UNIVERSITY*

INTRODUCTION: Patellofemoral pain (PFP) is one of the most common knee conditions that physiotherapists and physicians have to confront and has various aetiologies. To assess PFP, functional tests such as the squat and stair decent are routinely performed by clinicians (3). Little information exists, however, on the quantitative differences between healthy and PFP patients' movement patterns when executing these tasks, especially as neuromuscular activation may differ due to PFP (4).

METHODS: Ten healthy controls (age: 29.0 ± 6.6 years, height: 1.71 ± 0.11 m, body mass: 78.7 ± 16.32 kg, females: n = 5) and 10 PFP patients (age: 34.0 ± 9.1 years, height: 1.72 ± 0.09 m, body mass: 77.4 ± 18.9 kg, females: n= 5, referred by a consultant or general practitioner to NWW NHS physiotherapy department were recruited in this study. They performed a one leg hopping-landing-self-selected squatting task and a three-step descent task starting with the unaffected leg. 3D motion analysis was used to examine quadriceps angle (QAngle), knee flexion (KF), foot supination (FS), anterior and posterior pelvic rotation (PR_ASIS and PR_PSIS, respectively), and forward and backward pelvic tilt (PT_FWD and PT_XY, respectively) during execution of the squat or stair decent. Statistical Parametric Mapping (SPM) was used to compare the normalised kinematics time-series between controls and ACL patients for all the above variables and both tasks. Additionally, a 2 (group) x 2 (task) compared the maximum angle for QAngle KF and FS, followed with Bonferroni-corrected pairwise comparisons, where differences were revealed.

RESULTS: SPM revealed no changes in squat normalised kinematics time-series for QAngle, FS, and PT_FWD. KF differed significantly ($p < 0.05$) between 18-20% of the movement range, PR_ASIS between 0-32% and 35-100%, PR_PSIS between 0-20% and 78-100% and PT_XY between 4-12%. For stair decent, no significant differences were revealed for any variables. Finally, no differences were revealed for maximum angle for QAngle and FS. KF revealed a significant difference for task only, with a 48.2° higher knee flexion for squat ($p = 0.001$).

CONCLUSION: Our results suggest that discrete values from the functional tests used to assess PFP are unlikely to show differences between healthy and PFP patients. Similarly, the movement pattern of the stair decent is not affected by PFP, with only the squat showing such differences between groups. These findings contribute to understanding of PFP assess-

ment, while support calls for identification of more robust tests (1, 2) as well as for examinations of the full movement range rather than discrete values from it (5).

REDUCED SHOE DROP IN CHILDREN INDUCES A MORE MID-FOREFOOT FOOTSTRIKE WHILE SPRINTING BUT NOT WHILE WALKING

MARCHIS, A.1, LETENEUR, S.1, GILLET, C.1, GRIMPAMPI, E.2, SIMONEAU-BUESSINGER, E.1

UNIVERSITÉ POLYTECHNIQUE HAUTS-DE-FRANCE

INTRODUCTION: Physical activity and sport bring many health benefits for children. However, it can also cause musculoskeletal injuries. The immaturity of the musculoskeletal system of children, when subjected to repeated microtraumas, favors the appearance of growth pathologies, such as the Sever's disease. Among the factors predisposing to the risk of injury at the lower limbs, one of the most important is the use of unsuitable footwear. Although research on adult footwear is extensive, the impact of the footwear on children's locomotion remains largely unknown. In adults, the reduction of the heel-to-toe drop seems to induce a footstrike pattern modification more on the forefoot1,2,4,5. It would thus make it possible to reduce the constraints applied under the calcaneus, which is closely related with the Sever's disease1,5. This reduction would also lower the maximal knee flexion and therefore limit the elongation of the patellar tendon3,4, which is a key factor in Osgood's disease. Thus, the main objective of this study was to analyze the acute effects of drop reduction on the kinematics and dynamics of child's locomotion during walking and sprinting.

METHODS: Eleven children (8 boys and 3 girls, age 7.8 ± 1.6 yrs, height 1.29 ± 0.11 m, body mass 26.3 ± 6.3 kg), who regularly practiced physical activities in addition to physical education, tested 3 sport shoes, only differing by their heel-to-toe drop: 0 mm, 4 mm and 8 mm. The experimental walking and sprinting conditions were carried out across a motion capture system (Vicon MX, Oxford, UK) with 4 forceplates (Kistler 9286BA, Switzerland). Repeated measures ANOVA's were performed on spatiotemporal, kinematic and dynamic parameters. When a significant effect was detected ($p<0.05$), Bonferroni's post-hoc test was applied.

RESULTS: For the sprinting condition, the drop reduction induced a modification of the footstrike pattern, transitioning from a rearfoot strike to a mid-forefoot strike. There was indeed a significant difference ($p=0.004$) between a 0 mm drop and a 8 mm drop (1.6 ± 6.4° and 5.9 ± 8.4°, respectively). A significant reduction ($p=0.04$) was also observed in the occurrence rate of the vertical ground reaction force impact peak in the 0 mm drop (62 ± 25%) compared to the 8 mm drop (76 ± 19%) . For the walking condition, the drop reduction did not significantly impact the investigated parameters.

CONCLUSION: The main finding of this study was that sprinting gait in children was influenced by wearing reduced heel-to-toe drop shoes. Such drop reduction, by implying a more mid-forefoot footstrike, would induce a forward shift of the plantar constraints distribution. These biomechanical adaptations would reduce the compression forces under the calcaneus and could contribute to reduce the risk of Severs disease.

OP-SH08 Cognition I

COGNITIVE FUNCTION IN RESPONSE TO AN ACUTE, HIGH INTENSITY EXERCISE – DOES GENDER PLAYS A ROLE?

PILZ-BURSTEIN, R., KLEIN-GRUFI, H., YAKOBIAN, D., ARNON, M.

GIVAT- WASHINGTON ACADEMIC COLLEGE OF EDUCATION; WINGATE CAMPUS IN THE ACADEMIC COLLEGE LEVINSKY-WINGATE

Introduction: The growing evidence favoring the positive effect of exercise on cognition is mostly based on men participants (75 %). We therefore exposed females and males to acute intensive exercise session and evaluated gender cognitive response to this intervention.

Method: Thirty- two adults (M=17; F=15) ages 18-34 participated in the study. Exercise consisted of ten repetitions: 10 seconds sprints at maximal speed, following by 50 seconds active recovery. Stroop test (ST) 1-3; Trail-making test (TMT) 1-2; Word fluency were evaluated at three time points: prior to, immediately post exercise, and at 45 recovery. Two-way ANOVA with repeated measures (three test points X 2 gender groups) was used to test the effect of exercise on cognitive performance.

Results: Both males and females reached close to maximal heat rates at the end of the 10th running round. This finding and the Rate of Perceived Exertion- RPE at the end of the effort (range 16-20 males, 13-20 females) indicates that the exercise stimulation was at a high level of effort for both sexes. Stroop 1- 2 results improved for both males and females from pre to post exercise ($p<0.01$). After 45 males returned to pre-exercise while females still retained high values. For Stroop 3 both genders improved from pre to post ($p<0.01$), and retained high values after 45. For TMT-1 males showed no response while females results improved immediately and at 45 post intervention ($p<0.01$). For TMT-2 both genders improved immediately after exercise ($p<0.01$); however, only females continued improving at 45 recovery. Word fluency was positively affected by exercise in males only.

Conclusions: Acute intensive bout of exercise has a positive immediate effect on cognitive performance both in males and females; however only females retained the positive effect of exercise for longer time periods, at least 45 minutes after intervention and possibly longer.

Since our data point to gender variability in cognitive response to the exercise stimulation, thus future research should include female participants to broaden database on both genders.

A PROSPECTIVE STUDY OF CARDIORESPIRATORY FITNESS AND NEUROCOGNITION IN MIDDLE-OLD ADULTS WITH AND WITHOUT APOLIPOPROTEIN E4 ALLELE

KAO, S.C., CHU, C.H., CHANG, Y.K.

PURDUE UNIVERSITY

Introduction

Although cardiorespiratory fitness has been identified as a potential protective factor for age-related decline in prefrontal-dependent inhibitory control, it remains unknown whether longitudinal changes in cardiorespiratory fitness have effects on inhibitory control and whether such effects are affected by the apolipoprotein E4 allele (ApoE4) carriage during aging. Accordingly, the purpose of this study was to determine the effects of longitudinal changes in cardiorespiratory fitness on behavioral and neuroelectric measures of inhibitory control performance in ApoE4 carrier versus non-carrier older adults.

Methods

A prospective study including a baseline assessment and a 18-month follow-up assessment was conducted from 7/1/2018 to 5/1/2021. One hundred and fifty-nine 50–70 years old adults without psychiatric, neurological, and cardiovascular conditions were initially recruited to participate in the study. Due to the COVID-19 pandemic and lockdown, 76 participants withdrew after completed the baseline stage, resulting in a final sample of 83 participants who completed the follow-up assessment for the registered (NCT05652140 at ClinicalTrials.gov) longitudinal analysis. Inhibitory control outcomes included the 18-month changes of response time, accuracy, and N1 and P3 amplitudes of event-related potential during a computerized Stroop test. Change score of the estimated maximum oxygen consumption (VO2max) from the baseline to 18-month follow-up assessments was quantified to form the four groups based on the directionality of fitness change (Gaining-Fit vs. Losing-Fit) and carriage of ApoE4 (carrier vs. non-carrier).

Results

The final sample of 83 participants included in the analysis had a mean age at 62.6±4.5 years, 65 females (78.3%), 33 in the Gaining-Fit group (39.8%), and 20 ApoE4 carriers (24.1%). Compared to the Losing-Fit Group, the Gaining-Fit group showed more positive changes over the 18-month period in behavioral (e.g., increased incongruent accuracy [6.4±2.3%, 95% CI: 1.9% to 10.9%, $p < .01$], decreased overall response time [-38.18±12.87ms, 95% CI: -63.79ms to -12.56ms, $p < .01$]) and neuroelectric outcomes (e.g., increased overall P3 amplitude [3.06±1.15uV, 95% CI: 0.77uV to 5.35uV, $p < .01$]) of inhibitory control. ApoE4 carriage did not influence these effects.

Discussion

In this study, older adults with and without carrying ApoE4 who gained cardiorespiratory fitness showed positive changes in inhibitory control performance and neuroelectric marker of attention allocation processes. These findings suggest that increasing cardiorespiratory fitness may have beneficial effects on inhibitory control and associated brain functioning during aging regardless of the presence of the genetic risk factor for cognitive impairment.

THE FIT BRAIN: UNDERSTANDING THE RELATIONSHIPS BETWEEN CHILDREN'S AEROBIC FITNESS AND COGNITIVE FUNCTION THROUGH NEURAL EFFECTIVE CONNECTIVITY

LIGEZA, T.S.1, RAINE, L.B.2, PONTIFEX, M.B.3, WYCZESANY, M.1, HILLMAN, C.H.2

<1> JAGIELLONIAN UNIVERSITY, KRAKOW, POLAND; <2> NORTHEASTERN UNIVERSITY, MA, USA; <3> MICHIGAN STATE UNIVERSITY, MI, USA

INTRODUCTION: The growing trend of sedentary behavior among children has sparked interest in the relationship between cardiorespiratory fitness and cognitive function. Studies have shown an association between lower fitness and decreased cognitive performance, but the neural mechanisms underlying this relationship are unclear. To gain a deeper

understanding of the relationship between fitness and cognition in children, we employed effective connectivity (EC) measures, which examine the dynamic interactions between brain regions. We hypothesized that lower fitness would be correlated with decreased EC within the cinguloopercular network, a crucial brain network involved in domain-independent task performance that includes anterior regions of the cingulate cortex, insula, and prefrontal cortex.

METHODS: Preadolescent children (M age=10years) were bifurcated into two groups based on their aerobic fitness. Children with VO2max above 70th percentile (n=24) formed the higher-fit group (HFG), while those below the 30th percentile (n=24) formed the lower-fit group (LFG). Participants completed a modified flanker task while EEG and task performance were recorded. The EEG signal was filtered from 1-48Hz, segmented into 1 second epochs, and processed through independent component analysis to classify brain and artifactual components, which were then localized using the minimum norm solution (estimation of neuroelectric activity based on scalp potentials) and reconstructed into regions of interest: dorsal anterior cingulate (dACC); bilateral anterior insula (rAI/lAI); and bilateral anterior prefrontal cortex (raPFC/laPFC). The EC for correct trials was only estimated in the theta band using the Directed Transfer Function (a Granger causality and multivariate autoregressive modeling method).

RESULTS: LFG showed decreased overall response accuracy compared to HFG (M=78.2% vs. M=84.7 %, p = 0.02). LFG also showed decreased EC compared to HFG in the following five directions: dACC to lAI; rAI to lAI; rAI to raPFC; raPFC to dACC, and raPFC to lAI (p's<0.05). The first four of these connections were positively related to overall task accuracy (r=0.32 to 0.38; p's<0.05).

CONCLUSION: Our study confirms the link between lower cardiorespiratory fitness and poorer cognitive performance in children. This investigation extends prior studies by revealing that children with lower fitness levels exhibited weaker connectivity within the cinguloopercular network, which underlies task performance and was related to cognitive function in this study. Our study demonstrates the value of using EC measures to understand the relationship between cardiovascular fitness and brain function in children. These findings provide evidence for promoting physical activity and reducing sedentary behavior to improve children's brain health and cognition.

OP-MH12 Physiotherapy/Ankle-Foot

DEFICITS IN NEUROCOGNITIVE PERFORMANCE IN PATIENTS WITH CAI PERFORMING A DYNAMIC BALANCE TASK.

MARICOT, A., VERSCHUEREN, J., ROELANDS, B., MEEUSEN, R., TASSIGNON, B.

VUB

INTRODUCTION: Chronic ankle instability (CAI) is a common chronic condition characterised by a feeling of giving way, pain and persisting dysfunctions. While many patients recover from an initial ankle sprain and become copers, up to 40% of patients develop CAI, which implies an elevated ankle injury risk which impacts their daily lives. Recent literature shows that patients with CAI develop neural adaptations, which could contribute to the aetiology and chronic nature of CAI. Studies have suggested that deficiencies in neurocognitive performance may influence the incidence rates of musculoskeletal injuries, including LAS and CAI. However, we must be aware of performance differences between patients with CAI and healthy controls on neurocognitive balance tests commonly used in clinical practice as they have only recently been developed. These allow clinicians and researchers to evaluate the accuracy and VMRT, integrate these outcomes in injury prevention, and return to sport decision-making to gauge injury risk. Hence, why we used the reactive balance test (RBT) to evaluate the neurocognitive balance performance of patients with CAI compared to healthy controls.

METHODS: In this case-control study, we enrolled 27 patients with CAI and 21 recreationally active athletes based on the International Ankle Consortium Guidelines for inclusion and exclusion criteria. Each participant completed the reactive balance test (RBT) once on each leg, and we measured their accuracy based on previous research1. Additionally, we calculated the visuomotor response time (VMRT) corrected for the accuracy measure.

RESULTS: Patients with CAI had significantly lower RBT accuracy scores, 83.12% (± 8.04%), compared to healthy controls (CON), 91.80% (± 5.16%). There were no significant differences in accuracy or VMRT between the left and right sides in either group (regardless of the self-reported affected side), indicating consistency in performance. Notably, VMRT alone did not differ significantly between the CAI and CON groups, with reaction times of 776.03ms ± 107.77ms and 739.47ms ± 98.43ms, respectively (p = 0.584).

CONCLUSION: Compared to healthy controls, neurocognitive functional performance is impaired in patients with CAI, as evidenced by decreased accuracy scores in the RBT. Visuomotor response time did not differ between CAI and control. Therefore, it may be beneficial to incorporate neurocognitive stimuli into rehabilitation programs for patients with CAI, especially since previous research has demonstrated the value of visuomotor training in preventing injuries in football players. Furthermore, future research should explore whether neurocognitive training may avert ankle injuries in other sports, such as table tennis, basketball, or rugby, where neurocognitive performance is essential.

THE EFFECTS OF AN ANKLE INJURY RISK REDUCTION PROGRAM IN ELITE JUNIOR AUSTRALIAN FOOTBALL PLAYERS

MCDONALD, J.

UNIVERISTY OF SOUTH AUSTRALIA

INTRODUCTION: Published research indicates ankle injuries are consistently one of the most common injuries in junior Australian Football (AF) (1). Injury prevention programs have proven successful in reducing ankle injuries in similar sporting codes; however, there are time burden and associated compliance issues with more generalised programs (2). Therefore, the primary aim of this study was to evaluate the implementation of an ankle injury risk reduction program (AIRRP) in junior AF athletes. Secondly, the effectiveness of the AIRRP on ankle injuries and changes in ankle function and stability were explored.

METHODS: 214 healthy elite junior male (15-18 years) athletes from four clubs competing in the state level under-18 competition participated. The study was a non-randomised control trial using historical club control data for comparison (2015-21). Club medical staff reported injuries that resulted in a missed regular season game. Injury burden was the product of injury incidence (number of ankle injuries) and severity (missed games per ankle injury). Players at participating clubs undertook a multiple hop test (MHT) at the start of preseason to determine baseline ankle function and stability. The clubs implemented the program consisting of balance and sport specific exercises, increasing in intensity and difficulty over the course of the season. The players completed follow-up MHT at the start and conclusion of the regular season. Implementation evaluation was determined by conducting exit interviews with club strength and conditioning coaches and exit surveys with players.

RESULTS: Exit interviews with club strength and conditioning coaches concluded that the program was beneficial and served as an important addition to attempt to reduce the risk of ankle injuries, however, player adherence and engagement were common reported issues. 89% of players agreed that the AIRRP was a valuable use of training time. There were 12 new ankle injuries in the 2022 season compared to 12.5 in the control years across the four clubs. The burden in the 2022 season was 56 missed games compared to 40.5 missed games in the control years. There was no significant difference in ankle burden (IRR=1.6; 95% CI=0.8-3; P=0.159). There was a significant positive effect on ankle function and stability across the season as measured by the MHT (all $p<0.05$). Player exit surveys concluded that 91% of players perceived their ankle stability was better at the final MHT compared to the baseline MHT.

CONCLUSION: Coaches and players perceived the program to be beneficial. Although the AIRRP did not significantly reduce ankle injuries, the MHT analysis did note improvements in ankle function and stability.

BRAIN PLASTICITY RELATED TO LIGAMENTEOUS ANKLE INJURIES: A SYSTEMATIC REVIEW

TASSIGNON, B., DICK, E., WALRAVENS, A., PLUYM, B., LATHOUWERS, E., DE PAUW, K., VERSCHUEREN, J., ROELANDS, B., MEEUSEN, R., MARICOT, A.

VRIJE UNIVERSITEIT BRUSSEL

INTRODUCTION: Lateral ankle sprains (LAS) are one of the most prevalent injuries in sports. Hitherto, it is still regarded as an innocuous sports injury despite an increased re-injury risk and almost half of LAS patients developing chronic ankle instability (CAI) with persistent dysfunctions and potential long-term sequelae. In addition, researchers found preliminary evidence of neuroplasticity at the spinal and supraspinal levels after (repeated) LAS. These alterations might explain persisting dysfunctions, an increased injury risk, and the likelihood of developing CAI. Nevertheless, an overview of possible brain adaptations after LAS and CAI is currently lacking. Therefore, this systematic review aims to synthesize scientific literature on brain plasticity related to ligamentous ankle injuries (and CAI).

METHODS: The PRISMA 2020 guidelines were followed to perform the systematic review. The Pubmed, Web of Science, Embase, Scopus, PEDro, The Cochrane Central Registry for Controlled Trials (CENTRAL) and SPORTDiscus databases were searched from conception to 14/12/2022. Studies eligible for inclusion researched brain outcome measures in patients with LAS or CAI. Studies investigating other injuries (e.g., ankle fractures, syndesmosis injuries or post-operative), animals or cadavers, effects of treatment interventions, or not investigating the brain's function or structure were excluded.

RESULTS: Two authors independently screened 1375 unique articles from seven databases using a two-stage process. In total, the systematic review included 20 studies. Patients with LAS showed lower white matter microstructure superior cerebellar peduncles than healthy controls. CAI populations displayed an increased sensitivity of intermediate inhibitory neurons and a decreased sensitivity of excitatory neurons in the corticospinal pathway. They also found more variability in cortical activation in the superior parietal lobe, pre-and postcentral gyrus and the supplementary motor area with lower corticomotor excitability in several lower limb muscles in patients with CAI.

CONCLUSION: Brain plasticity was found in patients experiencing a LAS and with CAI compared to healthy individuals and copers. Both functional and structural brain adaptations were observed in the motor cortex, supplementary motor area, somatosensory cortex, middle frontal gyrus and dorsal anterior cingulate cortex. These supraspinal adaptations might play a role in the persisting dysfunctions found in these patients. Some of these alterations correlate with worse patient-reported outcomes after ligamentous ankle injuries. Whilst these findings may support the hypothesis of brain plasticity in patients with ligamentous ankle injuries, all studies were either of a retrospective or cross-sectional nature. Most studies

used different measurement methods, making direct comparisons difficult and limiting the strength of this reviews evidence. Future research should focus on understanding the underlying neurophysiological mechanisms.

A RELIABLE FIELD METHOD TO QUANTIFY ANKLE EVERTORS, INVERTORS AND DORSIFLEXORS STRENGTH DEFICITS IN A POPULATION WITH CHRONIC ANKLE INSTABILITY

AGUILANIU, A., SCHWARTZ, C., ABRAN, G., BAUDOUX, L., CROISIER, J.L.

UNIVERSITÉ DE LIÈGE

INTRODUCTION: Ankle muscle strength is crucial for rehabilitation after a lateral ankle sprain (LAS) because a strength deficit could lead to chronic ankle instability (CAI). No field method is available to obtain quantitative ankle isotonic strength values. The purpose of this study was to validate a one-repetition maximale (1-RM) method to assess ankle muscle strength.

METHODS: We recruited 31 healthy adults (18 women, 13 men, 23 ± 2.2 years old) and 32 adults with CAI (18 women, 14 men, 24 ± 2.2 years old). The dorsiflexors, evertors and invertors 1-RM was performed twice by healthy and CAI volunteers at one-week intervals. The intraclass correlation coefficient (ICC) and minimal detectable change (MDC) were calculated. Then, strength values were compared between healthy and CAI population. Finally, we suggested normative strength values based on the healthy group using the 20th percentile as a limit.

RESULTS: The ICC ranged from 0.76 to 0.88 and the MDC range from 19% to 31%. CAI volunteers obtained evertors (3.0 vs 3.5 N/kg) and invertors (2.9 vs 3.7 N/kg) strength values lower than healthy volunteers ($p<0.03$). CAI volunteers also obtained weaker dorsiflexors strength ($p<0.05$), but the proportion of CAI volunteers with important dorsiflexors deficit (16%) is lower than the proportion of CAI volunteers with important evertors and invertors deficit (53% and 50%). The CAI volunteers have an evertors/invertors strength ratio similar to the healthy volunteers ($p > 0.05$).

CONCLUSION: The 1-RM method is a reliable field method to assess isotonic evertors, invertors and dorsiflexors strength in young and active patients. Although no evertors/invertors strength ratio imbalance was detected, the 1-RM method is able to detect an isotonic ankle strength deficit in CAI population. Thus, 1-RM method will help clinicians to obtain isotonic ankle strength values on the field. Then, quantitative strength field values will also help clinicians to decide whether a patient required to normalized strength or not, and finally to individualize a strengthening planning if necessary.

OP-SH28 Technology and psychology

ACCEPTANCE BY ATHLETES OF A VIRTUAL REALITY HEAD-MOUNTED DISPLAY INTENDED TO ENHANCE SPORT PERFORMANCE

MASCRET, N., MONTAGNE, G., DEVRIÈSE-SENCE, A., KULPA, R.

AIX-MARSEILLE UNIVERSITY / RENNES UNIVERSITY

Many technological devices are being used effectively to improve sports performance (e.g., sensors, heart rate monitors, cell phone applications). However, it is not because a technology is objectively efficient that it is automatically accepted by its potential users who may refuse to use these devices even before trying them or gradually stop using them in their training. This may also be the case for immersive virtual reality (VR) devices such as head-mounted displays (VR-HMD). However, in the literature on VR in sport, this acceptance is almost taken for granted ("Since VR-HMD is used to improve sports performance, it is bound to be accepted by athletes"). It is therefore necessary to question acceptance from a scientific point of view. The purpose of this communication is to identify the self-reported variables that influence the approval and use of VR-HMD in athletes, based on the most widely used theoretical model, the Technology Acceptance Model. This model identifies the variables that influence the intention to use a technology (perceived usefulness, perceived ease of use, perceived enjoyment, but also subjective norms, i.e., the social influence of the environment). It was recently applied to the study of acceptance by athletes of a VR-HMD intended to enhance sport performance.

A total of 1162 athletes usually involved in competitive sport (from recreational to international level) participated in this cross-sectional study. After reading a short text introducing the VR-HMD and its benefits for improving sport performance, the athletes completed a questionnaire assessing their acceptance of the VR-HMD prior to initial use. The results of the structural equation modeling analysis revealed that perceived usefulness, perceived ease of use, perceived enjoyment, and subjective norms were positive predictors of intention to use the VR-HMD. Overall, the VR-HMD is fairly well accepted by athletes to improve their sport performance, regardless of their level of competition, although recreational athletes had a mitigated opinion on its actual usefulness for them. On the other hand, athletes at all other levels felt that their environment (e.g., teammates, coaches) would not encourage them to use VR-HMD, unlike elite athletes. Finally, the results also revealed differences in acceptance between sports. Participants in some sports (e.g., swimming, gymnastics, athletics, cycling) did not find VR-HMD useful for improving their sport performance, while participants in other sports (e.g., soccer, tennis, badminton, fencing, basketball) did. Understanding the acceptance of a VR-HMD before it is first used seems crucial to identifying possible initial barriers to using this technology to improve sports performance.

This work is part of the REVEA project supported by a government grant managed by the French National Research Agency (ANR) as part of the "France 2030" program (20-STHP-0004).

DOES INTENSITY MODERATE THE ACUTE EFFECTS OF IMMERSIVE VIRTUAL REALITY EXERGAMING ON EXECUTIVE FUNCTION AMONG YOUNG ADULTS?

GU, Q.
SHANDONG UNIVERSITY

INTRODUCTION: Virtual reality (VR) exergaming has emerged as a new physical activity intervention strategy designed to help people increase their exercise participation. VR exergaming may enhance the potential benefits by acting on the prefrontal cortex to improve emotional and executive function. However, the effects of immersive VR exergaming intensities on executive function have not been thoroughly investigated, nor have corresponding intervention strategies have not been established. The aim of this study was to investigate the effects of 15-min of immersive VR exergaming at different intensities on executive function and emotional response.

METHODS: In a cross-over study design, 33 sedentary young adults (mean age = 22.2 ± 2.5 years, 51.4% female) participated in three experimental conditions in the random order: active control (AC) VR exergaming, moderate-intensity (MI) VR exergaming, and high-intensity (HI) VR exergaming, each for 15 min. Executive function was assessed using the Eriksen flanker task and the task-switching paradigm programmed in E-Prime 3 professional (Psychology Software Tools, Inc., Sharpsburg, PA, USA), respectively. The Feeling Scale and the Felt Arousal Scale were used to measure participants' emotional valence and emotional arousal of participants during exercise. Repeated measures ANOVAs were used to assess the differences between the different interventions in terms of condition (AC/MI/HI VR exergaming) and task duration (pre/post).

RESULTS: A main effect of VR exergaming condition on reaction time for the flanker task was also observed, $F(2, 62) = 4.45$, $p = 0.02$, $\eta 2 = 0.13$. The results showed that the performance on the flanker task was improved after MI (332.96 ± 28.17ms) and HI (333.65 ± 38.31ms) immersive VR exergaming compared to AC (348.88 ± 29.41ms) VR exergaming (all $p < 0.05$). No such difference was observed between the MI and HI conditions. Conversely, the accuracy and reaction time in the task-switching paradigm were not affected by the VR exergaming ($p > 0.05$). Meanwhile, VR exergaming increased the level of emotional valence with increasing intensity $F(2, 64) = 4.41$, $P=0.02$ $\eta 2 = 0.12$. HI (3.76±1.12) VR exergaming increased emotional valence was significantly higher than AC(2.79±1.22) VR exergaming, and MI (3.39±1.25) VR exergaming increased emotional valence was significantly higher than AC VR exergaming (all $p< 0.001$).

CONCLUSION: The intensity of movement in a single VR exergaming plays a significant role. Our results suggest that immersive VR exergaming could increase the arousal levels, and acute moderate or high intensity could improve specific cognitive performance in young people.

SELF-CONTROLLED VIDEO FEEDBACK FACILITATES LEARNING TACTICAL SKILLS IN TENNIS

VAN DER MEER, B.
VRIJE UNIVERSITEIT AMSTERDAM

Self-controlled video feedback facilitates learning tactical skills in tennis

Bart R. van der Meer

Department of Human Movement Sciences, Vrije Universiteit Amsterdam

ClOS Haarlem Hoofddorp, ROC Nova College

INTRODUCTION: Providing feedback effectively is highly relevant for supporting the acquisition of sport skills. One crucial aspect to enhance motor learning is to manipulate the feedback schedule, that it is the timing (i.e., after which trials do learners get feedback) and frequency (i.e., how often do learners get feedback) of feedback provision [1]. In recent years, researchers have demonstrated that giving learners control over the feedback schedule enhances motor learning compared to conditions in which a coach (or experimenter) decides upon the provision of feedback. Despite an increasing amount of evidence showing benefits of self-controlled feedback when learning technical motor skills, it is still unclear what the effect of self-controlled feedback is on learning tactical skills. Therefore, the main aim of this study was to investigate whether self-controlled video feedback enhanced learning of tactical skills in tennis.

METHODS: Twenty-three intermediately skilled tennis players were quasi-randomly assigned to a self-controlled video feedback group (SC) and a yoked video feedback group (YK). In three training sessions, once per week, participants practiced serve and volley play. A licensed tennis coach provided video feedback with attentional cueing and transitional statements that focused solely on individual tactical gameplay. Tactical performance was measured with a custom designed Tactical Tennis Tool (TTT) in a pretest, posttest (i.e., after the final practice session) and in a retention test one week after practice.

RESULTS: ANCOVA with pretest TTT score as covariate revealed that the self-controlled group showed significantly larger improvements from pre- to post and retention tests in tactical performance compared to the yoked group.

CONCLUSION: This study is the first to demonstrate that the advantage of self-controlled video feedback extends to the learning of tactical motor skills.

MOBILE-COMPUTER-SUPPORTED COLLABORATIVE LEARNING IN DANCING

SCHRÖDER, B., JAITNER, T.

TU DORTMUND UNIVERSITY

Mobile-computer-supported collaborative learning (mCSCL) enables high learning effects and deeper collaboration among learners through the digital medium (Sung et al., 2017). In dancing, a digital learning environment can support dance students in describing and evaluating their practical experiences during a composition process, but the method used – teacher guided video observation – might not be sufficient to enable reflection on a more general level of practical experience (Leijen et al., 2009). In order to link the practical experiences of composition processes with theoretical content, we designed and implemented a learning environment in higher education in which we combined the digital and collaborative learning approach. Our aim is to explore the development process of a dance choreography in an mCSCL environment.

Method

Following the design research approach (Prediger et al., 2015), a teacher-researcher used a video analysis-app on tablet computers within the collaborative learning model to support student learning. During three intervention cycles (2021 – 2023) video recordings of group working processes of 15 groups with N = 61 physical education students were taken. In addition, 22 interviews were conducted. Data analysis includes qualitative content analysis as well as qualitative video analysis.

Results and Conclusion

The learners considered mutual video feedback within their groups and especially in exchange with other groups as useful. First results of the video analysis indicate that students work collaboratively with videos during the composition process. This collaborative engagement leads to profound analyses of the dance compositions. In addition to the reflection of their own video performances, design aspects are discussed due to the camera perspective. Besides these benefits, technological challenges by the use of digital media must also be considered. Further analyses will reveal more detailed insights into the developmental processes.

DESIGNING COOLTACO: A DIGITAL HEALTH INTERVENTION WITH SMARTWATCHES TO PROMOTE SELF-REGULATION AND PHYSICAL ACTIVITY IN CHILDREN WITH ADHD

TUOHY, L.1, KAY, E.2, CIBRIAN, F.3, SILVA, L.2, BELTRAN, A.2, SCHUCK, S.E.B.2, HAYES, G.R.2, LAKES, K.D.1

1 DEPARTMENT OF PSYCHIATRY, UNIVERSITY OF CALIFORNIA RIVERSIDE, 2 UNIVERSITY OF CALIFORNIA IRVINE, 3 FOWLER SCHOOL OF ENGINEERING, CHAPMAN UNIVERSITY

Background. Attention Deficit Hyperactivity Disorder (ADHD) is the most prevalent childhood psychiatric condition, with an estimated worldwide pooled prevalence of 7.2%. ADHD is characterized by deficits in self-regulation, which can be improved through psychological interventions and physical activity (PA).

Methods. Using participatory design sessions with 40 participants (children, parents, teachers), we developed and piloted CoolTaco (Cool Technology Assisting Co-regulation), a smartwatch and mobile phone app that promotes self-regulation and daily PA in children with ADHD by augmenting the capabilities of the smartwatch of tracking PA (e.g., steps, calories, exercise) with an application that allows children and parents to set-up PA and other behavioral goals for children for which they earn tokens that can be exchanged for rewards. We studied children's and parents' perspectives of CoolTaco's potential to promote PA. We evaluated the feasibility and acceptability of this digital health intervention with two cohorts, each consisting of 10 children (ages 8 – 15 years) and their parent(s). Parents and children were individually interviewed after two and six weeks. We analyzed transcripts of semi-structured interviews.

Results. Qualitative analysis identified themes related to the use of CoolTaco to promote PA. 1) Children used their smartwatches to track a variety of PAs based on individual preferences, access to equipment, and opportunity; PAs tracked included riding a bicycle, jumping on a trampoline, walking, running, playing basketball, hiking, and riding a scooter. 2) They reported feeling motivated by prompts and visualized activity data (e.g., duration, speed, distance), which led to their perceptions of having promoted their health or fitness level. 3) Parents reported that the creation of goals directly related to the visualizations provided by the watch (e.g., circles to show the PA) and exercises (e.g., riding a bicycle) helped them obtain accurate and measurable information about their child's PA as well as measure their progress over time.

Conclusion. Children's and parents' use of smartwatch exercise tracking features to satisfy goals provided by CoolTaco (via the paired parent application) allows in-the-moment self- and parent-tracking for evaluation of progress increasing PA, which is an essential contributor to self-regulation. As computational systems grow smaller and more powerful and

promoting PA among children continues to be a high priority, it will become increasingly important and relevant for mobile tools to be integrated into health promotion. Our results illustrate the potential for wearable and mobile systems to promote health behaviors among children.

OP-SH18 Mental health and disabilities

EFFECTS OF RECREATIONAL DIVING COMPANION SYSTEM ON EARLY ONSET DEPRESSION IN ADOLESCENTS

WEN, H.

CHINA UNIVERSITY OF GEOSCIENCES,WUHAN

INTRODUCTION: Depression is a significant concern among Chinese adolescents, with a detection rate of 24.6% and severe depression at 7.4%, reported by the Institute of Psychology of Chinese Academy of Sciences. Domestic and foreign research generally believe that exercise has a positive impact on improving early-onset depression in adolescents. The shadowing system refers to the need for a shadowing partner during the diving process. The main responsibilities of a diving partner during the diving process include equipment inspection before diving, assisting with dressing and undressing of equipment, identifying underwater hazards, etc. This article is based on research on recreational diving and recreational diving teaching activities, exploring effective influencing factors for early-onset depression in young divers and promoting educational innovation in water sports.

METHODS: Using the controlled variable method and data analysis, after obtaining the consent of the participants and their guardians, 12 adolescents aged 12-18 who were not taking medication, had obtained the Open Water Diver (OW) certification, and had scored 8-35 points on the Hamilton Depression Scale (indicating possible or definite depression but not severe depression) were randomly divided into a group with diving partners and a group without diving partners for a 12-session intervention training, with each session lasting approximately 50 minutes.

RESULTS: The results showed that both groups had a decrease in HAMD-17 score after the diving training process, with the experimental group showing a greater decrease than the control group. Before training, there was no significant difference in HAMD-17 scores between the two groups ($P>0.05$). After training, the HAMD-17 score of the experimental group was lower than that of the control group, and the difference was statistically significant ($p<0.05$). This indicates that leisure diving has an improving effect on adolescent depression. Diving with a partner has a better effect on improving adolescent depression than diving alone.

CONCLUSION: The companion system adds more emotional communication and tacit cooperation in the exercise process, cultivates the participants ability of empathy and communication, enhances the patients life hope and confidence, and enhances their sense of identity and belonging, which plays a positive role in the intervention of adolescent early-onset depression. Compared with traditional sports, the unique diving environment and the special companion system have a positive significance in improving early-onset depression in adolescents. It is suggested that more cooperation activities can be included in physical education.

ENHANCING MENTAL HEALTH AND LEARNING EXPERIENCES OF FIRST-YEAR SPORT, EXERCISE AND HEALTH SCIENCE AND PHYSIOTHERAPY STUDENTS THROUGH A FIELD-BASED, RESIDENTIAL OUTDOOR EDUCATION PRACTICUM

LUCAS, R.A.I., VELDHUIJZEN VAN ZANTEN, J.J.C.S., COOK, D., REED, W., NIGHTINGALE, T.E., WILLIAMS, S.E., QUINTON, M., LUCAS, S.L.E.

UNIVERSITY OF BIRMINGHAM

Introduction

For incoming undergraduate students, the transition to Higher Education is a high-risk period where maladaptive coping strategies and poor mental health can emerge. Student's mental health can be improved through outdoor education experiences, which promote a range of holistic benefits. The present study aimed to evaluate the efficacy of integrating a 4-day residential outdoor education practicum into year 1 of a Sport, Exercise and Health Science BSc (SEHS) and Physiotherapy MSci (Physio) undergraduate course at the University of Birmingham (UoB). The long-term goal is to examine if a practicum outdoor experience in first year improves programme-related theoretical understanding, as well as mental health outcomes in SEHS & Physio students.

Methods

298 first-year SEHS and Physio students were invited to attend a 4-day, 3-night outdoor practicum at the UoB's Raymond Priestley Outdoor Education Centre (RPC) in Coniston, Lake District. Students were able to select their preferred practicum dates (8 practica offered, each accommodating a maximum of 38 students). Upon arrival at the RPC centre, students were divided into smaller group (6-8 people) and performed a range of outdoor and team building activities with a RPC instructor (e.g., canoeing, abseiling, hill walking etc.). Students recorded their heart rate continuously and rated their perceived exertion periodically (modified Borg) during each activity. Each morning and evening students were asked to record their mood using a modified 8-item ecological momentary assessment questionnaire (Daily) to assess affect and physical feeling states (e.g., sad, happy, energetic) and questions on their perceptions of the day. Before (Pre) and after (Post) at-

tending their practicum, students were asked to complete questionnaire packs to assess their mental well-being, their sense of belonging, and their study/learning intentions.

Results

Six practica have been completed with 149 first-year undergraduate students attending (65% attendance rate). Practica run during the semester were the most popular (76% attendance rate). All students attempted to collected heart rate data, achieving successful data collection for at least one activity. There was high engagement in completing Daily, Pre- and Post- questionnaire packs. Qualitative data indicated that students felt outdoor activities improve their overall wellbeing, that they enjoyed the personal challenge, and that the practicum improved their sense of community/belonging.

Discussion

This practicum offers students an opportunity to engage in experiential learning and reflect on behavioural, physiological, and psychological factors that promote good mental health. Attending student's feedback has been very positive, with this practicum improving their sense of connectedness. There is a need to identify potential barriers for students choosing to not attend. Long-term, this practicum may improve help-seeking behaviour and mental health.

EMOTIONAL INTELLIGENCE AND MENTAL HEALTH IN JUDO

ACEBES-SÁNCHEZ, J., GARCÍA-MERINO, S., GARRIDO-MUÑOZ, M., BLANCO-GARCÍA, C., RODRÍGUEZ-ROMO, G.

UNIVERSIDAD FRANCISCO DE VITORIA; UNIVERSIDAD POLITÉCNICA DE MADRID

Introduction

Different research has evaluated the importance of sport in the development of psychological skills. Likewise, it has also been studied the other way around, how the role of psychological factors is related to better sports performance. Combat sports, such as judo, seem to have internal characteristics that develop the emotional intelligence of judokas. On the other hand, the practice of sports has also been linked to better mental health. However, the relationships of both variables within a group of judokas have not been investigated in a general way and by gender.

Method

The sample consisted of 703 judokas. 469 were male (40.32 ± 14.09 years) and 234 were female (31.42 ± 10.97 years). For the assessment of emotional intelligence, the Trait Meta Mood Scale (TMMS-24) was used, which reports information on three dimensions (attention, clarity, and emotional intelligence). For the assessment of mental health, the GHQ-12 was used. The higher the score on the GHQ-12.

Results

The results show that there is a significant correlation between the three dimensions of emotional intelligence and the GHQ-12, being emotional attention r =.233, p ≤ .001; emotional clarity r = -.370, p ≤ .001; and emotional repair r = -.418, p ≤ .001. In addition, there is also a significant correlation in relation to the number of years practising judo (r = -.195, p ≤ .001), years spent in competition (r = -.077, p ≤ .001) and the judokas grade (r = -.198, p ≤ .001). These results are similar when segmented by gender. If we compare the results of emotional intelligence between healthy people (score <4 in GHQ-12) and people with potential pathologies (score ≥ 4 in GHQ-12), the results are equally significant (p≤ .001) with lower emotional attention and higher emotional clarity and repair in the group of healthy judokas. The same behaviour was observed when segmented by gender. Finally, it should be noted that those judokas with high sports performance show significantly better mental health segmented by gender.

Discussion

The results show that the more years of practice, the more years competing and the higher the rank achieved, the better the emotional intelligence. Emotional clarity and emotional repair behave in a direct way and emotional attention in an inverse way. This is good, as paying too much attention to emotions is a negative aspect. On the other hand, these results are related to better mental health. Also, by splitting the sample analysed on the basis of the GHQ-12 scores, our results continue to point in the same direction. Finally, those judokas with high sporting performance, i.e. who have been selected by the country as high-performance athletes, who have been in the national team or who have been in the world ranking in the top 70, show significantly higher levels of emotional intelligence and better mental health than the rest of judokas. This could highlight the need for optimal psychological qualities to be among the elite.

EFFICACY OF INDIVIDUALIZED SENSORY-BASED MHEALTH INTERVENTIONS TO IMPROVE DISTRESS COPING IN HEALTHCARE PROFESSIONALS WITH PHYSICAL ACTIVITY: A MULTI-ARM PARALLEL-GROUP RANDOMIZED CONTROLLED TRIAL

BAUMANN, H.

UNIVERSITY OF HAMBURG

Psychosocial distress among healthcare professionals can lead to negative health outcomes such as psychological, musculoskeletal, and cardiovascular diseases. Physical activity has been shown to reduce chronic distress by decreasing the release of stress hormones, promoting relaxation, and improving physical and emotional well-being. Mobile health (mHealth) interventions incorporating sensor feedback have been proposed as a promising approach to deliver person-centered interventions that vary in individual needs and empower individuals to actively monitor their health. This study aimed to investigate the impact of individualized, sensor-based mHealth interventions on stress coping in healthcare

professionals by focusing on stress and physical activity. We hypothesize that individualized interventions would result in small to moderate positive effects on physical activity and stress-related outcomes, while non-individualized interventions would be ineffective.

The study utilized a multi-arm, parallel group randomized controlled trial design, comparing five intervention groups that represented varying levels of individualization to a control group (Interventiongroups: 1=web-based training, 2=need oriented web-based training, 3=need oriented web-based training with telephone coaching; 4=individualized app with sensory biofeedback, 5= individualized app with sensory biofeedback and personalized Health report). Both self-reported questionnaire data as well as electrocardiography and accelerometry-based sensory data were assessed at baseline and post-intervention (after eight weeks). Of the 995 eligible participants, 170 (26%) completed the post-intervention measurement (Group 1: N=21; Group 2: N=23; Group 3: N=7; Group 4: N=34; Group 5: N=16; Control Group: N=69). The baseline data showed no significant differences in demographic characteristics between the intervention and control groups. The average age of the participants was 41.1 ± 10.9 years, and the sample consisted of more female than male participants. MANOVA results indicated small to moderate time-by-group interaction effects for physical activity-related outcomes, including moderate to vigorous physical activity ($F(1,5)=5.8$, $p=<.001$, $\eta^2p=.057$) and inactivity disruption ($F(1,5)=11.2$, $p=<.001$, $\eta^2p=.100$), in the app-based intervention groups, but not for step counts and inactivity.

The findings suggest that interventions aimed at increasing physical activity in a work setting may not necessarily reduce stress levels, and that individualized app-based interventions may be more effective. However, further research is needed to determine the optimal level of individualization and design of interventions. Probably, more specific and continuous training is necessary to achieve cognitive and psychophysical adaptations through physical activity. The 8-week intervention may not be long enough to activate physiological mechanisms that have a stress-buffering effect.

DOES PARTICIPATION IN SPORT ACT AS A RESILIENCE FACTOR FOR ADOLESCENTS WITH A HISTORY OF CHILD MALTREATMENT?

DION, J., RODRIGUE, C., PARENT, S., BLACKBURN, M.È., HÉBERT, M., LALANDE, D., PAQUETTE, L.
UNIVERSITÉ DU QUÉBEC À CHICOUTIMI

The prevalence of child maltreatment (sexual, physical, and emotional abuse, exposure to inter-parental violence, and neglect), is overwhelming worldwide. In Canada, a third of the population has endured at least one form of child maltreatment. Considering the deleterious consequences associated with child maltreatment, it is essential to identify protective factors to help promote resilience in victims. This study investigated the potential role of an understudied factor, that is, sports participation in an organized context, in sustaining positive psychological adaptation. Overall, 825 adolescents aged 15–19 years (M = 15.84 years; SD = 0.73) completed self-reported questionnaires in their classrooms on electronic tablets assessing history of child maltreatment, sports participation, violence toward athletes, and a host of outcomes related to psychological adaptation (body satisfaction, self-esteem, life satisfaction, internalized and externalized symptoms, COVID-19-related-distress). More than 56.1% of the sample (80.8% non-binary adolescents, 62.4% girls, 50.7% boys) reported having experienced at least one form of child maltreatment. Moreover, 54.4% of the sample (19.2% non-binary adolescents, 52.9% girls, 56.7% boys) reported sports participation in an organized context. Among them, 58.6% also reported experiencing sports violence from coaches, teammates, or parents. Child maltreatment was significantly associated with all outcomes (i.e., lower levels of life satisfaction and self-esteem, and higher levels of body dissatisfaction, internalized and externalized symptoms). Controlling for sports violence, sports participation was significantly associated with positive adaptation. However, it only moderated the association between child maltreatment and body dissatisfaction, i.e., the association between child maltreatment and body dissatisfaction was weaker among those who participated in an organized sport. Moreover, COVID-19-related distress was associated with all outcomes (i.e., lower levels of life satisfaction and self-esteem, and higher levels of body dissatisfaction, internalized and externalized symptoms). Overall, these results suggest that sports participation reduces the consequences of child maltreatment, but only for body dissatisfaction, partly supporting the role of sports participation as a resilience factor. To play its protective role, sports participation should also be free of violence. Besides, as COVID-19-related distress was associated with worsened outcomes, one may wonder if it mitigates the protective role of sports participation for maltreated victims. Nonetheless, as sports participation was associated with positive outcomes, the current results reiterate the importance of promoting sports participation for all youth. Finally, considering the high level of violence experienced in the context of sports in the present sample, there is an urgent need to promote a safe and secure sports environment.

IS-BM06 Losing and retraining balance while ageing: perspectives for innovative interventions

POSTURAL TRACKING OF CONSTANT AND COMPLEX VISUAL MOTION CUES: IMPLICATIONS FOR VISUOMOTOR PLASTICITY IN OLD AGE

HATZITAKI, V.

ARISTOTLE UNIVERSITY OF THESSALONIKI

Ageing is associated with progressive degeneration at the central and peripheral levels of the nervous system. This results in a less efficient sensory motor integration which together with central slowness of information processing increases reliance on predictive control and proneness to falling (1). Postural tracking of visual cues has expanded into an exercise gaming intervention promising to strengthen the link between perception and action (2). Visuo-postural tracking paradigms are based on our current knowledge that humans can match their voluntary sway to a moving visual target when provided with online visual feedback (VF) of sway. With practice, spatiotemporal error, the discrepancy between the target motion and the VF signal, is reduced across sway cycles. However, due to neural conduction delays and noise in the processing of visual information, the transformation of visual error signals to appropriate motor commands is time consuming (3). To compensate for this, a forward model of the outgoing motor commands is acquired which allows prediction of the sensory consequences of action at a very short latency (4). This assumes that the pattern of the visual target motion remains constant across sway cycles. The problem with tracking of constant target motions is its limited generalization to other sensorimotor balance tasks, a problem known in the learning literature as task specificity of practice (5). Alternatively, tracking of complex visual target motions evokes sustained perception-based action which results in more persistent postural control (6) that is resilient to balance perturbations (7). Can tracking of complex visual motion cues generalize to functional balance control? The present talk will review evidence addressing this question in the context of balance retraining in ageing.

FALL-RESISTING SKILL TRANSFER AND RETENTION OF BALANCE RECOVERY RESPONSE ADAPTATIONS FROM TRIP-LIKE PERTURBATIONS

KARAMANIDIS, K.

LONDON SOUTH BANK UNIVERSITY

Daily-life locomotion constantly challenges the human neuromotor system to respond to changing environments. Thus, the ability to select and execute appropriate motor actions for external disturbances during gait, and to improve as well as to retain such skills are important for providing safe locomotion (1). Moreover, scoping fall resilience requires knowledge of factors enabling the neuromotor system to transfer stability control mechanisms between different environmental conditions (2, 3). In a series of studies (4, 5) we investigated how gait stability and adaptability during trip-like perturbations are affected by age and examined the impact of various exercise modalities and neuromuscular function on adaptation, retention, and transfer of improved stability recovery mechanisms to novel perturbations. Our data provide evidence that the ability to adjust and recalibrate locomotor commands is preserved with ageing, as older adults can learn and cope with repeated unexpected trip-like perturbations. A single session of balance perturbation exercise has the potential to elicit long-term retention of stability recovery performance and transfer to non-exercised tasks . However, transfer of stability recovery mechanisms from one task to another may be partly subject to the degree of similarity in recovery motor responses and neuromuscular control patterns between perturbations, which need to be considered to effectively assess

and influence balance recovery mechanisms in ageing. Currently, we are investigating whether locomotor training based in virtual reality stimulates motor skill learning and benefits gait in physical environments.

MOVING ON FROM INTERVENING ON MUSCLE STRENGTH TO IMPROVING SPECIFIC FALL-RESISTING SKILLS IN OLDER ADULTS

MCCRUM, C.

MAASTRICHT UNIVERSITY

One of the many physiological effects of ageing is the gradual decline in skeletal muscle size and strength. This has multiple effects on health and wellbeing and is frequently described as a causal factor in the increasing risk of falls with ageing. In the first part of this talk, evidence at multiple levels will be presented that dispute this supposed causal link. In addition to literature evidence, I will present results from a correlation analysis (1) looking at type II muscle fibre properties and a cross-sectional study looking at physical activity and sport participation levels in older adults (2) each in relation to performance of trip-like gait perturbation tasks and demonstrate that these properties alone do not seem to play a causal role in reactive balance recovery following balance perturbations. In the second part of the talk, the issue of falls will be approached from a motor skill, rather than skeletal muscle property perspective. Evidence from laboratory-based studies will be presented that demonstrate that older adults can rapidly improve their reactive balance recovery performance (3) and that this is feasible to apply in clinical settings (4). >From a motor skill perspective, three distinct fall-resisting skills (adaptability, robustness and reactive recovery) emerge and there is evidence that these can be trained successfully in older adults using innovative, technology-assisted interventions. To close, a framework for fall risk assessment and training through this fall-resisting skills lens will be proposed.

IS-PN06 Fuelling the Paralympic Athlete

ASSESSMENT OF ATHLETES ENERGY EXPENDITURE USING DOUBLY LABELLED WATER

PLASQUI, G.

MAASTRICHT UNIVERSITY

To assess energy expenditure in athletes, indirect calorimetry can be used in a lab setting or for short observation intervals (e.g. a training session) in the field using a portable system. However, to assess the true energy needs, a measurement in daily life is necessary that allows to accurately quantify the daily energy needs of an athlete in order to assure optimal nutritional strategies and hence performance.

Doubly labelled water can be used to accurately assess total daily energy expenditure, over observation intervals of 3-14 days with minimal interference for the athlete. The technique uses the two stable isotopes deuterium (2H) and oxygen-18 (18O) to obtain a measure of CO2-production. Once a measure of CO2-production is obtained, a respiratory quotient (RQ) needs to be assumed to calculate energy expenditure from CO2-production.

The technique can be used everywhere in daily life with minimal burden for the athlete. It only requires the collection of urine samples at specific time-points. It provides an accurate measure of energy expenditure over several days to weeks and hence represents the true energy needs of the athlete studied. This presentation gives an overview of the doubly labeled water method to assess energy expenditure athletes, and Paralympic athletes in particular.

ENERGY REQUIREMENTS OF PARALYMPIC ATHLETES

VAN DIJK, J.

HAN UNIVERSITY OF APPLIED SCIENCES

Along with the rapidly growing number of Paralympic athletes, there is an increased need for nutritional support in this population. Compared to non-disabled athletes, Paralympic athletes may differ with regard to body composition, physiological responses to exercise, and training load and habitual physical activity patterns. Therefore, Paralympic athletes have their own specific nutritional needs. So far, the energy requirements of Paralympic athletes have been based primarily on prediction equations of resting metabolism combined with estimates of exercise energy expenditure.

In a recent collaborative project between the Netherlands and Norway (ParaNut), we applied the gold standard doubly labeled method to assess energy expenditure in a large cohort of Dutch and Norwegian Paralympic athletes. The doubly labeled water method was combined with indirect calorimetry measurements at rest and during exercise. As such, this project generated comprehensive data on the total daily energy expenditure and its components in Paralympic athletes competing in various sport disciplines. This information also allowed to evaluate the nutritional intake of the Paralympic athletes in light of their energy requirements. Furthermore, based on this data, the energy availability of Paralympic athletes was assessed.

During this presentation, the latest insights regarding the energy needs and energy availability of Paralympic athletes will be shared. This information forms the basis for new dietary guidelines and nutritional strategies for Paralympic athletes. The presentation is therefore of interest to professionals working with Paralympic athletes, as well as physiology and nutrition scientists.

STRATEGIES TO FUEL PARALYMPIC ATHLETES

JONVIK, K.

NORWEGIAN SCHOOL OF SPORT SCIENCES

Currently, the dietary counseling of Paralympic athletes is mostly based on nutritional guidelines for non-disabled athletes. Nutritionists are actively searching for knowledge and effective strategies to provide evidence-based dietary recommendations to this group.

Although there is very little research available in Paralympic athletes, it has been suggested that individuals with a disability may experience altered physiology related to relative energy deficiency in sports (RED-S) symptoms when compared with non-disabled athletes. A chronically low energy availability can lead to impaired bone health, which will be further magnified in Paralympic athletes who remain non-weight-bearing and wheelchair bound. By improving the quality of dietary intake as well as energy expenditure methodology, we may be able to more accurately estimate and monitor the energy availability of individual athletes. Big data from several Paralympic sports and countries are needed, including particular focus on energy availability as well as bone health and body composition, in order to develop Paralympic specific dietary guidelines for energy and macro nutrient intakes. Furthermore, more knowledge is needed to identify RED-S symptoms in Paralympic athletes and whether these reflect nutritional status or is a result of the disability itself.

Based on the findings of the ParaNut project, as well as other recent relevant work, possible nutrition strategies for Paralympic athletes will be discussed in this presentation. Relevant questions to be considered are:

1. What are the main focus points for nutritional counseling and dietary intakes in Paralympic athletes competing in various sports disciplines?

2. How can nutrition strategies structurally develop the para sport and facilitate improved health and performance?

3. What are the focus points for research interventions in Paralympic athletes?

OP-PN17 Muscle Damage and Repair

COMPARISON OF DELAYED ONSET MUSCLE SORENESS LEVELS AFTER ACUTE RESISTANCE EXERCISE BETWEEN VEGANS AND OMNIVORES

KARELIS, A.D.1, NJEIM, P.1, FAUST, A.2, BOUTROS, G.H.2

1. UNIVERSITÉ DU QUÉBEC À MONTRÉAL; 2. RESEARCH INSTITUTE OF THE MCGILL UNIVERSITY HEALTH CENTER

INTRODUCTION: Acute resistance exercise could lead to delayed onset muscle soreness (DOMS), which in itself is an inflammatory response. There is evidence to suggest that a vegan diet may be associated with a lower inflammation profile. Thus, one can argue that a vegan diet may lead to a lower inflammation response following resistance exercise

and in turn to lower levels of DOMS. Therefore, the purpose of the present study was to examine the levels of DOMS markers between vegans and omnivores after acute resistance exercise.

METHODS: We recruited 54 young lean women (age: 26.8 ± 4.1 years; body mass index: 22.5 ± 2.7 kg/m2). Participants were classified as vegan (n = 27) or omnivore (n = 27) based on their eating habits. All volunteers followed either a vegan or an omnivore diet for at least 2 years. DOMS was induced by performing one eccentric resistance exercise session, which consisted of 4 exercises (leg press, chest press, leg curls and arm curls) with 4 sets of 8 repetitions. Body composition (DXA), dietary factors, muscle strength (1 RM leg and chest press), grip strength, perception of soreness as well as pressure point thresholds of the quadriceps, calf, chest and biceps muscles (algometer) were measured before and 48 hours after the exercise session.

RESULTS: At baseline, both groups were comparable for percent body fat, lean body mass, muscle strength, grip strength and pressure point thresholds. No differences in the change of the perception of muscle soreness between groups were found after acute resistance exercise. However, changes in pressure point thresholds were significantly better in vegans compared to omnivores for the quadriceps (Pre: 36.0 ± 15.7 vs. 37.1 ± 16.0; Post: 38.5 ± 20.3 vs. 29.5 ± 11.4 Newtons (N), respectively ($p<0.002$), calf (Pre: 34.6 ± 12.9 vs. 37.6 ± 15.8; Post: 39.6 ± 18.0 vs. 34.6 ± 15.3 N, respectively ($p<0.008$), chest (Pre: 23.3 ± 8.8 vs. 23.1 ± 10.4; Post: 27.5 ± 15.8 vs. 19.7 ± 11.7 N, respectively ($p<0.012$) and biceps (Pre: 25.1 ± 11.4 vs. 25.6 ± 12.3; Post: 29.2 ± 16.2 vs. 19.8 ± 9.5 N, respectively ($p<0.002$) muscles. Significant favourable changes were also observed for grip strength in vegans vs. omnivores (Pre: 231.2 ± 60.1 vs. 228.4 ± 59.9; Post: 233.5 ± 56.5 vs. 213.7 ± 57.7 N, respectively ($p<0.04$).

CONCLUSION: Vegans were associated with better changes in DOMS levels after acute resistance exercise compared to omnivores, which could suggest greater improvements in muscle recovery.

MUSCLE ANKYRIN REPEAT PROTEIN 1 (MARP1) ALTERS SARCOMERE STRUCTURES IN MAMMALIAN SKELETAL MUSCLE VIA TITIN ASSOCIATION

KUEHN, M.1, MA, W.2, HAN, S.W.1, FLEMING, J.3, MAYANS, O.3, IRVING, T.2, LINKE, W.1, HESSEL, A.1

UNIVERSITY OF MUENSTER, 1., ILLINOIS INSTITUTE OF TECHNOLOGY, 2., UNIVERSITY OF KONSTANZ, 3.

INTRODUCTION: The muscle ankyrin repeat protein (MARP) family are comprised of three isoforms that are binding partners with titin in striated muscle and play a role in regulating mechanical and mechano-signalling properties, sarcomeric integrity, force production, and muscle remodelling. During some myopathies, the MARP1 isoform upregulates from trace levels, translocates to the sarcomeric I-band region, and tethers titin to actin in a way that increases titin-based passive stiffness. To explore this phenomenon, we used small-angle X-ray diffraction to study the sarcomeric myofilaments before and after MARP1 incubation in permeabilized psoas myofibers.

METHODS: Small-angle X-ray diffraction is a specialized experiment that uses brilliant-spectrum X-ray beams to measure sarcomere structures in fibers at near-physiological conditions. X-ray data provided details about lattice spacing, myosin motor orientation, troponin orientation, and myofilament strain. Permeabilized fiber bundles were prepared from human anterior tibialis biopsies and placed in a muscle mechanics rig within the X-ray apparatus. X-ray diffraction data were collected at 2.4, 2.7, and 3.0 µm sarcomere length (SL) before and after MARP1 incubation. X-ray diffraction data were processed using the freeware MuscleX.

RESULTS: MARP1 incubation significantly increased equatorial intensity ratios, which is indicative of a closer proximity of myosin heads to the thin filaments, which is a typical feature of passive muscle that is linked to increased force development upon activation. Moreover, we found that the typical thick filament elongation for a given stretch amplitude was further increased after MARP1 incubation, which is most likely caused by an associated increase in titin-based forces against the thick filament. Taken together, our preliminary results suggest that, compared to controls, fibers incubated with MARP1 presented structural evidence of increased calcium sensitivity and force at longer SLs.

CONCLUSION: Clinically, MARP1 is present only after eccentric overload training or disease, suggesting a distinctive but as yet unclear signal transduction and remodeling pathway. Our data suggests its function is to "prime" passive muscles for enhanced force production upon activation. The purpose may be to serve as a compensation mechanism for force-deficient myopathic and/or damaged fibers. To our knowledge, this is the first demonstration of length-dependent structural priming in passive fibers of human skeletal muscle and should be further evaluated during contraction.

EFFECTS OF FAR-INFRARED RADIATION LAMP THERAPY ON RECOVERY FROM ECCENTRIC EXERCISE-INDUCED MUSCLE DAMAGE

CHEN, T.1, HUANG, Y.2, CHOU, T.1, HSU, S.1, CHEN, M.1, LIN, S.3, NOSAKA, K.4

1 NATIONAL TAIWAN NORMAL UNIVERSITY, TAIPEI, TAIWAN; 2 MING CHUAN UNIVERSITY, TAIPEI, TAIWAN; 3 NATIONAL PINGTUNG UNIVERSITY, PINGTUNG, TAIWAN; 4 EDITH COWAN UNIVERSITY, JOONDALUP, WA, AUSTRALIA

INTRODUCTION: Muscle damage represented by a prolonged loss of muscle function such as maximal voluntary contraction (MVC) torque, delayed onset muscle soreness (DOMS), and impaired proprioception is often inevitable after performing eccentric exercise, thus treatments to enhance recovery are necessary. A variety of treatments and interventions have been explored to facilitate the recovery, but none of them appears to be highly effective. Far-infrared radiation (FIR) therapy is a phototherapy in which a wavelength of 8-14 µm is used to increase cell growth and development in animal studies (Leung. Chin J Physiol 2015). However, no previous study has investigated the therapeutic effects of FIR lamp therapy on humans in a laboratory setting. Thus, the present study investigated the effects of a FIR lamp therapy on changes in mus-

cle damage and proprioception markers after maximal eccentric exercise of the elbow flexors (EF: Study 1) and the knee flexors (KF: Study 2) in comparison to a sham treatment condition.

METHODS: In each study, healthy sedentary women (20-24 y) were assigned to a FIR or a sham treatment group (n=12/group). They performed 72 maximal EF eccentric contractions (Study 1) or 100 maximal KF eccentric contractions (Study 2) with their non-dominant limbs. They received a 30-min FIR (wavelength: 8-14 μm) or sham treatment at 1, 25, 49, 73 and 97 hours post-exercise to the exercised muscles. MVC torque, muscle soreness, plasma CK activity, and proprioception assessed by position sense, joint reaction angle, and force match were measured before, and 0.5, 24, 48, 72, 96 and 120 hours post-exercise. Changes in the variables were compared between the FIR and sham groups in each study by a mixed-design of two-way ANOVA.

RESULTS: The outcome measures showed significant changes ($P<0.05$) at 0.5-hour post-exercise (before treatment) similarly ($P>0.05$) between the conditions; however, changes in all measures at 24-120 hours post-exercise were smaller ($P<0.05$) for the FIR than sham condition in both studies. For example, MVC torque returned to the baseline by 72 hours post-exercise for the FIR condition in both studies, but was still 19 ± 6% (Study 1) or 17 ± 12% (Study 2) lower ($P<0.05$) than the baseline at 120 hours post-exercise for the sham condition.

CONCLUSION: These results showed that the FIR lamp therapy enhanced the recovery from muscle damage induced by unaccustomed eccentric exercise, when the 30-minute FIR lamp treatment was provided at 1 hour post-exercise, and every 24 hours for 4 days thereafter in both studies. It appears that the FIR lamp therapy is effective for alleviating muscle damage in the days after eccentric exercise. The FIR lamp treatment effects shown in the present study appear to be much greater than those of other treatment modalities that have been reported in the previous studies (e.g., Chang et al. Evid Based Comple Altern Med 2021). The mechanisms underpinning the effects require further studies.

COMPARATIVE ANALYSIS OF RUNNING-INDUCED STRUCTURAL MUSCLE CHANGES BETWEEN MEN AND WOMEN

KUNIMASA, Y.1, MACCHI, R.2, ROSSI, F.3,4, SOUSTELLE, L.4, HOSTIN, M.A.4, MICHEL, C.P.4, BENDAHAN, D.4, NICOL, C.5
1 NIIGATA UNIVERSITY, NIIGATA, JAPAN; 2 SEP-EA7370, INSEP, PARIS, FRANCE; 3 UNIVERSITY OF BOLOGNA, BOLOGNA, ITALY; 4 AIX-MARSEILLE UNIV, CNRS, CRMBM-UMR 7339, MARSEILLE, FRANCE; 5 AIX-MARSEILLE UNIV,

INTRODUCTION: The repeated ground impacts occurring during running can induce muscle damage [1], which could differ between sex [2,3]. However, due to the difficulty of assessing muscle microstructure in humans (e.g., muscle biopsy), the effect of sex on structural muscle damage and recovery patterns after running has been scarcely investigated. Alternatively, microstructural changes and subsequent muscle inflammation can be investigated using diffusion tensor magnetic resonance imaging (MRI) [4]. The purpose of the present study was to determine the effect of sex on different indirect markers of exercise-induced muscle damage.

METHODS: A group of recreational runners (8 men and 8 women) performed a 20-km graded running race, while the control group (8 men and 8 women) did not participate in the run. Muscle volume, ultrastructural muscle changes (mean diffusivity: MD and fractional anisotropy: FA) for 12 lower limb muscles, muscle group soreness, and drop jump performance were measured using MRI, visual analog scale, and force plate once before the race (PRE), and twice in the following 4 days (D1-2 and D3-4), respectively. The control group performed the same measurements twice one day apart. A two-way (session*sex) ANOVA was performed for each group separately.

RESULTS: Regardless of sex, at D1-2, the experimental group showed a 4 ± 3 % decreased rebound height in drop jump ($p<0.05$), delayed onset muscle soreness (DOMS) in the quadriceps muscle group ($p<0.05$), and an increased volume of the semitendinosus muscle ($p<0.05$). Only women reported DOMS in the hamstrings ($p<0.05$). The MRI analyses revealed only a trend of increase ($p=0.07$) in MDs of the vastus lateralis, biceps femoris long head, semitendinosus, and semimembranosus muscles through D3-4, regardless of sex, while FAs did not change. In the control group, none of the parameters changed between sessions.

CONCLUSION: MR diffusion tensor imaging only revealed a trend of increase in MD while FA did not change in the thigh muscles until 4 days after the 20-km graded running race. This could reflect slightly increased muscle fibre bundle size in both transverse and longitudinal directions. Of interest, a sex difference was only found in the hamstring muscle soreness at D1-2. The discrepancy found between DOMS, jump performance, and diffusion parameters over the 4-day post-race period indicates that the commonly used DOMS reflects neither the amplitude nor the time course of the ultrastructural recovery. Our results provide the first evidence of the absence of a sex effect on ultrastructural muscle changes in-vivo human muscles after running.

OP-AP37 Warm-Up and Recovery

EFFECTS OF FORCE-POWER-VELOCITY RESISTED SPRINTS DURING WARM-UP ON RUNNING SPRINT PERFORMANCE AND MECHANICAL PROFILE IN NATIONAL ATHLETES: A PRELIMINARY STUDY

FORNASIER-SANTOS, C.1, BOURGEOIS, L.1, MARTIN, S., COUTURIER, A.1, GUILHEM, G.1, EDOUARD, P.2, SLAWINSKI, J.1, MORIN, J.B.2

1: INSEP, PARIS, FRANCE; 2: UNIVERSITY OF SAINT-ETIENNE, SAINT-ETIENNE, FRANCE

INTRODUCTION: Resisted sprints are a useful training strategy to improve the early acceleration phases of a sprint (1), and may be an effective post-activation potentiation stimulus used to acutely improve sprint performance (2). A simple field method has been validated to compute the main sprint acceleration mechanical outputs (3,4), and several on-field systems can be used to do so such as radar and motorized linear encoder (5). Warm-up content for sprint races has not been often studied and explored, especially regarding the use of resistances to cover the full force-velocity spectrum of sprint acceleration. The aim of this preliminary study was to determine the effectiveness of an implementation of a force, power and velocity resisted sprints during warm-up on the force-velocity profile and the 40-m linear sprint running performance.

METHODS: Five national level sprinters performed two warm-up sessions separated by one week. During the first warm-up session (CON), athletes performed their own individual warm-up followed by a load-velocity test. During the second warm-up session (FPV), athletes implemented at the end of their individual warm-up 3 resisted sprints (Force: 10-m against a load eliciting a 75% velocity decrease compared to their individual maximal unresisted velocity (Vdec), Power: 20-m at 50% Vdec, Velocity 30-m at 25% Vdec, and a final unresisted acceleration).

Running times were computed every 5-m with the motorized linear encoder (1080 Sprint; 333 Hz), and the Force-velocity profiles for the best time trial of each session were computed from the radar (Stalker Pro II; 48 Hz) data with the method proposed by Samozino et al. Maximal velocity (Vmax), theoretical maximal velocity (V0) and horizontal component of the ground reaction force (F0), and maximal power (Pmax) were calculated. Mean, percentages of differences and effect sizes (ES) were computed.

RESULTS: 40-m time was similar (5.52±0.40 vs 5.53±0.36 s; +0.6%; ES=0.03) between CON and FPV warm-up sessions. Regarding the main sprint-acceleration variables computed from the radar raw data, Vmax (8.94±0.76 vs 8.97±0.67 m.s-1;+0.3%; ES=0.04) and V0 (9.47±0.90 vs 9.43±0.86 m.s-1;-0.4%; ES=0.05) were similar. Despite very small percentage of difference for relative F0 (7.18±1.07 vs 7.28±0.76 N.kg-1; +1.4%; ES=0.11) and Pmax (16.86±3.40 vs 17.04±2.72 W.kg-1; +1.1%; ES=0.06) no statistical differences were found between warm-up sessions.

CONCLUSION: The results of this preliminary study on a small sample size of national athletes seem to show that implementing force, power and velocity resisted sprints during warm-up is a feasible strategy. Indeed, this could have no negative effects on sprint-acceleration mechanical profile and 40-m sprint performance. However, a larger number of athletes from various level should be included to confirm the results obtained.

THE EFFECT OF WARM-UP ON DETERMINING THE PRESSURE DIFFERENCES NECESSARY TO OBTAIN ARTERIAL OCCLUSION PRESSURE (AOP).

BICHOWSKA, M., FOSTIAK, K.

GDANSK UNIVERSITY OF PHYSICAL EDUCACION AND SPORT

INTRODUCTION: Partial or total occlusion of blood flow to the working muscles, also known as blood flow restriction (BFR), has been used as a complementary training method, aimed to further increase acute as well as chronic adaptation changes. Completely occluding arterial blood flow into the limb is referred to as arterial occlusion pressure (AOP). However, the previous research procedures assumed the measurement of AOP either before (pre warm-up) or after the warm-up (post warm-up). The pressure required to obtain AOP may depend on whether the measurement was made before or after the warm-up. Therefore, the main goal of the study was to determine the differences in pressure necessary to obtain AOP in the measurements made before and after the warm-up.

METHODS: Twenty-one healthy resistance trained women and men volunteered for the study (aged 24.1±5.8 years, body mass 75.6±19.4 kg, height 177.8± 10.7 cm). The measurements of AOP were conducted twice on each lower limb during rest. The first measurement of the AOP was made before the warm-up and the second one after the 15-minute warm-up. For BFR the 10-cm wide cuffs were used. The warm-up contained jogging (5-min) and dynamic exercises (10-min) such as the gluteal stretch walk (10 repetitions (reps)), quadriceps grab walk (10 reps), bouncing on spot (double leg) (28 reps),

gluteal run (14 reps per leg), walking lunges (6 reps) and jump CMJ (4 reps) (O'Grady et al. 2021). The protocol of the study was approved by the Bioethical Committee at the Regional Medical Chamber in Gdansk (11/22).

RESULTS: The 2-way ANOVA [2 legs (right, left) x 2 time (pre, post warm-up)] showed a statistically significant main effect for time AOP measurement p <0.001 (pre vs. post warm-up). The post hoc analysis for main effect showed significant higher pressure required to AOP in post warm-up measurement compared to pre warm-up (206.05 vs. 193.19 mm/Hg; p <0.001). There were no significant interaction effect (p= 0.26) as well as no significant main effect (p = 0.45) for comparison between the left and right legs.

CONCLUSION: The main finding of the study was that the pressure needed to obtain AOP was significantly different between the measurements performed before and after the warm-up. Therefore, it is necessary to consider whether pre or post warm-up AOP should be taken into account in the programming of scientific research and implementation of sports training. In addition, despite the increase in AOP after warm-up compared to pre warm-up values, there were no significant differences in the pressure needed to obtain AOP between the right and left leg. The increase in the AOP can be explained by the increase of the total blood pressure and heart rate resulting from the warm-up. As a result, higher total blood pressure may require a higher cuff pressure in order to occlude the limb. Moreover, the timing of AOP determination in the upper or lower limbs is important in the selection of the appropriate BFR pressure during exercise.

COMPARISON OF THE EFFECTS OF COLD-WATER IMMERSION AND PERCUSSIVE MASSAGE ON THE RECOVERY AFTER EXHAUSTING ECCENTRIC EXERCISE: A THREE-ARMED RANDOMIZED CONTROL TRIAL

HEINKE, L., JAVANMARDI, S., RAPPELT, L., KONRAD, A., SCHLEIP, R., KNICKER, A., BAUMGART, C., FREIWALD, J.

UNIVERSITY OF WUPPERTAL

INTRODUCTION: Athletic training has to involve an overloading stimulus to induce adaptions of the organism, but also adequate recovery is needed to enhance athletic performance. Recovery by cold water immersion (CWI) has become particularly popular in various sports, and in recent years, even handheld percussive massage (PM) devices have been widely-used as a recovery tool, but with lacking scientific evidence. Therefore, this study aimed to investigate and compare the effects of CWI and PM treatment on performance recovery after exhausting eccentric exercises.

METHODS: 23 healthy sport students (f = 7, m = 16, 24.4 ± 4.1 y, 178 ± 9.8 cm, 74.3 ± 13.1 kg) were randomly assigned to CWI (n = 8), PM (n = 8) or a passive rest group (PR, n = 7). On five separated laboratory sessions, all participants completed a familiarization, an exhausting eccentric protocol as well as 24, 48, and 72 h posttests. Immediately before (PRE) and after (POST) the eccentric protocol as well as during the posttests (POSTrec, 24, 48 & 72h) subjective perception of muscle soreness (0 to 10 scale), perceived stiffness (visual analog scale, VAS), skin temperature, as well as the creatine kinase activity (CK), squat jump (SJ) and countermovement jump height (CMJ) on a force platform were measured. The exhaustion protocol consisted of the following tasks: 15 min downhill-running on a treadmill (slope: -12%, speed: 10 km/h) and 3 sets of successive depth jumps from a dropping height of 60 cm. Within the first 2 sets, participants performed 20 jumps. In the final set, participants continued the jumps until they could not maintain at least 90% of the mean jump height of the first sets in 3 consecutive jumps. After POST measurements, participants received 12 min of either CWI (11 ± 0,5°C), PM (40 Hz) or PR (supine posture) recovery treatment.

RESULTS: Subjective performance recovery parameters (soreness, VAS) and CK revealed no group * time interaction effects. Group * time interactions were only found in skin temperature ($F(4.45,42.27) = 37.55$, $p < .001$, $\eta p^2 = .80$) as well as SJ ($F(4.6,43.73) = 2.78$, $p = .03$, $\eta p^2 = .23$) and CMJ ($4.93,46.8) = 2.82$, $p = .03$, $\eta p^2 = .23$). Post hoc pairwise comparison for SJ ($p < .001$; CWI: -24.9 ± 5.9%, PM: -12.5 ± 4.7%, PR: -14.7 ± 3.5%) and CMJ ($p < .001$; CWI: -24.9 ± 4.4%, PM: -16.5 ± 3.4%, PR: -17.1 ± 4.2%) showed group differences only at POSTrec, revealing higher jump heights reduction in in the CWI group.

CONCLUSION: Neither CWI nor PM showed enhanced recovery in the course of 72 h after exhausting eccentric exercise in comparison to PR. Acute performance losses immediately after CWI may be explained via a significantly lowered skin temperature further associated with a potential reduction in muscle temperature as well as an alteration in nerve conduction velocity.

USE OF RECOVERY STRATEGIES IN ENDURANCE ATHLETES AT DIFFERENT LEVELS OF COMPETITION-A SURVEY STUDY

LI, S., KEMPE, M., LEMMINK, K.

UNIVERSITY MEDICAL CENTER GRONINGEN

INTRODUCTION: In general, numerous studies have been conducted on recovery strategies in athletes. However, only few studies took the level of competition into account when examining recovery strategies. This study aims to explore the use and perceived barriers of recovery strategies among endurance athletes of various competitive levels.

METHODS: Endurance athletes were asked to fill out an online survey on recovery strategies, which included 25 subcategories across five main recovery strategies (active, nutrition, massage, temperature-base and other strategies) using Qualtrics. The survey was conducted from April 2022 to January 2023. The athletes competition level, type of sport, and gender between groups were compared using the chi-square test. Each answer was reported as the group percentage or frequency.

RESULTS: A total of 91 (53 male, 38 female) endurance athletes completed the survey. Athletes were divided into four competition levels, namely international (n=15), national (n=48), regional (n=22), and recreational (n=6). There was no signifi-

cant difference (p=0.29) between athletes competing at different levels and the sources of recovery strategies. Athletes primarily got information via their coaches (32.1%) and websites (23.7%) but less from scientific magazines (8.9%) or scientific staff and conferences/workshops (5.8%). Surprisingly, athletes at the national level had the highest use of recovery strategies (56%) compared with regional (29.7%), international (16.5%), and recreational (8.8%). Barriers for the use of recovery strategies were too little time (73.9%), too little knowledge (60.9%), and lack of motivation (54.5%). As with all strategies, warm baths, cold showers, cold packs, and caffeine were most used (in total 30.8, 69.2, 60, and 16.7%) by international, national, regional, and recreational levels, respectively. 46.2% of all athletes reported being satisfied with the recovery strategies they use.

CONCLUSION: The study results reveals that in daily practice athletes are more likely to follow coaches or other athletes for recovery suggestions instead of scientific knowledge. Given the shortage of time, most athletes seem to prefer relatively simple recovery strategies that are easy to implement (like baths or showers). To optimize recovery in endurance athletes, future research should focus on implementing scientific knowledge/resources/information on effective recovery strategies.

EFFECTS OF TIME EXPOSURE OF CRYOSTIMULATION BEFORE BEDTIME ON SLEEP AND RECOVERY OF WELL-TRAINED ATHLETES

DUPUY, O.1, DUGUÉ, B.1, PLA, R.2, BOUZIGUON, R.3, BOSQUET, L.1, ARC-CHAGNAUD, C.1

1 -LABORATORY MOVE, FACULTY OF SPORT SCIENCES, UNIVERSITY OF POITIERS, 2- NATIONAL FRENCH SWIMMING FEDERATION, 3- UNIVERSITÉ DE FRANCHE-COMTÉ, UFR STAPS BESANÇON,

INTRODUCTION: To accelerate recovery from intense training sessions, athletes usually employ various techniques. Among these practices, cold therapies have demonstrated their effectiveness in the athlete population. Whole body cryostimulation (WBC) consists of total body exposure to dry air at a cryogenic temperature below -90°, becoming democratized in high-level athletes as a recovery strategy. Indeed, WBC leads to numerous valuable physiological effects. It produces analgesic effects, improves well-being, and reduces inflammation and muscle damage. In the context of an athletes recovery, WBC may help prevent the detrimental effects of intense training sessions. Indeed, intense exercises increase body core temperature (BCT), sympathetic nervous system activation and muscle soreness. Especially when training is performed in the evening, all these perturbations can induce sleep disturbances and finally impair athletes abilities to recover appropriately.

The objectives of the study were (i) to evaluate the effect of WBC after training as an effective tool to improve sleep and recovery, (ii) to state which exposure schedule for WBC (immediately after training vs 1h before bedtime) is the most appropriate to improve sleep and recovery.

METHODS: Twenty-two well-trained male athletes or triathletes were recruited in this controlled cross-over protocol. It consisted of 3 experimental sessions, each composed of a running training session followed by one night of sleep analysis. Depending on the experimental condition, subjects were exposed - or not - to WBC immediately after training (7 pm) or 1h before going to bed. All participants were randomly assigned to each condition (CONT; CRYO 7 pm; CRYO 10 pm), spaced 7 days apart. During the 3 nights of analysis, sleep was monitored via actimetry and cerebral activity recordings. Heart rate variability (HRV), body core temperature (BCT) and various perceptual measures were also assessed during the entire protocol.

RESULTS: WBC after training did not modify subjective or objective sleep parameters the following night. However, WBC, whatever the timing was, significantly improved recovery perception, muscle soreness, and HRV parameters. More specifically, the parasympathetic branch of the autonomic nervous system was more activated during the night when WBC took place 1h before bedtime. It was attested by reduced LF/HF ratio, resting HR and increased PNS index, especially during the slow wave sleep period. Body core temperature 1h after bedtime was the lowest in the CRYO 10 pm condition, coinciding with a more significant drop in BCT after the WBC session.

CONCLUSION: This study confirmed the effectiveness of WBC as a recovery technique after intense evening training. It suggested that WBC may exhibit the most significant benefit on recovery if the session is realized 1h before bedtime, acting on subsequent parasympathetic activation and body core temperature drop.

OP-BM08 Neuromuscular Physiology: Fatigue III

PURELY EXPLOSIVE ISOMETRIC CONTRACTIONS INDUCE MOSTLY CENTRAL FATIGUE

BOCCIA, G.1, D'EMANUELE, S.2, BRUSTIO, P.R.1, RAINOLDI, A.1, SCHENA, F.2, TARPERI, C.2

1 UNIVERSITY OF TORINO, ITALY, 2 UNIVERSITY OF VERONA, ITALY

INTRODUCTION: The neural drive to the muscle is the primary determinant of the rate of force development (RFD) in the first 50 ms of an explosive contraction. However, it is still unproven if repetitive explosive contractions specifically induce central fatigue, thus impairing the net neural drive. Indeed, previous studies on this topic adopted repetitive maximal contractions characterized by a first phase of explosiveness followed by a holding phase of 1 to 3 s. Thus they could not

distinguish the peculiar way the rapidity/explosiveness induces fatigue. Indeed, while the explosive phase of a contraction lasts about 200 ms, adding even just 1 s of holding phase makes most of the contraction a holding maximum contraction (200 ms of explosive phase vs 1 s of holding phase).

METHODS: To isolate the fatiguing effect of contraction explosiveness, 17 male adult volunteers performed 100 purely explosive isometric contractions - i.e. brief force pulses without holding phase - of the knee extensors. The response to electrically-evoked single and octet femoral nerve stimulation was measured together with high-density surface electromyography (HD-sEMG) from the vastus lateralis and medialis muscles. Root mean square (RMS) and muscle fiber conduction velocity (MFCV) were normalized to M-wave peak-to-peak amplitude and MFCV, respectively, to compensate for peripheral properties changes.

RESULTS: We found a decrease in early RFD ($d = -0.56$, $P < 0.001$) and an increase in time to peak force ($d = 0.90$, $P < 0.001$) and time to peak RFD ($d = 0.56$, $P = 0.034$). While we did not find clear signs of peripheral fatigue, there was a substantial decrease in neural efficacy, i.e. voluntary/octet force ratio ($d = -1.50$, $P < 0.001$). Relative RMS ($d = -1.10$, $P = 0.006$) and MFCV ($d = -0.53$, $P = 0.007$) also decreased.

CONCLUSION: We isolated the fatiguing impact of contraction explosiveness by adopting a protocol constituted by purely explosive contractions, i.e. brief force pulses without any holding phase. We found that the high level of neural drive required to repeat purely explosive contractions resulted in mostly central fatigue that caused a slowing in voluntary force production. The slowing was mainly evident in the first 50 ms of contractions.

IMMEDIATE AND PROLONGED EFFECTS OF KNEE FLEXOR FATIGUING EXERCISES ON POSITION SENSE USING POSITION-POINTING TASKS

DA SILVA, F., COLSON, S.S., CORCELLE, B., PIPONNIER, E., GIODA, J., MONJO, F.

UNIVERSITÉ CÔTE DAZUR - LAMHESS

INTRODUCTION: The effect of exercise-induced neuromuscular fatigue on kinesthesia has mainly been studied using bilateral joint position-matching tasks [1,2]. However, these tasks are limited in evaluating fatigue effects in unilateral contexts since they require a non-fatigued reference limb. The recent development of unilateral position-pointing tasks that involve extrapersonal body representation offers an alternative method to assess position sense in ecological settings. However, to date, no study has investigated fatigue-induced effects on position sense with such tasks that seem highly dependent on central processes [3]. Therefore, we designed a study to compare the immediate and prolonged effects of submaximal isometric, concentric and eccentric fatiguing exercises of knee flexors (KF) on position-pointing accuracy.

METHODS: Fourteen healthy young men were recruited. Isometric and dynamic KF fatiguing exercises were performed one week apart on the right limb and were stopped when the maximal voluntary isometric contraction torque dropped to 80% of its initial value. Position-pointing tasks were performed at 40° and 70° of knee flexion in both the fatigued and the non-fatigued limb. Electrical myostimulations were used to assess KF neuromuscular fatigue etiology (central and peripheral factors). Measurements were taken before, immediately after (POST), and 24 hours (POST24) after each fatiguing exercise. All parameters were analyzed using repeated measures ANOVAs.

RESULTS: Alterations in KF neuromuscular function were identified only at POST regardless of the fatiguing exercise performed, with contributions from central and peripheral factors considering the significant reductions in voluntary activation levels ($p < .05$) and electrically evoked torques ($p < .05$).

Additionally, irrespective of the fatiguing exercise performed, position sense alterations were evidenced after the exercise-induced neuromuscular fatigue. After the isometric and dynamic KF fatiguing exercises, position-pointing accuracy was impaired only at 40° of knee flexion in the fatigued limb at POST ($p < .01$) and POST24 ($p < .05$).

CONCLUSION: This study provides the first evidence that exercise-induced neuromuscular fatigue can affect position-pointing accuracy. Contrary to recent hypotheses that pointed to the involvement of central mechanisms in fatigue-induced position sense alterations [2], the results of this study suggest that peripheral mechanisms (e.g., altered muscle spindle sensitivity at long muscle length in the fatigued limb) may disturb extrapersonal body representations.

INDIVIDUALIZED MENTAL FATIGUE DOES NOT IMPACT NEUROMUSCULAR FUNCTION AND EXERCISE PERFORMANCE

HOLGADO, D.

UNIVERSITY OF LAUSANNE

INTRODUCTION: Previous work has shown that mental fatigue may have negative consequences on physical performance. Although recent reports question this previous empirical evidence. In this study, neurophysiological and physical responses to an individualized mental fatigue task are analyzed in order to investigate the critical role of individual differences in susceptibility to mental fatigue.

METHODS: We conducted a pre-registered (https://osf.io/xc8nr/), randomized, within-participant design experiment. Twenty-two active recreational athletes completed a cycling time to failure at 80% of their peak power output in two separate sessions, under mental fatigue (individualized mental effort) or control (low mental effort). Subjective feeling of mental fatigue, rate of perceived exertion, knee extensor neuromuscular function and corticospinal excitability were measured before and after the cognitive tasks. We conducted sequential Bayesian analysis until it reached strong evidence in favor of the alternative hypothesis (BF10 > 6) or the null hypothesis (BF10 < 1/6).

RESULTS: The individualized mental effort task resulted in a higher subjective feeling of mental fatigue in the mental fatigue condition: 0.50 (95%CI 0.39 - 0.62) compared to control: 0.19 (95%CI 0.06 - 0.339). However, exercise performance was not impaired. Control: 410 (95%CI 357 – 463) seconds and mental fatigue: 422 (95%CI 367 – 477) seconds. The Bayes factor (BF10 = 0.15) indicated that the observed data moderately to strongly supported the null hypothesis that the individualized mental fatigue did not have a detrimental effect on physical performance. Likewise, mental fatigue did not impair knee extensor maximal force generating capacity (BF10 = 0.928) and did not change the extent of fatigability or its origin after the cycling exercise.

CONCLUSION: Our data does not suggest that mental fatigue has a detrimental effect on physical exercise and neuromuscular function. Even when mental fatigue is individualized, this does not seem to affect physical performance when it is induced by computerized tasks. Future studies should seek to assess mental fatigue in a more realistic and meaningful context for an individual and its impact on training and performance.

MENTAL FATIGUE AND FORCE PRODUCTION CAPACITIES DURING A HANDGRIP CONTRACTION

JACQUET, T.

UNIVERSITÉ DE BOURGOGNE

INTRODUCTION: Mental fatigue is a psychobiological state caused by prolonged periods of demanding cognitive activity and characterized by subjective feelings of tiredness and lack of energy. Although its impact on physical performance is now well documented, these effects on force production capabilities remain uncertain. Studies have mainly focused on the effects of mental fatigue on maximal force production capacities. However, the rate of force development (RFD), a neuromuscular parameter related to most performances in both sport-specific and functional daily tasks, is poorly investigated and could provide valuable information about the effects of mental fatigue on force production capacities. As most activities of daily living are performed at submaximal intensities, RFD measured during contraction at submaximal intensities could have a higher ecological validity than RFD measured during maximal contractions. This study aimed to investigate the effects of mental fatigue on maximal force production, neuromuscular quickness, and force steadiness during handgrip contractions.

METHODS: Fourteen participants performed two randomized sessions, during which either they carried out a cognitively demanding task or a documentary watching for 62 min. The mental fatigue was evaluated subjectively (visual analogue scale) and objectively (cognitive performances and EEG). Sleepiness was also evaluated after both tasks. Maximal voluntary contraction (MVC) force and neuromuscular quickness using RFD-SF were recorded before and after the cognitively demanding task and documentary watching.

RESULTS: Feeling of mental fatigue was higher after completing the cognitively demanding task than after the documentary watching ($p < .001$), objectively evidenced by an increase in errors, missed trials and a decrease in N100 amplitude over time. Alpha power was higher (all ps < .002) during the completion cognitively demanding, but no specific changes overtime were reported. Sleepiness did not differ after the cognitively demanding task or the documentary watching ($p = .730$). Decrease in MVC ($p = .040$), lower slope ($p = .011$), and a reduction in R^2 ($p = .011$) of RFD-SF relation were observed after both cognitively demanding task and documentary watching.

CONCLUSION: These results indicate that both cognitively demanding task and documentary watching induced a decrease in maximal force production and in neuromuscular quickness at submaximal contraction intensities. Although the results of this study cannot be specifically attributed to mental fatigue, it is possible that, because of its effect on anterior cingulate cortex activity, mental fatigue impacts central control of muscles during contractions (e.g., motor unit firing rate and agonist-antagonist coordination). This would explain the effects on maximal force production and neuromuscular quickness. Future studies with more robust control tasks are needed to confirm our findings.

ADAPTIVE FORCE IN PATIENTS WITH LONG COVID AND DURING RECOVERY: MAXIMAL HOLDING CAPACITY MIGHT SERVE AS BIOMECHANICAL MARKER

SCHAEFER, L.V., DECH, S., BITTMANN, F.N.

UNIVERSITY OF POTSDAM

INTRODUCTION: Long COVID is frequently accompanied by symptoms like fatigue, muscle weakness and pain.[1] Since suitable diagnostics are still missing,[2] examining muscle function could be a supportive approach. The maximal isometric Adaptive Force (AFisomax) was previously suggested to be especially sensitive for disruptive stimuli.[3] It was assumed that this holding capacity would also be reduced in post-infectious diseases as Long COVID. The study aimed at investigating the Adaptive Force (AF) in patients with long COVID and their recovery process.

METHODS: This non-clinical study examined AF parameters of elbow/hip flexors in long COVID patients at three timepoints (pre: long COVID state, post: immediately after first treatment; end: substantial health improvement/recovery). The AF of each muscle was assessed three times by a manual muscle test objectified by a handheld device which captures force

and angle simoultaneously. The patient's task was to maintain an isometric position for as long as possible while the tester applied an increasing force on the patient's limb. Main parameters for comparison between the three timepoints (RM ANOVA) were the maximal isometric AF (AFisomax; highest force under isometric conditions) and the maximal AF (AFmax; peak value of one trial). Moreover, the intensity of 13 common symptoms was queried for baseline (prior to COVID-infection; retrospectively), in long COVID state, and at recovery.

RESULTS: In long COVID state patients could maintain the isometric position up to 46.58 ± 15.91% and 49.25 ± 12.01% of the AFmax for elbow and hip flexors, respectively. AFmax was then reached during muscle lengthening, indicating an unstable adaptation. AFisomax increased significantly to 98.63 ± 3.20% of AFmax at post and to 99.78 ± 0.71% at end (average of both muscles). This reflects stable adaptation. In turn, AFmax was statistically similar between all timepoints for both muscles. Symptoms intensity decreased significantly from long COVID state to end.

CONCLUSION: Long COVID patients showed initially an impaired length-tension control during adaptation to an external increasing force reflected by the significantly reduced AFisomax. With substantial health improvement, the muscular adaptation returned to normal function. The maximal AF did not show this behavior. It is suggested that especially the maximal holding capacity – not maximal forces as the AFmax – might be a suitable sensitive functional parameter to assess long COVID patients and to support their therapy process.

OP-AP36 Technology for Training and Recovery

A VIDEO-BASED TRAINING TO IMPROVE SURFERS INTUITIVE DECISION MAKING IN COMPETITION: A MIXED-METHOD PILOT STUDY

BERTET, E., VACHER, P., BOSSARD, C.

UNIVERSITÉ DE BRETAGNE OCCIDENTALE

INTRODUCTION: Surfers' performance in competition is evaluated while they are riding a wave, even though they spend far more time paddling, sitting or lying on their boards (Mendez-Villanueva et al., 2006). Athletes spend the majority of their time understanding their environment and making decisions, such as which wave to ride or which maneuver to use. Given the increasing demands of performance in sports situations (Klingner et al., 2022), how to develop decision making is an important research issue. The aim of this pilot study was to explore the effects of video-based training on intuitive decision-making during competition.

METHODS: Five athletes (2 females and 3 males) from a national surfing center participated in a 4-week video training intervention, including 3 sessions per week. A video based training session consisted of watching 5 waves of international surfers, frozen at a point that was considered appropriate for making a decision. Based on the study of Klatt et al. (2019), the athletes were then asked to (1) name outloud, (2) write down the first decision they think and (3) write down as many additional appropriate solutions that they can think of how to continue the sequence by imagining they were the athlete on the screen. Over the 4 weeks, quantitative data was collected: the responses of each athlete in each session as well as the responses of the coaches, in order to evaluate the accuracy of the decisions made by the athlete. To assess potential changes in the participants intuitive decision-making, a qualitative analysis was conducted during real competitions before and after the video-based training.

RESULTS: During video-based training, repeated measures ANOVAs show an increase in the accuracy of all decisions and especially the first one (from 75% to 84.1%). The video-based training seems to have contrasting effects on decisions in real competition: significant inter-individual differences in accuracy and decision processes.

CONCLUSION: This pilot-study highlights the potential impact of video-based training on intuitive decision-making of surfers, which should in future take into account practice variability and familiarity with the competition venue.

MODULATION OF PHYSICAL EXERCISE INTENSITY IN MOTOR-COGNITIVE BRAIN TRAINING USING THE SKILLCOURT TECHNOLOGY

HÜLSDÜNKER, T.1,2, ERDOGAN, G.3, TRAUSCH, A.1, VOGT, L.3, GIESCHE, F.3, FRIEBE, D.3, MIERAU, A.1,2, BANZER, W.3
<1> LUNEX INTERNATIONAL UNIVERSITY, DIFFERDANGE, LUXEMBOURG <2> LUXEMBOURG HEALTH AND SPORT SCIENCE RESEARCH INSTITUTE , DIFFERDANGE, LUXEMBOURG <3> GOETHE-UNIVERSITY FRANKFURT/MAIN, GERMANY

INTRODUCTION: Cognitive abilities substantially contribute to sport performance and numerous trainings aiming to improve cognitive functions were created. While computer-based interventions have been criticized due to their limited transferability, the suggestion to combine cognitive tasks with physical activity resulted in the development of motor-cognitive training. One major argument is the release of neurotrophic factors during exercise that should support neural plasticity according to the concept of guided plasticity facilitation. However, motor-cognitive tasks typically involve low to moderate intensities and provide limited flexibility to modulate physical effort which limits its integration into training apart from a "fun-factor". Therefore, this study evaluated the physiological profile of motor-cognitive trainings on the novel SKILLCOURT technology aiming to cover a broad range of exercise intensities.

METHODS: 28 healthy university students performed five motor-cognitive trainings combining physical and cognitive tasks using the SKILLCOURT technology. In the cognitive domain, the tasks required decision making, conflict inhibition, working memory, dual-task ability, logical thinking, and planning ability. Physical demands were modulated by varying the motor response between stationary stepping movements and highly dynamic agility runs on a 4x4 m court that was continuously scanned by a LiDAR system. Each training was performed 3 times with a standardized break of 30 seconds between trials. To determine the physiological demands of the motor-cognitive trainings, VO2 was measured using a mobile gas analyzer and compared to the individual VO2max determined during a ramp-test on a treadmill. In addition, average heart rate (HR) and metabolic equivalents (MET) were calculated. Differences in physical demands between the training tasks were determined using repeated measures ANOVA analysis.

RESULTS: Exercise intensity as reflected by oxygen uptake (VO2) ($p<0.001$, eta2 = 0.92) as well as average heart rate ($p<0.001$, eta2 = 0.93) revealed significant differences between trainings. Across the 5 training tasks, intensity varied between 50% to 88% for maximum HR and 22% to 77% for VO2max. The same applied to the MET ($p<0.001$, eta2 = 0.91) that covered a range between 4.1 to 14.9 MET's. Overall, the training tasks covered all categories from light to high exercise intensity.

CONCLUSION: The results suggest that physical exercise intensity in motor-cognitive training can be systematically modulated on the SKILLCOURT by changing the cognitive and motor task demands. While more stationary training involves minimal physical effort corresponding to light intensity, dynamic tasks can be considered vigorous to high intensity exercises. Since the release of neurotrophic factors depends on exercise intensity, the type of physical exercise incorporated into the cognitive task may have a major influence on neural plasticity which should be considered when using motor-cognitive training in sports.

GETTING PAST BASKETBALL DEFENDER IS NOT JUST A MATTER OF SIZE

MORICE, A.1, SOLTANI, P.2
1 AIX-MARSEILLE UNIVERSITY, 2 STAFFORDSHIRE UNIVERSITY

INTRODUCTION: Affordance theory (Gibson, 1977) has been promoted as a relevant framework for understanding information-movement coupling in sport (Fajen et al., 2009). With virtual reality, it is now possible to show how decision-making is shaped by the perception of affordance, notability in "duel" situations against a virtual opponent (Watson et al., 2011). We explored the perception of affordances in basketball, by scrutinizing the possibility to throw without being contested by a virtual defender. We investigated whether expertise, player size, and permission to jump, affect the throwing decision.

METHODS: 20 experienced and 19 novice basketball players were divided into two comparable subgroups, tall and short, based on their median height. Participants had to decide whether it was possible to throw an instrumented ball into a virtual basket without the shot being contested by a virtual animated defender. We manipulated the distance to the virtual defender (0.755, 1.055, 1.3355, 1.655, 1.955, 2.255m) as well as the "permission" to jump for throwing.

RESULTS: Both experienced and novice players threw more frequently as distance to the virtual defender increased ($p < 0.05$). In the jump-allowed condition, all players also had 6% more throws ($p < 0.05$) as compared to the no-jump-allowed condition, shifting the threshold for triggering throws from 1.05 to 1.4m from the virtual defender. Finally, experienced short and tall players behaved similarly (64.58%), while tall novice players threw 20% more frequently than their short counterparts (68.40 vs. 48.93%; $p < 0.05$).

CONCLUSION: These results suggest that the throwing decision is rooted in the perception of both body-scaled (Warren & Whang, 1987) and action-scaled affordances (Fajen & Matthis, 2011). With expertise, the action-scaled can override the body-scaled affordances, particularly by providing sufficient muscle power to propel the ball and compensate short height of release. This may have practical implications for coaches who wish to train their athletes specifically in "duel" situations.

COMPARATIVE EFFICACY OF ROBOTIC AND MANUAL MASSAGE INTERVENTIONS ON PERFORMANCE AND WELL-BEING: A RANDOMIZED CROSSOVER TRIAL

KERAUTRET, Y., DI RIENZO, F., EYSSAUTIER, C., GUILLOT, A.

LABORATOIRE INTERUNIVERSITAIRE DE BIOLOGIE DE LA MOTRICITÉ

INTRODUCTION: Both autogenic and manual massage are proven beneficial in eliciting greater relaxation. However, manual massage elicits more pronounced relaxation state than autogenic massage, as revealed by our previous study comparing both objective and subjective indexes. Also in regards to motor control frameworks, both massage interventions differ. Manual massage mainly engages the person in a retroactive mode of action control. Conversely, autogenic massage involves voluntary actions and therefore engages the person in a proactive mode of action control. With the arise of interactive robotic massage solutions participants can now engage in a novel sensorimotor experience. Real-time interactions with the massage gestures through remote control of the robot allow participants to switch between proactive and retroactive modes of action control. Robotic innovation is represented as a support solution for repetitive and simple tasks, and recently paving the way to sustainability and reproduction of manual massage gestures. Manual massage (MM) interventions can improve psychophysiological states relaxation and well-being. In the present, robotic massage (RM) represents a promising, but currently understudied, solution.

The present single-blind randomized crossover trial aimed at comparing the effects of MM and RM on psychometric, behavioral, and neurophysiological indexes of motor/cognitive performances and well-being.

METHODS: Twenty-one participants experienced two massage intervention targeting back soft tissues. During a first condition, the intervention was performed by a physiotherapist, whereas during a second condition the intervention was performed by a collaborative robot. We collected a series objective and subjective indexes of performances and well-being before and after each massage intervention. We also collected physiotherapist's self-reports of perceived fatigue, tension, and ability to maintain the massage routine.

RESULTS: Skin conductance decreased from the pretest to the posttest in both conditions (partial R-squared = 0.44, 95% CI [0.30, 1.00], $p < 0.001$), although the decrease was more pronounced after MM. While both interventions were associated with improved subjective sensations, e.g. pain, warmth, well-being (partial R-squared = 0.08, 95% CI [0.06, 1.00], $p < 0.001$), MM yielded additional benefits compared to RM. The physiotherapist reported greater fatigue and tension and reduced perceived massage efficiency along with repeated massage interventions. MM outperformed RM to elicit a psychophysiological state of relaxation.

CONCLUSION: RM exhibited a comparable pattern of changes to that of MM, for both objective and subjective indexes of relaxation and well-being. Clinical relevance: RM could represent a prophylactic option to prevent the onset of counterproductive fatigability states in physiotherapists' professional.

THE EFFECTS OF NOVEL GRAPHENE-BASED HEATED GARMENTS ON BODY TEMPERATURE AND PEAK POWER OUTPUT POST-WARM-UP

BEZODIS, N., PARRY, H., BURNIE, L., WALDRON, M., CLAYPOLE, J., CLAYPOLE, A., LEEDER, J., JOHNSON, F., CUNNINGHAM, D., CLAYPOLE, T., KILDUFF, L.

SWANSEA UNIVERSITY

INTRODUCTION: Heated garments can attenuate the drop in muscle temperature often observed during 'heat loss windows' prior to competition (1). However, these garments traditionally use wire heater elements, which are limited by an inability to generate heat uniformly. A printed graphene-based solution enables more uniform heating over larger areas and avoids local hot spots (2). This study aimed to quantify the technical performance of garments containing graphene-based heaters, and the effects of the use of these garments on lower-body peak power output (PPO) following a simulated post-warm up 'heat loss window'.

METHODS: Firstly, in off-person testing, the graphene-based garments were hung inside out whilst images of the heater panels were captured using a thermal imaging camera. Time to reach target temperature, mean temperature, battery life, and rate of temperature decline over battery life were quantified. These were compared to two wire heater-based commercially available garments. Secondly, the graphene-based garments were worn by six participants resting in a controlled 20°C environment for 15-min to assess the effects on body surface temperature using thermal imaging immediately after their removal. Finally, nine participants completed a standardised cycling warm-up, followed by 30-min passive rest in cold (5°C) and temperate (20°C) environments with the graphene-based garment heating either enabled or

disabled (i.e. four trials in total). PPO during counter-movement jumps was assessed at various times pre and post warm-up.

RESULTS: In the off-person testing, the trousers and jacket took 4.4-min and 10.6-min to reach target temperature, respectively. The mean temperature across all panels was 47.0°C (trousers) and 42.7°C (jacket). On full power, the batteries lasted for 2.49-h (trousers) and 3.22-h (jacket), with a temperature decline of 0.6 and 1.2°C/h, respectively. When activated, the garments led to an increase in body surface temperature in all heated regions after just 15-min. Post warm-up, compared to an inactivated worn garment, the activated garments significantly increased skin temperature, thermal comfort and thermal sensation in both cold and temperate conditions (all $p < 0.05$). Core temperature was raised but not significantly at any measured timepoint. When the garments were activated, PPO was 57 W (1.6%) to 145 W (3.9%) greater in the 30-min post warm-up, and this difference was significant in the cold environment after 30-min.

CONCLUSION: Graphene-based heaters integrated into competition-ready garments provided greater heat output than commercial wire-heater garments. The graphene-based garments increased body surface and skin temperature, and attenuated the reduction in PPO during the 30-min post warm-up. Further consideration of garment control and design could improve the practicality and performance further.

CONTRIBUTIONS OF ANKLE JOINT AND GASTROCNEMIUS MUSCLE-TENDON UNIT BEHAVIOR TO REBOUND JUMP PERFORMANCE

TOMARI, K.1, TASAKA, H.1, HOMMA, D.1, MANTECON-TAGARRO, C.J.1, TANAKA, F.2, OTANI, T.2, KAWAKAMI, Y.1

WASEDA UNIVERSITY

INTRODUCTION: The stretch shortening cycle (SSC) type or joint movement has been known as an important aspect of explosive sports activities (1). In the SSC movement such as jumping, involved joints store elastic energy in the flexion (negative) phase, and then release it in the extension (positive) phase which can be optimized by muscle activity (2, 3). However, limited information is available about how inter-individual differences in ankle joint, MTU mechanics and muscle activities affect jumping performance. The purpose of this study is to clarify the inter-relationships of the ankle joint, MTU mechanical work and muscle activity for optimizing the vertical jump performance.

METHODS: Nine subjects (21.5 ± 1.2 yr; mean ± SD) participated in this study. The jump trial was consisted of 5 consecutive rebound jumps (RJ) from the stand position with their arms set at the hips. Subjects were instructed to mainly use the ankle joint, avoiding knee flexion as much as possible, to achieve the highest performance at the final jump. The height of the center of gravity in the final jump was used for the RJ performance. During the RJ trial, the ground reaction force and joint angles (knee/ankle) were recorded using force platforms and goniometers, which were used to calculate the jump height and the mechanical work at the ankle joint and the gastrocnemius MTU. Muscle activities of the gastrocnemius medialis (GM), soleus (SOL) and tibialis anterior (TA) were recorded with surface electromyography (EMG). The relationship of RJ performance and other variables were tested by Pearson's correlation analysis.

RESULTS: The absolute negative work of the ankle joint and GM-MTU were positively correlated with the RJ performance ($r = 0.81$, $p = 0.01$, and $r = 0.77$, $p = 0.02$ respectively). It was suggested that better jumpers stored more elastic energy in the ankle joint as well as the major agonist (GM) during the negative phase, and utilized it for the later jump. There was a significant relationship between RJ performance and the GM muscle activity in the negative phase ($r = -0.77$ $p = 0.02$), suggesting the importance of deactivating the agonist muscle in this phase for achieving a higher jump. The subject showing the greatest amount of negative joint and GM-MTU work was characterized by the largest ankle joint range of motion. It is suggested that the amount of negative ankle joint and GM-MTU work is affected by the excursion of ankle joint, allowing for the storage and release of elastic energy.

CONCLUSION: CONCLUSION: The negative phase in SSC is important, in such a way that the mechanical work of the joint and agonist MTU store the sufficient amount of elastic energy for the better jump performance. Making the ankle joint range of motion larger by deactivating the agonist muscle in its stretch phase, can be the strategy for it.

MUSCLE TENDON KINEMATICS PRECEDING CONTACT DURING LANDING AND DROP-JUMPING

BECHET, R., TISSERAND, R., FRADET, L., COLLOUD, F.

INSTITUT PPRIME

INTRODUCTION: To coordinate joint rotations with the external constraints of a motor task, our Central Nervous System (CNS) programs muscular anticipatory activations [1]. In movements involving large momentum, such as landing (L) or drop-jumping (DJ), electromyography studies suggested that anticipatory activity in bi-articular muscles crossing the hip and knee are mainly responsible for energy absorption rather than propulsion [2]. However, their role during anticipation remains unclear, partly because the kinematic consequences of this anticipatory muscular activity have not been described. This role can be determined with the change in length of muscle tendon unit (MTU). The objective of this study was to characterize the evolution of lower-limb MTU lengths during the anticipation phase and for a 50 ms period following the ground contact (GC), during L and DJ tasks.

METHODS: Ten young healthy participants (5 females and 5 males, 25±5 years old) performed L and DJ from a 50-cm elevated platform, on two forceplates recording the 3D ground reaction forces (GRF) at 2000 Hz. For each subject, only the best trial for L (i.e. the lowest vertical GRF peak) and for DJ (i.e. the shortest contact time) was analyzed. GC was determined when the vertical GRF exceeded 20N. The 3D trajectories of 64 reflective markers placed on anatomical landmarks were recorded by 19 infrared cameras at 200 Hz. MTU lengths of rectus femoris (RF), biceps femoris long head (BF) and psoas major (P), were computed with an individualized full-body musculoskeletal model [3]. MTU kinematics were then computed using MTU length derivatives (negative values for shortening). The onset of MTU length change before GC was also identified. Paired t-tests were performed for each variable to compare between L and DJ.

RESULTS: For all muscles, participants and trials, all MTU changed length before GC and their kinematics where the same before and during the first 50 ms of GC: P shortened and RF lengthened in both L and DJ; whereas BF lengthened in 9 out of 10 subjects during L and shortened in 7 out of 10 subjects during DJ. P tended to shorten later during DJ than during L (56±50 vs 106±62 ms, p=0.08), while there was no difference for the onset of RF lengthening (68±27 vs 66±35 ms, p=0.88). BF started shortening during DJ later than it started lengthening during L (82±64 vs 208±128 ms, p=0.02).

CONCLUSION: These results show that the CNS anticipates by preparing muscle kinematics to the forthcoming constraints of the motor task. These results also suggest that BF could prepare for hip extension rather than favor energy dissipation. Analysis of MTU kinematics reveals how the CNS anticipates for external motor constraints, can inform about the muscular contraction consequences, and could be a biomarker of optimal coordination in sport.

KINEMATIC PROFILE OF ELITE HIGH JUMPERS – WHAT DISTINGUISHES GOOD FROM GREAT HIGH JUMPERS?

PETROVIC, M., GISLADOTTIR, T.

UNIVERSITY OF ICELAND

INTRODUCTION: It has been shown that the success in high jump very often relies on the ability of a jumper to manipulate biomechanical factors that are closely related with optimization of the. Effectiveness in high jumping largely depends on the take-off (TO) action, contact time with the ground, ankle, and knee angles at touch-down (TD) and TO, height of the center of mass (CoM) at TO. We hypothesized that the highest successful attempt will be correlated with kinematic parameters related to peak CoM and peak pelvis position.

METHODS: Data were obtained from the report of Nicholson et al. (2019), on 12 female (body height 182.3±6.9 cm; body weight 63.4±6.8 kg) and 11 male (body height 192.5±2.3 cm; body weight 75.9±6.67 kg) finalist of the IAAF World Championship, that was held in March 2017 in Birmingham, UK. Following variables were analysed and presented: body height; body weight; H1: the height of the centre of mas (CoM) at the instant of touchdown (TD) during the final contact; H2: the height of the CoM at the instant of toe-off (TO) during the take-off phase; H3: peak CoM location; peak pelvis height; knee angle at TD/TO; ankle angle at TD/TO; time spent in knee flexion; time spent in knee extension; TO contact time. Correlations between the highest successful attempt and kinematical parameters, for both women and men, were obtained by calculating Pearson's correlation, by using Jamovi.

RESULTS: In women, significant correlations were found among highest successful jump and peak CoM location (r=0.61, p=0.033) and peak pelvis height (r=0.85, p=0.001). On the other hand, in men, significant correlations were obtained among highest successful attempt and the height of the CoM at the instant TO (r=0.60, p=0.05); peak CoM location (r=0.85, p=0.001); peak pelvis height (r=0.83, p=0.001); and ankle angle at TD (r=0.67, p=0.024).

CONCLUSION: Similar to Čoh & Supej (2008), our study has shown that success in high jump often depends on CoM and pelvis position as well as ankle angle at TD. All jumpers in this study achieved excellent results despite very large variability in kinematic parameters, proving that coordination, strength, and speed patterns are different, but they have not been a disadvantage. From the coaching perspective, training program must be tailormade individually, considering one's physical attributes, strength, and speed qualities as well as individual technical aspects.

CHARACTERISTICS OF KNEE JOINT KINEMATICS IN THE MODIFIED SIDE HOP TEST

YOSHIDA, M., NAKAJIMA, C., ISHIKAWA, R., YOSHIDA, M., YAMAMOTO, K.
HOKUSHO UNIVERSITY

INTRODUCTION: The side hop test (SHT) is a performance test for the functional assessment of the lower extremities after injuries. For assessment using SHT, the patients are asked to hop as quickly as possible on one leg from side-to-side in a 30-cm-wide area. However, because there are no detailed specifications regarding jump height, the jump heights may differ among the patients undergoing SHT. Differences in jump height may affect hopping motion during SHT, and the joint angle or moment in the lower extremity is expected to change. In this study, we aimed to analyze knee joint kinematics during SHT conducted at a defined jump height (modified side hop test, MSHT).

METHODS: Fourteen male with no lower extremity injuries participated in this study (age 19.9 ± 0.9 years ; mean ± SD). All participants underwent SHT and MSHT. The SHT was repeated 10 times for each participant as follows: the participant stood on the test leg and then jumped from side-to-side as fast as possible between two parallel lines placed 30 cm apart. MSHT was performed following the same method as that of SHT, but with the added condition that a 15 cm-high rubber tube was placed in the center of a defined 30 cm-wide area, and the participant was asked to jump without touching the tube. The knee joint angle and moment (flexion/extension, varus/valgus, and internal/external rotation) during both tests were measured and calculated using a 3D motion analysis system and a force plate. The calculated data were normalized based on the results of one cycle of SHT or MSHT (medial landing, lateral hop, lateral landing, and medial hop). Principal component analysis was conducted for statistical analysis. Paired t-tests were used to compare principal component scores for both tests.

RESULTS: Differences were observed in the shape and the size of the graphical curves depicting the knee joint angle and moment data. The principal component scores revealed that the angles of knee flexion during the lateral and the medial hop phases in MSHT were significantly greater than those in SHT ($p < 0.01$). The peak knee extension moments during the lateral and the medial landing phases in MSHT occurred earlier than those in SHT. The magnitude of change in the knee extension moment in MSHT was larger than that in SHT. The values of the knee varus moment during the medial landing phase and the knee valgus moment during the lateral landing phase were higher in MSHT than those in SHT ($p < 0.01$). Moreover, in MSHT, a large knee external rotation moment during the medial landing phase and a large knee internal rotation moment during the lateral landing phase were observed ($p < 0.01$).

CONCLUSION: It was found that when SHT was performed at a certain height, the varus/valgus and the internal/external rotation stresses on the knee joints increased. We suggest that MSHT is an appropriate method for the assessment of functional limitations in patients returning to sports following knee injuries.

OP-MH16 Ageing and resistance training

ASSOCIATION BETWEEN QUALITY OF LIFE AND GAIT VARIABILITY DURING DUAL-TASK IN THE ELDERLY

TOSI, I., FOLADOR, G., GALVANI, C.
UNIVERSITÀ CATTOLICA DEL SACRO CUORE

INTRODUCTION: The decrease of executive functions is a physiological condition associated with aging. In the elderly it becomes essential to focus on the cognitive aspect that intervenes in brain tasks such as memory, but also in motor tasks such as walking. To demonstrate the association between cognition and gait, the dual-task paradigm is widely used, which allows to estimate brain functions in the early stages of cognitive decline, thus allowing to identify the elderly at high risk of progression of dementia, loss of mobility and falls1. The dual-task reflects everyday life situations in which walking must be integrated into another activity2. The aim of this study was to define associations between physical and mental well-being, physical performance and gait variability.

METHODS: Fifteen older adults (8 women and 7 men) were involved in the study (age: 67,7±2,7 yrs; BMI: 25,2±2,5 kg/m2). Quality of life (36 Health Status Survey_SF-36v2)3, physical performance (preferred walking speed_PWS)4, and gait variability (expressed as coefficient of variability_CV of spatiotemporal parameters of gait during dual-task treadmill walking)5 were measured. The dual-task consisted in a counting backward task6.

RESULTS: A significant and positive correlation was found between both SF-36v2 Mental Component Summary (MCS) and Physical Component Summary (PCS) and PWS (MCS: r=0,6; p=0,0250; PCS: r=0,6; p=0,0154). A significant and negative correlation was found between CV stride length and both PWS and MCS (PWS: r=-0,6; p=0,0208; MCS: r=-0,6; p=0,0198). The ability to walk at higher speed was explained by participant quality of life (R2=0,511; p=0,0137), whereas a less variable gait performing a dual-task was explained only by MCS (R2=0,344; p=0,0215).

CONCLUSION: Gait is an attention-demanding task, and any concurrent cognitive task, disturbed walking performance7. Elevated quality of life, both physically and mentally, has been directly related to augmented gait speed. Mental health status affected the ability to walk while performing a dual-task. It seems reasonable to assume that improved mental health would allow to manage the proposed cognitive load and to reduce gait variability.

MUSCLE POWER THROUGH THE CHAIR STAND-UP TEST IN THE SPPB BATTERY

MONFERRER-MARÍN, J.1, ROLDÁN, A.1, CORDELLAT, A.1, MONTEAGUDO, P.1,2, MARCO-BARRIGUETE, I.1, DÍAZ-MARTÍNEZ, A.S.1, GONZÁLEZ, R.3, BLASCO-LAFARGA, N.M., MIR, C., NAVARRO-PÉREZ, J., BLASCO-LAFARGA, C.

1 UIRFIDE, PHYSICAL EDUCATION AND SPORT DEP, UNIVERSITY OF VALENCIA; 2 JAUME I UNIVERSITY; 3 HOSPITAL CLÍNICO VALENCIA; INCLIVA RESEARCH INSTITUTE; 4 CAP AREA CLINICO-MALVARROSA & DR. PESSET, VALENCIA

INTRODUCTION: The five sit-to-stand test (5STS), a clinically valid tool, assesses the trajectory of functional capacity in relation to age by calculating muscle power using the Power-frail app (1). Similarly, the Short Physical Performance Battery (SPPB), which is one of the most widely tests used in the field of assessment of older adults (2), includes the same test but with a different protocol. The present study analyses the muscle power values obtained in the SPPB batterys chair stand-up test, using the Power Frail application in order to compare power outcomes with the 5STS. and study the possibility of unifying the contribution of both proposals in a single measurement.

METHODS: Sixty-five participants (72.55 ± 10.75 years; 70.47 ± 13.11 kg; 27.40 kg/m2 ± 4.57 of BMI; 51 of them women) performed both tests (5STS and SPPB) in randomised order, following the indications of their authors. The protocol was approved by the scientific ethics committee of the University Clinical Hospital of Valencia (2022/172). Later on, both tests were analyzed with the Power-Frail app, adapting its formula (from 5 to 4 cycles). The main percentiles were also considered on normalized and allometric power, as proposed by Alcazar et al. (1): P3, P10, P25, P50, P75, P90, P97, both in the five sit-to-stand test and the SPPB batterys chair stand-up test.

RESULTS: The average values (P50) of 5STS (2.95 W/kg; 80.79 W/m2) and SPPB (3.03 W/kg; 82.47 W/m2) tests showed a Chronbachs α and ICC of 0.89 and 0.94 for normalised power (W/kg), and 0.90 and 0.94 for allometric power (W/m2) respectively. The other muscle power percentiles both for 5STS (P25: 2.51W/kg; 66.20 W/m2; P75: 3.33W/kg; 95.19 W/m2) and SPPB (P25: 2.43W/kg; 68.01 W/m2; P75: 3.51W/kg; 96.11 W/m2) showed within similarity, as wells as with the Spanish sample in the study of Alcazar et al. (3), with identical age, body weight and BMI values.

CONCLUSION: The power values, both relative and allometric, show a high between correlation, confirming their similarity. Percentiles corroborate it, also regarding previous outcomes in the 5STS literature (3). The slight differences among tests could be due to the lower fatigue experienced in 4 complete cycles of the SPPB compared to the 5 cycles of the 5STS. Considering the low energy availability of older adults (4), future studies might confirm the use of the SPPB sit-to-stand test as a valid measure of power, avoiding duplication of tests in those studies that already use the SPPB battery aiming to assess also balance and gait speed.

AN EDUCATIONAL PROGRAM IMPROVES PHYSICAL FUNCTION IN OLDER ADULTS WITH FRAILTY PHENOTYPE: THE FRAGSALUD PROJECT

CASALS, C.1, VÁZQUEZ-SÁNCHEZ, M.Á.2, GONZÁLEZ-MARISCAL, A.1, ÁVILA-CABEZA-DE-VACA, L.1, MIER-PERULERO, A.1, REBOLLO-RAMOS, M.1, CORRAL-PÉREZ, J.1

1. UNIVERSITY OF CADIZ, 2. UNIVERSITY OF MALAGA

INTRODUCTION: Frailty has become a common state in older adults (1). This state has been defined as a progressive physiological and functional decline. Physical function outcomes have been associated as protective factors against frailty (2). Thus, interventions to reduce the impairment of physical frailty are required. This study aims to determine the effect of a health-focused educational program on physical function of older adults with frailty phenotype.

METHODS: This study includes preliminary results from the FRAGSALUD randomized clinical trial. A total of 80 participants with frailty phenotype were randomly allocated in to the intervention group (n=40) and control group (n=40). The invention group assisted to 4 different 1-hour sessions during 6 months focused on key components of frailty such as frailty development, physical activity, nutritional recommendations, and mental well-being. Pre- and post-intervention outcomes included lower body performance (5 repetition sit to stand test) and handgrip strength. Results were analysed with a mixed factorial ANOVA with Bonferroni post hoc comparisons, significance was set at $p<0.05$.

RESULTS: After 6 months of the educational program, the intervention group significantly reduced the time in performing the 5 repetition sit to stand test in 6.5±14.3 seconds ($p<0.05$) and maintained handgrip strength in 0.06±2.27 kg ($p>0.05$),

whereas the control group remained stable for 5 repetition sit to stand test (0.2±11.9 seconds, p>0.05) and decreased handgrip strength (3.42±6.29 kg, p<0.05). A time-by-group interaction was found for both variables (p<0.035).

CONCLUSION: Our results showed that a 6-month educational program focused on the prevention of frailty is able to improve the lower body performance and handgrip strength of older adults with frailty phenotype. Thus, the FRAGSALUD educational program is an effective strategy to reduce the physical function decline in older adults with frailty phenotype which is relevant in an increasingly aging population.

PHYSIOLOGICAL AND PSYCHOLOGICAL EFFECTS OF SHORT-TERM WALKING FOOTBALL IN OLDER ADULTS

BOITHIAS, M.1, BELLI, A.1, LE, T.T.T.2, NICAISE, V.2, GUILLET-DESCAS, E.2

<1>UNIVERSITY OF SAINT ETIENNE, FRANCE ; <2> UNIVERSITY LYON 1, FRANCE

INTRODUCTION: Physical activity (PA) is recommended across the lifespan to maintain good health. PA is also known as an effective and preventive strategy to counteract the detrimental adaptations of the aging process. An active lifestyle and participation in sport are protective factors that play a key role in determining quality of life and well-being in older adults. In this context, walking football (WF) which is a small-sided football games mostly played recreationally at a walking pace is in line with the recommendations for PA in older adults (King & Guralnik, 2010). However, while the physiological effects of WF are well demonstrated (Arnold et al, 2015), there remains a lack of research examining physiological and psychological effects in shorter periods. The aim of this study was then to examine both physiological and psychological effects of short-term walking football in older adults.

METHODS: Fifteen participants (12 men and 3 women; 68.28 ± 5.07 (mean ± SD) years old, range 60-80 years old; 76.33 ± 12.83 kg; 1.73 ± 0.08 m; 25.49 ± 3.00 kg/m2) were asked to practice sessions of walking football during 90 min (including warm-up and cooling) twice a week, during 6 weeks. Before (PRE) and after (POST) the 6 weeks training they performed physiological tests including anthropometric measures and tests from the Senior Fitness Test Manual which gives functional evaluation tools for people over 60 years old. Basic Psychological Need Satisfaction and Frustration questionnaire was also submitted to subjects before and after training.

RESULTS: Body mass and BMI significantly decreased respectively by 1.44% (p<0.5) and 1.57% (p<0.5) in average after the training intervention. There was no significant PRE – POST differences in functional evaluation tests performed for people over 60 years old. A significant difference was found between PRE and POST intervention for the dimensions "frustration of need for autonomy" (p<.05) and "frustration of need for competence" (p<.05). In addition, changes in autonomy need frustration were significantly correlated with changes in body mass (p<0.05, r=0.62) and body mass index (p<0.05, r=0.59).

CONCLUSION: It was expected that regular physical activity could improve general physical fitness. Finally, 6 weeks of walking football were not sufficient to affect significantly physiological parameters except body mass and BMI. At the same time significant psychological benefits were observed and associated with a decrease of body mass and BMI. Further investigations should focus on the influence of longer training periods especially for physical parameters.

THE 12-WEEK RESISTANCE AND AEROBIC EXERCISE INTERVENTIONS ON COMMUNITY-DWELLING OLDER WOMEN: STUDY ON FUNCTIONAL FITNESS BY MEANS OF THE SENIOR FITNESS TEST

HONG, J., WANG, J.

SHANGHAI RESEARCH INSTITUTE OF SPORTS SCIENCE (SHANGHAI ANTI-DOPING AGENCY)

INTRODUCTION: Increasing or maintaining mobility, functional independence and quality of life in older adults are vital in healthy aging. From this perspective, the Senior Fitness Test (SFT) was developed to evaluate functional fitness in older adults, including strength, aerobic endurance, agility/dynamic balance, and flexibility. Evidence has emphasized the significance of physical activities on health-related outcomes in older adults. The purpose of this study was to assess the effects of 12-week resistance and aerobic exercise on functional fitness by means of the SFT in a group of community-dwelling older women.

METHODS: A total of 118 older women (60 to 79 years old) who were willing to participate in program were recruited from communities of Shanghai, China. They were assigned to the resistance training (RT) group, aerobic training (AT) group and control (CON) group. Participants assigned to the RT group received elastic band resistance training (20 minutes/time, 3

times/week) for several body parts. Each body part engaged in 2 to 3 sets of 10 to 15 repetitions for every set, with a rest period of 60 to 90 seconds among sets. Participants assigned to the AT group received moderate-intensity aerobic dance exercises (45 to 60 minutes/time, 3 times/week). The intensity of the exercise was controlled at a moderate intensity through the combination of heart rate and subjective perceived rate of exertion. All trainings involved warm up and recovery activities and were supervised by social sports instructors or fitness coaches. No intervention was applied to the CON group. Anthropometric variables, demographic variables, strength aerobic endurance, agility/dynamic balance, and flexibility were measured at baseline (T0) and immediately after the 12-week period intervention (T1).

RESULTS: In total, 97 female participants (mean age: 65.0 ± 4.3 years) completed 12-week intervention program. The RT group consisted of 32 participants (65.0 ± 3.4 years), and the AT group consisted of 36 participants (63.8 ± 4.3 years), and the CON group consisted of 29 participants (66.6 ± 4.7 years). Four performances out of six tests of the SFT were found significantly changed. In the RT group, upper-body flexibility significantly improved (back scratch test: T0 = -1.3 ± 12.1, T1 = 1.2 ± 7.9, p< 0.05). In the AT group, upper-body strength significantly decreased (30-second arm curl test: T0 = 24.7 ± 4.3, T1 = 22.8 ± 3.7, p < 0.05). In the CON group, upper-body strength (30-second arm curl test: T0 = 24.7 ± 5.2, T1 = 21.6 ± 4.5, p < 0.05), lower-body strength (30-second chair stand test: T0 = 24.4 ± 6.4, T1 = 21.8 ± 5.8, p < 0.05), and lower-body flexibility significantly declined (chair sit-and-reach test: T0 = 12.5 ± 7.9 cm, T1 = 9.4 ± 8.5 cm, p < 0.05)

CONCLUSION: The 12-week resistance and aerobic exercise programs was efficient in improving flexibility, and preventing strength decline in community-dwelling older women. However, no effects on aerobic endurance, and agility/dynamic balance were observed.

EFFECT OF EXERCISE BEFORE AND/OR DURING TAXANE-CONTAINING CHEMOTHERAPY TREATMENT ON CHEMOTHERAPY-INDUCED PERIPHERAL NEUROPATHY IN WOMEN WITH BREAST CANCER

BROWNSON-SMITH, R., ORANGE, S.T., CRESTI, N., HUNT, K., SAXTON, S., TEMESI, J.

NORTHUMBRIA UNIVERSITY

INTRODUCTION: Taxane-containing chemotherapy regimens can lead to dose-limiting chemotherapy-induced peripheral neuropathy (CIPN) in breast cancer patients. CIPN often persists beyond treatment termination and is accompanied by fatigue. Both CIPN and cancer-related fatigue are associated with reduced health-related quality of life (HR-QoL). Current reviews of the literature indicate that exercise peri-chemotherapy (including after) can improve CIPN, HR-QoL and fatigue levels. However, post-chemotherapy interventions could be tracking a natural easing of CIPN symptoms and improvement of QoL, therefore aiding rehabilitation as opposed to modulating CIPN symptom severity. A review is yet to be conducted that investigates how exercise only before and/or during taxanes impacts these outcomes. The purpose of this systematic review with meta-analysis was to assess the efficacy of exercise intervention implemented before and/or during taxane-containing chemotherapy regimens on CIPN, HR-QoL and fatigue in women undergoing breast cancer treatment.

METHODS: An electronic search of PubMed, EMBASE, Cochrane Central, SPORTDiscus, CINAHL, ClinicalTrials.gov, and ISRTCN was run independently by two authors from inception to 15th September 2022. Randomised controlled trials (RCTs) reporting on the effects of exercise interventions in women with breast cancer who were receiving taxane-containing chemotherapeutic treatment were selected. Two independent reviewers screened the search results and extracted data from eligible trials. Meta-analyses were performed to evaluate the effects of exercise on CIPN symptoms, HR-QoL and fatigue. Standardised mean differences (SMDs) with 95% confidence intervals (CIs) were pooled using random effects models. The review was registered via PROSPERO (CRD42021272036).

RESULTS: Ten trials involving exercise interventions ranging between 2-12 months were included. The combined results of four RCTs consisting of 171 participants showed a reduction in CIPN symptoms in women who exercised versus usual care controls (standardised mean difference -0.71, 95% CI -1.24 to -0.17; p=0.012; moderate-quality evidence, I2=76.9%, (p<0.001)). A meta-analysis which included data from six RCTs with 609 participants showed that exercise interventions before and/or during taxanes-containing chemotherapy improved HR-QoL (SMD 0.42, 95% CI 0.07 to 0.76; p=0.03; moderate-quality evidence, I2=49.6% (p=0.06)). There was no difference in cancer-related fatigue between exercise and usual care groups (SMD -0.39, 95% CI -0.95 to 0.18; p=0.15).

CONCLUSION: This systematic review found reduced levels of CIPN symptoms and an improvement in HR-QoL in women with breast cancer who exercised before and/or during taxane-based chemotherapy versus usual care controls. This evidence supports the role of exercise as an adjunctive treatment for attenuating the adverse effects of taxane-containing chemotherapy on CIPN symptoms and HR-QoL.

ASSOCIATION BETWEEN SELF-REPORTED HEALTH MONITORING OUTCOMES WITH QUALITY OF LIFE IN PATIENTS WITH BREAST CANCER INVOLVED IN HIGH INTENSITY INTERVAL TRAINING DURING CHEMOTHERAPY

KLAVINA, A., CESEIKO, R., CAMPA, M., LLORENTE, A.

LATVIAN ACADEMY OF SPORT EDUCATION

INTRODUCTION: During chemotherapy patients with breast cancer (BC) often exposed to physical discomfort, sleep disturbances, psychological and emotional stress that adversely effects their quality of life. Physical exercise interventions for patients with BC may reduce fatigue, decline of functional skills, improve physical fitness, self-esteem and quality of life. Traditionally, quality of life is assessed before and after intervention, while no studies have explored association between health symptoms and overall quality of life of patients with BC involved in high-intensity interval training (HIIT) throughout the NT therapy. In this study we examined the relationship between quality of life and weekly self-reported health monitoring outcomes in women with BC participating in HIIT during NT.

METHODS: Fifteen women (mean age 47.40, SD = 8.38 years) with newly diagnosed breast cancer (stage II and III) and prescribed neoadjuvant chemotherapy were randomized to HIIT group (n= 8) and control group (CG) (n = 7). The HIIT group participated in 4x4 min interval walking training at 85–95% HRmax with 3 min of active resting periods at 70% HRmax between each interval 3x/week for 6 months. All participants completed the European Organisation for Research and Treatment of Cancer questionnaire (EORTC QLQC30) with the BR module supplement (BR23) before and after the study. In addition, weekly self-reported health monitoring was applied by using online survey including seven questions related to physical and psychological complaints, pain, fatigue, social life and side effects of the chemotherapy.

RESULTS: After NT treatment the HIIT group in total presented 32 (28%) high significant correlations between weekly health monitoring and quality of life outcomes. For example, the psychological and social health variables presented high significant correlations with eight EORTC QLQC30, BR23 subscale outcomes related to Symptom Scale (r = -.826, p =.001; r = -.970, p = .00, respectively), Functional Scale (r = .862, p = .006 and r = 814, p = .014, respectively), Body Image (r = 723, p = .043 and r = .723, p = .043), NT Side Effects (r = -.934, p = .000 and r = - 852, r = .006) and Breast Symptoms (r = -.814, p = .014 and r = -.951, p = .000, respectively). In opposite, CG presented only one significant correlation between the weekly social health variables and Social Scale of the EORTC QLQC30 (r = -.971, p = .001).

CONCLUSION: HIIT improved health, reduced side-effects of NT and contributed quality of life of patients with BC during six months of the neoadjuvant chemotherapy in patients with breast cancer.

SUGGESTED TARGETS FOR IMPROVING EXERCISE INTERVENTION COMPLETION IN CANCER PATIENTS – AN INDIVIDUAL PATIENT DATA META-ANALYSIS FROM THE POLARIS STUDY

WESTERN, B., IVARSSON, A., DEMMELMAIER, I., VISTAD, I., BERNTSEN, S., BUFFART, L.M.

UNIVERSITY OF AGDER

INTRODUCTION: Physical activity has been associated with reduced cancer morbidity and mortality, improved health, reduced treatment side effects, and better quality of life in patients with cancer. Targeted exercise prescriptions accounting for individual prerequisites have been called for to support physical activity promotion in the cancer follow-up and to ensure feasibility of exercise programs. Exercise intervention effectiveness and feasibility depends on the participants' ability to complete the interventions. Patients with cancer not completing exercise interventions are often insufficiently assessed and dropout rates differ considerably between studies. The objective of the present study was to assess which participant- and intervention characteristics were associated with non-completion across different exercise interventions in patients with cancer.

METHODS: We used harmonized individual patient data from the intervention arms of 34 RCTs (n= 2487) investigating effects of exercise in patients with cancer treated with curative intent, available through the POLARIS database. Participant characteristics included age, sex, educational level, body mass index (BMI), and cancer type. Intervention characteristics included intervention timing, exercise type, exercise intensity, supervision, number of weekly exercise sessions, exercise session duration, and intervention duration. An adjusted logistic regression model was used to study associations with non-completion in the total sample. A decision tree was further applied to assess interactions between variables resulting in the greatest separation of intervention completers and non-completers.

RESULTS: In the total sample, post treatment interventions (OR 2.5, p<0.01)), durations >6 months (OR 3.2, p<0.01), resistance (OR 7.5, p<0.01) and mixed exercise (OR 4.6, p<0.01), BMI (OR 1.06, p<0.01), and low-medium education (OR 1.6, p<0.05) was positively associated with non-completion of exercise interventions. The decision tree split the sample on BMI 28.4, intervention timing and intervention duration, resulting in four distinct subgroups. In participants with BMI ≤28.4, non-completion was 5.1% in patients exercising during treatment and 9.8% in patients exercising post treatment. In participants with BMI >28.4, non-completion was 10.8% in patients assigned to interventions lasting ≤6 months and 20.7% for durations >6 months.

CONCLUSION: Significant associations with non-completion were observed for intervention timing, intervention duration, exercise type, BMI and education. BMI, and intervention timing and duration divided the sample into subgroups with the highest and lowest levels of non-completion ranging from 5.1-20.7%. These associations may have implications for the feasibility and effectiveness of exercise interventions in patients with cancer. Approaches to facilitate completion should be further assessed in cancer patients with high levels of non-completion, informing the development of tailored exercise prescriptions.

CANCER-RELATED FATIGUE OF BREAST CANCER PATIENTS IS MAINLY CAUSED BY THE EMOTIONAL DIMENSIONS AT DIAGNOSIS: PRELIMINARY RESULTS OF THE BIOCARE FACTORY COHORT

LECLERCQ, A.1, MOREL, B.2, CHATRENET, A.1, BOURGEOIS, H.3, COJOCARASU, O.4, RAHMANI, A.1

1 LE MANS UNIVERSITÉ, MIP; 2 UNIVERSITÉ SAVOIE MONT BLANC, LIBM; 3 ELSAN-CLINIQUE VICTOR HUGO, CENTRE JEAN BERNARD, LE MANS; 4 CENTRE HOSPITALIER, LE MANS

INTRODUCTION: Cancer-related fatigue (CRF) is defined by persistent and distressing tiredness, and lack of energy associated with cancer and its treatment, that does not subside with adequate sleep or rest, and is disproportionate to recent activity [1]. CRF is multidimensional in its manifestation involving physical, emotional, and cognitive dimensions. Little research has been done to identify the CRF specific dimensions at diagnosis moment. This study aimed to identify correlates of CRF based on sleep disturbance, depression, cognitive ability and neuromuscular fatigability parameters.

METHODS: This study is part of the BIOCARE Factory project, that aims to build a biopsychosocial model of CRF. Fifty-three patients (54±12 years) volunteered to participate in this study. CRF were assessed using the FA12 questionnaire. Patients were classified as 'Fatigued' when the FA12 total score was higher than 22 [2]. Critical force (FCr) of the ankle plantar flexors was determined during an all-out isometric test as the mean force during the last minute (in N.kg-1). Cognitive ability, Depression symptoms and sleep quality were assessed respectively with MOCA, HAD and PSQI questionnaire. The depression and sleep scores were reversed (the higher the better) so being in the same direction as the other variables. Fatigue vs. non-fatigue groups were compared using a T-test. A principal component analysis (PCA) was used to describe the variation of FA12 with a combination of MOCA, Depression, PSQI scores and FCr.

RESULTS: T-tests and PCA revealed that the non-fatigue group was less depressed, sleep better and has fewer cognitive impairments than the fatigue group, the FCr being not different. Principal components 1 and 2 accounted for 33.5% and 30.1% respectively. PCA reveals that Depression and FCr, were independently related on fatigue (orthogonal directions of the PCA).

CONCLUSION: The comparison between breast cancer patients before any treatment, and a healthy population matched in age reveals no difference in the physical dimension of CRF with the FA12 [3]. However, differences between the two populations are observed in the emotional and cognitive dimensions of CRF. Only the depression, The MOCA and the PSQI stand out as significant, unlike FCr. So, neuromuscular fatigability is not a defining feature of CRF at diagnosis although the physical dimension is known to became of major importance after the first line of treatment and in particular after chemotherapy. The heterogeneity of fatigue profiles, as suggesting by the PCA, could be relevant to insist on individualized supportive care according to each profile.

INTRODUCTION: Breast cancer survivor (BCS) women are at increased risk for developing diabetes and metabolic syndrome compared to cancer-free women [1]. Aerobic exercise is an effective strategy for improving glycemic control; however, the association between exercise and glucose homeostasis in BCS has remained inconclusive [2]. The main aim of this study is to evaluate the effects of a supervised aerobic exercise training program on glycemic control in BCS.

METHODS: Sixteen non-diabetic BCS were randomly assigned to an intervention arm (IA; n = 8) or control arm (CA; n = 8). Both groups received lifestyle recommendations, in addition the IA received a 12-week aerobic exercise training program with a progressive increase of exercise intensity (40%-70% of HRR) and duration (20-60 min). Anthropometric measurements (BMI, weight, waist circumference, % body fat) and metabolic markers (glucose, insulin, triglycerides, LDL and HDL) were analysed at baseline and after the 12-week intervention period. Moreover, food intake and indices of glycemic variability obtained by continuous glucose monitoring (CGM) were analysed in the first and last 14 days of the study intervention.

RESULTS: At the end of the study, the VO2max increased by 2.2% in the CA group (p=0.64) and by 16.4 % in the IA group (p=0.02). The fasted insulin level was reduced in both CA (–34%, p=0.01) and IA (–18.5%, p=0.05) groups. Anthropometric measurements and other metabolic markers did not improve after the intervention period. The caloric intake was increased at the end of the study both in CA (19%, p=0.06) and IA (28.1%, p=0.03). The analysis of 24h CGM data reveals that time spent in hyperglycemic state (glucose >140 mg/dL) slightly increased in the CA group after the intervention period, while it remained stable throughout the study in the IA group. The baseline patients BMI and the improvement of VO2max were strong predictors for the reduction of intraday glucose variability indices.

CONCLUSION: Anthropometric and metabolic parameters were only slightly modified after the 12-week aerobic exercise program in BCS, despite a significant improvement in the cardiorespiratory fitness. The increased caloric intake observed at the end of the study might at least partially explain these findings. Interestingly, the CGM data showed that BCS with high BMI and those who strongly improved their VO2max ameliorated the time spent in hyperglycemic ranges and glucose variability indices.

MORNING AND EVENING PHYSICAL EXERCISE PROLONG NON-REM SLEEP: AN ECOLOGICAL STUDY

GOLDBERG, M.1, PAIROT DE FONTENAY, B.1, BLACHE, Y.1, DEBARNOT, U.1,2

1 INTER-UNIVERSITY LABORATORY OF HUMAN MOVEMENT BIOLOGY-EA 7424, UNIVERSITY CLAUDE BERNARD LYON; 2 INSTITUT UNIVERSITAIRE DE FRANCE

INTRODUCTION: Relationship between physical exercise and sleep has received considerable attention with the ultimate goal to promote health and wellbeing [1]. Sleep hygiene guidelines advised to avoid vigorous exercise 3h before bedtime as the increasing of arousal, body temperature and heart rate may disturb sleep quality [1]. Yet, such recommendation is challenged by recent findings that did not find any objective (i.e. architecture) or subjective sleep deteriorations following evening vigorous exercise [2], and some emphasized even positive changes on sleep architecture [3]. Besides, there is a lack of knowledge on the comparison between morning and evening vigorous exercise on sleep features, while morning being the recommended training time [1]. Nowadays, recent advances in ambulatory EEG-sleep technologies provide the opportunity to examine the influence of exercise timing on both combined objective and subjective outputs in daily life context. Here, we investigated whether a vigorous aerobic exercise performed either in the morning or in the evening influences the objective and subjective sleep features in an ecological context.

METHODS: Sixteen recreational runners were tested during two sessions of three successive days separated by a week. Participants had to perform a 45 to 60 min completed-run (70 % VO2) in their own environment either in the MORNING (30 min to 2h after waking up) or in the EVENING (2h to 30 min before sleep); a REST control day separated the two exercise conditions. Sleep was objectively assessed by means of wireless electroencephalography -headband and subjectively using the Spiegel sleep inventory. Actimeters were further used to control both exercise timing and intensity.

RESULTS: As compared to REST, we found that both MORNING and EVENING exercises significantly increased the durations of non-rapid eye movement sleep (NREM, +24.9 min and +22.7 min [p = 0.01], respectively). Such NREM lengthening was mainly due to the increase in sleep stage 2 (N2) duration after both MORNING (+20.8 min) and EVENING (+22.8 min) relative to REST (p = 0.02). No effect of exercise timing was found on the subjective perception of sleep quality.

CONCLUSION: The main finding revealed that independently of the training time (MORNING or EVENING), vigorous exercise extends NREM duration and especially stage N2 duration. Prior studies observed that prolactin and growth hormone secretions occur mainly during NREM, and have been associated to neural and peripheral restoration [4]. This ecological study provide evidence that evening vigorous exercise has no adverse effect on sleep compared to morning exercise and may even adjust sleep architecture required to recover compared to no physical exercise. Because of the numerous health beneficial effects of physical exercise, sleep hygiene guidelines should be updated to promote vigorous exercise regardless the time of the day.

IMPROVED SLEEP QUALITY AFTER THREE MONTHS OF BALANCE LEARNING IN OLDER ADULTS

SCHERRER, S., EGGER, S., WICK, A., RASCH, B., LAUBER, B., TAUBE, W.

UNIVERSITY OF FRIBOURG

INTRODUCTION: Almost every second adult over the age of 60 reports having sleep problems [1]. Cognitive behavioural therapy and pharmacotherapy are the most commonly employed treatments against insomnia. Unfortunately, these two treatments are either associated with high costs or increased mortality and fall rates [2]. Therefore, there is a need for new effective and affordable treatments without severe adverse effects. An important role for the initiation and maintenance of sleep is attributed to the modulation of cortical inhibition [3]. Moreover, it has been shown that cortical inhibitory control is reduced in older adults compared to younger adults [4]. As intracortical inhibition was enhanced following balance learning in young adults [5], we hypothesized that three months of balance learning would enhance intracortical inhibition in older adults. Accordingly, we also hypothesized that balance learning would improve sleep quality in older adults.

METHODS: Thirty-six healthy volunteers aged 65-85 years were randomly assigned to either follow a three-month balance learning intervention (minimum of 30 training sessions) or to continue with their daily routines. Before and after the three-month period, balance performance and short interval intracortical inhibition (SICI) while balancing on a wobble board were evaluated. Furthermore, sleep quality was assessed before and after the intervention with the Pittsburgh Sleep Quality Questionnaire (PSQI). Differences between pre and post measurements were analysed using paired t-tests and Wilcoxon signed-rank tests.

RESULTS: Balance performance improved significantly after balance learning (decrease of sway area on the wobble board by 29 %, p = 0.005) while SICI measured on the wobble board slightly increased by 5.1 % (+ 42 %, p = 0.066). Most importantly, the overall PSQI score decreased significantly by 1.2 score points (- 21 %, p =0.037), indicating better sleep quality after balance learning. No significant changes were observed for the passive control group.

CONCLUSION: After three months of balance learning, older adults showed an improvement in balance performance, a task-specific upregulation of intracortical inhibition and an improvement in their subjective sleep quality. These results suggest that balance learning improves sleep quality in older adults. Furthermore, enhanced GABA-mediated cortical inhibition might be one of the underlying mechanisms driving this change.

THE EFFECT OF LONG-TIME ENDURANCE EXERCISE ON SLEEP CHARACTERISTICS IN ELDERLY

BERISHA, G.1, KOVÁCOVÁ, K.1, ORESKÁ, L.1, BUZGÓ, G.1, CERNÁCKOVÁ, A.1, HAMAR, D.1, CVECKA, J.1, KERN, H.2, LÖFLER, S.2, ZEMAN, M.1, STEBELOVÁ, K.1, OKULIAROVÁ, M.1, SEDLIAK, M.1

1 COMENIUS UNIVERSITY IN BRATISLAVA, SLOVAKIA; 2 INSTITUTE FOR PHYSICAL MEDICINE, PHYSIK UND RHEUMATHERAPIE, ST. PÖLTEN, AUSTRIA;

INTRODUCTION: Ageing is associated with changes in sleep characteristics. The senior population generally experience a higher frequency of nocturnal awakenings, lower sleep efficiency and shorter sleep time. Aerobic exercise helps to improve sleep quality, there is a reduced frequency of night awakenings and preservation of the length of sleep stages compared to seniors with a sedentary lifestyle. This study aims to investigate effects of long-term endurance exercise on sleep characteristics in elderly.

METHODS: The study involved a total of 20 healthy male subjects divided into two groups: 1) master endurance runners (MA; n = 10, age range 65–80 years); 2) elderly sedentary (ES; n = 10, age range 65–80 years). The group of master endurance runners involved only the active marathon runners performing more than 150 minutes of running activity in higher intensity (for at least 15 years). Sleep characteristics were measured by the MotionWatch8© wrist-worn actigraphy unit (MW8) (CamNtech; Cambridge, UK). Participants wore the actigraphy on a non-dominant wrist during the entire 10-day period. Obtained data were analyzed by using the MotionWare software. To detect the difference between groups in sleep characteristics including assumed sleep (AS), actual sleep time (AST), immobile mins (IM), sleep efficiency (SE) and fragmentation index (FI), Mann Whitney U-test was used.

RESULTS: Mean AS was 7:42 ± 0:28 h in MA and 6:34 ± 0:49 h in ES. Significant differences were found between the groups (U = 11.5; P = 0.002). Mean AST was 6:33 ± 0:25 h in MA and 5:33 ± 0:45 h in ES. The difference between groups was significant (U = 9; P =0.001). IM was significantly longer in MA (6:39±0:26 h) compared to ES (5:40 ± 0:43 h; U = 10; P = 0.002). Surprisingly, no significant difference was found in SE (MA = 84.53±7.6 % and ES = 82.88±4.08 %; P = 0.218). The FI score was 29.15 ± 14.95 in MA and 30.81 ± 6 in ES. There is no significant difference between these groups either (U = 35; P = 0.2799).

CONCLUSION: As hypothesized, endurance running exercise seems to be an effective tool to maintain sleep duration even when ageing occurs. There was no significant difference in sleep efficiency and fragmentation index. Master endurance runners had significantly longer immobile mins than elderly sedentary.

THE LIKELIHOOD OF TACKLER SUCCESS WHEN CONTACTING THE BALL-CARRIER AT DIFFERENT HEIGHTS FOR DIFFERENT TYPES OF TACKLES ACROSS YOUTH, SENIOR AND ELITE LEVELS

HENDRICKS, S., TILL, K., SCANTLEBURY, S., DALTON-BARRON, N., GILL, N., DEN HOLLANDER, S., KEMP, S., KILDING, A., LAMBERT, M., MACKRETH, P., OREILLY, J., OWEN, C., SPENCER, K., STOKES, K., TEE, J.

UNIVERSITY OF CAPE TOWN AND LEEDS BECKETT UNIVERSITY

Tucker, R., Vaz, L., Weaving, D., Jones, B.

INTRODUCTION: Reducing head injury, at all levels, is a top priority for rugby stakeholders and governing bodies. Accordingly, World Rugby and national governing bodies have proposed tackle law changes to lower the height of a legal tackle. Any tackle technique injury prevention strategy that negatively affects tackle performance is not likely to be accepted and implemented by players or coaches. If where the tackler contacts the ball-carrier (i.e. tackle height) is going to be a key tackle injury prevention strategy, its relationship to tackle success needs to be studied at the different levels of play. The purpose of this study was to compare the probability of tackler success when contacting the ball-carrier at different heights for different types of tackles across seven levels of play.

METHODS: Video footage of 271 male rugby union matches were analysed for tackle characteristics across seven independent playing groups (Under(U) 12, n=25 matches; U14, n=35; U16, n=39; U18 Amateur n=39; U18 Elite n=38; Senior Amateur, n=40; Senior Elite, n=50) within England, New Zealand, South Africa, Portugal and USA. This equated to a total of 52 204 tackle events. A logistic regression model with type of tackle, tackle direction, first point of contact, tackle sequence, number of players, and attacker intention as explanatory variables and tackle success as the outcome variable was computed. Based on the model, post-estimation marginal effects were used to determine the probability of success (Pr Tackler Success) for the interaction between type of tackle (arm, active shoulder, passive shoulder, smother) and the first point of contact (head/neck, shoulder, mid-torso and legs). Differences between Pr margins were also calculated, with the a priori alpha level set at $p<0.05$.

RESULTS: Within senior elite, senior amateur, U18 amateur, U14 and U12, for all four types of tackles, the probability of success did not significantly change ($p>0.05$) when contacting the head/neck compared to the other points of contact (for instance, for active shoulder tackles within senior elite: head/neck Pr 0.84 95% CI 0.86-0.89; shoulder Pr 0.87 95% CI 0.86-0.89, mid-torso Pr 0.83 95%CI 0.81-0.85, legs Pr 0.81 95%CI 0.79-0.83). For tackles within the legal tackle height, irrespective of type of tackle, the contact point with a high probability of success at all levels was the shoulder (for instance, at the senior elite arm Pr 0.75 95% CI 0.74-0.77; active shoulder Pr 0.87 95% CI 0.86-0.89, passive shoulder Pr 0.84 95%CI 0.82-0.86, smother Pr 0.86 95%CI 0.84-0.87).

CONCLUSION: Contacting the head/neck area does not benefit tackling performance and contacting lower areas of the ball-carrier has a higher likelihood of tackler success. These findings complement video analyses studies on tackle injuries. Knowing that contacting the head/neck area does not benefit the tackler's ability to succeed strengthens and supports injury prevention initiatives that is aimed at encouraging players to contact the ball-carrier lower.

OP-BM26 Kinematic

EFFECT OF COMPUTING JOINT ANGLES IN 2D OR 3D DURING FATIGUING DOUBLE POLING CROSS-COUNTRY SKIING EXERCISE

DANIELSEN, J., SEVERIN, C.

NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY

INTRODUCTION: Human movement typically occurs in all three planes in three-dimensional (3D) space, and it is often recommended to use 3D analysis when studying kinematics such as joint angles. In movements that appear to be uniplanar, e.g., cycling (sagittal plane), the difference between computing the knee angle using 3D or 2D (sagittal plane) kinematics is trivial. In double poling (DP) cross-country (XC) skiing, most of the movement appear to take place in the sagittal plane but considerable movement occur also in the other planes. However, much of the XC-skiing literature on kinematics are inconsistent and unclear in the reporting of how joint angles are computed, and both 2D and 3D analyses are used. It is likely that kinematic results presented across studies are affected by whether 2D or 3D analyses were performed. The purpose of this study was to examine the difference between XC-skiing kinematics obtained using 2D and 3D methodology. In addition, we examined if a possible fatiguing effect exists on kinematics and whether this effect is dependent on methodology.

METHODS: Nine XC-skiers performed 2 h of continuous roller skiing on a large treadmill, utilizing the DP technique only. Each skier performed at an individual constant speed of 65% of their DP VO2peak (at 6% incline). Motion capture (Qualisys, 100 Hz) tracked reflective markers for ~60 s for each 20 min of the 2 h protocol. Ankle, knee, hip, shoulder, and elbow

joint angles were computed using both 2D and 3D kinematics1,2. Linear mixed models were fitted, with participants as random effects (intercept only), and method (2D vs 3D) and time as fixed effects.

RESULTS: For sagittal plane range of motion (ROM), there were no interaction effects between time and method for any joint (all $p>0.6$). There was a significant effect of fatigue on ROM for the hip joint ($p=0.046$), with reduced ROM (~2-3deg), with no effect of fatigue on any other joint. The 2D yielded slightly smaller sagittal plane ROM for the ankle and knee (both ~2-3 deg, $p<0.001$), while it yielded considerably larger sagittal plane ROM for the hip (~25 deg), shoulder (~10 deg) and elbow (~9 deg, all $p<0.001$). In the frontal plane, there was a large effect of method on (abduction-adduction) ROM for the shoulder, ($p<0.001$), with 2D yielding ~47 deg larger ROM, while there was no effect of fatigue here.

CONCLUSION: These results indicate that computation method used (2D or 3D) in the study of XC-skiing kinematics may have a major impact on the calculated joint angles. However, we found no interaction effects between method and fatigue, which suggest that the differences due to method are not dependent on fatiguing exercise. Further, we found only small effects of fatigue in general, with joint angles becoming somewhat smaller over time. Both science and practice must take computation method used into account when comparing XC-skiing kinematics across studies.

ESTIMATING ABSOLUTE 3D HUMAN POSE ESTIMATION WITH INDIVIDUAL BODY SHAPE INFORMATION FROM A SINGLE CALIBRATED CAMERA

CHIU, C.

SPORTS ENGINEERING RESEARCH GROUP, SHEFFIELD HALLAM UNIVERSITY

INTRODUCTION: Accurate sports biomechanical analysis often requires an understanding of joint locations. Conventionally, this was typically achieved by the use of multiple cameras to measure 3D joint locations. Recently, advanced machine learning techniques have been developed to estimate 3D human poses from images captured from a single camera. However, this kind of method usually does not consider the individual body shape information thoroughly. As a result, only joint rotation can be obtained. The accurate absolute joint position including the body translation cannot be acquired for sports biomechanical analysis. This research aims to examine whether absolute 3D human pose can be estimated from the image captured by a single calibrated camera with known body shape information.

METHODS: The BML-MoVi dataset (Ghorbani et al., 2021) was used to generate data to evaluate the developed method. This dataset, acquired from the Archive of Motion Capture As Surface Shapes (AMASS) database (Mahmood et al., 2019), includes 3D joint positions, joint rotations, and body shape information for 86 participants performing different movements. The 2D pose estimation results were generated by projecting 3D joint points. The non-translated 3D joint locations were estimated using the deformable human models with inputted joint rotations and body shape information. The body translations were predicted from these 2D pose estimation results and non-translated 3D joint locations using the pose computation techniques. The mean error between the ground truth and the predicted absolute 3D joint location was calculated to determine the performance of the developed method.

RESULTS: The mean error between the ground truth and the prediction with body information is 0.018 m which is better than the performance of the estimation with mean body shape (0.023 m) and random body shape (0.063 m). The findings suggest that considering body shape information can improve the absolute pose estimation with the accuracy of 3D joint locations.

CONCLUSION: The results showed that incorporating body shape information can enhance absolute 3D human pose estimation from the images captured by a single calibrated camera. Further tests with real-world data are necessary to investigate the effect of error in joint rotation on the accuracy of the developed methods.

ANALYSIS OF KEY KINEMATIC FACTORS AFFECTING PERFORMANCE OF MENS SINGLE 10M PLATFORM 109C

WANG, X.

BEIJING SPORT UNIVERSITY

INTRODUCTION: To analyze the correlation and regression results of kinematic parameters and performance in each stage of 109C, and to determine the key kinematic parameters affecting the performance of mens single 10m platform 109C.

METHODS: Three digital 4K all-in-one recording machines (Sony FDRAX700) were used to shoot the 109C movements of 6 high-level mens single 10m platform divers with two-dimensional fixed points, and the Fastmove 3D Motion analysis system was used to analyze the 21 human body points frame by frame. The coordinates and kinematic parameters of the human body in two-dimensional space are obtained.

RESULTS: The overall movement time in the air had a significant positive predictive effect on the 109C score (t = 7.842, P < 0.01), while the average time of the somersaults had a significant negative predictive effect on the 109C score (t = -2.817, P < 0.05).

CONCLUSION: The time in the air and the average time of the four somersaults are the key kinematic parameters affecting the mens single 10-meter platform 109C diving score. Increasing the take-off height is the key to extending the time in the air. The average time of the four somersaults is an important part of the time in the air. Thus, it is extremely important to shorten the average time of the four somersaults to improve the performance of the 109C movement.

INFLUENCE OF A SOFT-BACK EXOSKELETON ON TRUNK KINEMATICS AND MUSCLE ACTIVITY DURING SIMULATED ORDER PICKING

THEVENOT, C., FAVENNEC, A., PIERRE, X., MORNIEUX, G.

UNIVERSITÉ DE LORRAINE

INTRODUCTION: Due to required handling flexibility in intralogistics, most of the working tasks in this field, such as palletizing, are performed manually [1]. However, low back pain (LBP) risk factors are associated with this type of task, i.e repetitive lifting, forward bending and heavy weight manipulation. The use of exoskeletons might be a solution to reduce the prevalence of LBP [2], and could reduce kinematics and muscular stress during manual palletizing [3].

The aim of this study was to evaluate the effects of an exoskeleton during a simulated manual palletizing task on trunk kinematics and neuromuscular activity.

METHODS: Eight male volunteers performed a simulated manual palletizing task with the soft-back exoskeleton CORFOR® (EXO) and without (FREE), using two different lifting techniques as usually found in the industry, i.e the STOOP and SQUAT techniques. This exoskeleton is made of a pair of elastic bands attached to shoulders and knees, stretched during hip and trunk flexion. The participants had to move a 7kg box from one pallet to another for 2 minutes at a rate of 5 handlings/min. Participants were familiarized to the exoskeleton before starting the experiment. The configuration of the task replicated the one typically carried out in the company and a soundtrack recording of the work environment was played during the task execution.

3D kinematics data were collected (Arqus A12, Qualisys, Sweden) to access trunk sagittal inclination (TSI) and trunk angular velocity (TAV). Muscle activity of erector spinae (ES), rectus abdominis (RA), obliquus externus (OE), rectus femoris (RF) and biceps femoris (BF) was recorded with surface EMG (Trigno, Delsys, USA) and their RMS value was averaged over all cycles.

RESULTS: No difference was observed for TSI or TAV during palletizing with EXO compared to FREE.

Also, no difference was found on the ES muscle activity in EXO compared to FREE (p=0.17), despite some slight reductions observed when using the exoskeleton during the STOOP (-4.0 ± 3.3%) or the SQUAT (-5.5 ± 3.6%). During STOOP, OE and RF muscle activities significantly increased in EXO compared to FREE (OE: +23.1 ± 45.8%, p=0.037.; RF: +27.2 ± 43.6%, p=0.048).

CONCLUSION: The lack of influence of the CORFOR® exoskeleton on ES muscle activity might be explained by the complexity of the manual palletizing task, involving motions out of the sagittal plane, and therefore reducing the effectiveness of its designed assistance through the elastic bands. However, the CORFOR® exoskeleton did not alter trunk kinematics. The increase of OE and RF muscle activities with EXO during STOOP could be due to the additional effort participants had to make to stretch the exoskeleton while bending the trunk forward. Further evaluations over a longer period of time should be carried out to confirm these results.

COMPARISON OF PEAK LUMBAR LORDOSIS BETWEEN SOME TYPICAL SKILLS OF WOMENS ARTISTIC GYMNASTICS

EYSSARTIER, C., BILLARD, P., THOREUX, P., SAURET, C.

ARTS ET MÉTIERS INSTITUTE OF TECHNOLOGY

INTRODUCTION: Back pain is prevalent among gymnast populations (1). One of the known risk factor is the repetition of lumbar hyperextensions which increase intervertebral stress and may lead to acute lumbar spine traumatic events or overuse injuries (2,3). A better understanding of the risks associated with each gymnastics skill would help to preserve gymnasts' health. From the hypothesis that extreme lumbar lordosis (LL) would be associated with low back injury risk, this study aimed at quantifying the maximum of LL reached in five typical floor skills of womens artistic gymnastic (split leap, front handspring, round off back handspring, front and back walkovers) performed by seven national level gymnasts.

METHODS: Data collection involved a motion capture session (one static acquisition in upright standing posture and one to five successful trials of each skill), 82 reflective markers being placed on the skin of the subject. Then, a micro-dose biplanar radiograph (EOS system) in neutral standing posture was done, with the subject still equipped with the markers, allowing both bones and markers to be seen on the radiographs (4).

To get 3D kinematics of the spine during gymnastics skills, a full body kinematic model, previously developed with Opensim software (5), and fed by motion capture data was used (4). This generic model having a fully articulated spine, was scaled and personalised to each gymnast for the thoraco-lumbar spine and the pelvis from bones 3D reconstructions based on EOS images (4). Joints and bodies kinematics were determined using OpenSim multibody kinematics optimization algorithm (4,5). The LL, defined as the angle between the sacral endplate and the first lumbar vertebra was then calculated throughout each trial. Peaks of LL were extracted. Non-parametric statistical tests for paired data of Wilcoxon (rank sum test) were conducted, with a significance level at 0.05.

RESULTS: The skills requiring the most lumbar extension were the front and the back walkovers (mean LL: 106°±23° and 103°±21°, respectively) followed by the back handspring (96°±14°), the front handspring (93°±16°) and finally the split leap (88°±15°). High variability can be observed between the gymnasts in particular for skills requiring the most lumbar extension. Peaks of LL were not significantly different between skills at the threshold of 0.05 (p-values ranging from 0.06 to 0.31).

CONCLUSION: Skills requiring the most lumbar extension were identified but more gymnasts would be necessary to conclude with significant differences. In addition, another identified risk factor for back pain in gymnastics is ground impact (1,3). However, these first results may help coaches and medical staff to build more spine friendly training sessions.

OP-SH27 Ageing

ACTIVELY RESPOND TO THE AGING POPULATION: THE CHARACTERISTICS AND INFLUENCING FACTORS OF PHYSICAL ACTIVITY OF THE ELDERLY IN CHINA

HUAN, W, ZHANG, Y., REN, L.

CHINA INSTITUTE OF SPORT SCIENCE

Actively Respond to the Aging Population: the Characteristics and Influencing Factors of Physical Activity of the Elderly in China

Huan Wang1, Yanfeng Zhang1, Liying Ren2

1. China Institute Of Sport Science; 2. Chinese Academy of Social Sciences

Introdution:

Promoting the physical activity level of the elderly is an important measure to actively respond to the aging population in the new era. In order to improve the development level of physical activities of the elderly, it is necessary to fully understand the characteristics and related factors of activities of the elderly in China, and provide strategic basis for promoting the health of the elderly

METHODS: This study was based on 20897 survey data from the 60-90 year old people in 2020 Physical Activity Survey. The elderlys exercise type, physical activity level, individual cognition and PA support environment are analyzed, and the factors affecting the elderlys participation in PA are analyzed by regression model.

RESULTS: 1) 48% of the elderly participated in exercise at least once a week, and 26.1% of the elderly participated in exercise at least three times a week; the exercise intensity of the elderly is mainly of moderrate intensity, and the duration is concentrated in 30-60 minutes. The most popular PA items are walking and running, and Square Dance is the most popular among urban elderly women.

2) There are differences between urban and rural areas, gender, and age and exercise behavior in the cognitive level of physical activity of the elderly, which are the important factors to promote the elderly becoming active.

3) About 70% of the elderly live in the "15-minute fitness circle" built by the government. The elderly take part in exercise organizations and activities with the characteristics of "being around". Less than half of the elderly have received exercise guidance, of which about 10% have received professional guidance;

4) The elderly who live in a 15-minute fitness circle, participate in exercise organizations, and have received guidance are 2 to 3 times more likely to be active in physical activities than those who are not active in physical activities.

CONCLUSION: The physical activity of the elderly in China is becoming more and more active. In order to further improve the activity level of the elderly, it is suggested that developing the strategic layout of physical activity in Life Circle of the elderly, strengthening the supporting environment for convenient to participate in exercise, and improving the cognitive level of individual exercise.

THE ASSOCIATION BETWEEN SOCIAL PROVISIONS AND PHYSICAL ACTIVITY LEVELS IN SENIORS LIVING IN RESIDENTIAL HOMES: A TEN MONTHS OF FOLLOW-UP.

MARCHANT, G., GUILLET DESCAS MEZZOUR, E., GAUTIER, A.

UNIVERSITY OF ROUEN NORMANDY, CLAUDE BERNARD UNIVERSITY LYON 1

Introduction.

The coronavirus disease 2019 (COVID-19) has adversely affected seniors social contact and physical activity (PA) levels. Social isolation due to the COVID-19 pandemic has been a health determinant for seniors living in communities. Keeping seniors active and independent through PA practice during the pandemic can improve health and well-being and reduce health risks in this population. Social provisions are a psychosocial determinant of health that may improve PA in seniors and reduce their sedentary behaviour time, but this association has yet to be studied. This study investigated the relationship between PA, social provisions, and sedentary time among seniors during the COVID-19 pandemic.

Methods

This study was ten months of follow-up. Participants (N=27; 82% women) were seniors between 60 and 94 years (M=82.3, SD=8.96) living in aged care residences. Participants completed a questionnaire on the Social Provisions Scale: emotional support, social integration, reassurance of worth, tangible help and orientation. Seniors wore an accelerometer at the beginning of the intervention, at the three-month mark, and at the end of the study. Data analysis included three mixed models. The first model determines the relationship between sedentary behaviour and social provisions variables. The second established the relationship between low-light physical activity and social provisions. The third indicated the relationship between high light physical activity and social provisions.

Results

Seniors with high levels of reassurance of worth were the ones who most significantly reduced the time spent in sedentary behaviours ($p \leq .05$). In the case of physical activity behaviours, seniors who felt emotionally supported had higher levels of low-light physical activity. There was no relationship between high light intensity and social provisions.

Discussion

In order to have a more active and healthy ageing population, it is vital to investigate ways to increase physical activity levels and reduce sedentary behaviours in older adults.

This study on the relationship between physical activity and sedentary behaviours objectively measured, and social provisions highlight the importance of psychosocial factors.

Seniors with higher reassurance of worth were likelier to spend less time in sedentary behaviours. Identifying whether this feeling comes from family, friends, nursing home staff, or other residents is essential.

Emotional support represents emotional closeness from which one derives a sense of security. Thus, it is understandable that this factor has played an essential role in the levels of light physical activity. Seniors describe security as manageable living conditions where they achieve a good end of life, balancing dependency and independence.

Interventions to reduce sedentary behaviour and increase physical activity in seniors who live in a care residence should consider these factors.

PARTICIPATION IN OCCUPATIONAL HEALTH-PROMOTION PROGRAMS IN NURSING HOME FACILITIES: THE ROLE OF OCCUPATIONAL AND PERSONAL FACTORS

JANSSEN, T.I.2, VOGEL, O.1, OTTO, A.K.1, GRÜHN, L.A.1, KLOTZBIER, T.4, KORBUS, H.4, HILDEBRAND, C.7, VOELCKER-REHAGE, C.2

1 UNIVERSITY OF HAMBURG, 2 UNIVERSITY OF MÜNSTER, 3 TU BERLIN, 4 UNIVERSITY OF STUTTGART, 5 UNIVERSITY OF PADERBORN, ...

INTRODUCTION: As a result of the growing ageing population, the need for nursing staff has increased significantly. Nursing staff in nursing home facilities are exposed to demanding occupational conditions, which can lead to job fluctuations, might promote unhealthy behaviour or sickness. In addition, mental and musculoskeletal disorders are prominent in this occupational field. Occupational health promotion interventions are offered to counteract this unfavourable trend; however, participation is limited. Overall, it is known that company size and sex have an influence on participation in occupational health-promotion programs. Further, different physical load, psychological stress, culture of the facility and personal factors have been shown to affect health outcomes. The factors that favour or reduce participation in health-promotion programs among nursing staff have not been analysed. Consequently, we aimed to investigate which factors have an impact on nurses participation in health-promotion programs.

METHODS: This cross-sectional study was conducted in 47 nursing home facilities in Germany, between April 2017 and March 2020. After recruitment and the baseline assessment, participants randomly were allocated to an ergonomic and posture training and/or the subsequent back-fitness training program. Participation was assessed using a questionnaire administered after the intervention. A logistic regression was used to identify factors that influence participation. Psychological stress, physical load, working environment as well as institutional and personal factors were included in the analysis.

RESULTS: Overall 310 nurses (mean age = 42.3 ± 11.7 years, female = 77.1%) were included in the analysis. 39,4 % of the subjects did participate in the program. The regression model was statistically significant, explaining 18.3% of the variance, and predicting 64.3% of the cases correctly. The regression indicated that variations in participation depended on psychological stress (OR = 0.338), psychological demand (OR = 0.694), work atmosphere among colleagues (OR = 0.727), physical activity resources (OR = 0.750), and information-sharing and co-determination rights in the workplace (OR = 1.456).

DISCUSSION:

The results showed that psychological stress, good occupational communication and co-determination negatively affected participation. Good team cohesion and a high level of personal physical activity resources favour participation. As we explained only 18.3% of the variance, other barriers, such as personal intentions and other occupational factors such as specific barriers in the occupational sector, should be analysed in further studies to provide a comprehensive picture of health promotion program implementation. Similarly, the programs should be analysed more closely in order to assess whether intervention components have an impact.

OLD DOGS CAN LEARN NEW TRICKS! RE-ANALYSIS OF BBC UK DATA COMPARING THE EFFECTS OF BRIEF PSYCHOLOGICAL SKILLS TRAINING BY AGE

LANE, A.M., CLOAK, R., DEVONPORT, T.J.

UNIVERSITY OF WOLVERHAMPTON

Almost worldwide, both the numbers and percentage of older people are rapidly increasing. Ageing comes with an inevitable decline in our physical and mental capacity. Government agenda in many countries has focussed on encouraging healthy ageing and to look toward maintaining the quality of life as people age. The present study considers this issue and does so by re-examining data from a largescale project that investigated the effects of brief psychological skills training on performance (Lane et al., 2016). Using an online performance test which required participants identify numbers in a randomly assorted grid as quickly as possible, Lane et al. (2016) found watching a training video of <2 mins led to improved performance over the control group. Each training video was presented by former Olympian Michael Johnson, a successful athlete who delivered persuasive messages (see Lane et al., 2021).

In the present study data were grouped into one of 4 groups and data were analysed by comparing baseline data against post intervention data. We compared active psychological skills training, where participants learned one of 12 different interventions – imagery, self-talk, and if-then planning which were focused on an outcome goal, process goal, skill instructions, and arousal regulation against a no-treatment data. The control group were a no-treatment group that emerged from participants who skipped doing the intervention (Lane et al., 2021). It is expected that younger participants would attain a higher score (find more sequential numbers within the time provided) than older participants. However, we tested the extent to which the age would influence the effects of following the intervention, an intervention which we knew was positive (Lane et al., 2016, 2021).

We analysed data from the extended sample of 74,205 (Age: M = 34.65, SD = 14.11) with 46,819 participants in the intervention group and 13,864 in the no-treatment group. In terms of age-group membership, 27,299 were in the 16-29 age group, 23,483 aged 30-49 years, 9,259 aged 50-67 years, and 642 in the 68-92 years age group. Repeated measures ANOVA results indicated no significant 2-way interaction effect for differences in performance by intervention-control and age group. As expected, younger participants were significantly faster at identifying sequential numbers than older participants. However, the absence of a significant interaction for older participants indicates that they also benefited from engaging in brief psychological skills training.

As psychological skills are associated with enhanced performance and range of positive mental health outcomes, finding offer encouraging results for focusing future work on teaching psychological skills to elderly participants. We suggest future research considers developing and testing brief interventions that target elderly participants to examine if learning effects can be enhanced for the benefit of physical and mental health.

INSUFFICIENTLY PHYSICALLY ACTIVE ELDERLY ADULTS: CHARACTERISTICS AND FACTORS INFLUENCING INCREASED PHYSICAL ACTIVITY

WAGNSSON, S., GUSTAFSSON, J., HÖGMAN, J.

DEPARTMENT OF EDUCATIONAL STUDIES

Introduction

The need to promote healthy and active aging is crucial both for individuals and society, and is also emphasized in the global development goals. One way to enhance healthy aging is through regular physical activity. There is extensive research on the motivations for exercise among younger and middle-aged individuals. However, what motivates elderly adults is not as well investigated. Hence, it is particularly important to investigate what characterizes elderly adults who are insufficiently physically active and what factors that are influencing them to become more physically active.

Methods

Using a questionnaire with a mix of validated instruments (e.g., Godin-Leisure-Time Exercise Questionnaire; EQ-5D) and self-constructed questions (e.g., what would make you more physically active?) data from 242 elderly adults (65-100 years; female 70%), living in senior safety housing in Sweden were collected.

Results

The results indicated that the majority of elderly adults were physically active enough from a health perspective, but also that a significant proportion (25%) were sedentary or insufficiently physically active. Furthermore, it was found that those belonging to the group of insufficiently physically active i) reported having lower health ii) reported lower socioeconomic status, and to a greater extent iii) lived alone, iv) needed assistive devices, and v) required home care. Additionally, the results showed that those who were insufficiently physically active would like to be more physically active provided that the activities are available in close proximity to their home, if they have the opportunity to engage in the activities with someone, if the activities have low or no costs at all, and/or if they receive support from educated and competent staff who can demonstrate how to perform the activities without risking their health.

Discussion

Based on these results, suggestions for interventions that could promote the insufficiently physically active elderly adults are discussed, such as organizing activities close to seniors homes, starting up regular walking groups, establishing accessible and adaptable gyms both indoors and outdoors, adapting activities to meet mobility needs, training staff to coach the elderly in physical activity, and sports clubs engaging in outreach activities.

OP-SH09 Cognition II

AN ACUTE BOUT OF ORIENTEERING ENHANCES HUMAN COGNITION

HEISZ, J.J., WADDINGTON, E.E.

MCMASTER UNIVERSITY

Introduction: Exercise can augment human cognition and its effects may be additive when combined with a cognitively challenging task. Orienteering is a sport that simultaneously combines high-intensity exercise with spatial navigation, and expert orienteers report greater hippocampal-dependent memory than non-orienteers (Waddington & Heisz, 2023). The present study examined whether lactate mediates the acute effects of orienteering on hippocampal cognition. Research in animal models suggests that the lactate produced by contracting muscles during high-intensity exercise increases brain-derived neurotrophic factor and improves cognition (El Hayek et al., 2019). Therefore, it was hypothesized that orienteering at a higher intensity would increase lactate and boost cognition more than orienteering at a moderate intensity.

Method: Recreationally active, healthy young adults (N = 38, Mage = 20.8 ± 2.5 years) with no orienteering experience were recruited to navigate an outdoor orienteering course while exercising at a high (80-85% of HRR) or moderate (40-50% of HRR) exercise intensity. A control group engaged in high-intensity exercise without navigation to test for the additive effects of orienteering above that of exercise alone. Lactate was measured throughout the acute session and the measurement taken at the end of the course was analyzed. Immediately before and after the acute session, spatial memory was assessed using the Groton Maze Learning Test.

Results: High-intensity exercise with (5.2±2.5 mmol/L) or without orienteering (5.3±2.4 mmol/L) increased lactate more than moderate-intensity orienteering (1.7±1.3 mmol/L). Higher lactate correlated with better spatial memory ($r(36) = .35$, $p = .015$). The largest percent change in spatial memory was observed for the high-intensity orienteering group (35±45%) over high-intensity exercise without orienteering (27±35%) and was lowest for moderate-intensity orienteering (16±24%).

Discussion: These preliminary results suggest that lactate may drive the acute effects of exercise on human cognition and that combining high-intensity exercise with navigation via orienteering may improve spatial memory more than high-intensity exercise alone.

EFFECT OF MOTOR COMPLEXITY ON COORDINATIVE EXERCISE-INDUCED ACUTE CHANGE IN PROACTIVE CONTROL

CHENG, M.H., FU, H.L., TUNG, P.C., YANG, C.T., KAO, S.C., WANG, C.H.

NATIONAL CHENG KUNG UNIVERSITY

Introduction

Recent studies have shown that acute exercise can temporarily improve cognitive control, with evidence suggesting that manipulating exercise doses such as intensity and duration can moderate these changes. However, it is not yet clear if the level of motor complexity involved in exercise also affects this outcome. This is interesting given that some research suggests that exercises requiring complex motor skills (i.e., coordinative exercises) may enhance cognitive control more effectively. This study thus aims to investigate if motor complexity level of coordinative exercise moderates the acute change in proactive control and uses event-related potential (ERP) to examine the underlying neurocognitive mechanisms.

Methods

Forty-four college students were recruited and randomly assigned to a low complexity coordinative exercise (LCCE) group (n = 22, mean age = 19.9 ± 1.3) or a high complexity coordinative exercise (HCCE) group (n = 22, mean age = 21.5 ± 1.8). The exercise complexity was manipulated by two difficulty levels of drills using a rope ladder. Behavioral and ERP outcomes during a cognitive control task (i.e., AX-CPT task) were measured before and after a 20-min exercise intervention. The proactive behavioral index (PBI) and the early contingent negative variation (CNV) were used to evaluate the changes in proactive control process at the behavioral and neural levels, respectively.

Results

Our results revealed that the LCCE group exhibited a decrease in PBI from pretest to posttest, suggesting weaker use of proactive control. On the other hand, the HCCE group showed maintained PBI following exercise. Further, the HCCE group exhibited a larger early CNV amplitude for the condition requiring higher level of proactive control compared to the LCCE group in the post-test stage, suggesting an enhancement in the neural processing related to proactive control. In contrast, LCCE group showed a trend of decreased CNV amplitude from pretest to posttest, reflecting a weaker engaging in proactive behavior.

Conclusion

We concluded that increasing motor complexity during exercise may induce acute effect on the proactive control process, as reflected by a stronger neural index of proactive control, and result in stability in the index of cognitive processes underlying proactive behavior. Taken together, our findings suggest the potential benefit of engaging in coordinatively-challenging physical activity for preventing failure to proactively recruit goal-relevant information.

ENVIRONMENTAL ENRICHMENT MODULATES AEROBIC EXERCISE-INDUCED CHANGES IN NEUROCOGNITIVE PROCESSES ASSOCIATED WITH COGNITIVE CONTROL

FU, H.L., YANG, C.T., KAO, S.C., WANG, C.H.

NATIONAL CHENG KUNG UNIVERSITY

Introduction

The Adaptive Capacity Model suggests that combining an engaging environment with aerobic exercise enhances cognitive benefits. However, the effect of environmental stimulation on exercise-related cognitive benefits is unclear. Thus, this study aimed to address this issue directly through a randomized controlled trial (RCT).

Method

Forty-two participants were recruited and assigned randomly to two groups: an outdoor exercise group (OE, n = 21, aged 21.14 ± 1.01 years) and an indoor exercise group (IE, n = 21, aged 21.43 ± 1.33 years). Both groups participated in a 5-km moderate-to-vigorous run, 3 times a week for 4 weeks. Specifically, the IE group ran on a treadmill, while the OE group ran outdoors, with the route being manipulated to increase cognitive engagement during exercise. The effects of exercise on aerobic fitness and cognitive control were measured using a Progressive Aerobic Cardiovascular Endurance Run (PACER) test and a flanker task with concurrent electroencephalography (EEG) recording.

Results

The results showed that both groups improved aerobic fitness while the OE group had faster reaction time and lower accuracy after the exercise intervention, possibly due to the speed-accuracy tradeoff. In contrast, the IE groups performance remained similar level between pre- and post-tests. Further, EEG results showed that the OE group had smaller frontal-midline theta power in the condition involving higher level of cognitive control compared to the IE group after the intervention, indicating that the OE might lead to consuming less degree of cognitive control while processing conflicting information.

Discussion

In summary, our findings indicate that the exercise environment can have a moderating effect on exercise-induced cognitive changes. This supports the Adaptive Capacity Model that emphasizes the role of the exercise environment in optimizing cognitive benefits through physical exercise.

INHIBITORY CONTROL IN ELITE YOUNG SOCCER PLAYERS: A PROPENSITY-SCORE MATCHED CROSS-SECTIONAL STUDY

BIRKLBAUER, J.1, STOLLNBERGER, D.1, GONAUS, C.1, HÖDLMOSER, K.2, MÜLLER, E.1, POINTINGER, M.1, DIRNBERGER, J.1, FINKENZELLER, T.2, AMESBERGER, G.1, RICHLAN, F.2

1: DEPARTMENT OF SPORT AND EXERCISE SCIENCE, UNIVERSITY OF SALZBURG ; 2: CENTRE FOR COGNITIVE NEUROSCIENCE AND DEPARTMENT OF PSYCHOLOGY, UNIVERSITY OF SALZBURG

INTRODUCTION: Inhibitory control is suggested to be critical for success in soccer since players are required to stop inappropriate or ongoing movements, to suppress irrelevant or interfering information and to keep their attentional focus on what is most important. A few studies have in fact found that adult and youth elite players outperform non-elites in response inhibition ranging from medium to large effects. In order to further substantiate these findings, we compared the Stop-Signal Task performance of the top Austrian youth soccer players with a carefully matched sample of lower-league players within the framework of an fMRI study.

METHODS: The study included 28 (16.9±0.5 yrs of age) out of 32 male field players of the highest national soccer talent program and 30 (16.9±0.5 yrs) non-elite peers. For the reference sample, 115 players of 21 local-league clubs were preselected and 71 of them who regularly trained and competed but never had been part of any development program were matched by the logistic propensity score according to their exact age, training years, education and video gaming. The Stop-Signal Task created and evaluated in accordance with the consensus paper (1) was conducted during the fMRI scans. To get familiar with the tracking procedure, all subjects completed the same task more than 4 weeks prior to the scans in an online version and another 1-2 weeks prior to that in a shorter version without stop-signals to get the baseline RT.

RESULTS: During task-based fMRI, elite and non-elite players showed similar stop-signal RT (183±32 ms vs 188±24 ms: p=.505) and RT on go trials (340±34 ms vs 344±27 ms: p=.695) with trivial effects (SSRT: d=0.176; RTgo: d=0.104). Two-sided Bayesian t-tests (with a Cauchy prior centred at zero and a scaling parameter of 0.707) revealed moderate evidence in favour of H0 (SSRT: BF01=3.1; RTgo: BF01=3.5). In contrast, elite players outperformed non-elites during familiarization with 23 ms faster SSRT (228±41 ms vs 250±32 ms: p=.037; d=0.622; BF10=1.8) and 28 ms faster RTgo (390±59 ms vs 418±41 ms: p=.058; d=0.561; BF10=1.3) and showed a trend towards faster baseline RT (348±39 ms vs 367±36 ms: p=.071; d=0.496; BF10=1.1).

CONCLUSION: The comparable response inhibition performance of the best national youth soccer players and their matched non-elite peers contradicts previous findings of better stop-signal inhibitory control in elite players than in lower-level athletes. Such differences were only apparent in our study when the players completed the task for the first time, despite the fact that detailed instructions, block-based feedback and a practice block prevented proactive, progressive and post-error slowing. In this first run, the included matching variables did not eliminate the group effect. We expect the analysis of the fMRI data to provide insights on whether the behavioural outcomes of the first run are also evident at the neural level in the second test run.

INHIBITION CONTROL TRAINING FOR PERFORMANCE IN SPORT AND OTHER HIGH-PRESSURE CONTEXTS

NIEUWENHUYS, A., BELL, R., KENNEDY, D., ORTEGA-AURIOL, P., SULLIVAN, R.
THE UNIVERSITY OF AUCKLAND

INTRODUCTION: Performance in sport and other high-pressure contexts may be adversely impacted as pressure-induced increases in anxiety cause individuals to experience difficulty inhibiting stimulus-driven thought and action. Two pilot experiments – one in soccer and one in a policing context – were conducted to examine whether inhibition control training (ICT) that is conducted under low-pressure circumstances, may help to improve inhibitory performance and prevent negative effects of pressure during (simulated) task performance.

METHODS: Both experiments employed a pretest-intervention-posttest design. Experiment 1 included 12 participants (male soccer players) and examined effects of soccer-specific Go-NoGo training (3x20min sessions; n=6) vs. active control (video watching; 3x20min sessions; n=6), on participant's inhibitory performance during an in-vivo 'stop-signal' penalty shooting task under low- and high-pressure. Experiment 2 included 29 participants (14 male / 15 female; 9 working police officers) and examined effects of home-based Go-NoGo training (3x20min sessions; n=12) vs. passive control (n=17), on muscle activity and performance during a computer-based shoot-don't shoot task under low- and high threat.

RESULTS: Experiment 1 (soccer) showed improved training task performance for the ICT group across the three training sessions (GoRT S1: 701±23ms, S3: 655±36ms, P=.027; NoGo accuracy S1: 79±4%, S3: 93±2%, P=.017). After training, under low-pressure conditions, inhibitory performance during penalty shooting was better for the ICT group than for the active control group (stopping success ICT: 80±10%, Control: 49±10%, P=.067), whereas no between-group difference existed at the pretest (before training; P=.864). At the posttest, inhibitory performance was maintained under high-pressure. Experiment 2 (policing) showed marginal improvement in inhibitory performance during the shoot-don't shoot task for both the ICT and passive control group (NoGo accuracy PRE: 92±1%, POST: 96±1%, P=.038). Significant improvements in Go response times were observed for the ICT group only (GoRT PRE: 423±8ms, POST: 380±8ms, P<.001). Improvements in behavioural responding were largely matched by corresponding changes in task-relevant muscle activity (EMG burst analyses). No effect of threat on inhibitory performance was observed.

CONCLUSION: Across both pilot experiments, findings indicate that inhibition control training can help to improve relevant aspects of task performance in sport and other high-pressure contexts. Within-task effects of training transferred to reflect superior inhibitory performance during in-vivo penalty shooting in soccer (Experiment 1) and faster (correct) responding across a wide range of shoot-don't shoot scenarios (Experiment 2). Future studies with larger sample sizes are required to corroborate the current findings, examine transfer to increasingly realistic task conditions, and consider the durability of observed effects

OP-MH33 Metabolic fitness/Flexibility

LOW ENERGY AVAILABILITY REDUCE CUMULATIVE MYOFIBRILLAR AND SARCOPLASMIC PROTEIN SYNTHESIS IN TRAINED FEMALES

HANSEN, M.

AARHUS UNIVERSITY

INTRODUCTION: Background

Low energy availability (LEA) describes a state where the energy intake is not sufficient to cover the energy costs for exercise and that needed to support and maintain basal body functions. Cross-sectional studies in female athletes have shown that LEA is associated with impaired bone health, endocrine function, and mental health. However, the influence of LEA on skeletal muscle protein synthesis in females performing exercise training is still uncertain. Consequently, we aimed to investigate the impact of 10 days of LEA on cumulative myofibrillar and sarcoplasmic protein synthesis in young trained females.

Methods

Thirty young trained eumenorrheic females were matched in pairs based on training history and randomized into two groups; 10 days of LEA (25 kcal/kg Fat-Free Mass (FFM)/day) or 10 days with an energy-balanced diet (EB, 50 kcal/kg FFM/day). The diets were matched for protein content (2.2 g/kg lean mass/day). Before the intervention, both groups underwent a five-day energy-balanced 'run-in' period. A standardized supervised exercise training program was performed over the experimental period. Deuterium oxide (D2O) was ingested daily, and saliva samples were collected to determine body-water tracer enrichment. Pre- and post-intervention testing included muscle biopsies for tracer enrichment and protein expression analysis, and 24h urine collection for urinary nitrogen balance.

Results

In comparison to EB, LEA resulted in significant reductions in cumulative myofibrillar protein synthesis ($p<0.001$, LEA: -0.082%/day 95%CI [-0.13 to -0.034] vs. EB: 0.095%/day 95%CI [0.047 to 0.143]) and sarcoplasmic protein synthesis ($p<0.001$, LEA: -0.197%/day 95%CI [-0.263 to -0.131] vs. EB: -0.005%/day 95%CI [0.070 to 0.060]. In addition, urinary nitrogen balance in the last 24h of the intervention period compared to the last 24hrs of the control period was negative in the LEA group (LEA: -0.24g/day 95%CI [-0.01 to -0.47]) and significantly different ($p=0.022$) from the EB group who was in nitrogen balance (0.09g/day 95%CI [-0.14 to 0.31]). Total-S6K protein expression was lower in the LEA group but not in the EB group ($p=0.024$, LEA: -0.27 AU 95%CI [-0.45 to -0.05] vs. EB: 0.08 AU 95%CI [-0.13 to 0.31].

Conclusion

Ten days of LEA results in marked reductions in cumulative myofibrillar and sarcoplasmic protein synthesis and negative urinary nitrogen balance in trained females. Our results highlight that LEA may have consequences for skeletal muscle adaptations when performing exercise training.

This study was funded by Team Denmark and the Danish Ministry of Culture.

METHODS: RESULTS: CONCLUSION: GENOTYPE-PHENOTYPE MODELS PREDICTING VO2MAX RESPONSE TO HIGH-INTENSITY INTERVAL TRAINING IN PHYSICALLY INACTIVE CHINESE

YANG, X.1, LI, Y.1, BAO, D.1, MEI, T.1, WUYUN, G.2, ZHOU, D.3, NIE, J.4, XIA, X.5, ZHANG, Z.1, GU, Z.1, HE, Z.6

INTRODUCTION: Exercise training contributes to improvement of VO2max, however 16%~31% adults were non-responders after standardized exercise. Distinguishing these non-responders before exercise may help to recommend personally tailored exercise protocols to enhance individual health. The aim of our study was to analyze the inter-individual differences of the VO2max response of 12 weeks High-Intensity Interval Training (HIIT), the genotype-phenotype models were constructed to predict the effect of HIIT on VO2max, and these models were used to provide recommendations for precision exercise protocols.

METHODS: A total of 228 physically inactive healthy adults who completed a 12-week HIIT were analyzed. The leukocyte DNA in whole blood was extracted, and a genome-wide association study (GWAS) was conducted to identify genetic variants associated with VO2max response. Non-responders, responders and the highest training responders were defined as the ES<0.2, ES≥0.2 and ES≥0.8 respectively. We generated polygenic predictor score (PPS) using lead variants and constructed predictive model for VO2max response based on the multiple linear stepwise regression analysis.

RESULTS: (1) The VO2max increased significantly after 12 weeks of HIIT on average, but with a high degree of inter-individual differences (4.44±4.38ml/min/kg, range: -7.8~17.9 ml/min/kg). For 27% of participants, the VO2max showed no improvement (ES<0.2). (2) We identified one genetic locus near GABRB3 (rs17116985) associated with VO2max response at the genome-wide significance level (P<5×10-8), and additional nine SNPs at the suggestive significance level(P<1×10-5). SNPs rs474377(P=1.51×10-7), rs9365605(P=4.22×10-6) and rs17116985 (P=3.22×10-8) respectively explained 11%, 9% and

6.2% of variance in VO2max response. Additionally, 13 SNPs at suggestive significance level(P<1×10-5) were found on chromosome 6(Position: 148209316 - 148223568). (3) Individuals with a PPS greater than 1.757 had the highest training response (ES≥0.8), and those with a PPS lower than -3.712 were non-responders (ES<0.2) after 12 weeks HIIT. (4) PPS, baseline VO2max, sex, and body weight could explain 56.4% of the variance in VO2max response, the major predictor was PPS which could explain 39.4% of the variance in VO2max response.

CONCLUSION: VO2max increased 4.44ml/min/kg (range: -7.8~17.9 ml/min/kg) after 12 weeks of HIIT. Ten lead SNPs were associated with VO2max response beyond the suggestive significance level(P<1×10-5). SNP rs474377(P=1.51×10-7), rs9365605(P=4.22×10-6) and rs17116985(P=3.22×10-8) could respectively explain 11%, 9% and 6.2% variance of VO2max response. PPS, baseline VO2max, sex and body weight could explain 56.4% of the variance in VO2max response. The mainly predictor was PPS, which had the highest contribution of 39.4%. Individuals whose PPS were more than 1.757 could have the highest training response, and whose PPS was lower than -3.712 would be non-responders after 12 weeks HIIT.

EFFECTS OF ESTROGEN THERAPY ON METABOLIC FLEXIBILITY IN POSTMENOPAUSAL WOMEN

FARLOV, J.E., KLEIS, A., LARSEN, S., SCHMÜCKER, M., HELGE, J.W., DELA, F.

XLAB, CENTER FOR HEALTHY AGING, DEPARTMENT OF BIOMEDICAL SCIENCES, FACULTY OF HEALTH SCIENCES, UNIVERSITY OF COPENHAGEN, DENMARK

INTRODUCTION: Menopause is characterized by an abrupt decrease in estrogen production, resulting in a chronic estrogen deficiency in the postmenopausal period. The hormonal changes are associated with an increased accumulation of metabolic risk factors, such as central obesity, dyslipidemia and insulin resistance [1]. These are, in turn, associated with deteriorating metabolic flexibility [2]. We hypothesized that estrogen treatment in postmenopausal women receiving oral hormonal therapy with estrogens would preserve metabolic flexibility to a greater extent than in non-treated postmenopausal women (control).

METHODS: This ongoing study included 20 healthy postmenopausal women, where ten were in oral hormonal treatment with estrogens, and ten were not (age:55±4 and 55±6 years; BMI: 22±2 and 23±2 kg/m2, respectively). Metabolic flexibility was assessed in the overnight fasting state by measuring the capacity for fat oxidation at rest (ventilated hood) and the maximal fat oxidation (MFO) during an incremental test on a cycle ergometer (breath by breath-measurements of the pulmonary gas exchange) by indirect calorimetry. In addition, data from anthropometric measures, visceral fat mass and total body fat mass (DXA scanning) were obtained. The subjects were matched by VO2max, as training status is closely associated with maximal fat oxidation capacity [3]. Unpaired t-tests were used to compare these parameters between the two groups. Pearson's Product-Moment Correlation was used to assess the correlation between MFO and visceral fat mass. Data are shown as mean±SD.

RESULTS: Estrogen-treated women had significantly higher MFO rates than controls (0.33±0.07 and 0.27±0.07 g/min, respectively; (P= 0.03)). Furthermore, estrogen-treated women had a lower visceral fat mass than controls (226±114 and 510±415 g, respectively; (P= 0.04)). A significant negative correlation was found between MFO and visceral fat mass in the control group (P=0.04), but not in the estrogen-treated group (P=0.5). No significant differences were observed in resting fat oxidation rates (RER: 0.79±0.06 and 0.79±0.09, respectively; (P= 0.66)) or total body fat mass (16.5±5 and 21±6 kg, respectively; (P=0.1)). There was no difference in lean body mass (46±5 and 45±5 kg, respectively; (P=0.27)) or in VO2max (37±5 and 34±6 ml/kg/min, respectively; (P=0.33)) between the two groups.

CONCLUSION: Estrogen replacement may affect parameters of metabolic flexibility, such as MFO capacity. Furthermore, the capacity for fat oxidation may be linked with the accumulation of visceral fat mass in the absence of estrogen treatment, as observed in the control group. MFO is not linked with whole body fat mass in any of the groups.

UNCOVERING THE PHYSICAL LIMITATIONS AND EXERCISE INTOLERANCE IN POST-COVID PATIENTS

TRYFONOS, A.1, ASPLUND, N.1, JÖRNÅKER, G.1, ERIKSSON, L.1, ENGVALL, M.1,2, POURHAMIDI, K.1,3, RUNDQVIST, H.1, GUSTAFSSON, T.1,2, LUNDBERG, T.1

1.DIVISION OF CLINICAL PHYSIOLOGY, DPT OF LABORATORY MEDICINE, KAROLINSKA INSTITUTET, SE 2.UNIT OF CLINICAL PHYSIOLOGY, KAROLINSKA UNI HOSPITAL, SE 3.UNIT OF NEUROPHYSIOLOGY, KAROLINSKA UNI HOSPITAL

INTRODUCTION: Post-COVID syndrome poses an unprecedented challenge to modern society, affecting millions of people worldwide. Persistent fatigue, breathlessness and muscle pain are among the most common complaints of these patients. Importantly, such symptoms are worsened following exercise (post-exertional malaise; PEM). As such, healthcare providers are often reluctant to incorporate exercise into the rehabilitation program, which risks exacerbating physical deconditioning. This study aims to conduct a thorough physiological assessment including respiratory, cardiac, vascular, muscular and neurophysiological function in post-COVID patients and age-, sex-matched healthy controls to improve our understanding towards the phenotype and symptoms seen in this patient group.

METHODS: Fourteen post-COVID patients who were experienced PEM ≥3 months after covid infection and had no previous chronic disease (44.2±11.6 yr, 64.2% female, 24.2±2.3 kg/m2) and 10 healthy controls (45.8±13.3 yr, 60% female, 25.5±4.3 kg/m2) were enrolled in the study. Subjects performed cardiopulmonary exercise testing (CPET) to assess exercise capacity, echocardiography (cardiac function) spirometry (lung function), arteriography (vascular function), dynamometry (muscular strength), TILT-test and needle electromyography (EMG) to assess nerve responses. Statistical analysis was performed through SPSS 29 and independent t-test was used to assess difference between the groups (P<0.05).

RESULTS: Post-COVID group showed a trend of lower VO2peak when compared to controls (29.7±8.2 ml/kg/min vs. 37.3±11.2 ml/kg/min; P=0.077). Force vital capacity (4.3±1.1L vs. 4.1±1.0L; P=0.691), forced expiratory volume in 1 second (3.3±0.9L vs. 3.0±0.8L; P=0.691) and single-breath diffusing lung capacity for CO (8.7±2.5 mmol/min*kPa vs. 8.4±2.4 mmol/min*kPa; P=0.778) were similar between post-COVID and controls respectively. Isometric strength assessed in knee extensor (145.5±56.7 Nm vs. 173.6±59.7 Nm; P=0.255) and handgrip (post-COV: 36.4±20.1, Con: 39.4±12.5; P=0.660) were similar between the groups. There was a trend of higher pulse wall velocity in post-COVID patients compared to controls (8.9±1.4 m/s vs. 7.7±1.3 m/s; P=0.07). Post orthostatic tachycardia syndrome was observed in 4 post-COVID patients and none in the control group. Needle EMG showed myopathies in 3 post-COVID patients and none in controls. No abnormalities were observed in echocardiography in none of the subjects and ejection fraction was not different among the groups (post-COV: 57.1%±2.3, Con: 58.2%±1.6; P=0.799).

CONCLUSION: Outcomes suggest a trend of reduced physical capacity in post-COVID individuals experiencing PEM, however cardiac and respiratory functions were relatively preserved. In contrast, signs of dysautonomia and myopathies suggesting nervous system involvement in the pathophysiology of long covid. More subjects are required to draw a definitive conclusion whether there is a predominant mechanism underlying exercise intolerance in post-COVID syndrome.

INFLUENCE OF A PRIOR MAXIMAL FAT OXIDATION TEST ON VO2MAX DETERMINATION IN A SINGLE DAY IN TYPE 2 DIABETES MELLITUS: VALIDITY AND RELIABILITY STUDY

MARÍN-GALINDO, A., OPAZO-DÍAZ, E., MONTES-DE-OCA-GARCÍA, A., CORRAL-PÉREZ, J., PÉREZ-BEY, A., CASALS, C., PONCE-GONZÁLEZ, J.G.

UNIVERSITY OF CÁDIZ AND CÁDIZ AND BIOMEDICAL RESEARCH AND INNOVATION INSTITUTE

INTRODUCTION: The determination of maximal fat oxidation (MFO) and maximum oxygen uptake (VO2max) is normally a 2-day laboratory evaluation and there is not a validated one-day MFO and VO2max test. The main aim of this study was to validate VO2max determination in a single-day test including MFO and VO2max. We also aimed to analyze the relationship between the MFO test duration and the VO2max test outcomes.

METHODS: Twenty overweight or obese adults with type 2 diabetes mellitus (10 women; 53.12±8.8 years old) were included. MFO and VO2max were determined by indirect calorimetry on a cycle ergometer. MFO test was performed until respiratory exchange rate (RER) was greater than 1.0, and VO2max was performed until exhaustion. The participants attended the laboratory on two randomized different days in a fasted state of 8-10h, avoiding caffeine, alcohol, and vigorous physical activity in the previous 24hrs. One day, participants were cited in the laboratory for an MFO test (1) before a short VO2max test with five minutes of passive recovery between tests. This short VO2max test consisted of 15W 1-minute steps beginning with the last load of the MFO test. On another day, the participants were called to the laboratory to do a traditional VO2max test to validate these results. In addition, after 15 minutes of passive rest, a VO2max verification protocol was carried out to confirm that the VO2 values were maximum (2). The Bland-Altman method and intraclass correlation coefficient (ICC) were used to determine the validity and reliability of the single-day test for MFO and VO2max measurements. Repeated analysis of variance (ANOVA) with Bonferroni comparisons were used to examine the difference in VO2max between both tests. To examine de relation between the duration of the MFO test (MFOt) and the delta between maximum oxygen uptakes from VO2max-1 and VO2max-2 the Pearson correlation coefficient was used.

RESULTS: There were no significant differences in VO2max between tests (p=1.00) and the ICC for VO2max was excellent (ICC=0.983). There was no relationship between MFOt and the delta of VO2max values in tests (r=0.302, p=0.195).

CONCLUSION: In conclusion, the single-day test for maximal fat oxidation and VO2max measurements is a valid protocol to use in patients with type 2 diabetes mellitus, independently of the duration of the MFO test.

OP-PN32 Genetic Associations

NO ASSOCIATION OF ACTN3 AND ACE GENOTYPES WITH STRENGTH QUALITIES IN INDIAN BOXERS

GROVER, V.K., SHARMA, N., VERMA, J.P., KUMAR, A., TIWARI, P.K.

RAMAKRISHNA MISSION VIVEKANANDA EDUCATIONAL AND RESEARCH INSTITUTE

INTRODUCTION: Boxing is a weight restricted sport. Relative strength is one of the key indicators of boxing performance. The force generated by both the upper and lower limbs is important for punching force (Chaabe`ne et al., 2014). The strength qualities of an individual is determined largely by genetic factors (heritability estimates for power-related phenotypes ranges from approximately 49% to 86%; Ahmetov et al., 2022). ACTN3 R577X and ACE I/D gene polymorphisms are the most studied gene polymorphisms for the association of strength qualities with contradictory findings across different populations (Ahmetov et al., 2022).

The aim of this study was to investigate the differences in strength qualities among Indian boxers based on their ACE I/D and ACTN3 R577X gene polymorphisms.

METHODS: For the purpose of this study, 39 elite Indian boxers were recruited and 2-3 ml saliva sample from participants was used for DNA isolation. PCR-RFLP method was used to observe the gene polymorphisms. The strength qualities of the boxers were measured at National Coaching Camp, Patiala. Maximal strength of the upper body and lower body was measured with 1RM strength test (bench press and back squat, respectively). Lower body upward power was assessed by countermovement jump test. Maximum static strength of both hands was assessed by maximal handgrip strength test. One way ANOVA test was used (after testing assumptions) to analyze the differences in strength qualities of the Boxers.

RESULTS: Elite Indian boxers had relative strength of 1.28 (± 0.09) in their lower body and 1.11 (± 0.04) in their upper body. The participants performed countermovement jump with a height of 48.13 cm (± 3.36). The maximum static strength of their left and right hands was 48.70 kg (± 3.30) and 49.94 kg (± 2.68), respectively. After categorizing Indian boxers based on their genotypes, we observed no significant differences ($p > 0.05$) in their relative strength (upper and lower body), lower body power, and maximum static strength of both hands.

CONCLUSION: On the basis of the findings of this study, we infer that the ACTN3 R577X and ACE I/D gene polymorphisms do not differentiate Indian boxers for their strength qualities.

GENETIC ASSOCIATION BETWEEN ACTN3 R577X POLYMORPHISM AND ENDURANCE PERFORMANCE IN KOREAN POPULATION

CHAE, J.H.1, JUNG, J.H.2, EOM, S.H.1, LEE, J.Y.1, KIM, C.H.1

SOONCHUNHYANG UNIVERSITY1, CENTER FOR SPORT SCIENCE IN CHUNGNAM2

INTRODUCTION: ACTN3 is a gene that expresses the α-actinin-3 protein. α-actin-3 protein is expressed only in type 2 fiber, and another isoform of α-actinin-2 is expressed ubiquitously in the muscle fiber type. The α-actinin-3 protein expressed in the fast twitch muscle affects the cohesion of the cytoskeleton of the Z-line. α-actinin-3 is inhibited in expression in about 20% of the total population because the single-base polymorphism of the ACTN3 gene(rs1815739) replaces the R577th protein, Arginine, with a stop codon. People of the α-actinin-3 deficient genotype, express more α-actinin-2 to compensate for the deficiency. According to previous studies, the RR genotype has already been well-known for power performance. Conversely, there is no solid evidence yet that X Homozygous is fit for endurance performance. Therefore, this study aims to verify the distribution of ACTN3 genotypes in Korean adults and Korean endurance athletes and to find out the genetic link between ACTN3 genotypes and Korean endurance performance.

METHODS: The distribution of ACTN3 genotypes was investigated and compared, respectively, with data from Koreans with no health problems(n=977, Controls) and athletes in Korean endurance events(n=117). Endurance athletes were selected as athletes using 90~100% aerobic energy based on the energy metabolism ratio of each event. The genotype was divided into RR type and RX+XX type, and the frequency and ratio were calculated by applying the Hardy-Weinberg formula and verified by the Hardy-Weinberg law. The difference verification between groups was conducted through Chai-Square, and the odds ratio was calculated.

RESULTS: The genotype distributions of RR, RX, and XX in healthy Koreans were 30.2%, 50,7%, and 19.1%, respectively. As a result of the analysis, the frequency of XX and RX genotypes in the control group was 69.7%, and that of endurance athletes was 77.8%, which was significantly different at P=0.044. Regarding the RR genotype, the control group showed a distribution of 30.2%, and the endurance athlete showed a distribution of 22.2%. The odds ratio was 1.52 times higher for ordinary people with the RX or XX genotype than for those with the RR genotype.

CONCLUSION: Contrary to our hypothesis that only pure XX type in Koreans will be involved in endurance ability, even if the R allele is reduced by more than half, it is involved in endurance ability. Power is the determination of performance in all dynamic sports events. Therefore, type 2 fibers cannot be completely excluded. RX type is expected to have more impact when making the final spurt for endurance performance. RX is expected to code phenotypes with fast muscle characteristics and endurance characteristics because at least 50% of the α-actin-3 protein is expressed. As far as we know, this is the first finding that Koreans have an advantage in endurance performance when they have the XX and RX genotypes that reinforce the characteristics of slow twitch muscles while leaving the characteristics of fast twitch muscles.

EFFECT OF THE ACTN3 R577X POLYMORPHISM ON THE ASSOCIATION BETWEEN CK LEVELS AND SPRINTING TIMES DURING GAME IN BRAZILIAN PROFESSIONAL SOCCER PLAYERS

DE ALMEIDA, K.1, ZEMPO, H.2, CETOLIN, T.3, MARRERO, A.3, AGUIAR-JUNIOR, A.3, KIKUCHI, N.1

1. NIPPON SPORT SCIENCE UNIVERSITY, 2. TOKYO SEIEI COLLEGE, 3. FEDERAL UNIVERSITY OF SANTA CATARINA

INTRODUCTION: The ACTN3 R577X (rs1815739) polymorphism is associated to sports performance, where the R allele is related to muscle strength and power, and the X allele to muscular endurance. Previous studies also suggested the association of this polymorphism with the risk of sports injury, that can be different depending on populations and modalities. Therefore, this study aimed to evaluate the relationship between post-game Creatine Kinase (CK) levels and the number of sprints performed, and the influence of the ACTN3 genetic polymorphism on this response in Brazilian Professional Soccer Players.

METHODS: A total of 23 professional soccer players (25 ± 3.9 years old; 77 ± 5.6 kg; 180 ± 4.7 cm) belonging to first division of the Brazilian Championship were sampled through blood collection. The DNA was extracted by the Salting out method and the polymorphisms genotyped by Polymerase Chain Reaction (PCR) and Restriction Fragment Length Polymorphism (RFLP) with restriction enzyme. The post-game CK level was measured 48h after official games of Brazilian Championship, and the number of Sprints during each competition was estimated with Global Positioning System (GPS). The data was collected accordingly to the number of times the player participated at official games, average of 10 ± 4.8 measures per player. For each player, the 5 median CK measures were used for analysis together with their respective GPS data (≥60 min/game), totalizing 115 combinations of GPS+CK data analyzed.

RESULTS: From the 23 players, 13 were RR genotype and 10 were X allele carriers (RX and XX genotypes). Athletes ACTN3 RR had significantly higher mean weight (RR 78.8 ± 4.9 kg, X 74.6 ± 5.6 kg, $p<0.001$) and height (RR 181 ± 4.6 cm, X 179 ± 4.6 cm, $p=0.02$), while X athletes were significantly older (RR 24.5 ± 2.3 years old, X 25.8 ± 5.2 years old, $p=0.04$). A significant positive correlation was seen between the number of sprints (>19 km/h) performed during the game and the CK levels ($p=0.009$). When divided by the ACTN3 genotypes, athletes with the RR allele had higher CK levels as more sprints were performed ($p=0.017$). However, X allele carriers did not present significant relationship ($p>0.05$). The RR athletes also had a significantly higher mean of CK levels compared to X individuals (RR=876 ± 598, X=536 ± 211, $p<0.001$). However, there was no significant difference in the number of sprints between the genotypes (RR 24.8 ± 18.3 times, X 20.6 ± 16.8 times, $p>0.05$)

CONCLUSION: Our results suggest that the number of sprints is directly related to the concentration of the extracellular biomarker of muscle damage, where the greater the number of sprints, the greater the levels of CK in the blood, especially in athletes with RR genotype. Hence, RR genotype can be more susceptible to microlesions due to a better physical performance in high intensity activities, requiring a better control of workloads and recovery time in order to prevent the development of chronic severe conditions as a consequence of repeated microinjuries.

THE OLYMPIC MIRNOME: AN ANALYSIS OF THE COMPLETE PLASMA MIRNA PROFILE IN MAXIMAL AEROBIC TESTS DURING THE SAME SEASON IN OLYMPIC MEDALIST KAYAKERS.

FERNANDEZ-SANJURJO, M., FERNANDEZ-VIVERO, D., NOGUERO, C., TERRADOS, N., FERNANDEZ-GARCIA, B., IGLESIAS-GUTIERREZ, E.

INSTITUTO DE INVESTIGACIÓN SANITARIA DEL PRINCIPADO DE ASTURIAS

INTRODUCTION: MicroRNAs (miRNAs) are small non-coding RNA molecules, conserved between species. They can be found intracellularly, controlling gene expression, or circulating in biological fluids, as plasma, creating a crosstalk between tissues (1). Several circulating miRNAs have been described to respond to acute exercise and training (2). However, Olympic medalist athletes were not analyzed until now, so the aim of this study was to identify new biomarkers in medalist athletes to define their training response to an aerobic macrocycle and their acute response to maximal tests previous and after that macrocyle.

METHODS: Four plasma samples were collected from 4 kayakers (28.8.2±4.0 y) medalist in Tokyo Olympics. The four sampling points were done before and after two maximal aerobic capacity tests in kayakergometer. These two maximal tests had been done at the starting point of the season (A- pretest 1, and B- posttest 1) and after the macrocyle of aerobic development (C, pretest 2, and D posttest 2). In both tests, VO2max and HRmax were recorded. A 752-miRNA plasma profile was measured by qPCR using miRNome panels (Qiagen). Raw data was pretreated by 2^(-ddct) method using to normalize mean miRNA expression values. One factor ANOVA was carried out to compare between points. Pearson analysis was performed to correlate expression with VO2max and HRmax.

RESULTS: Our results defined a specific response of miR-223-3p at each of the points, an increase in levels between A and D based on training response, and an increase in its expression in acute response in both maximal tests. Specifically in

response to training, miR-19a-3p, miR-320b and miR-425-5p increase their expression. In acute response to the early season maximal test, miR-150-5p and miR-197-3p are overexpressed, while miR-132-3p and miR-192-5p levels are reduced, a response that is for the first time described in this work since all maximal test data so far defined an overexpression of miRNA levels. However, in the maximal aerobic performance phase the reality is different, obtaining only the response of overexpression in two miRNAs: one common to the other maximal test miR-197-3p and one specific to this phase, miR-103a-3p. On physiological response no differences were observed neither in HRmax nor in VO2max.

CONCLUSION: Moreover, as previously described, miR-150-5p was increased in acute response and miR-106b-5p was correlated with aerobic performance (3). However, in these high-performing subjects, new miRNAs emerge as responders not previously considered in the exercise response.

All in all, we have defined a new specific miRNA profile in Olympic medallists in both acute and training response, which is also related to maximal aerobic performance. This opens the door to possible functional analyses of epigenetic differences on high-performance athletes.

ASSOCIATION BETWEEN CYP1A2 RS762551 C/A POLYMORPHISM AND ENDURANCE RUNNING PERFORMANCE

SAKAMOTO, Y., MIYAMOTO-MIKAMI, E., TAKARAGAWA, M., FUKU, N.

JUNTENDO UNIVERSITY

INTRODUCTION: Caffeine is widely used by athletes because of its ergogenic effect on athletic performance. However, the ergogenic effect of caffeine has been found to vary considerably between individuals and is influenced by a genetic polymorphism (rs762551 C/A) in the gene encoding cytochrome p450 1A2 (CYP1A2), a caffeine metabolising enzyme. A previous study reported that pre-exercise caffeine intake reduced 10km cycling time by 6.8% in individuals with the AA genotype, but increased it by 13.6% in those with the CC genotype. Therefore, this study aimed to examine the association between the CYP1A2 rs762551 C/A polymorphism and long-distance running performance in Japanese athletes who regularly consume caffeinated beverages, such as Japanese tea, coffee, and others.

METHODS: In total, 283 Japanese long-distance runners (227 men and 56 women) were included in the study. Total DNA was isolated from the saliva of the participants using the Oragene DNA Extraction Kit. CYP1A2 rs762551 C/A polymorphism was analysed using the TaqMan SNP Genotyping Assay. The International Association of Athletics Federations (IAAF) score for each athlete was calculated from the 2017 edition of the IAAF Scoring Tables based on their personal best records in 5,000 and 10,000 m runs, half-marathons, and marathons.

RESULTS: There existed a significant difference between the IAAF scores of athletes with AA + AC genotype and those with the CC genotype in men but not in women. Male athletes with AA + AC genotype had significantly higher IAAF scores than those with the CC genotype (1041 ± 122 vs. 991 ± 214, $p < 0.05$).

CONCLUSION: Our findings showed that the CYP1A2 rs762551 C/A polymorphism was associated with the physical performance of long-distance male runners. Caffeine ingestion prior to exercise has been attributed to increased serum free fatty acid (FFA) levels, which increase lipid metabolism, decrease muscle glycogen utilisation, and consequently potentiate endurance performance. The CYP1A2 rs762551 C/A polymorphism alters CYP1A2 enzyme activity. Based on the CYP1A2 enzyme activity, individuals can be categorised as fast or slow caffeine metabolisers. Fast metabolisers (i.e., individuals with the AA genotype) have higher levels of paraxanthine (caffeine metabolite) than slow metabolisers (i.e., individuals with the CC genotype). Paraxanthine exhibits higher binding potency for the adenosine receptor than caffeine and may lead to higher FFA blood levels. Moreover, our data showed gender differences. A previous study reported consistently higher caffeine intake during competitions by male athletes than by female athletes. This may be explained by the results of the present study which suggest that there is no association between the CYP1A2 rs762551 C/A polymorphism and endurance performance in female athletes. In conclusion, the CYP1A2 rs762551 C/A polymorphism is associated with endurance performance in men.

OP-SH19 Teacher and teaching education

PEDAGOGICAL CONTENT KNOWLEDGE IN MOVEMENT AND PHYSICAL ACTIVITY AMONG EDUCATORS IN EARLY CHILDHOOD EDUCATION AND CARE.

SOLLERHED, A.C.

KRISTIANSTAD UNIVERSITY

Introduction

Movement and physical activity (MoPA) are critical to children's health and development. Most children aged 1-5 years are enrolled in Early Childhood Education and Care (ECEC) in Sweden, and high expectations are placed on educators to deliver education of sufficient quality to support children's development.

Methods

The aim of the 18-month-long action-based study was to investigate how 88 ECEC educators in five preschools perceived and experienced the priority and teaching of MoPA. The educators planned and implemented MoPA sessions among children in a trial-and-error manner. They filmed sequences from the sessions, which later were shown in the focus groups. The filmed sequences were the starting point for the collegial discussions with the researcher as a moderator. Content analyses of the transcribed focus group discussions were conducted.

Results

The content analyses revealed three themes with associated subthemes (in brackets): Teaching aspects (Competence; Role modeling); Educational aspects (Children's development; Children's health and wellbeing); Structural aspects (Curriculum; Environment).

Discussion

During the project with the trial-and-error MoPA teaching, the educators detected insufficient pedagogical content knowledge to teach MoPA and the teaching was often replaced with free play. By the end of the project, they had completely run out of exercises and activities and the lack of pedagogical content knowledge became tangible. The increased metacognition made the educators aware of children's different MoPA levels and that free play did not always increase all children's skills. The perceived insufficient pedagogical content knowledge to teach MoPA was perceived as a troublesome barrier for promoting MoPA. The educators' metacognition about MoPA increased and they became more observant on children's MoPA. They also became aware of children's different MoPA levels and that free play did not always increase all children's skills. Despite of increased metacognition about MoPA and its importance for children's development and health, most of the educators were not ready to leave their comfort zones and were not open to extra work or effort when it came to plan and implement more MoPA in the daily rutines. Organizational barriers such as group size of children, lack of available facilities, vague formulations in the curriculum were highlighted, but also personal barriers such as attitudes and fitness levels. The educators demonstrated the need for improved education in MoPA in early childhood teacher education, as well as the need for continuous education for working educators in ECEC to enhance the pedagogic content knowledge for adequate teaching in MoPA, which is important for children's present development and future health.

ACCURACY OF PRIMARY TEACHER JUDGMENTS ON BASIC MOTOR COMPETENCIES

NIEDERKOFLER, B.

FREE UNIVERSITY OF BOZEN-BOLZANO

Introduction: Assuming that students' motor competence development is a goal of physical education, pedagogical diagnostics (in the sense of teacher's perception and interpretation in an diagnostic situation) as well as teachers' decisions (in the sense of teachers' judgement and instructional decisions) should be particularly proficient in context of students' motor competence status. Generally, one should trust teachers' instructional decisions, but various studies suggest (eg. Seyda, 2018), that physical education teachers show difficulties in assessing students specific learning levels. This shows that the quality of teachers diagnose can be doubted, too. Therefore, this study was conducted to assess the accuracy of primary teacher judgements of basic motor competencies (BMC) in 2nd and 4th grade. Methods: 16 teachers (age 39.5 ± 12.43 years, 87% female) were asked to judge the BMC of 2nd (n = 151, age 7.9 ± 0.8 years) and 4th graders (n = 103, age 9.6 ± 0.6 years). In addition, students BMC were assessed using the MOBAK-1-2 for 2nd graders and MOBAK-3-4 test for 4th graders (Herrmann, 2018). The tests inform about the status of students self-movement (SM) and object-movement competence (OM). Three judgment components were calculated according to Schrader (1989): the skill to judge students level of BMC (level), the skill to judge students competence rank within the class (rank) and the skill to judge the heterogeneity of motor performance. Results: The calculations showed an overestimation of BMC level, an accurate assessment of BMC heterogeneity in OM as well as its underestimation in SM, and a medium judgment accuracy for the BMCs ranking. Discussion: Except the accurate assessment of BMC heterogeneity in OM, the results confirm previous studies that found difficulties in teachers' judgement of students' specific learning levels. Nevertheless, these findings suggest a promotion of primary teachers diagnostic competence.

DIAGNOSTIC COMPETENCE OF P.E. TEACHERS - HOW IS IT LINKED TO INSTRUCTIONAL AND DIAGNOSTIC ACTION?

SEYDA, M., LANGER, A.

TU DORTMUND & UNIVERSITY OF FLENSBURG

Introduction

Successful teaching requires pedagogical content knowledge (PCK) in order to make subject content understandable (Blömeke et al., 2020). This includes, among other things, diagnostic competence, i.e. the ability to accurately assess students and performance-relevant facts (Schrader, 1989). Research on diagnostic competence show that assessing their students is a challenging task for teachers (Südkamp et al., 2012). It is examined how physical education (PE) teachers deal with this task and if different level of diagnostic competences are linked to divergent instructional and diagnostic action in PE.

Methods

A mixed-method approach was used. In the quantitative part of the study, 43 PE teachers (70% women) rated the physical performance of 742 third/fourth grade students (48% girls) on a likert-scale of 1 to 5. Parallel the physical performance of the students was determined using a standardized motor test (also via a likert-scale of 1 to 5). The quality of the assessment was measured using the Schrader-components (1989), that focus on rank, level and differentiation of the teacher judgements. For the qualitative part of this study ten of the 43 PE teachers with different levels of diagnostic competences were identified and interviewed concerning their instructional and diagnostic activities in PE. Three groups of different level (high, medium, low) were formed and the interviews were qualitatively compared.

Results

The quantitative results showed that PE teachers have difficulties in correctly assessing the physical performance: They overestimate the level and heterogeneity and they struggle to correctly asses how their students compare to each other in terms of performance. In the qualitative group comparisons, it is shown that predominantly PE teachers with high diagnostic competence try to assess each child individually. In addition, they create time for diagnosing through their didactic actions in class. In contrast, PE teachers with medium and low diagnostic competence assess the learning requirements of the entire class. Their diagnostic and didactic activities often interfere, so that they cannot concentrate on the assessment.

Discussion

Overall, differences in the quality of diagnostic competence and linked activities are recognizable. The findings show approaches on how diagnostic competence can be improved.

IS-BM07 How to sprint fast and safe? Segment and muscle coordination in sprint-based sports

INTER-SEGMENTAL COORDINATION STRATEGIES DURING INITIAL SPRINT ACCELERATION

BAYNE, H.

UNIVERSITY OF PRETORIA

Proficient sprint acceleration requires a combination of large mass-specific force applied against the ground with a horizontally orientated force vector, short ground contact times and high step frequencies. To achieve this, athletes must produce kinematic solutions to position their limbs in such a way that enables optimal muscle forces to be generated across joints and to translate the centre of mass forwards and upwards. This combination of kinetic and kinematic parameters establishes 'sprint acceleration technique', which is of interest to anyone looking to enhance performance of this task.

The body is a complex system with numerous redundant degrees of freedom. Coordination patterns in the execution of motor skills (such as sprint acceleration) emerge by self-organisation through interaction with a set of constraints imposed by the nature of the task, the environment and the individual. In research and practice, sprint acceleration technique is typically studied by analysing the configuration of specific body segments and joints at key events during the stride. However, the measurement of isolated kinematic variables at discrete points in time fails to capture the coordination pattern

that occurs between these events and does not directly assess the relative motion of multiple segments. Recent studies have provided the first description of inter-segmental coordination during initial sprint acceleration in highly trained athletes and revealed some characteristic features that indicate strong task constraints. However, between-athlete variation is also evident due to individual constraints and there are potentially important performance implications of these coordination pattern variations. Once these are understood, it would be beneficial for practitioners to have a framework for identifying movement strategies to guide any technical or physical interventions.

This presentation will, firstly, summarise the typical features of inter-segmental coordination and the implications for understanding the demands of initial sprint acceleration. Secondly, novel findings of coordination pattern sub-groups and the association with sprint acceleration performance will be presented. Finally, a practical framework for assessing athletes coordination pattern will be proposed.

The target audience would include researchers with an interest in sprinting or the biomechanics and motor control of movement tasks, in particular during running. Furthermore, coaches and sport scientists who are interested in understanding the technical demands of sprint acceleration would also be addressed. The topic is of relevance to provide a more holistic understanding of sprint acceleration technique and is directly related to the growing area of coaching interest in this field, supporting the integration of research and practice.

INTERMUSCULAR COORDINATION STRATEGIES DURING SPRINT ACCELERATION

HEGYI, A.

UNIVERSITY OF NANTES

Effective sprint propulsion is a result of heterogeneous contribution of muscles to the force applied to the ground. This heterogeneity is partly due to the distinct force-velocity and force-length properties of different muscles. For example, the semitendinosus can produce relatively large force at fast velocities, therefore is believed to contribute to high step frequency in sprint running. This may be related to higher muscle volume of the semitendinosus and gluteus maximus as compared to other hip extensors in sprinters compared to non-sprinters. However, to exploit the maximum capacity of these muscles to produce force, they should be highly excited. Not only the magnitude of excitation but also the timing seems to be crucial for optimising intermuscular coordination. Additionally, intermuscular coordination is likely altered when external resistance is increased, such as during certain methods of sprint acceleration training.

Muscle excitation is frequently examined using electromyography (EMG). The EMG signal provides information about the magnitude and timing of muscle activation with high temporal resolution. However, studies relating the magnitude and timing of EMG activity to kinematics and force-velocity properties of sprint acceleration are scarce. Additionally, recent technological advances allow for data acquisition with improved signal quality in field settings.

This presentation will show novel results from the FULGUR project, which includes high-level athletes from sprint-based sports (track & field, bobsleigh, rugby). In the first part of the presentation, a comprehensive analysis of EMG patterns from 16 muscles of the lower body will be linked to performance variables such as sprint force-velocity profile, step length, and step frequency. Secondly, the magnitude, timing, and distribution of muscle excitation in resisted sprints will be presented. EMG activity will be interpreted in the context of segment kinematics, which we acquired using state-of-the-art markerless pose estimation. Finally, future directions in the assessment of muscle excitation in highly dynamic movements will be presented.

This presentation will be relevant to those interested in understanding muscle activation strategies in resisted and non-resisted sprint acceleration. A broader audience interested in how to acquire and process EMG signals in dynamic movements will also benefit.

IMPORTANCE OF SEGMENT AND MUSCLE COORDINATION IN SPRINTING FOR HAMSTRING INJURY RISK MANAGEMENT

SCHUERMANS, J.

GHENT UNIVERSITY

Hamstring strain injuries are highly common in explosive field sports demanding repeated sprinting and acceleration efforts. In particular, the long head of the biceps femoris presents a high vulnerability to strain and rupture in the sprinting-related injury mechanism. Sprinting is a complex motor task, necessitating precisely fine-tuned interplay between different parts and entities of the kinetic chain. Therefore, athletes presenting neuromuscular coordination deficits might be at increased risk of sprinting-related injuries. These deficits potentially impact muscle loading via two mechanisms: (i) neural guiding alterations might negatively influence muscle contraction patterns and (ii) associated kinematic deviations might introduce excessive strain and strength production demands on the muscle-tendon system.

The extent to which sprinting induces strain and the exact timing of maximum excitation of each hamstring muscle belly during the gait cycle in high speed running have repeatedly been investigated before. However, the effect of neuromuscular coordination and associated kinematic variations on hamstring injury risk during high speed running has not been investigated so thoroughly.

This presentation will first summarize a case-control study with prospective follow-up that aimed to examine the causative importance of muscle activation, intermuscular coordination, and lower limb and trunk kinematics in the running-related hamstring strain injury vulnerability in male football players. Muscle functional magnetic resonance imaging (mfMRI) scans were taken before and after strenuous eccentric hamstring exercise to assess intermuscular coordination patterns

and amount of metabolic hamstring muscle activation comparing the three bi-articular hamstring muscle bellies. Then, surface electromyography (EMG) activity of the trunk, pelvis and lower limb muscles as well as lower limb and trunk kinematics were collected during repeated overground sprint acceleration. Our results indicate that muscle and segment coordination are essential in hamstring injury risk management. The second part of this presentation will provide practical recommendations on which coordination patterns to examine in sprint-based sports to minimize hamstring injury risk.

The target audience includes researchers and practitioners interested in the preventive value of assessing segment and muscle coordination in sprint-based sports.

Oral presentations

OP-AP17 Resistance Training Methods

THE EFFECTS OF TWO DIFFERENT STRENGTH TRAINING SESSIONS (PULL UPS VERSUS DIPS) ON HAND GRIP STRENGTH.

MYLONAS, V., SAVVA, S., NIKODELIS, T.

ARISTOTLE UNIVERSITY OF THESSALONIKI

INTRODUCTION: Over the last years bodyweight exercises regained popularity. Both professional and recreational athletes are using them. Calisthenics is a type of training that uses bodyweight to improve muscle strength, endurance, and control. Elite calisthenics athletes often use external weights to further load their training sessions. Such activities are linked with the strength of the hand grip. Pulls ups and Dips are widely used exercises both highly depended on the stabilization of the grip. However, grip has a totally different role in these to exercises. The purpose of the present study was to investigate possible effects on grip strength measured at two different elbow angles after a training session for maximal strength in Pull ups and Dips with additional weights.

METHODS: Six healthy, young male adults performed Hand Grip Strength (HGS) measurements. Two wireless Hand grip Dynamometers (K-grip @Kinvent) were used (one at each hand) pre-post the training sessions on Pull ups and Dips. The training sessions were randomized and had 7-day difference between them. Participants followed a maximal strength training protocol designed to reach their Repetition Maximum. Strength measurements included six 4sec isometric trials (3 with elbow at 180o and 3 at 90o) with 30s rest time. Participants performed the grip strength measurements with both hands simultaneously. From each trial a time series of force was extracted, and four variables were calculated for analysis as the average of both hands (Max Force, Average Force, Maximum Rate of force development (RFD) until maximum force and Time until maximum force). A Shapiro–Wilk test was used to validate the normality of the distribution. For the assessment of the hypothesis, a repeated (within subjects) measures analysis of variance was used with 3 factors (time, type of training, angle of test) of 2 levels each.

RESULTS: Significant interaction was noticed between the type of training and angle factors in the Time to max variable which was significant lower in the 180 degrees angle only in Pull session. In addition, marginal interaction was noticed between the time and type of training factors for the RFD to max variable. Although not significant, the values were lower in Pull session compared to Dip post training. Regarding significant main effects both max and average force were significantly lower in 90o - compared to 180o.

CONCLUSION: The type of exercise has an effect on HGS. An explanation could be involved by the grip position in each exercise considering that the vertical reaction forces act more favorable for the dip instead of the pull facilitating less active role for the grip at the dip exercise. The lower values in 90o flexed elbow compared to the 180o position verify the theory of the length-tension relationship. Forearm bi-articular grip flexor muscles such as Palmaris Longus and Flexor Digitorum Superficialis are in optimal length when the elbow is at 180o, leading to higher grip strength.

EFFECTS OF DIFFERENT ARM-SPECIFIC TRAINING ON THE PULL-UP PERFORMANCE OF CLIMBERS

DEVISE, M., VIGOUROUX, L.

AIX-MARSEILLE UNIV

INTRODUCTION: Sport climbing performance is known to be highly related to strength and endurance in upper limb. Trainers and climbers therefore focus on developing the ability of the fingers to hang on holds and the arms to pull up from one position to another. Although finger-specific assessment and training methods are widely analysed in the literature, no study has yet quantified the effects of arm-specific training. These programs usually consist of different muscle contraction regimes (isometric, eccentric…). The aim of this study is then to compare the effects of these different types of training on climbers pull-up capabilities.

METHODS: 35 advanced to high-elite climbers (23±7y/o; 176±8cm; 62±8kg) performed 5 weeks of training (twice a week) based on pull-ups on hangboard, and were randomly divided into 4 different groups: eccentric (ECC; n=9), stato-dynamic (SD; n=9), plyometric (PLYO; n=9) and no specific trainings (CTRL; n=8). Before and after training, they were tested on a force-sensing hangboard (SmartBoard, France). Force, velocity, muscle power and muscle work were analysed during 3 various pull-up exercises: pull-ups at body weight ("jump tests" with or without coordination, or preceded by a descending phase), incremental weighted pull-ups and maximal number of pull-ups ("exhaustion test"). These tests were used to characterize the climber's abilities (body coordination skills, concentric capabilities of arm muscles, force-velocity profile

and capacity to resist fatigue). The comparison between groups before and after training were assessed by ANOVAs with post-hoc tests and principal component analysis (PCA).

RESULTS: Performance between the pre- and post-tests was similar in the CTRL group, but significantly improved after training in the SD, PLYO and ECC groups. Significant interaction effects were found, showing that improvements varied according to the training programs. Especially, the training programs differed in their effects on the velocity parameters during jump tests (+27±11% with PLYO) which led to a greater muscle power, on a higher maximum load during weighted pull-ups (+5±2% with ECC) and on the maximum number of pull-ups (+21±19% with PLYO) and muscle work (+34±17% with PLYO) during the exhaustion test. To summarize, the evolution of each participant on a 2-factor PCA was quantified and showed that the effects of training depended both on the training type (either PLYO, ECC or SD) and on the individual characteristics prior to the training.

CONCLUSION: This study pointed out that the muscle contraction regimes used during the arm training programs affected the benefits. It seemed that ECC improved force variables, PLYO enhanced velocity and endurance parameters whereas SD had lower effects. Overall, all program effects were dependent on the individual initial characteristics. This study provided new quantification and knowledge that is available to trainers and climbers to help them optimise their improvements.

COMPARATIVE STUDY OF LOWER STRENGTH AND ANAEROBIC CAPACITY IN JUVENILE ATHLETES USING BLOOD FLOW RESTRICTION AND MUSCLE ELECTRICAL STIMULATION COMBINED WITH LOW-INTENSITY RESISTANCE TRAINING

QIU, J., ZUO, Q.K., MI, W.G., WANG, J.H., TAN, C.H.

SHANGHAI INSTITUTE OF SPORTS SCIENCE

INTRODUCTION: The purpose of this experiment is to explore the adaptive differences between BFRT and EMS combined with low-intensity resistance training on the maximum strength, explosive power and anaerobic capacity of lower limb muscles of juvenile athletes, and provide reference for athletes and coaches to select appropriate training methods at relevant stages to improve juvenile athletes ability.

METHODS: This experiment Recruited a total of 24 running juvenile athletes (ages between 15-18y) ,were randomly divided into three groups, eight in each group. Besides daily running training, take 6 weeks, three times a week fitness training. BFRT group and EMS group were combined with 30% 1RM resistance training, while CON group only took 30% 1RM resistance training. The isokinetic peak moment of knee joint flexion and extension at 60 °/s, the height of counter movement jump (CMJ), and the root mean square amplitude (RMS) of surface electromyography during CMJ were measured before and after training. They were recorded as lateral femoral muscle: RMSVM, rectus femoris: RMSRF, medial femoral muscle: RMSVL, and biceps femoris: RMSBF, 30 s Wingate anaerobic test peak power (PP), relative PP, mean power (MP), relative MP.

RESULTS: There was a significant increase in the isokinetic peak moment of bilateral knee flexion compared with that before training in the group, The left knee isokinetic peak torque of EMS group after training was significantly higher than that before training. The muscle strength ratio of the right knee joint in the EMS group after training was significantly higher than that before training. The CMJ height of EMS group afte training was significantly higher than that before training. And the difference before and after intervention after training was significantly different from that of BFRT group. After training in the EMS group, there was a significant improvement in the group. PP and relative PP in the EMS group decreased significantly after training. MP and relative MP after training were significantly lower. After training, there was a significant difference between the EMS group and the BFRT group in the relative PP and relative MP difference before and after intervention.

CONCLUSION: 6-weeks BFRT combined with low-intensity resistance training increased the maximum strength of knee flexion of juvenile athletes to a certain extent, and the explosive power level did not significantly improve, nor did it affect the anaerobic capacity of juvenile athletes; 6-week EMS combined with low-intensity resistance training enhanced the maximum strength of the vulnerable limb of the young athletes through the interaction effect, which made the maximum strength of the knee flexor muscle without electrical stimulation enhanced, and the explosive power level significantly improved, but the 6-week training weakened the ability of the anaerobic energy supply system of the juvenile athletes.

PERSONALIZING RESISTANCE TRAINING MITIGATES NEUROMUSCULAR AND PERCEIVED FATIGUE: THE AUTOREGULATION CLUSTER TRAINING METHOD

DELLO IACONO, A., HILLAN, J., WATSON, K.

UNIVERSITY OF THE WEST OF SCOTLAND

INTRODUCTION: Traditionally, resistance training is prescribed in the form of rigid, non-personalized training programs. To illustrate, fixed structures of sets, repetitions, and rest intervals are prescribed alongside percentages of the maximal load a person can lift for a single repetition (1RM) in an exercise. Although this approach is promoted at group level, it fails to account for the variability of day-to-day performance. In fact, prescribing resistance training based upon rigid training variables may lead to an overloading stimulus in some days and an underloading in others due to the acute fatigue accumulating within the ongoing session. A strategy to mitigate fatigue within a session is the cluster-set training approach, which consists in splitting up the total number of repetitions performed into clusters (e.g., 4–16) of fewer repetitions (e.g., 2–6) interspersed by brief rest intervals (e.g., 10–60 s) . However, all cluster-training variants are designed like the traditional-set approach by using predetermined and fixed configurations of clusters, repetitions per cluster and between-

cluster rest intervals. Therefore, we conceptualized the Autoregulation Cluster Training (ACT) method, which personalizes cluster-set configurations by accommodating changes to cluster-set structures in a dynamic manner during the ongoing training session based upon an autoregulation target. The aim of this study was to compare the effects of predetermined and ACT resistance training sessions on neuromuscular and perceived fatigue.

METHODS: Twenty-six resistance-trained men completed three sessions including the back squat and bench press exercises matched for load (75% of 1 repetition maximum), volume (24 repetitions) and total rest (240 s). Sessions were randomly performed as: traditional-set (TRA), 3 sets of 8 repetitions with 120 s inter-set rest; cluster inter-set rest redistribution (IRR), 6 clusters of 4 repetitions with 48 s inter-cluster rest; ACT, a personalized combination of clusters, repetitions per cluster and between-cluster rest regulated upon a velocity loss threshold. The comparative effects were evaluated on velocity loss outputs measured with a linear encoder and perceived fatigue responses reported using a single-item scale.

RESULTS: IRR and ACT induced less velocity loss compared to TRA ($b = -2.09$, $P < 0.001$). ACT also mitigated velocity loss more than IRR ($b = -2.31$, $P < 0.001$). The back squat resulted in greater velocity loss compared to the bench press ($b = 1.83$, $P < 0.001$). Perceived fatigue responses mirrored the pattern observed for the velocity loss outputs (IRR and ACT vs. TRA: $b = -0.64$, $P < 0.001$; ACT vs. IRR: $b = -1.05$, $P < 0.001$; back squat vs. bench press: $b = 0.46$, $P = 0.005$).

CONCLUSION: IRR and ACT reduced neuromuscular and perceived fatigue likely due to their cluster-set structures embedding frequent windows of inter-set rest. However, the ACT was overall more effective, presumably given its personalized structure.

TRADITIONAL RESISTANCE TRAINING MAY NOT BE ENOUGH. IS ACCENTUATED ECCENTRIC LOADING THE ANSWER?

ARMSTRONG, R., LANGAN-EVANS, C., BALTZOPOULOS, V., CLARK, D., JARVIS, J., STEWART, C., O'BRIEN, T.

LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: During traditional resistance training (TRAD), the same absolute external loads are used during the concentric (CON) & eccentric (ECC) phase of an exercise. However, greater forces can be produced during ECC contractions than CON contractions [1]. Despite this, the ECC joint moments during TRAD squatting are significantly smaller than CON joint moments [2]. It has however been demonstrated that ECC joint moments can be enhanced with accentuated eccentric loading (AEL) [2]. Therefore, the aim of this study was to investigate if training with AEL leads to greater strength & hypertrophy adaptations than TRAD

METHODS: 22 strength trained males (squat 1RM >1.5x body mass) were split into a TRAD or 1 of 2 AEL groups (work matched or repetition matched). The TRAD group performed squats with 80% of 1RM during the CON & ECC phases. Both AEL group performed squats with 80% during the CON phase & 120% in the ECC phase. All groups trained for 6 weeks with progressive overload each session. RPE & muscle soreness was collected throughout the intervention. Pre/post testing assessed; CON, ECC & isometric knee extensor joint moment (accompanied by vastus lateralis EMG), jump performance & squat 1RM. Vastus lateralis muscle architecture was assessed at the distal, mid-belly, & proximal site to identify muscle hypertrophy. ANOVA was used to assess the effects of the intervention & between groups differences. Effect size was calculated as omega-squared values. Significance was set at $P<0.05$

RESULTS: There was a significant effect of training on knee extensor joint moments ($P=0.007$), ECC EMG ($P=0.019$), & squat 1RM ($P<0.001$). There was no effect of the intervention for any of the groups on muscle architecture, jump performance or CON EMG ($P>0.005$). Between group differences identified that only the AEL groups improved their ECC knee extensor joint moments ($P=0.004$, $ES = 0.378$). All groups improved their CON & isometric joint moments, with no difference between groups ($P=0.133$). Only the AEL groups displayed an increase in ECC EMG ($P=0.010$, $ES = 0.40$). At the start of the intervention, muscle soreness & RPE was significantly higher in the AEL groups than TRAD, however by session 8, no differences existed between groups. No differences were found between the work matched or repetition matched AEL groups for any outcome measure

CONCLUSION: This study has shown AEL training, but not TRAD, resulted in improvements in ECC strength. These adaptations may be driven by neural mechanisms rather than changes in muscle architecture, at least in the short term. The perceived negative effects of AEL training appear to be overcome after 4 weeks of training & thus we recommend that AEL training should be prescribed in blocks exceeding this time frame. AEL training did not negatively impact on any other adaptations compared to TRAD, & therefore may be a valuable training method in sports that require high levels of ECC force production such as changes of direction

COMPARISONS OF VISCERAL ADIPOSE TISSUE AND LIVER FAT CONTENT BETWEEN HIGHLY TRAINED AND RECREATIONALLY ACTIVE OLDER MEN AND THE EFFECTS OF REPEATED PROLONGED EXERCISE

POGGI, A.I.1, ANDREASEN, M.W.1, SAHL, R.E.1, RØMER, T.1, HANSEN, M.T.1, LINDEN, F.H.2, HØGH-SCHMIDT, E.2, BOESEN, M.P.2, LARSEN, S.1, DELA, F.1, HELGE, J.W.1

1.XLAB, CENTER FOR HEALTHY AGING, DEPARTMENT OF BIOMEDICAL SCIENCES, UNIVERSITY OF COPENHAGEN; 2. DEPARTMENT OF RADIOLOGY, BISPEBJERG AND FREDERIKSBERG HOSPITAL, COPENHAGEN, DENMARK.

INTRODUCTION: Visceral adipose tissue (VAT) and liver fat (LF) content is increased with age (1) and is associated with the development of cardiometabolic disease (2). Exercise is effective in reducing fat content in both areas, however, VAT and LF content has not been measured in trained older males. We therefore measured VAT and LF content in trained older men, before and after 16 days of repeated prolonged cycling around the Baltic Sea. Baseline values were compared with values obtained from recreationally active older men matched for age and BMI. We hypothesized that both VAT and LF content would be lower in the group of trained older men, and that repeated prolonged exercise would result in unchanged VAT and LF content, proposedly due to low amounts at baseline.

METHODS: Five trained older men (66.3±6.7yrs, BMI 23.9±0.63) and eight recreationally active older men (69.9±3.7yrs, BMI 24.3±1.76) performed identical tests. A graded bicycle ergometer test with collection of respiratory gasses was performed to determine maximal fat oxidation (MFO), the relative workload at which MFO occurred (FatMax) and maximal oxygen uptake (VO2max). Heart rate (HR) was monitored to determine HRmax. Anthropometrics including VAT content was determined by DXA. The fraction of liver fat relative to water content (FLF) was quantified using MRI. HR during cycling was measured, for estimation of workload relative to HRmax. Baseline and post cycling values were compared using paired t-tests. Baseline measurements were compared between groups using unpaired t-tests.

RESULTS: The trained older men had lower VAT content ($p=0.02$), and a tendency towards lower FLF ($p=0.06$) compared with the recreationally active older men. The trained older men had a higher VO2max ($p<0.01$) and MFO ($p<0.01$) but similar FatMax ($p=0.2$). The trained older men cycled an average daily distance of 170±25km/d at 67% of HRmax, which resulted in a 9.2% decrease in FLF ($p=0.02$), despite unaltered VAT content ($p=0.79$), weight, fat mass and lean mass. VO2max, MFO and FatMax was not affected by repeated prolonged exercise either.

CONCLUSION: VAT but not LF content was lower in trained older men, compared with recreationally active older men. However, repeated prolonged exercise reduced LF, but not VAT content, proposedly due to a low VAT content at baseline.

The study indicates, that physical activity does not protect from increases in LF content to same degree as VAT content, with increasing age, which is also reflected in different responses to repeated prolonged exercise. We propose that a lower limit for VAT content is present. Further research with higher statistical power is however needed to confirm these findings.

MODERATE-INTENSITY CONTINUOUS TRAINING VERSUS HIGH-INTENSITY INTERVAL TRAINING ON INSULIN SENSITIVITY AND MAXIMAL FAT OXIDATION IN ADULTS WITH TYPE 2 DIABETES.

GONZÁLEZ-MARISCAL, A., ÁVILA-CABEZA-DE-VACA, L., MONTES-DE-OCA, A., MARÍN-GALINDO, A., CORRAL-PÉREZ, J., REBOLLO-RAMOS, M., CASALS, C., PONCE-GONZÁLEZ, J.G.

UNIVERSITY OF CADIZ

INTRODUCTION: Type 2 diabetes (T2D) is a disease associated with distinctive features such as reduced insulin sensitivity and impaired ability to oxidize lipids at rest and during exercise (1). Recent studies have shown that physical exercise has beneficial effects on insulin sensitivity (2). Both high-intensity interval training (HIIT) and moderate-intensity continuous training (MICT) induce similar acute improvements in peripheral insulin sensitivity 24h after exercise and similar long-term metabolic adaptations in skeletal muscle in adults (3). Thus, this study aims to compare the impact of HIIT and MICT on insulin sensitivity and maximal fat oxidation (MFO) in adults with T2D, and whether these changes are related to each other.

METHODS: This is a preliminary analysis of EDUGUTION/APETEX/LIPIDOX randomized controlled studies with 46 subjects with T2D (55.70 ± 6.97 years). Participants were allocated to MICT (n=20, 8 women), HIIT (n=15, 4 women) and control group (CG) (n=11, 4 women). HIIT consisted of 10×1 intervals pedalling at 90% of peak power output, MICT consisted of continuous pedalling at 10% above the first ventilatory threshold for 50 minutes, and the CG remained inactive. The program consisted of 12 weeks of training of three sessions per week on non-consecutive days. The measurements consisted of two days assessed before and after the intervention. On day 1, blood glucose was measured at fasting basal as well as at 90 minutes in an oral glucose tolerance test. On the second day, MFO was evaluated through an incremental test on a cycle ergometer (15-W/3-min) with indirect calorimetry. A mixed factorial ANOVA with Bonferroni post hoc comparisons were applied. Pearsons correlation was performed with MFO and insulin sensitivity changes. Significance was set at $p<0.05$.

RESULTS: Basal and 90 min glucose levels significantly decreased in HIIT (p=0.046; p=0.019) and MICT (p=0.021; p=0.008). No significant results were found between groups or the time by group interactions. The MFO was significantly higher after 12 weeks of training (HIIT and MICT) compared to the CG, with a significant time by group interaction (p=0.010). In the MICT group, there is a significant correlation between MFO and insulin sensitivity (p=0.002).

CONCLUSION: Both training programs improved insulin sensitivity and MFO in adults with T2D, being the HIIT a time-efficient exercise strategy in the management of T2D.

REPEATED HIGH-INTENSITY INTERVAL TRAINING INTERVENTIONS AFFECT HUMAN SKELETAL MUSCLE EPIGENETICS AND PROMOTE MUSCLE MEMORY

PILOTTO, A.M., MAZZOLARI, R., TURNER, D.C., GORSKI, P.P., CREA, E., ZUCCARELLI, L., BROCCA, L., PELLEGRINO, M.A., GRASSI, B., BOTTINELLI, R., SHARPLES, A.P., PORCELLI, S.

UNIVERSITY OF PAVIA

INTRODUCTION: Skeletal muscle epigenetic memory of hypertrophy has been identified in humans. Resistance training promotes retention of DNA modifications and related gene transcription which lead to enhanced hypertrophic response when the anabolic stimulus is later experienced (Seaborne et al., 2018). Repeated single-leg moderate-intensity endurance training does not induce differences in transcriptomic alterations and results in similar skeletal muscle adaptations (Lindholm et al., 2016). However, training at higher intensity seems to promote epigenetic modifications and consequently altering gene expression of mitochondrial biomarkers (Barrès et al., 2012). This study explored whether repeated high-intensity endurance training interventions could evoke an epigenetic muscle memory facilitating enhanced metabolic gene expression and oxidative muscle adaptations. We hypothesized the higher exercise intensity would positively modulate methylome and transcriptome responses.

METHODS: Eleven healthy subjects (25±5 yrs) performed two repeated interventions of high-intensity interval training (training and retraining) separated by 12 weeks of detraining where exercise was completely suspended. Intervention consisted of 8 weeks of combined high-intensity and sprint interval cycling exercises performed 3 days per week. At baseline and after training, detraining and retraining, vastus lateralis muscle samples were collected and genome-wide DNA methylation, gene expression and mitochondrial respiration (O2 flux by high-resolution respirometry) were analyzed.

RESULTS: Training induced hypomethylation in 14,516 differentially methylated positions (DMPs). Epigenetic memory profiles were identified in at least 1,190 DMPs showing a retained hypomethylated state even after detraining and retraining. Six genes: ADAM19, INPP5a, MTHFD1L, PDGFB, CAPN2 and SLC16A3 were identified as epigenetic memory genes with increased expression after training, retained expression after detraining and enhanced expression after retraining. Mitochondrial O2 flux in maximal uncoupled respiration rate through complexes I+II combined improved in both training and retraining (+13.1±17.8 and +24.1±16.0 pmol·s−1·mg−1 respectively, both $p<0.05$). Importantly, O2 flux changes observed after retraining were greater than after training ($p<0.05$).

CONCLUSION: Across repeated interventions, memory profiles were highlighted at epigenetic level characterized by retention of hypomethylation after training into long-term detraining and retraining periods. At transcriptional level, memory of earlier training was observed in genes involving calcium signaling, lactate and pyruvate transport and mitochondrial enzymes, suggesting epigenetic memory not only provides the mechanistic basis for the positive effect on mitochondrial function but is also relevant for muscle contractile function. Human skeletal muscle possesses a molecular and functional memory from repeated aerobic training interventions when exercise intensity is kept above a critical value.

DO EXERCISE AND ENERGY METABOLISM EXERT A SELECTIVE PRESSURE ON GUT MICROBIOME? LESSONS LEARNED FROM THE EXOMIC PILOT CLINICAL STUDY

MARTIN, D.1, BONNEAU, M.1, DEMAY, R.1, LECOMMANDEUR, E.2, HAZON, M.2, MONBET, V.3, BOUMPOUTOU, R.4, CRESSARD, C.2, CRESSARD, P.2, DERBRÉ, F.1

<1> LABORATORY "MOVEMENT, SPORT AND HEALTH SCIENCES", UNIVERSITY RENNES 2, FRANCE <2> NAHIBU, RENNES, FRANCE <3> IRMAR - UMR CNRS 6625, FRANCE <4> STADE RENNAIS FOOTBALL CLUB, FRANCE

INTRODUCTION: Microorganisms living in the gastrointestinal tract provide a variety of benefits to its host. Our research team identified a direct link between gut microbiota, skeletal muscle and endurance performance (Nay and al. 2019). Over the last decade, substantial studies observed that microbial α-diversity and fecal short-chain fatty acids (SCFA) concentrations were higher in elite athletes than sedentary population supporting the hypothesis that highly trained individuals would possess an optimized microbiome extracting more energy from food. However, all of these studies present some important limitations, including the lack of control for dietary habits, which are clearly known to significantly affect the composition and function of the gut microbiome.

METHODS: In this context, we conducted a clinical study (NCT05220657) to characterize the gut microbiome of male participants ranging from sedentary individuals to elite athletes with high (i.e. elite soccer players) or even very high energy requirements (i.e. elite cyclists). All volunteers (n=50) performed an incremental exercise test and a fasting submaximal exercise test. Measured metabolic parameters (e.g. VO2max, carbohydrate and fat oxidation) were then linked to the metagenomic shotgun and metabolomic data from fecal samples. Participants also completed a Food Frequency Questionary (FFQ) to quantify habitual dietary intakes.

RESULTS: As expected, we recruited a heterogeneous population on VO2 max (i.e. from 38.7 to 85.6 ml/min/kg) and maximal fat oxidation (i.e. from 0.5 kcal/min to 13.30 kcal/min). On contrary to our expectations, α-diversity showed an inverse U-shaped relationship with VO2max. Two groups of participants can be distinguished (using Bray Curtis Distance): one (n = 21) with an overrepresentation of bacteria from the Prevotellaceae (P) family, and another (n = 29) exhibiting a majority of Bacterodaceae (B). The majority of cyclists had a P enterotype (n = 12/14; 86%), whereas almost all sedentary participants had a B enterotype (n = 18/21; 85%). Participants exhibiting a P enterotype were related to the higher fat oxidation values during exercise ($p < 0.01$). Although P enterotype participants displayed lower gut microbiome α-diversity ($p < 0.01$), fecal concentrations of SCFAs (i.e. propionate and valerate, $p < 0.01$) were higher compared to B enterotype. Neither dietary intake of carbohydrates, fat, fibers nor proteins explained the enterotype shift.

CONCLUSION: From this population matched for dietary habits and BMI, cyclists with a majority of Prevotellaceae appear to produce more SCFA, probably conferring an advantage for endurance performance. These changes in gut microbiome are not related to diet habits, but rather to fat oxidation and thus energy metabolism. Further experiments including fecal transplantations in mice will determine if a causal relationship really exists between gut microbiome and energy metabolism during submaximal exercise.

MOVEMENT VARIABILITY IN SIX RUNNING CONDITIONS: A COMPLEX SYSTEMS APPROACH

TEIXEIRA, A.1, SAMPAIO, J.1,2, EXEL, J.3, MATEUS, N.1,2, AMARAL, A.1, SANTARÉM, D.1, ABRANTES, C.1,2

1UNIVERSITY OF TRAS-OS-MONTES AND ALTO DOURO; 3UNIVERSITY OF VIENNA, DEPARTMENT OF SPORT SCIENCE BIOMECHANICS, KINESIOLOGY AND COMPUTER SCIENCE VIENNA

INTRODUCTION: Variability is an essential trait to describe all movements either from a performance or from a health perspective. The analysis of variability requires the usage of analytical methods to describe the complexity of the system, such as sample entropy (sampEn) [1]. The aim of this study was to compare the variability in acceleration during six different running conditions.

METHODS: Fifteen healthy adults were tested (age=31.43±9.39 yrs). After a familiarisation session, the participants performed the following six running variations in random order: high-knees (90° knee angle), tethered, shoulder-wide, shoulder-wide coreboard, treadmill (10.9 m/s at 0% of slope), and slope treadmill (10.9 m/s at 6% of slope). All conditions had a pre-defined cadence (130 or 150 bpm), over 90sec with 5-min rest interval between them. Perceived exertion (RPE) was assessed using the Borg scale (6-20), and inertial measurement units (Blue Trident, Vicon, NZ) placed on both ankles to capture accelerations. Matlab® routines were employed to calculate sampEn and the complexity index of acceleration (CI). The coefficient of variation (CV) was also determined. A Friedman-test was used for analysis ($p \leq 0.05$). Data are expressed as median (25th-75th percentiles).

RESULTS: The sampEn was higher ($p<0.001$) in slope treadmill and coreboard in right (Mdn 0.45; IQR 0.40-0.53) and left ankles (Mdn 0.53; IQR 0.37-0.66). Differences were also identified for the CI [right ankle, $X2(5) = 36.49$, $W=0.52$; left ankle, $X2(5) = 38.78$, $W=0.55$; $p<0.001$], with the coreboard showing higher CI values when compared to the other variations (right ankle, Mdn 12.25; IQR 11.43-12.64; left ankle, Mdn 13.82; IQR 11.36-15.28). Running with high knees exhibited higher CV (right ankle, CV= Mdn 2.04; IQR 1.89-2.20; left ankle, CV= Mdn 2.08; IQR 1.09-2.26), in comparison to the other variations ($p \leq 0.05$). The high knees also showed higher values in RPE (Mdn 16.71; IQR 15-18).

CONCLUSION: Coreboard and slope running resulted in higher CI and sampEn values, suggesting that irregular surfaces lead to more complex and irregular movement patterns, which might require greater neuromuscular control, coordination, and adaptability. Also, high knees resulted in higher variability, possibly due to the increased intensity and muscular demands, coordination, and joint flexibility required to perform this movement.

NOVEL APPROACH FOR A HYBRID CUSHIONING SYSTEM IN RUNNING SHOES BASED ON HALBACH ARRAYS

KORNFEIND, P., BACA, A.

CENTRE FOR SPORT SCIENCE AND UNIVERSITY SPORTS, UNIVERSITY OF VIENNA

INTRODUCTION: Based on a novel magnetic spring construction (Halbach arrays), an innovative midsole cushioning concept for running shoes has been developed (patent granted). Laboratory tests of hybrid material samples showed higher stiffness (more progressive behaviour) with faster rebound compared to conventional midsoles [1]. A pilot study has been conducted to investigate possible effects on selected biomechanical parameters when used in a conventional running shoe. The primary goal of this study was to identify possible changes in EMG [2,3] and force characteristics during gait and running.

METHODS: Four male subjects (26.5±5.4 yrs, 184.8±5.6 cm, 78.8±3.3 kg) wearing two different types of the same running shoe were investigated. The first shoe was original (unmodified) while the second shoe (modified) had the magnetic module installed in the longitudinal arch between the heel bone and the metatarsus. Subjects were asked to perform 10 trials walking and 10 trials running over force measuring plates (Kistler 9281EA) mounted into the ground. In addition to the ground reaction forces, we recorded surface EMG data (Delsys Trigno) of vastus medialis, biceps femoris, tibialis anterior and gastrocnemius medialis muscles. The force and EMG data of the left and right leg were time and amplitude normalized and the mean time courses were calculated to analyze differences between the two running shoes.

RESULTS: Two subjects showed markable changes in the breaking impulse of the anterior-posterior (AP) ground reaction force (GRF) impulses (subject 2: -35.7 %, subject 4: -12.9 %) when running with the modified shoe. Also a reduction in the amplitude of the passive peak (running) of the vertical ground reaction force could be observed (subject 2: -15.6 %, subject 4: -8.2 %). The same subjects showed slightly increased muscle activity in the m. tibialis anterior just before foot strike with the integrated magnetic spring in the shoe. In contrast, no noticeable difference in the observed parameters could be found in subjects 1 and 3, neither during walking nor during running.

CONCLUSION: The observed effects in ground reaction forces are likely related to muscular pre-activation of the lower leg leg muscles. It is possible that the magnetic spring generates some kind of mechanical stimulus in the longitudinal arch (foot reflex zone), which causes an interaction effect and slightly varies the movement pattern. The intraindividual differences indicate that both responders and non-responders were included in the subject group and further investigation will be needed.

CASE STUDY OF RECORD-BREAKING IRONMAN ATHLETE IN RESPONSE TO CUSHIONED FOOTWEAR AND FATIGUE STATES

KNOPP, M., CIGOJA, S., FRITZ, J., MILES, H., SCHWEIZER, F., RUIZ, D.

ADIDAS AG, HERZOGENAURACH, GERMANY

INTRODUCTION: Technological advancements in footwear have gained increasing attention due to their performance benefits particularly on the road racing marathon distance [1]. Focusing on the cushioning element of these shoes, previous research has found that softer midsoles improve running economy [2]. Other than road runners, Ironman athletes also use such footwear during the marathon leg of a race but start in a more fatigued state. Previous research has found that alterations in running kinematics with worse running economy have been linked to fatigue in prolonged running [3]. Interestingly it has also been found that despite being in a muscle damaged state, highly cushioned shoes continue to improve running performance [4]. Knowing this, the aim of this study was to investigate if fatigue levels alter the running economy response in a world-class Ironman athlete to different shoe conditions.

METHODS: This case study included one world-class Ironman athlete (age: 36 years; weight: 65.8 kg; height: 178 cm) who 3 weeks prior had broken the Ironman run course record with the fastest marathon time of 2:30:32 (h:min:sec) during an Ironman competition. We conducted submaximal laboratory-based assessments during two different sessions. The first testing session included steady state running economy trials at the average marathon pace (17 km/h) of his most recent Ironman race in two different shoe conditions in a randomized counterbalanced repetitive order. The second session consisted of a similar protocol but was conducted with each steady-state trial following a 15-minute race level (260 W) biking leg. The shoe conditions included an advanced footwear technology shoe consisting of a curved stiff element in the forefoot and a 40 mm high stack height of a lightweight resilient foam, as well as a maximal shoe, with matching technology but with an even higher stack height of 50 mm. These shoes differ particularly in terms of their cushioning properties with the maximal shoe having 9.0% (1.6 mm) more maximal deformation under 2000 N of force as measured on a material testing machine.

RESULTS: At average marathon speed, in a non-fatigued state, the advanced footwear technology condition (55.6 mL/kg/min) was more efficient than the maximal shoe (56.3 mL/kg/min). Testing in a fatigued state revealed an opposing trend with the maximal shoe (55.1 mL/kg/min) being more efficient than the advanced technology condition (56.9 mL/kg/min).

CONCLUSION: While this is a single case study example, for this Ironman triathlete, when adding the fatigue from the bike leg, the increased deformation of the maximal shoe benefits the efficiency of this runner by 3.2% whereas in a non-fatigued state this athlete does not appear to benefit from the additional stack height.

HIGH MIDSOLE RESILIENCY AND LOW SHOE MASS DO NOT CONSISTENTLY ALIGN WITH BEST RUNNING ECONOMY MEASURES

AGRESTA, C., ZENDLER, J., ROSSANIGO, R., BERTULETTI, S., CARAMIA, F., DE LAZZARI, B., QUAGLIAROTTI, C., CEREATTI, A., CAMOMILLA, V.

UNIVERSITY OF WASHINGTON

INTRODUCTION: Innovations in running shoes have demonstrated promising preliminary results for enhancing performance [1,2]. New lightweight midsole material allows for increased height without added weight. The added height provides space for carbon fiber plate additives and, along the material composition, enhances the cushioning system of the shoe. The critical parameter that enhances running performance via improvement in running economy remains unclear [3]. Existing studies vary in findings, in part, because of methodological inconsistencies with respect to footwear testing and feature control [4-8]. To advance footwear recommendation and design, a better understanding of how specific features influence performance is needed. Our study purpose was to determine the influence of changes in midsole cushioning and shoe mass on running economy in shoes with and without carbon fiber plates.

METHODS: We conducted two separate experiments to achieve our study purpose. In experiment 1, we had 10 recreational runners use three different shoes (Nike Vaporfly [NV], Nike Pegasus [NP] and Diadora Volo [DV]) and four insole conditions resulting in 8 conditions that varied in the amount of midsole resilience while shoe mass was controlled at 282g. In experiment 2, we had 10 recreational runners use the same shoes and native insoles resulting in 7 different conditions with varied mass: native shoes, NV 178g, NV 258g, NV 282g, NP 258g, NP 282g, and DV 282g. In both experiments, participants ran at 14 km/h on a treadmill for 5-minutes while breath-by-breath gas exchange was collected (CosMed, Fitmate, Rome, IT). Caloric cost unit (kcal/kg/km) was our primary outcome. For experiment 1, we expected the order of most to least economical trials to follow most to least resilient shoes (NV, NP, DV). For experiment 2, we expected the order of most to least economical trials to follow lightest to heaviest shoe mass condition within each shoe group (NV and NP).

RESULTS: Ten percent (1/10) of runners responded with the expected economical order in experimental set 1 and zero percent (0/9) in experimental set 2. Neither shoe (p=0.99) nor insole (0.99) had a significant effect on running economy in set 1. Neither shoe (p=0.31) nor mass (p=0.85) had a significant effect on running economy in set 2. No interactions were observed.

CONCLUSION: No consistent or predictable relation was found between running economy and footwear conditions with varying shoe mass and resiliency. The subject-specific response indicates we are missing a key parameter from running biomechanics that is likely mediating the interaction of the shoe and the runner. Future work should be directed at understanding the interplay between the shoe and the runner to develop better recommendation and design guidelines.

OP-BM25 Muscle and tendon function

ACTIVE AND PASSIVE RIGIDITY OF HAMSTRING MUSCLES DEPENDS ON HIP ANGLE

BOUVIER, J., FOURÉ, A., MARTIN, C.

UNIV LYON, UNIVERSITÉ CLAUDE BERNARD LYON 1, LABORATOIRE INTERUNIVERSITAIRE DE BIOLOGIE DE LA MOTRICITÉ , F-69622 VILLEURBANNE, FRANCE.

INTRODUCTION: Intramuscular passive structures seem to play an underestimated role in numerous aspects of sport practice (1) but there has been a growing interest for their interaction with muscle active structures in the last decades (2). Shear wave elastography (SWE) has been proved reliable to estimate muscle rigidity at rest and during submaximal voluntary contractions, the latter being linked to individual muscle force (3). The aim of this study was to determine the impact of hip angle on the active and passive contributions to hamstring muscles rigidity during submaximal voluntary contractions.

METHODS: The Shear Wave Speed (SWS) was assessed using SWE in the biceps femoris (BF), semitendinosus (ST) and semimembranosus (SM) at rest and during submaximal isometric knee flexions (at 25%, 50% and 75% of the maximal voluntary contraction [MVC] torque) for a knee angle of 90° and two hip angles (90° and 70°) in 22 women. Surface electromyographic (sEMG) signals from the hamstring muscles were acquired during the experiment. The active SWS (aSWS) was defined as the difference between the SWE measurement realized during submaximal contraction and at rest (pSWS). Both aSWS and pSWS were expressed in percent of the SWS measured during the submaximal contractions. A three-way ANOVA was used to investigate the effect of hip angle on the aSWS, SWS and sEMG root mean square (RMS) in each muscle and for each contraction intensity. A two-way ANOVA was used to examine the effect of hip angle on the pSWS in

each muscle. Post-hoc analysis was conducted using Tukey HSD test. A Student t-test was performed to evaluate the impact of hip angle on MVC torque.

RESULTS: Regardless of the muscle studied and the intensity of submaximal contractions, a change in hip angle had no significant effect on SWS (P=0.26), while pSWS and aSWS significantly changed between 90° and 70° of hip flexion ($P < 0.001$ and $P < 0.01$, respectively). Post-hoc tests showed that pSWS increased with hip flexion while aSWS decreased. The mean sEMG RMS over the three muscles and contraction intensities also decreased with hip flexion ($P < 0.05$). No difference in MVC torque was observed between the two hip angles ($P = 0.29$).

CONCLUSION: The three hamstring muscles presented a greater resting rigidity for a hip angle of 70° than at 90°, which did not lead to a difference in SWS during contraction because of the smaller aSWS and activation observed at 70°. Such an effect of muscle length on the hamstring muscles pSWS and sEMG RMS had already been reported (4,5). However, muscle activation strategies dependent on the passive mechanical properties of the muscles had never been reported before and still warrant further examinations.

EFFECTS OF HIP EXTENSION TRAINING PERFORMED WITH FULL VERSUS PARTIAL RANGE OF MOTION AT LONG MUSCLE LENGTHS ON MUSCLE HYPERTROPHY AND SPRINT PERFORMANCE

MAEO, S.1,2, KOBAYASHI, Y.1, KINOSHITA, M.1, WU, Y.1, ONO, M.1, ARAI, H.1, SUGIYAMA, T.1, FOLLAND, J.P.2, KANEHISA, H.3, ISAKA, T.1

INTRODUCTION: The hip extensors appear to play an important role in sprint running performance (Miller et al., 2021; 2022). However, it is unknown whether hip extension training improves sprint performance. Growing evidence suggests that training at long muscle lengths produces greater hypertrophy than training at short muscle lengths (Maeo et al., 2021; 2022). Although resistance training guidelines generally recommend wide or full range of motion (ROM) (ACSM, 2011; Schoenfeld & Grgic, 2020), training with partial ROM at long muscle lengths may be superior for muscle hypertrophy and consequently also sprint performance. Thus, we examined the effects of hip extension training performed with either full ROM versus partial ROM at long muscle lengths, on muscle hypertrophy and sprint performance.

METHODS: Thirty-four healthy young adults were allocated to a full (FULL: n = 18) or partial (PART: n = 16) group, and they completed the study. The participants conducted unilateral hip extension training in a standing position either with full ROM (hip 90°-flexed to 0°) or partial ROM at long muscle lengths (hip 90°-flexed to 45°-flexed), as allocated, with the knee kept straight. Each leg performed 5 sets of 10 repetitions (2 s for each of the concentric/eccentric phases) at 70% of one repetition maximum (specific to FULL/PART) during each training session, and 2 sessions/week for 12 weeks. Before and after the intervention, T1-weighted axial 3-T MRI scans (FOV: 200*200 mm, slice thickness & gap: 5 mm) were obtained to assess muscle volume of the hip extensors (the gluteus maximus and hamstrings), and 60-m sprint time was also assessed.

RESULTS: After the intervention, muscle volume significantly increased in all hip extensors for both groups ($P \leq 0.006$). The changes in muscle volume were greater for PART than FULL in the gluteus maximus (+6.1 vs +2.4%, $P = 0.038$, Cohens'd = 0.90) and biceps femoris long head (+9.4% vs +4.2%, $P = 0.014$, Cohens'd = 1.04), but statistically not different between groups in the semitendinosus (+7.3 vs +4.6%, $P = 0.891$, Cohens'd = 0.37) and semimembranosus (+7.2% vs +3.9%, $P = 0.109$, Cohens'd = 0.75). Consequently, the change in muscle volume of the whole hip extensors was greater for PART than FULL (+6.8 vs +3.1%, $P = 0.025$, Cohens'd = 0.96). 60-m sprint performance significantly increased (i.e. shorter/faster time) in both PART and FULL without a significant difference between groups (-2.5% vs -1.1%, $P = 0.108$, Cohens'd = 0.79).

CONCLUSION: Hip extensor hypertrophy was greater after hip extension training performed with partial ROM at long muscle lengths compared to full ROM, while both types of training improved sprint performance similarly.

TRAINING AND CONTRALATERAL EFFECTS OF 6 WEEKS ISOKINETIC ECCENTRIC EXERCISE ON PLANTARFLEXOR MUSCLE-TENDON MECHANICS

KAY, A.D.1, TYSOE, J.C.1, BLAZEVICH, A.J.2, BAXTER, B.A.1

1: UNIVERSITY OF NORTHAMPTON , 2: EDITH COWAN UNIVERSITY

INTRODUCTION: Large increases in joint range of motion (ROM) have been reported after eccentric resistance training [1], however limited data exist on the potential mechanisms associated with these changes. Furthermore, while the contralateral effects of eccentric training are well documented for strength [2], no data exist for ROM. Therefore, the present study examined the training and contralateral effects of a 6-week isokinetic eccentric plantarflexor training programme on muscle-tendon mechanics.

METHODS: Before and after the 6-week programme, dorsiflexion ROM, stretch tolerance, elastic energy, plantarflexor muscle-tendon stiffness, gastrocnemius medialis (GM) architecture, and maximal isometric plantarflexor torque were measured using dynamometry and sonography in both lower limbs of 13 participants (5 males, 8 females, age [mean ± SD] = 22.1±2.4 y, height = 1.7±0.1 m, mass = 71.3±16.2 kg). Training was performed twice-weekly on the right limb, consisting of 5 sets of 12 maximal isokinetic eccentric plantarflexor contractions performed at a 10°·s-1 velocity through a 30° ROM, with each contraction terminating at full passive dorsiflexion ROM.

RESULTS: Significant (P<0.05) increases in dorsiflexion ROM (trained = 9.5±5.4°, d=1.75; contralateral = 4.0±4.1°, d=0.98), stretch tolerance (trained = 95.9±40.8%, d=1.48; contralateral = 46.2±23.9%, d=1.48), elastic energy (trained = 161.3±49.6%, d=1.70; contralateral = 51.7±37.3%, d=1.34), and isometric strength (trained = 38.0±40.2%, d=1.09; contralateral = 44.2±33.4%, d=1.75) were detected in the trained and contralateral limbs, respectively. Within the trained limb, significant increases were also observed in GM thickness (6.1±8.1%, d=0.79), fascicle length (7.6±8.5%, d=0.94), and plantarflexor muscle-tendon stiffness (28.5±37.0%, d=0.67). Significant correlations were detected between the changes in trained and contralateral limb dorsiflexion ROM (r=0.59), stretch tolerance (r=0.70), elastic energy (r=0.66), and isometric strength (r=0.69).

CONCLUSION: The large increase in ROM after eccentric resistance training was associated with changes in neurological, mechanical, and structural adaptations in the trained limb, with evidence of a contralateral effect primarily being associated with a neurological (stretch tolerance) adaptation. The substantial and similar increases in isometric strength in both the trained and contralateral limbs are consistent with a previous review [2] confirming a stronger contralateral effect following eccentric resistance training than other contraction modes. The large changes in structural and functional measures combined with substantial changes in the contralateral limb have important implications for exercise prescription in healthy and clinical (e.g. injured, diseased, aged) populations where periods of inactivity may negatively influence these outcome measures.

MILD DAMAGE IN KNEE EXTENSOR MUSCLES ACCUMULATES AFTER TWO BOUTS OF MAXIMAL ECCENTRIC CONTRACTIONS

MORIN, T., SOURON, R., BOULAOUCHE, I., JUBEAU, M., NORDEZ, A., LACOURPAILLE, L.

NANTES UNIVERSITY

INTRODUCTION: Most of sport activities involve repeated eccentric contractions that is a major cause of cytoskeletal disruptions, commonly referred as muscle damage. Muscle damage trigger a cascade of symptoms such as long-lasting strength loss, muscle soreness, and inflammatory response. While many authors considered that muscle damage could accumulate with the repetition of intense efforts, the current literature still lacks of robust experimental evidences to draw definitive and practical conclusions. This study aimed to determine whether mild muscle damage accumulates on the knee extensors after two bouts of maximal eccentric contractions performed over two consecutive days.

METHODS: Thirty participants performed an initial bout of maximal eccentric contractions of knee extensors during the first day of the protocol (ECC1). Then, they were splitted in two groups. The experimental group (EXP, n = 15; 6 females; age: 21 ± 2 years; height: 175.5 ± 9.6 cm; weight: 66.8 ± 10.2 kg) repeated the eccentric bout 24h later (ECC2) while the control group (CON, n = 15; 6 females; age: 21 ± 1 years; height: 171.1 ± 11.7 cm; weight: 64.9 ± 11.1 kg) did not. Indirect markers of muscle damage (i.e., strength loss, muscle soreness, and shear modulus) were measured to quantify the amount of muscle damage and their time course

RESULTS: We reported a significant time × group interaction on strength loss and muscle soreness (both $P < 0.01$). Two days after the initial eccentric session, participants from EXP had a higher strength deficit (-14.5 ± 10.6 %) than CON (-6.7 ± 8.7 %) ($P = 0.017$, $d = 0.9$). Similar observations were found on muscle soreness. Although both groups exhibited a similar increase in knee extensors shear modulus after ECC1, we found a second significant increase in muscle shear modulus (+13.3 ± 22.7 %; $P < 0.01$; $d = 0.5$) after ECC2 for the EXP group, despite the presence of initial mild muscle damage (i.e., strength loss about -16.2 ± 7.4%).

CONCLUSION: The current protocol induced mild damage on the knee extensors after one (CON) or two (EXP) work-matched bouts of maximal eccentric contractions performed one day apart. Both the concomitant alteration of the time

course of the strength loss and muscle soreness, combined with an increase in shear modulus after the second bout of eccentric contractions provide evidence that EXP group exhibited an accumulation of muscle damage.

THE IN VIVO PASSIVE STRETCHING RESPONSE OF THE PECTORALIS MAJOR DIFFERS BETWEEN MUSCLE REGIONS

WOLFRAM, S., LIPPS, D.B.

UNIVERSITY OF MICHIGAN

INTRODUCTION: The stretching response of skeletal muscle has been investigated in vivo for individual muscles (1), muscles belonging to a muscle group (2) and regions within the same muscle (3). However, the examined muscles have a strap-like shape and most have pennate architecture. The stretching response of broad, fan-shaped muscles like the pectoralis major (PM) has not been investigated. The purpose of this study was to investigate the stretching response of the clavicular, sternocostal and abdominal PM regions during shoulder abduction.

METHODS: Passive stretching response of the PM regions during shoulder abduction was determined for 20 healthy males (age 29.1 ± 8.8 years, height 172.3 ± 25.0 cm, body mass 80.3 ± 27.7 kg). Ultrasound shear wave elastography (SWE) was used to assess stiffness of the clavicular, sternocostal and abdominal regions at rest as the shoulder was abducted in intervals of 0.1 rad. Shear wave velocities (SWV) were extracted from the resulting SWE images as a measure of muscle stiffness. We used a repeated-measures ANOVA with joint angle as within-subjects factor and muscle region as between-subjects factor to test whether SWVs differ between the PM regions. A piece-wise exponential model was fitted to SWV-joint angle data to extract slack angle, SWV at slack and elasticity constant of the SWV increase for each PM muscle region. Differences in these parameters between the PM regions were determined using a linear mixed model with muscle region as fixed factor and participant as random intercept.

RESULTS: SWVs increased for all PM regions as the shoulder abduction joint angle increased ($p < 0.001$), with significant differences in SWVs between the clavicular, sternocostal and abdominal regions ($p < 0.001$). The measured SWV-joint angle data for the clavicular region rarely followed the exponential model, so data was only fitted for the sternocostal and abdominal regions. Slack angle was smaller for the sternocostal region (47.5 ± 19.6°) than for the abdominal region (62.3 ± 23.7°), trending towards significance ($p = 0.08$). SWV at slack was significantly greater ($p = 0.005$) for the sternocostal region (2.42 ± 0.37 m/s) compared to the abdominal region (2.15 ± 0.28 m/s). The difference between the elasticity constants of the two regions trended towards significance ($p = 0.08$; sternocostal: 0.0058 ± 0.0018, abdominal: 0.0075 ± 0.0037).

CONCLUSION: The difference in SWV at slack between PM regions indicates differences in material properties. Specifically, the sternocostal region appears to be stiffer than the abdominal region. Differences in slack angle and elasticity constant trended towards significance and require further investigation with a larger sample size. These results provide the first insights into differences in stretching response between muscle regions within a fan-shaped muscle with a broad origin.

OP-BM09 Balance and posture II

OPTIMAL MERGING OF KINEMATIC AND KINETIC INFORMATION TO DETERMINE THE POSITION OF THE WHOLE BODY CENTER OF MASS

LE MOUEL, C.

UNIVERSITÉ PARIS CITÉ, UNIVERSITÉ PARIS SACLAY, ENS PARIS SACLAY, CNRS

INTRODUCTION: Stability analyses of standing and walking rely on accurate measurements of the position of the center of mass (CoM). Unfortunately, this cannot be directly measured, and is typically estimated using kinematic markers placed on the body. Various kinematic models of the CoM have been proposed, ranging from very simple (a single marker on the sacrum) to very detailed (38 markers). The accuracy of these models is however unknown. The aim of this study is: first, to evaluate the accuracy of state-of-the-art kinematic models of the CoM; and second, to improve this accuracy by combining kinematic and forceplate measurements.

METHODS: Data from a publicly available database were analyzed. Two subjects performed treadmill running for one minute at 3 m/s and 4 m/s. Marker positions were used to calculate the CoM position according to three kinematic models: 1. the state-of-the-art model, requiring 38 markers, 2. a simplified version requiring 13 markers, 3. the hip mid-point. To determine the error in acceleration, the CoM position was differentiated twice to obtain acceleration, and only the flight phases of running were analyzed. To determine the error in position, the step-triggered average CoM position was obtained as the double integral of the step-triggered average acceleration obtained from the force plates, corrected to remove drift.

A Kalman filter structure was adapted to optimally combine the measurement of CoM position from kinematics and the measurement of CoM acceleration from forceplates.

RESULTS: During the flight phase of running, the acceleration of the CoM is equal to gravity, i.e. null in the horizontal plane and downwards of amplitude 9.81 m/s2. However, the mean acceleration calculated from all three kinematic models had a bias both in the vertical direction and in the horizontal plane. Altogether the mean error in acceleration was largest for the hip markers (32 % of gravity), followed by the simplified model (15 %) and the full model (9 %). Likewise, the mean error in position was largest for the hip markers (11.6 mm), followed by the simplified model (4.9 mm) and the full model (3.5 mm).

The proposed Kalman filter merges high-frequency force plate information and low-frequency kinematic information. The cutoff frequency is automatically determined from the ratio of kinematic noise to force noise. When using this novel filter, the error was drastically reduced for both acceleration and position.

CONCLUSION: State-of-the-art kinematic models of the CoM were found to have very low accuracy. On the other hand, estimating the position of the CoM from force plates alone requires high-pass filtering the force plate signal at an arbitrary frequency. The proposed Kalman filter optimally combines kinematic and forceplate information to improve the accuracy of CoM measurements. The code for calculating the CoM position from kinematics alone and from combining kinematic and force plate measurements will be made available online.

DOES MINI-TRAMPOLINE TRAINING REDUCE LOWER LIMB ASYMMETRIES?

DI ROCCO, F., DE MAIO, M., PAPALE, O., FESTINO, E., FUSCO, A., CORTIS, C.

UNIVERSITY OF CASSINO AND LAZIO MERIDIONALE

INTRODUCTION: Inter-limb asymmetry is defined as the performance imbalance (i.e. strength, balance) of a limb with respect to the other. Asymmetries between limbs are influenced by several factors as lateral dominance (left vs right), injuries and sports. In particular, team-sports athletes exhibit significantly greater inter-limb asymmetries with respect to non-athletes, due to the large number of unilateral actions such as jumping and changes of direction. Studies widely demonstrated how plyometric and balance trainings could minimize inter-limb imbalance by reducing asymmetries and the relative risk of sport-related injuries. Among the different plyometric training modalities, an effective method is represented by mini-trampoline training, such as SuperJump (SJ). Therefore, this study aimed to evaluate the acute effects of SJ on dynamic balance Unilateral Asymmetry Index (UA).

METHODS: 37 healthy subjects were randomly allocated in SJ group (SJG n=20) and Control group (CON n=17). SJG participated in SJ session, whereas CON did not receive any workout. SJ included a 30-min workout with a warm-up including mobility exercises, a central phase with jumping exercises alternating movements of upper and lower limbs and a cool-down. Before (PRE) and after (POST) SJ subjects performed Wobble Board (WB) balance test consisting of 3-min of free familiarization with the board followed by 1 test trial of 30s per limb with 1-min of rest in between. Subjects stood barefoot on the board in a single leg stance by adopting a comfortable and central foot position, knee slightly bended and hands on the hips. To visualize real time balance performances on a monitor, subjects were asked to focus on a motion marker (MM) and try to minimize its displacement with the aim of keeping it inside the target zone (TZ) as long as they could. WB performance was represented by the time the MM spent in the TZ. To evaluate the magnitude of UA Index, the formula [(100/high·low)·-1]+100 was used, where high and low correspond to the greater and lower limb values for WB test.

RESULTS: The linear repeated measures mixed model analysis showed significant differences ($F(3,35) = 3.29$; $p=0.005$) for UA Index between PRE (36.9±27.7%) and POST (17.9±13.6%) in the SJG. No differences were found PRE (32.2±19.3%) and POST (30.5±15.0) for the CON group.

CONCLUSION: Results suggested that SJ training played a key role in reducing UA. Structured training programs aiming at eliminating or limiting the asymmetries, should not only focus on the execution of exercises for the less performing limb. In fact, monopodalic training could lead to a change in the direction of asymmetry, from the dominant limb to the non-dominant one or conversely, by not getting improvements in UA. Therefore, bipodalic exercises, such as repetitive vertical jumps on SJ, could represent an important method in improving UA in healthy young and athlete population.

UPPER EXTREMITY MUSCLE ACTIVITY DURING M-CKCUEST

DE SOUSA, T.1, ROGOWSKI, I.1, DEGOT, M.1, BLACHE, Y.1

1 UNIVERSITÉ DE LYON, UNIVERSITÉ LYON 1, LABORATOIRE INTERUNIVERSITAIRE DE BIOLOGIE DE LA MOTRICITÉ – EA 7424, UFRSTAPS, VILLEURBANNE, FRANCE.

INTRODUCTION: The Closed Kinetic Chain Upper Extremity Stability Test (CKCUEST) was proposed to assess the upper extremity closed kinetic chain function (1). In a push-up position with hands spaced at a half arm span (m-CKCUEST, 2), the participant alternatively touches, as fast as possible, the floor outside the stance hand with the other hand (phase 1) and returns in starting position (phase 2) during three 15-s bouts. The stance limb supports about 65% of the body weight (3) and superior mediolateral peak force was reported for the nondominant limb than for the other side (4), suggesting effect of dominance on loads and muscular activation. This study aimed to assess the influence of dominance, phase and muscle on stance-limb muscle activity during m-CKCUEST.

METHODS: Electromyography activities of lower, middle and upper trapezius, triceps brachii, posterior, lateral and anterior deltoid, and serratus anterior were recorded bilaterally for 14 male athletes (22.3±2.1 yrs, 1.66±0.06 m, 66.5±6.6 kg) per-

forming m-CKCUEST. The effects of dominance, phase and muscle on the stance-limb muscle activity (% of a maximal voluntary isometric contraction) were analyzed with linear mixed model.

RESULTS: For 26±2 touches per athlete, only a significant effect of phase*muscle interaction ($p<0.001$) on muscle activity was found. During phase 1, serratus anterior (31±13%), posterior deltoid (30±13%) and triceps brachii (27±14%) were more activated ($p<0.05$) than lower (18±8%), middle (17±10%) and upper trapezius (21±10%), lateral (19±6%) and anterior (19±8%) deltoid. During phase 2, the serratus anterior (33±11%), anterior deltoid (29±12%) and triceps brachii (25±11%) were more activated ($p<0.05$) than lower (15±5%), middle (15±6%) and upper (9±4%) trapezius, posterior (21±16%) and lateral (16±6%) deltoid. All muscles presented similar activity during both the phases, excepted the anterior deltoid, which was significantly more activated ($p=0.04$) during the phase 2 (29±12% vs. 19±8%).

CONCLUSION: Our findings showed muscular activities were similar for dominant and nondominant stance limbs, and confirmed m-CKCUEST challenges the upper limb stability (3). During both the phases, serratus anterior may resist to trapezius action by rotating internally and upwardly the scapula, and triceps activated to maintain elbow in full extension. When the moving hand reached out the stance hand, posterior deltoid may counteract humeral flexion, while, when the moving hand returned to starting position, anterior deltoid may counteract humeral extension, hence limiting body anteroposterior displacement. The upper extremity muscle activities may thus be coordinated to maintain the glenohumeral joint above the stance hand during the m-CKCUEST.

THE IMMEDIATE EFFECTS OF PLANTAR FASCIA ROLLING ON POSTURAL CONTROL IN HEALTHY SUBJECTS AND PATIENTS WITH NECK PAIN

BEINERT, K.

GERMAN UNIVERSITY OF HEALTH AND SPORTS

INTRODUCTION: The fascial system is organized in chains along the body and is thought to have proprioceptive and nociceptive function (Adstrum 2017). One such chain, the superficial backline, connects the plantar fascia of the foot with the head (Myers 2013). The foot and the head are also crucial players in providing sensory information for maintaining postural control (Henry 2019) and patients with neck pain display decreased postural control (Peng 20219). To test whether manipulation of the plantar fascia improves postural control, we were interested in the immediate effects of plantar fascia rolling on postural control and pain in healthy individuals and patients with neck pain.

METHODS: 45 individuals participated in this study. 15 patients with neck pain and 30 healthy controls were tested by blinded outcome assessors regarding Y-balance test performance, cervical joint position sense acuity and pressure pain threshold of neck muscles. Patients with neck pain received plantar fascia rolling. Healthy subjects were randomly allocated to plantar fascia rolling or placebo. Patients with neck pain and healthy individuals rolled their plantar fascia with about 25% of their bodyweight for one minute on the right and then for one minute on the left side. Both sides were alternately rolled twice. In total, the therapy consisted of 2 x 1 min rolling on the left and 2x1 min rolling on the right side. The placebo group received sham-ultrasound to the plantar fascia. Post-test measurements were performed immediately after the intervention, in a standardized sequence.

RESULTS: A significant time effect ($F1, 42=42.84$; $\eta 2=0.503$; $p<0.001$) but no time*group effect was observed for the Y-Balance test. Cervical joint position sense revealed no time and no time*group effect. Pressure pain threshold showed a trend ($F1, 42=3.1$; $\eta 2=0.07$; $p=0.084$) for time but no time*group interaction.

Comparing healthy individuals, a significant time ($F1, 28=7.96$; $\eta 2=0.500$; $p<0.001$) and time*group interaction ($F1, 28=5.42$; $\eta 2=0.162$; $p=0.027$) was found for Y-Balance performance. Pressure pain threshold demonstrated a significant time ($F1, 28=7.96$; $\eta 2=0.221$; $p<0.009$) and time*group interaction ($F1, 28=5.42$; $\eta 2=0.162$; $p<0.027$). No significant results were observed for cervical joint position sense.

Comparing patients with neck pain and healthy subjects regarding their Y-Balance performance, a significant time effect ($F1, 28=44.38$; $\eta 2=0.613$; $p<0.001$) was observed, but no time*group interaction was found. Pressure pain thresholds demonstrated a significant time ($F1, 28=27.36$; $\eta 2=0.494$; $p<0.001$) effect, but no time*group interaction. No effects were observed for cervical joint position sense.

CONCLUSION: A single session of plantar fascia rolling improved Y-balance performance in healthy subjects and patients with neck pain but did not affect cervical joint position sense. How long this effect maintains is unclear. For patients with neck pain, other therapies such as balance training, neck muscle vibration or mental training seem

"NEURO SOCKS": ACUTE AND LONG-TERM EFFECTS ON BALANCE

PECHATSCHEK, T., MÜLLER, E., DIRNBERGER, J., BIRKLBAUER, J.
UNIVERSITY OF SALZBURG

INTRODUCTION: Deterioration of balance in old age is a significant predictor of fall risk. Wearing special socks or insoles would be a relatively simple and inexpensive option to improve balance. The company VoxxLife claims that wearing their socks with a special tactile pattern (Human Performance Technology) triggers a neural response in the brainstem that leads to numerous improvements in a wide variety of areas, including enhanced balance. The aim of the present study was to examine whether wearing these "Neuro Socks" has acute and/or long-term effects on balance ability compared to standard socks.

METHODS: In a randomized controlled trial, 60 subjects (20-63 yrs of age; 31 females) were allocated to wear either Neuro Socks or standard socks for 5-6 weeks. Pre and post static balance performance with Neuro Socks and standard socks were measured using a multiaxial-unstable balance board (MFT Challenge Disc®). To evaluate acute and long-term effects, frequentist and Bayesian 3-way ANOVA with Time (pre, post) and Socks (Neuro, standard) as within-subject factors and Group (intervention, control) as between-subject factor was calculated using JASP 0.16 (with default prior). Separated 2-way ANOVAs and t tests were employed for post-hoc comparisons.

RESULTS: Changes in the balance performance from pre- to post-test were similar between groups (Group X Time: $p=.546$) with trivial effects ($eta^2p=0.006$) and moderate evidence in favour of H0 ($BF01=3.33$). In the pre-test, wearing Neuro Socks during balance testing did not significantly differ from wearing standard socks ($p=.246$; $d=0.151$) with moderate evidence in favour of H0 ($BF01=3.69$). In the post-test, a significant interaction of Group X Socks was found ($p=.031$; $eta^2p=0.078$; $BF10=1.99$) with the Neuro Socks intervention group showing worse balance abilities when tested with Neuro Socks ($p=.004$; $d=0.572$; $BF10=9.98$).

CONCLUSION: The findings of our intervention study contradict the notion that wearing Neuro Socks improves the static balance ability in young to middle-aged healthy subjects. This applies to both short-term and long-term effects. For any balance improvements, it seems rational that there must be a change in the foot-ground interface. In order to do this, the socks would need to be able to generate a certain threshold of intense afferents. The Neuro Socks with a relatively small HPT pattern, however, seem to be insufficient to stimulate the sensorimotor system in this manner. Whether they have positive effects on other areas such as pain, strength or speed must be verified in further studies.

OPTIMAL ARROW GROUPING BASED ON ARROW MECHANICAL PROPERTIES AND VANES POSITIONNING

KUCH, A., MONNET, T., DURAND, F., COLLIN, R., DEBRIL, J.F.
INSTITUT PPRIME - UNIVERSITÉ DE POITIERS

INTRODUCTION: The material used by an archer affect the score, alongside the shooting technique and conditions [1]. Since different arrows are shots during an event, selecting a set of similar arrows based on their properties is crucial [2]. To obtain optimal grouping on the target, which leads to better score, matching characteristics have been identified: diameter [2], straightness [3], mass [4] or stiffness [4]. In addition, stiffness around the arrow shaft is variable [5] but never considered in those studies, nor the vanes positions with respect to the stiffness pattern. This work aims to investigate if these two aspects influence arrow grouping.

METHODS: Sixty arrow shafts were analyzed using a test bench to obtain their diameter, straightness, and stiffness. Every shaft started on a standardized position (S) according to their labels, then rotated four times around its longitudinal axis, with eight measures per rotation. A sine wave was used to characterize the stiffness. The mean, amplitude, frequency, and phase were found by a Fourier transform and nonlinear fitting. Each shaft was associated with an arrow point and fletched so that out of three vanes, one was placed on S. The angular position of the maximum and minimum of the stiffness, relative to S and therefore one of the vanes was computed. The mass of the shaft, point and assembled arrow were also considered. Five sessions were made with a shooting machine, using the same bow, at the Olympic distance of 70 meters, indoor. The average coordinates of a given arrow across the five shots were collected with graph paper.

The normalized Cartesian distance between every existing pair of arrows ($n = 1770$) on the target was computed. Likewise, the normalized mechanical distance for the pairs were evaluated for every existing combination of the eleven parameters ($n = 2047$). Finally, to assess which parameters to consider for arrow grouping, the RMSE between the two distances were computed.

RESULTS: For each arrow, the standard deviation of the positions was 2.2 ± 1.1 cm on the horizontal axis and 2.0 ± 1.0 cm on the vertical axis. The minimum for the RMSE between target and mechanical distances was found for a combination of three parameters: mean stiffness, frequency and assembled arrow mass.

CONCLUSION: This work provides three parameters to consider for arrow selection, from the eleven parameters that were considered initially. As expected, arrows that had similar stiffness and total mass were closer to each other on the target. The third parameter was the sinusoidal frequency of the stiffness, which suggest that the stiffness pattern variation around

the shaft has also to be considered for optimal arrow grouping. Shaft diameter, straightness and vanes positions with respect to stiffness extrema were found to be less relevant in arrow grouping.

KINEMATIC AND NEUROMUSCULAR PATTERNS OF UPPER LIMBS DURING ROWING ERGOMETER: DESCRIPTION AND IMPACT OF AN ERGONOMIC HANDLE.

SIMON, F.R.1,2,3, ERTEL, G.N.1,3, MORNIEUX, G.1,2,3, GAUCHARD, G.C.1,2,3

1.UNIVERSITÉ DE LORRAINE, DEVAH, NANCY, FRANCE ; 2.UNIVERSITÉ DE LORRAINE, FACULTY OF SPORT SCIENCES, NANCY, FRANCE ; 3.UNIVERSITÉ DE LORRAINE, CARE GRAND EST, NANCY, FRANCE

INTRODUCTION: In rowing, arms transfer all the power produced to the handle and generate 22% of the whole power (1). Therefore, a large articular stress might be applied to the upper limbs. However, no study has evaluated their kinematics and neuromuscular activities to further understand these constraints. In addition, the use of an ergonomic handle might reduce the injury risk (2) and increase comfort (3). Therefore, the aim of this study was to describe neuromuscular and kinematics patterns of the upper limb during rowing ergometer and evaluate the impact of an ergonomic handle.

METHODS: 29 experimented rowers performed two randomized bouts at a competitive rate on a rowing ergometer (RP3®, Care RowPerfect BV, The Netherlands): one with a standard handle (Concept II Inc., USA), and another with a new ergonomic handle (Caremosim™, France) having six faces, with a round placed at the thenar eminence and a plane at the hypothenar eminence, and a 1:1.25 adapted size ratio (2) based on the average hand length of the subjects (194±9mm). Left shoulder, elbow and wrist kinematics were measured with 4 IMU (iSen, STT Systems, Spain) and neuromuscular activity of Triceps Brachii Longus (TBL), Flexor Carpi Ulnaris (FCU), Deltoideus posterior (DP), Brachioradialis (BR), and Biceps Brachii (BB) with surface EMG sensors (Trigno™, Delsys, USA). A comfort scale evaluated separately the perceived grip, size, and shape of handles (4). Handle effect on upper limb joint range of motion, averaged EMG RMS and rower's comfort was investigated with paired Student's t-test.

RESULTS: Upper limb kinematics and EMG were not significantly different during the drive phase between standard and ergonomic handles. However, the ergonomic handle was significantly more comfortable in terms of grip ($p<0.01$) and shape ($p<0.001$). The shoulder yielded a 80° retropulsion with a 30° abduction (20° to 50°) occurring during the last quarter of the drive. The elbow did a 60° flexion (20° to 80°) during the last quarter. The wrist ulnar deviation reached 15° along the drive phase with a 25° flexion at the end. TBL was active only during the first half of drive phase, followed by FCU at middle drive and then DP, BR, and BB during the second half.

CONCLUSION: This study described upper limb kinematics and neuromuscular activity in rowing ergometer. TBL, BR and FCU are important to transfer power at the handle by stabilizing upper limb mainly during the first half of drive phase with isometric contractions. DP, BR and BB allowed arms power production during the second half with concentric contractions. Ergonomic handle increase rower's comfort. Individualization of this ergonomic handle would need to be investigated.

HOW TO MEASURE INTENSITY DURING ON-WATER SPRINT KAYAKING?

DE ZEE, M., KRISTIANSEN, M., LAURIDSEN, H.B., KLITGAARD, K.

AALBORG UNIVERSITY

INTRODUCTION: In cycling the use of power meters is the most used way to assess the intensity of the athlete. It is an objective measure of intensity, and it is not dependent of the slope and/or weather conditions. The measurement of power is relatively easy and mechanically transparent. However, the measurement of power in on-water sprint kayaking is actually very complicated. The reason is that for measuring power you need a force and a velocity. The force one could get from an instrumented paddle, but the question remains which velocity to take and at the same time make sure that the calculated power output is independent from for example wind conditions.

In this work, we present therefore an alternative method to calculate the intensity of a kayaking athlete using impulse based on measured paddle forces.

METHODS: One male national athlete (Age: 20; Body mass: 91.5 kg; Height: 179.5 cm) participated in a test. The athlete did an all-out effort on a 500m on-water kayak sprint. Paddle forces, footrest forces, and velocity were obtained with a sample rate of 100 Hz using the E-kayak system (APlab, Rome, Italy). Bonaiuto et al. (1) has described this system in more de-

tail. The impulse was calculated as a moving integral of the absolute paddle force values over a window of 5 seconds and is expressed in N·s.

RESULTS: The time over the 500 meter was done in 115 s. The moving impulse over 5 seconds peaked already at 10 seconds with a value of 1500 N·s after which the produced impulse decreased over time. The velocity shows the same development as the 5-second impulse indicating that the intensity goes down because of fatigue.

CONCLUSION: The advantage of using impulse is that the calculation is straightforward, transparent, and mechanically sound. The calculation of impulse is based on the forces delivered by the athlete and is, therefore, independent of environmental conditions. Therefore, with headwind the same athlete would produce the same kind of impulse, but the speed would be lower. There is great potential that in the kayak community, impulse could be used as an intensity measure like power output is used in the cycling community using wearable devices. However, the expectation is that the interpretation and acceptance of impulse as an intensity measure will need time and more athlete data before kayak athletes and coaches will use it.

A NEW JIG FOR VALIDATION OF INSTRUMENTED PADDLE SHAFTS IN SPRINT KAYAKING

ROSDAHL, H.1, NILSSON, J.1, AITKEN, D.2, OSBORNE, M.

1 SWEDISH SCHOOL OF SPORT AND HEALTH SCIENCES 2 PADDLE AUSTRALIA AND AUSTRALIAN INSTITUTE OF SPORT

INTRODUCTION: The interest to use new technologies to record paddle stroke forces and power in kayaking has increased over the last decade as a tool for performance development in elite athletes. However, a comprehensive validation of this new technology is needed. For this purpose, a jig is required to handle the physical inconsistencies and characteristics of the paddles, as well as differences in measurement principles. The aim was to further develop a previously described calibration jig (Aitken and Neal 1992) concerning calibration and evaluation of sensors attached to paddle shafts to record stroke forces.

METHODS: A jig was developed by means of modifying a strength training weight stack and adding commercially available aluminum profiles (40x40mm) with open grooves that permit versatile fastening of various panel elements such as shaft and blade support and rotation devices. A force transducer was positioned beneath each support position to record the blade and top hand forces in the vertical plane. To record the bottom hand force a sling was placed around the shaft at the bottom hand position and connected to a force transducer attached to the weight stack. A linear motion path recorder enabled vertical and horizontal displacement was attached to the jig frame to calculate shaft stiffness and measure positions. Two strain gauge based counter-levered moveable sensors (MS) measuring force in one plane were mounted on a GUT-wing blade elite-paddle and sensor responses were recorded with stepwise vertical loading from 5 to 50kg and the paddle rotated stepwise from ±15º to ±45º from the initial vertical force direction. In addition, the response of embedded force sensors (EFS) in four paddle shafts (Gen 2.1, One Giant Leap, Port Nelson, NZ) with Jantex and Bracá blades were recorded at stepwise vertical loading (10, 20, 30 and 40kg) without rotation.

RESULTS: The recorded responses of all force sensors showed correlation coefficients indicating a highly linear response in the vertical force direction. The r-values for MS were 0,9945 (left) and 0,9979 (right) while for EFS the range was from 0,9992 to 0,9998 (n=8). A lowered response of the MS sensors was significant in stepwise rotation of the paddles from the initial vertical force direction on both left (L) and right (R) sides. At +45º L 69%, R 63%; +30º L 83%, R 75%; +15º L 95%, R 85%; -15º L 94%, R 90%; -30º L 86%, R 81% and at -45º L 68%, R 67%.

CONCLUSION: Performance of sensors based on different measuring methods to measure stroke forces during sprint kayaking can be feasibly evaluated during static conditions with the versatile jig. In addition, the present study shows decreased responses in one plane sensors with rotation out of force plane.

STRUCTURAL OPTIMISATION OF A BICYCLE USING A MULTI-INSTRUMENT EXPERIMENTAL DESIGN

NUNEZ, M., ALGOURDIN, P., OSTRE, B., JOLIFF, Y.

UNIVERSITY OF TOULON

INTRODUCTION: Optimising the structure of the bike is a key element in increasing rider performance. Studies show that parameters such as saddle height modify the mechanical work of the lower limb joints and alters the pedalling efficiency (1)

A multifactorial experiment was developed to optimise the bike structure according to the settings and therefore the position of the rider. The objective of this study is to optimise certain parts of the bike such as the bottom bracket, the headset and the saddle tube/frame junction by studying the effects of the parameters on the structure using inertial measurement units on the rider and deformation gauges on the test bench.

METHODS: The study was performed by 6 non-professional riders (3 males 3 females). 4 IMUs (COMETA WaveTrack) were placed on the subjects. One in the lower back, one on the upper right thigh, one under the right knee and the last one on the right foot (2). Strain gauges have been placed on the handlebars (left and right) and on the saddle and calibrated before each test (3). These datas are collected through an ARDUINO board. The pedals are instrumented to obtain the cyclists cadence and pedalling power (GARMIN Vector 3).

The full factorial experiments have as parameters and levels: the saddle height (distance from the ground to the crotch *0.883 or -5% of this value), the position of the handlebars on the axis of the bicycle, and the pedalling rate (60 or 80 rpm (4)).

The test session consisted in a 10 min warm-up and 8 trials of 30 seconds duration where the pedal rate is stabilized, each with a different parameters combination.

IMU data was processed with a quaternion based Kalman Filter. The data sets were implemented in a Matlab 2022 code to obtain the associated rotation matrices and therefore the Euler angles.

RESULTS: Several results were obtained in this study showing the influence of some major parameters. As example, results show that there is a 100% increase between the 2 extremes positions of the experiment on pedalling power. On the other hand, the saddle height has little influence.

CONCLUSION: The results obtained from this multi-instrument experimental design have shown that the parameters of the test bench settings, and therefore of the riders position, influence the forces applied to the structure. An optimization model is proposed to improve a specific structure for each rider.

IS-MH08 In-hospital precision-based exercise in children, adolescents and young adults with cancer as the new frontier of "exercise is medicine" paradigm

EXERCISE TOLERANCE IN CHILDREN, ADOLESCENTS AND YOUNG ADULTS WITH CANCER: NON-INVASIVE ASSESSMENT IN COMPLEX CLINICAL SETTINGS

LANFRANCONI, F.

UNIVERSITY OF MILANO, LITA

A meticulous approach to Precision-based exercise programs (PEx) includes a sensible functional evaluation of every CAYA-C to set the right amount of training, in quality and quantity provisions, exactly as pharmacological treatments are typically prescribed. This is a big challenge for clinical exercise physiologists and pediatricians; however, the reward could be enormous, and the CAYA-C disability conversation flaws lessened. Collection of accurate data regarding the follow-up of CAYA-H's exercise tolerance is not trite: due to the pharmacological toxicity related to life-saving treatments and bedridden consequences, they experience a roller coaster of symptoms that vary from days where PEx are fully affordable to others where severe fatigue is prevalent. The fatigue also affects a patient's motivation to be evaluated and trained. Phenotyping correctly a population before starting PEx is mandatory in order to facilitate personalized risk assessment and the development of targeted exercise prescriptions to optimally prevent or manage systems toxicity after a cancer diagnosis. Following this rationale and because the efficiency of our systems is really understood when the oxidative metabolism pathway is under stress (during an augmented metabolic request), the researchers of the FORTEe research program (EU Horizon 2020 fund) would like to introduce performance tests in hospital for CAYA-C undergoing PEx. The study participants will be randomly assigned to one of two groups: the experimental group (exercise group) receiving a PEx and a control group which receives usual care.

Customizing PEx requires a battery of functional evaluation tests such as those used amongst athletes, including the evaluation of endurance, resistance, balance, and flexibility capacities. An exhaustion test for example can contribute to the correct allocation into a specific phenogroup with a correspondent training protocol. The complication is that functional evaluation tests have to be performed in restrictive clinical settings and require a daily consultation between sport medicine experts and pediatricians. Evaluating the individual maximal exercise tolerance is the most accurate way to define PEx and to assess longitudinally their impact in CAYA-C. By using a careful evaluation of the impact of exercise on physiological and social outcomes is possible to adapt the intervention that can be modulated on a daily basis. The use of technology to motivate training in CAYA-C can make a difference in the adherence to evaluation and training sessions.

For the purposes of the FORTEe project, evaluation protocols have therefore been written and are used by the exercise professionals of the 8 clinical centres across Europe that are recruiting 450 CAYA-C over 30 months. These evaluation protocols, once tested and proved to be useful, could become international guidelines.

PRECISION-BASED TRAINING PROGRAMS IN CHILDREN, ADOLESCENTS AND YOUNG ADULTS WITH CANCER: QUANTITY AND QUALITY MATTER WHEN WORKOUTS ARE IN COMPLEX CLINICAL SETTINGS

KAJ FRIDH, M.

UNIVERSITY HOSPITAL OF COPENHAGEN, RIGSHOSPITALET

Exercise programmes based on precision-adapted exercise (PEx) are an emerging therapeutic option in paediatric oncology and fully encompass the indications provided by the WHO Global Disability Action Plan. The exercise as medicine paradigm is fulfilled by PEx, especially when they start from the earliest days of neoplasia onset and include the most medically fragile CAYA-C, with the inclusion of organ transplant recipients. This is a great challenge for clinical exercise physiologists and paediatricians; however, the rewards could be enormous and the shortcomings of the CAYA-C disability conversation reduced. PEx can also be useful in order to demonstrate sub-clinical impairment of oxidative metabolism systems, compared with what clinicians could diagnose after a medical visit during bed-rest. The body systems are critically challenged during exercise, which triggers structural weaknesses or damages as well as a reduced cardio-respiratory reserve.

The use of generic exercise prescriptions may actually mask the full therapeutic potential of exercise treatment in oncology. In essence, the manipulation of training variables such as volume, intensity, frequency and recovery is an attempt to systematically structure training through phases to optimize physiological and psychological adaptations in an athlete who is also a cancer patient. Finally, recovery and rest are crucial in restoring the availability of nutrients and energy substrates to replace necessary system components (protein in muscle). The researchers of the FORTEe research program (EU Horizon 2020 fund) would like to introduce PEx in hospital adapted to the intensity of the cancer treatment: the most adapted PEx are intended for the most medically fragile children, who usually require long hospital stays; CAYA-C under very intensive and moderately intensive cancer treatments can afford more intensive workouts and they usually are trained in the hospital, but outside the wards. Combined training will be available for CAYA-C of the FORTEe program: cardiorespiratory, resistance, neuromotor and flexibility are considered as part of the PEx. Training sessions are adapted each day in accordance with the clinical condition of the individual participant and after discussing with the treating paediatrician the types of exercise that may be risky for CAYA-C, a precision-based training approach.

For the purposes of the FORTEe project, PEx have therefore been written and are used by the exercise professionals of the 8 clinical centres across Europe that are recruiting 450 CAYA-C over 30 months. These training protocols, once tested and proved to be useful, could become international guidelines.

The impact of this intervention seems to demonstrate, according to the first results of FORTEe project, that PEx are safe and really inclusive also of the frailest CAYA-C.

DEVELOPMENT OF NOVEL TECHNOLOGY APPLICATIONS IN PRECISION-BASED EXERCISE PROGRAM IN CHILDREN, ADOLESCENTS AND YOUNG ADULTS WITH CANCER: MOTIVATION IS A MUST

DREISMICKENBECKER, E.

UNIVERSITY OF MEDICINE JOHANEES GUTTEMBERG-UNIVERSITY OF MAINZ

An important innovation in the precision-based exercise programs (PEx) and sports in children, adolescents and young adults with cancer (CAYA-C), is the use of technology to motivate training as well as to maintain a high adherence to evaluation and training sessions. Another common challenge faced by families and CAYA-C during several periods of cancer treatment is that the patients immune system is compromised. Thus, CAYA-C are advised to keep their physical distance and stay at home instead of going to kindergarten, school or work. In order to face these specific challenges, all participants in the FORTEe research program (EU Horizon 2020 fund) will receive additional training at home during periods of recovery from cancer treatment. Within the FORTEe research project there are several technologies:

1) a FORTEe app for exercise (on a dedicated tablet provided by the exercise professional team), will help exercise professionals to personalise training. The application will also include a visualisation adapted for children, with the aim of increasing their motivation to participate in the process of personalising training. The tool will also contain a catalogue with different exercises with graphics adapted to children and young people;

2) An augmented reality app (on a dedicated smartphone provided by the exercise professional team), will try to improve training adherence and increase the flexibility of the training site.

3) A virtual personal trainer (on a dedicated TV screen in the gym in the hospital) will allow PEx where CAYA-C can imitate the movements and perform exercises settled by the exercise professionals after a consultation with the pediatricians. The screen captures over 30 points of the body and provides children with feedback on correct posture. This helps to avoid incorrectly performed movements. The tool allows exercise professionals supervising the intervention to integrate exercises that are customised to the individual patient. This will eventually increase the CAYA-C compliance.

Another essential part of the use of technology is the possibility of creating databases dedicated to collecting data that may emerge from multi-centred clinical trials and simultaneously monitoring the recruitment process and evaluating the impact of PEx on this population.

SEX-SPECIFIC KINETIC AND KINEMATIC CHARACTERISTICS UNDERPINNING CHANGE OF DIRECTION PERFORMANCE IN BASKETBALL PLAYERS

BAENA-RAYA, A., DÍEZ-FERNÁNDEZ, D.M., MARTÍNEZ-RUBIO, C., LÓPEZ-SAGARRA, A.

UNIVERSITY OF ALMERÍA

INTRODUCTION: In basketball, change of direction (COD) activity comprises ~20.7% of the speed demands, being determinant during both offensive and defensive moments of the game (1). Although there is a great deal of literature investigating COD performance related factors (2), sex-specific information is still limited (3). Consequently, training for women basketball players is often informed from men data. Interestingly, the recent inclusion of microtechnology allow basketball coaches to monitor reliable kinetic and kinematic measures during sport-specific tasks (4,5), which might help to provide a precise sex-specific characterization of different CODs. Therefore, the aims of this study were to (I) evaluate the sex-specific kinetic and kinematic outcomes underpinning COD performance, (II) compare the kinetic and kinematic outcomes across three different COD tasks, and (III) examine the sex- and test-specific outcome most strongly related to COD performance in basketball players.

METHODS: Thirty young basketball players (17 men and 13 women) competing at the national level were assessed for the modified 505 test, modified T-test and V-cut test. The maximum values of acceleration (ACCmax), deceleration (DECmax), velocity (VELmax), and centripetal force (CentFmax) were measured using Local Positioning System technology (WIMU PRO, Realtrack Systems S.L., Almería, Spain).

RESULTS: Men players displayed greater ACCmax, VELmax, DECmax, and CentFmax outputs for each section of the 505 test, T-test, and V-cut test (all, $p < 0.05$), resulting in a faster COD performance than women players across tests (all, ES > -1.42; 95% CI = -3.45 to -0.57). The 505 test demanded significantly greater kinematic outputs than T-test, and V-cut test for men ($p < 0.001$) and women players ($p < 0.01$), respectively. In addition, ACCmax explained ~26-58% of the variability in COD time for men players, while DECmax and VELmax explained 38% and 53% of the variability in T-test and V-cut test time, respectively.

CONCLUSION: These findings suggest that using men and women COD data as interchangeable information may lead to important errors of interpretation when testing and training. The test-specific kinematic profile should be considered to regulate COD intensity, especially to progress in the ACCmax and DECmax demands, which require an optimal player's physical capacity to tolerate the associated loading. Men and women basketball players present different COD determinants, which may help coaches to prescribe individualized training programs.

ANALYSIS OF THE BIOMECHANICAL RESPONSE TO UNANTICIPATED IMPACTS IN PROFESSIONAL RUGBY UNION

KNEBLEWSKI, A., VALDES-TAMAY, L., BOURGAIN, M., ROUCH, P.

ENSAM PARISTECH

INTRODUCTION: The concussion study is of growing interest in professional rugby union, in particular due to the increase of its incidence in last decades. Concussion prevention requires a better understanding of the biomechanical parameters involved in risky play phase. Tackle is identified as the main cause of concussion and certain factors are likely to increase this risk. During unanticipated tackle, the players attention is focused on ball possession or teammates movement, and therefore, the player is more vulnerable to collision. The aim of this study is to analyze the biomechanical response of professional rugby players to unanticipated impacts.

METHODS: 17 professional rugby players participated in this study. They were categorized into two position groups: forwards and backs. An impact simulation device has been developed to reproduce unanticipated tackles under safe and reproducible conditions. Each participant experienced a total of 12 impacts, on the right and left lateral faces, during a motor dual task situation. To evaluated the kinematics response to the impact, players were equipped with 4 inertial units (Vicon, 1200 Hz), positioned on the head, the C7 cervical vertebra, the sternum and the sacroiliac line. The influence of position on player kinematic response was identified using a one-way analysis of variance.

RESULTS: The maximum values of linear and angular accelerations were calculated for each segment. The variance analysis revealed a significant influence of the position on the linear and angular head accelerations: the acceleration peaks are higher for the backs than for the forwards ($p<0.001$). Two head injury criteria were included in this study: the Severity Index and the GAMBIT. For these two parameters, the mean values are higher for the backs than for the forwards ($p<0.001$).

CONCLUSION: We propose an original experimental device for studying unanticipated impacts in a controlled environment. Results showed that the backs experienced higher head acceleration peaks and higher injury criteria than the forwards. These results indicate that when faced with the same impact, backs are characterized by a wider head kinematic response, exposing them to a greater concussion risk. These findings can be explained by the morphological characteristics, weaker for backs than for forward. Indeed, analysis revealed the existence of a negative correlation between the morphological characteristics and the head kinematic parameters associated with concussion risk. Another explanatory factor concerns the higher level of cervical strength in the forwards than in the backs, due to their greater involvement

in combat actions. It is possible that these adaptations also participate in limiting the concussion risk by reducing the magnitude of the head kinematics after the impact. This study improves our understanding of the biomechanical mechanisms involved in unanticipated tackle and provides intervention perspectives for sports staff to implement concussion risk prevention strategies.

THE EFFECT OF LEG DOMINANCE ON THE FREQUENCY AND 3D KINEMATICS OF SOCCER PASSING IN FEMALE ACADEMY PLAYERS

OUTRAM, T., FREEMAN, H., BRILEY, S.

UNIVERSITY OF DERBY

INTRODUCTION: The execution of sub-maximal passes using both feet is fundamental in football as it underpins possession retention and goal scoring. Biomechanical research has focussed on maximal kicks performed by male players. Limited analyses of female players have generally examined gender differences in adult populations. There is a need for female specific research especially within the youth development phase where skill acquisition occurs most easily (1). The aim of this study was to examine the effect of leg dominance on the frequency and 3D kinematics of sub-maximal passes in female academy players.

METHODS: Twelve, female footballers (age: 13.7 ± 0.5 years) from an FA National League academy participated. The frequency and success rate of sub-maximal passes performed in a league game were established via live-match coding (SportsCode). 3D data were collected using a 12-camera Vicon motion capture system sampling at 240 Hz. 16 markers were attached to the lower body then using a 2-step run-up, participants completed ten sub-maximal passes, 5 on each leg towards a target (1.2m by 0.8m) 7m away. Temporal characteristics and kicking leg kinematics were calculated using Vicon Nexus, Pro-Calc and Matlab. Asymmetry was examined using paired-samples t-tests.

RESULTS: Players completed more passes ($p = 0.000$) with a higher level of accuracy ($p = 0.028$) with their dominant leg. In dominant leg passes, the pelvis was consistently in a significantly more closed position relative to the target with the difference ($p = 0.020$) being largest at ball contact (Dom = -34.1 ± 96.6°; Non-Dom = -43.1 ± 6.5°). Increased pelvis obliquity with an elevated kicking side was also observed at maximum kicking leg knee flexion (Dom = -10.0 ± 4.5°; Non-Dom = -7.0 ± 2.7°). Other differences included a significantly shorter leg cocking phase ($p = 0.011$), significantly less ankle dorsiflexion at ball contact ($p = 0.039$) and the standing foot being positioned significantly closer to the ball ($p = 0.018$) when the dominant leg was used.

CONCLUSION: The increased frequency and accuracy of sub-maximal dominant foot passes suggests that players only used their non-dominant foot when the match allowed for a lower level of accuracy (2). Superior accuracy with the dominant leg appears to be caused by increased technical proficiency. Less pelvis rotation away from the target and positioning the standing foot closer to the ball potentially created a smaller foot arc and encouraged players to strike through rather than across the ball (3). The increased pelvic obliquity during the leg acceleration phase could also have caused a rapid pelvis drop before ball contact which has been associated with improved foot speed and control. These findings provide important coaching cues for adolescent female footballers and highlight the need for further biomechanical research within this demographic.

DEVELOPMENT IN PHYSICAL FITNESS DURING YOUTH YEARS IN TEAM SPORT ATHLETES: A SYSTEMATIC REVIEW.

TINGELSTAD, L., RAASTAD, T., KEVIN, K., LUTEBERGET, L.

NORWEGIAN SCHOOL OF SPORT SCIENCE

INTRODUCTION: During youth, large improvements in physical performance occur due to growth and maturation. The timing and tempo in development vary considerably, and earlier maturing athletes are found to outperform their later matured counterparts in several physical performance tests (Malina, 2004). Whether training load have any additional effect is somewhat uncertain, with limited research addressing this matter. Physical development also varies between sexes, with girls tending to plateau their development at an earlier stage compared to boys, as observed in the general population (Malina, 2004). The aim of this systematic review was to investigate the development of physical fitness throughout youth years among team sport athletes.

METHODS: A systematic search of various electronic databases was conducted combining keywords related to physical fitness, youth athletes, team sport and study design. The included articles studied various physical characteristics tests

such as sprint, change of direction ability, endurance, and strength, as well as training load and maturation. Results were normalized and weighted relative to sample size to have a larger database for comparisons.

RESULTS: Hundred and seventy-four eligible articles were identified, but due to large diversity in testing methodology, data from 114 were included in the analysis. In general, the data showed a steady annual improvement in most physical characteristics over time for both boys (lower body strength 12.5 % (-6-27 %); specific endurance 13.5 % (10-16 %); CMJ 7.9 % (4-10 %); 30-m sprint -3.7 % (-6-1 %)) and girls (lower body strength 5.7 % (-1-9) %; specific endurance 10 % (-2-25 %); CMJ 5.1 % (2-7 %); 30-m sprint -1.9 % (-4-0 %)). Only 17 studies included measures of training load.

CONCLUSION: Findings shows a progressive improvement in most physical characteristics throughout the youth years, in both girls and boys. However, girls tend to have a less pronounced development compared to boys, likely due to less increase in lean mass (Malina, 2004). Comparable findings were observed in comparison to the general population, raising doubt regarding the potential additive effects of participating in team sports on this development. There is also a large diversity in testing methodologies for different physical qualities, limiting the effectiveness of comparisons with the literature for researchers and practitioners. Future research should include measures of training load data to better understand the effect training has during this period.

THE PREVALENCE AND APPLICATION OF 'OFF-FEET' TRAINING PRACTICES WITH PROFESSIONAL TEAM SPORT ATHLETES

HIGHTON, J.

UNIVERSITY OF CHESTER

INTRODUCTION: Metabolic conditioning of team sport athletes typically involves a combination of field-based high-intensity interval and game-specific training [1]. There has been recent interest in the effectiveness of 'off-feet' training (i.e., cycling, rowing, upper body ergometry), which has been advocated for athletes who might require careful load management. However, the prevalence and application of this form of training are not yet known. Therefore, the aim of this study was to explore off-feet training use in professional team sports.

METHODS: A snowball sampling approach was used, where those responsible for the delivery of strength and conditioning and rehabilitation of professional team sport players were targeted and then asked to forward an electronic survey. The survey comprised 27 questions in four sections (demographics, pre-season use of off-feet conditioning, in-season use of off-feet conditioning, and use of hypoxic training with off-feet conditioning). Fifty-nine respondents were included in the final analysis. Participants were sport scientists (28.8%), strength and conditioning coaches (49.2%), physiotherapists (8.5%) and 'other' (13.6%). The sports represented were rugby union (25.4%), rugby league (18.6%), soccer (40.7%), hockey (8.5%), netball (1.7%), cricket (1.7%), basketball (1.7%) and 'other' (6.8%). Respondents worked with males most often (89.8%).

RESULTS: Of the 59 respondents, only three reported not using off-feet training methods at any time. Cycling was used by more practitioners than other forms of training ($X2 = 93.6$, $P < 0.0001$). Thirty-seven (62.7%) of the respondents used more than one type of off-feet training, whilst 15 (12.7%) used only cycling. Season stage normally had no effect on whether off-feet conditioning was adopted. Practitioners typically prescribed 1-2 off-feet sessions per week (67.9%), but load managed players were likely to complete off-feet training more frequently than uninjured players ($X2 = 41.786$, $P < 0.001$). Load managed players were also more likely to undertake off-feet conditioning as a main training stimulus ($X2 = 30.42$, $P < 0.001$). Short intervals (< 60 s) were the most used forms of off-feet training ($X2 = 148.601$, $P < 0.0001$), and heart rate (50.8%), rating of perceived exertion (54.2%) and power output (37.3%) were the most frequent prescription methods ($X2 = 36.525$, $P < 0.001$). Eighteen (30.5%) participants reported using hypoxic training in conjunction with off-feet conditioning, with lack of facilities (50.8%) being cited as the most common reason for not using this approach.

CONCLUSION: Off-feet training is a prevalent approach to metabolic conditioning in professional team sport players, despite limited research on its efficacy. This research provides a basis for researchers to examine this training method and ensure best practice with athletes.

EFFECTS OF ROBOTIC SPRINT RESISTANCE TRAINING ON ACCELERATION AND SPRINTING PERFORMANCE OF FIELD HOCKEY PLAYERS

THUROW, H., SONNENBURG, R., MATTES, K.

UNIVERSITY OF HAMBURG

INTRODUCTION: Athletic abilities such as acceleration and maximum speed have gained overwhelming importance in recent years. Sprints in field field hockey are very short with an average distance of 8-13 m (Vanwanseele & Aeles, 2016). The majority of duels are decided in the first few meters and rule changes by the International Hockey Federation of 2015 (playing time 4x15 min) further increased the average intensity of the game. Morin et al. (2016) reported that in team sports with short sprints the relationship between sprint performance and horizontal force increases. Studies with individualized training are necessary to determine the appropriate loading parameters to improve athletic performance.

METHODS: For the study, 9 athletes each were recruited for the intervention group (IG) and for the control group (CG). The IG completed individualized resistance training using the 1080 Sprint, whereas the CG continued conventional sprint resistance training. The intervention included two training periods of 5 weeks (2 sessions) each (3x4x20-m sprint). Unfortunately, it was not possible to measure a CG during the first project stage. Therefore, the following are the results of the second training stage (April to May 2022) exclusively. In the first training session, a load-velocity profile (LVP) was created

for all athletes. Starting from the second week of training, the individual LVP was applied to achieve a targeted speed loss of 10 % to a maximum of 20 %. The sprint distance of the second training period was reduced to 3x4x10-m due to the high training and competition load.

RESULTS: There was a significant improvement in the IG of sprint time over 20 m of 0.07 s (3.22 s vs. 3.15 s). The CG values also showed a significant improvement of 0.06 s (3.18 s vs. 3.12 s) in the 20-m sprint. Sex-disaggregated data showed no marked differences between IG and CG. Despite better baseline performance, the IG showed higher performance improvements in the 20-m sprint than the CG.

CONCLUSION: It has been shown that individualized sprint resistance training with the 1080 Sprint improves sprint acceleration and maximal velocity of a 20 m sprint from a standing position. This supports scientific studies that have shown lower or comparable positive effects on acceleration in team sport athletes (soccer and rugby) with resistance training (Rakovic et al., 2018; Cross et al., 2018). However, this study did not demonstrate a superior effect of individualized resistance training over established training on sprint performance. Separated by gender, the performance level of both female and male players in the IG was higher than in the CG before and also after the intervention. In that circumstance, the increase in IG sprint performance after the second training period is all the more remarkable. In summary, individualized sprint training using the 1080 Sprint was shown to be a suitable and promising training tool to realize targeted performance progress in relatively short periods of time.

EFFECTS OF RESISTED SLED PUSH AND SLED PULL TRAINING ON SPRINT VELOCITY IN FIELD HOCKEY PLAYERS

SLAWINSKI, J.

NATIONAL INSTITUTE OF SPORTS SCIENCE

INTRODUCTION: During competition, field hockey players rarely reach their maximum velocity (Vmax); therefore, the ability to accelerate becomes very important on short distances inferior to 15m (West et al., 2013). To improve the acceleration abilities, one training method is to add resistance while sprinting and commonly referred to as "resisted sprint" (Cahill, al., 2019). This resistance can be added by sled pulling (SPull) or sled pushing (SPush). Both training modalities leads to different technical adaptations. SPull and SPush positions are similar to the start and acceleration phases of a sprint, but SPush does not allow to use trunk and arms that have a great importance in the forward propulsion (Slawinski et al., 2022). The aim of this study is to compare the effect of SPull and SPush training methods on sprint times and individual force-velocity (F-v) profile's factors.

METHODS: Fifteen young national field hockey were split into two groups: SPull (8) and SPush (7) training. Each group performed 12 resisted sprint training session twice a week. Training protocol was divided into 3 phases: power, strength and velocity. Pre and post tests were composed of a F-v test (Fornasier-Santos et al., 2022) to measure the theoretical force (F0), velocity (V0) and maximal power (Pmax). A 15m sprint with ball and cross test was also perform to measure field performance (P15m). To compare effect of training, data were analyzed using a repeated measures ANOVA in complement of a post-hoc test when necessary.

RESULTS: The results demonstrated that there was no interaction effect ($p>0.05$), just a training effect for V0 and F0. V0 decrease following training (8.48±0.48 vs 8.28±0.47 m.s-1; $p\leq0.001$) and F0 increase (7.3±0.5 vs 7.7±0.9 N.kg-1; $p\leq0.01$). Other parameters remained constant ($p\geq0.05$).

CONCLUSION: Both SPull and SPush allowed to improve F0 and to break down V0. Contrary to our hypothesis the use of the arms and the trunk during sprint training seems to have no effect in the modification of the F-v profile. To conclude, SPull either SPush can be used to improve the acceleration phase in sprint running.

CHANGES IN PEAK FAT OXIDATION FROM PRESEASON TO COMPETITIVE SEASON IN PROFESSIONAL MALE FOOTBALL PLAYERS

RØMER, T.1, HANSEN, M.T.1, SAHL, R.E.1, LANGE, K.1, BLOM, I.1, SCHMÜCKER, M.1, POGGI, A.I.1, LARSEN, M.N.2, DELA, F.1, KRUSTRUP, P.2, HELGE, J.W.1

< 1> DEPARTMENT OF BIOMEDICAL SCIENCES, UNIVERSITY OF COPENHAGEN; <2> DEPARTMENT OF SPORTS SCIENCE AND CLINICAL BIOMECHANICS, UNIVERSITY OF SOUTHERN DENMARK

INTRODUCTION: Football is an intermittent sport with high aerobic and anaerobic energy turnover demands, and high-intensity running bouts during matches are considered decisive. Interestingly, recent studies found that peak fat oxidation rates (PFO) are high in professional football players compared to other athlete types. It remains unexplored whether PFO varies during a season and if PFO has implications for physical performance in football. This ongoing study aims to investigate if PFO increases from the early preseason period to competitive season and if PFO is related to the physical performance in match-play for professional male football players.

METHODS: 36 professional male football players from the Danish Superliga undergo laboratory testing during the first week of winter preseason and 11 weeks later during the competitive season (in-season). Testing is conducted during season 2021/22 and 2022/23 and consists of a whole-body dual-energy x-ray absorptiometry scan (body mass: 79.4±2.5 kg, fat-free mass: 65.2±1.9 kg, fat percentage: 13.1±0.9%, (mean±95% confidence interval) and a graded exercise test on a treadmill determining PFO, the intensity eliciting PFO (Fatmax) and peak oxygen consumption (VO2peak) (0.63±0.07 g/min, 40 ± 3%VO2peak and 57.0±1.6 ml/min/kg, respectively).

Furthermore, the players' physical performance is assessed by in-match measurements of running speed and heart rate, but these data are yet to be collected and analysed.

RESULTS: At the current stage, nine players have completed in-season testing (season 2021/22) and compared with preseason levels (paired t test) no changes were observed for PFO (mean change: 0.03±0.11 g/min, p=0.494) and Fatmax (2±11%VO2peak, p=0.690). VO2peak did not increase significantly from preseason to in-season testing (1.6±1.7 ml/min/kg, p=0.064). The fat percentage decreased by 1.2±0.9%-points, p = 0.015, due to a 1.0±0.7 kg, p=0.014, decrease in fat mass and a numerical increase in fat-free mass (0.8±1.1 kg, p=0.126).

CONCLUSION: The preliminary results suggest that PFO and Fatmax are not increased in-season compared with early preseason, whereas VO2peak tends to increase and the body composition becomes leaner during the same period in professional male football players. This implies that football preseason training does not improve PFO in highly adapted players, however it remains to be seen whether PFO is associated with physical performance in match play for professional male football players.

OP-MH17 Health and fitness in children

SLEEPING VARIABILITY AND PHYSICAL ACTIVITY OF 17-YEAR-OLD ICELANDIC UPPER SECONDARY STUDENTS.

HJALMARSSON, B., STEFANSDOTTIR, R., JOHANNSSON, E.

UNIVERSITY OF ICELAND

INTRODUCTION: Adolescence is a period characterized by immense physical changes and neurological development [1]. Therefore, adolescents are especially sensitive to variations in their sleeping pattern and physical activity (PA) levels. Studies have shown that adolescents' sleep duration is both short and varied [2]. Similarly, adolescents live a sedentary lifestyle; over 80% of 11–17-year-olds are not fulfilling PA recommendations [3]. The aim of this study was to compare variability in sleep and PA between students with traditional (TSS) and college-style school schedules (CSS).

METHODS: Data was gathered in March-May of 2021. Free-living sleep and PA were measured via Actigraph accelerometry (ActiGraph Inc., Pensacola, Florida, USA) in 75 students at age 17 (28 male). Of those participants, 67% had CSS. Difference in sleep and activity between TSS and CSS were assessed with independent t-tests, ANOVA, and linear regression models, and adjusted for height, weight, BMI, total sleep time and sleep onset.

RESULTS: Difference in mean sleep duration was not significant between school systems; average sleep duration was 6.5 ± 0.8 hours. Intra-individual sleep variability was significant between school systems; mean variability was 0.8 ± 0.4 hours/night and 1.4 ± 0.8 hours/night in students with TSS and CSS, respectively ($p < .001$). Difference in sleep midpoint was also significant; mean midpoint of sleep was 04:01am ± 0.7 hours for students with TSS and 05:02am ± 1.2 hours for students with CSS ($p < .001$). Difference in PA was not significant between school systems; students with TSS had a mean of 20238 ± 7607 counts/day while students with CSS had a mean of 20054 ± 7662 counts/day.

CONCLUSION: Icelandic secondary students have both short and variable sleep schedules [4]. Our results indicate that students with CSS have greater variability in their mean- and midpoint of sleep compared to students with TSS. Difference in PA between school systems was not significant. This indicates that the more intermittent nature of CSS exacerbates students' already poor sleep compared to more structured school start times in TSS. Future studies should explore ways to reduce students' sleep variance via streamlining school schedules

IS CHILDREN'S SPORTS PARTICIPATION ASSOCIATED WITH THEIR HEALTH-RELATED PHYSICAL FITNESS?

SARA, P.1,2, KATZMARZYK, P.3, GARBELOTO, F.1, GARGANTA, R.1, SANTOS, C.1,2, GUIMARÃES, E.1, VASCONCELOS, O.1, FARIAS, C.1, BARREIRA, T.4, CHAPUT, J.P.5, STODDEN, D.6, TANI, G.7, HEDEKER, D.8, MAIA, J.

1UNIVERSITY OF PORTO; 2LUSÓFONA UNIVERSITY; 3LOUSIANA STATE UNIVERSITY; 4SYRACUSE UNIVERSITY; 5CHEO RESEARCH INSTITUTE; 6UNIVERSITY OF SOUTH CAROLINA; 7UNIVERSITY OF SÃO PAULO; 8UNIVERSITY OF CHICAGO

INTRODUCTION: The involvement of children in sports has been linked to health markers during adolescence and adulthood [1]. Also, health-related physical fitness (HRPF) is a marker of health [2]. Therefore, we investigated the relationship between sports participation (SP) and HRPF components.

METHODS: The sample comprised 821 Portuguese children (436 girls), aged 6-10 years, from 29 schools. Cross-sectional data were collected from January 2022 to June 2022 (after the COVID-19 pandemic). Several HRPF components were assessed: morphological (body mass index (BMI) and waist circumference (WC)), muscular (standing long jump and handgrip strength), motor (shuttle-run and 50 yards dash) and cardiorespiratory (PACER) [3,4]. Children's SP was obtained from parents via questionnaire. Given the hierarchical structure of the data (children nested within schools), multilevel modelling was used, with sex and age as covariates. All calculations were done in STATA 14.

RESULTS: Although girls (53%) tend to participate less in sports than boys (65%) (Chi-square=12.413, p<0.001); yet, no age-differences were found in SP for either sex (p>0.05). Multilevel results showed that in the morphological component, SP was not related to BMI (b=-0.26, SE=0.2, p=0.291) nor to WC (b=-0.77, SE=0.60, p=0.195). In the muscular component, SP was unrelated to handgrip strength (b=-0.46, SE=0.29, p=0.116) but was significantly linked to standing long jump (b=3.59, SE=1.38, p=0.010). In the motor component, SP was significantly associated with the shuttle-run (b=-0.25, SE=0.08, p=0.002) but not with the 50 yard-dash (b=-0.12, SE=0.08, p=0.146). Children more involved in SP had better cardiorespiratory fitness (b=2.56, SE=0.65, p<0.001). Further, and on average, boys tended to be fitter than girls in almost components (p<0.05), except the morphological one. Finally, as children grew, from 6 to 10 years of age, they were systematically fitter in all components (p<0.05).

CONCLUSION: Although boys were fitter than girls, SP proved to be an important asset to significantly associate with children HRPF. Yet, no such link was found for the morphological component.

This project was funded by the FCT – Foundation for Science and Technology Portugal (PTDC/SAU-DES/2286/2021).

DETERMINANTS OF FIVE YEAR IMPROVEMENTS IN MOTOR PERFORMANCE AND FITNESS AMONGST PRIMARY SCHOOL CHILDREN

LICHTENSTEIN, E., NEBIKER, L., HAUSER, C., HANSSEN, H., FAUDE, O.

EXERCISE AND MOVEMENT SCIENCES

INTRODUCTION: Motor performance is a cornerstone of being able to participate in organised sports and for establishing and maintaining an active lifestyle throughout the lifespan. Cardiovascular fitness during childhood is a good predictor of health in adult life. The development of those aspects during childhood is influenced by education, environment, nutrition and family habits. Identifying factors that negatively affect motor performance and fitness development could allow to target disadvantaged children to improve their activity and health outcomes in adulthood. The aim of this study is to identify determinants of motor performance and fitness development during primary school.

METHODS: In the first and fifth grade motor performance, fitness, and body composition were assessed in all children in the municipality. Parents were asked to indicate their monthly household income to assess socioeconomic status in seven categories. Motor performance tests included 20-meter sprint, balancing backwards and side hopping, while fitness was assessed by a 20-meter shuttle run. Linear mixed effects regression models were used to identify associations with developmental trajectories. Mean and standard deviations are presented for descriptive data and effect sizes (cohen's d) and p-values for regression results.

RESULTS: 1564 children were assessed in both grades and 418 questionnaires were returned. Children were 50% female, 7.4 (±0.4) years of age in first grade, BMI was 16.3 (±2.4) kg/m2, and SES was 5.4 (±1.8). There was no credible influence of socioeconomic status on developmental trajectories of any performance test (p>0.1). A higher initial BMI (+1kg/m2) was associated with slightly reduced improvements in jumping (d=-0.04, p=0.02), sprinting (d=-0.07, p<0.01), and shuttle-run (d=-0.12, p<0.01) performance but was not credibly associated with balance performance improvements (d=-0.03, p=0.86). Girls showed reduced improvements in jumping (d=-0.14, p<0.01) and shuttle-run (d=-0.44, p<0.01) performance but increased improvements in sprinting performance (d=0.22, p<0.01), while no credible difference was observed for balance improvements between the sexes (d=-0.02, p=0.78). Relatively (-1 year) younger children in the first grade developed stronger in jumping (d=0.33, p<0.01), balance (d=0.46, p<0.01), sprinting (d=0.49, p<0.01) and shuttle-run (d=0.53, p<0.01) performance.

CONCLUSION: Allocating resources to boost motor performance development of children with a higher BMI might be advised to improve their abilities required for participating in organised sports and maintaining an active lifestyle. This data can serve to curb expectations when it comes to motor development in older children of the same grade and girls, as their improvements are potentially reduced in some tests. In this cohort, economically disadvantaged children's development was fortunately not hampered.

EFFECTS OF A 12-WEEK SCHOOL-BASED EXERGAMING INTERVENTION ON STUDENTS' PHYSICAL FITNESS, PHYSICAL SELF-CONCEPT, AND ENJOYMENT- A RANDOMIZED CONTROLLED TRIAL

KETELHUT, S., RÖGLIN, L., STOLL, O., MARTIN-NIEDECKEN, A.L., KETELHUT, K.

UNIVERSITY OF BERN

INTRODUCTION: Exergames are interactive video games that stimulate an active, whole-body gaming experience. By combining electronic entertainment with physical exercise, exergames may offer novel opportunities to expand physical activity in different age groups and settings. This study aimed to investigate the effects of a school-based exergame intervention on anthropometric parameters, physical fitness, and physical self-concept (PSC). Furthermore, possible changes in enjoyment over time were assessed.

METHODS: Fifty-eight students (10.4±0.8 years; 48% girls) were randomized into an intervention (IG) and a control (CG) group. Both groups participated in regular physical education classes during the three-month intervention period. The IG additionally received a 20-minute exergame intervention twice per week in the ExerCube. At baseline and following the intervention period, body mass index (BMI) and waist-to-height ratio (WHtR) were assessed. Furthermore, a sprint test (ST), a countermovement jump test (CMJ), and a shuttle run test (SRT) were performed. PSC was assessed using the PSC scales for children (1), and enjoyment was measured using the Physical Activity Enjoyment Scale (PACES) (2).

RESULTS: A significant time × group interaction was determined in CMJ performance ($p<.001$; $\eta2=.403$), with a significant increase ($p<.001$; $\eta2=.315$) in the IG and a significant decrease ($p=.009$; $\eta2=.190$) in the CG. Furthermore, ST performance significantly improved in the IG ($p=.012$; $\eta2=.180$) but not in the CG, revealing significant interaction effects ($p=.02$; $\eta2=.157$). Significant time × group interaction was observed for the SRT ($p=.046$; $\eta2=.122$), with a significant increase ($p=.028$; $\eta2=.147$) in the IG and no changes in the CG. No significant interaction effects were detected in BMI ($p=.157$; $\eta2=.063$) and WHtR ($p=.063$; $\eta2=.114$). Significant time × group interaction effects were found for "PSC total" ($p=.015$; $\eta2=.178$), and the subscales "flexibility" ($p=.017$; $\eta2=.169$), "coordination" ($p=.045$; $\eta2=.124$), "strength" ($p>.001$; $\eta2=.388$), and "speed" ($p=.029$; $\eta2=.145$). The IG revealed significant improvements over time in "PSC total" ($p=.042$; $\eta2=.249$), "flexibility" ($p=.051$; $\eta2=.230$), and "strength" ($p<.001$; $\eta2=.551$). In the CG, no significant differences could be determined. The PACES reveal no significant changes in enjoyment ($p=.164$, $\eta2=.073$) over time in the IG.

CONCLUSION: The findings indicated that integrating regular exergaming sessions into a school setting increased physical fitness and PSC in elementary school children. These findings supported the implementation of exergames as innovative and enjoyable PA programs in school settings.

OP-BM05 Motor control: Fatigue

EFFECTS OF RUNNING-INDUCED FATIGUE ON THE STRUCTURE OF MOVEMENT VARIABILITY IN NOVICE RUNNERS

FADILLIOGLU, C.1, MÖHLER, F.1, SCHEFFLER, L.1, HERMANN, M.2, STEIN, T.1

1 KARLSRUHE INSTITUTE OF TECHNOLOGY, KARLSRUHE, GERMANY; 2 JUSTUS LIEBIG UNIVERSITY GIESSEN, GIESSEN, GERMANY

INTRODUCTION: Fatigue is a major issue in sports science, especially for endurance sports. Running is one of the most popular endurance sports worldwide. Consequently, there is a high number of people that start running without prior experience. On the other hand, novice runners were shown to be prone to injury, possibly because they lack an adequate running style or strength to deal with the loads acting on the body. On this basis, understanding the effects of fatigue in novice runners is crucial since fatigue may associate with injuries as well as with running economy. Nevertheless, studies analyzing the effects of fatigue in novice runners are rare. Previously, it was shown that running-induced fatigue does not affect spatiotemporal parameters in novice runners but influenced the center of mass (CoM) movement (1). Therefore, the aim of this study was to investigate how the movement variability structure stabilizing the CoM trajectory changes under running-induced fatigue in novice runners.

METHODS: Fourteen healthy male novice runners participated in the study. The experiment was conducted on a motorized treadmill (h/p/cosmos). After a treadmill familiarization protocol, the participants had two minutes to recover before running at a fixed speed of 13 km/h until subjective exhaustion. Kinematic data were recorded at 200 Hz using 16 Vicon cameras (Vicon Motion Systems, Oxford Metrics Group, Oxford, UK). The uncontrolled manifold (UCM) approach was applied to a 3D whole-body model using the joint angles as elementary variables, and the CoM as the result variable (2). The portion of variability that does not affect the CoM is referred to as UCM_par, whereas the portion that has effects on the CoM as UCM_ort. The ratio of UCM_par and UCM_ort (UCM_ratio) is used to operationalize the degree of stabilization (3). By using statistical parametric mapping (SPM), the differences between the PRE and POST fatigue conditions for three UCM parameters (UCM_par, UCM_ort and UCM_ratio) were analyzed.

RESULTS: The participants continued to run at 13 km/h for 6.18 ± 2.45 min. Their exhaustion was confirmed by a Borg-scale rating of 18.7 ± 1.0 ("very very hard" (4)). The SPM results revealed significant increases in the UCM_ort but no significant effects on the UCM_par or UCM_ratio.

CONCLUSION: The increases in the UCM_ort after running-induced fatigue can be interpreted as decreased control concerning the CoM (5). However, based on the unchanged UCM_ratio, it can be suggested that the stability of the CoM was not affected by fatigue. To sum up, the running-induced fatigue increased the step-to-step movement variability in novice runners and decreased the level of control of their CoM.

SEX DIFFERENCES IN FORCE STEADINESS AND MUSCLE ACTIVATION DURING AN INTERMITTENT ISOMETRIC EXERCISE TO TASK FAILURE

PASTORIO, E., COLOSIO, M., GATTI, M., LAMBOGLIA, M., VERNILLO, G., TEMESI, J., CARBONARO, M., BOTTER, A., PORCELLI, S.

UNIVERSITY OF PAVIA

INTRODUCTION: Previous studies have reported sex differences in the amplitude of isometric force fluctuations during submaximal isometric fatiguing contractions of elbow flexors with women (W) showing less steadiness than men (M) [1]. Similar results were observed during submaximal sustained knee-extensor (KE) contractions [2]. However, the relationship between fatigue and force steadiness of KE during intermittent isometric exercise protocols in W and M remains uninvestigated. Since exercise protocols that include intermittent rest periods may elicit considerably different responses at the muscle level in W and M compared to sustained steady-state contractions [3], this study aimed to evaluate sex differences in force steadiness and muscle activation during a fatiguing KE intermittent isometric task.

METHODS: Twenty-six young volunteers (13 W, age: 24±3yrs and 13 M, age: 26±2yrs) performed a fatiguing intermittent submaximal KE isometric exercise (3s on, 2s off) at 110% of the Critical Torque (CT) to task failure. CT was determined from the 5 minutes intermittent (3s on, 2s off) maximal voluntary isometric contraction (MVIC) test [4]. Performance fatigability was assessed as the loss in MVIC force from MVIC performed before (PRE), during (every 3 minutes) and immediately after (POST) task failure. Force steadiness was determined as the coefficient of force variation (CV) during each set of submaximal contractions. Muscle activation was calculated as root mean squared (RMS) of the EMG signal from vastus lateralis (VL) and rectus femoris (RF) normalized to RMS EMG of MVIC (PRE). All measures were extracted from a 2-second epoch in the middle of the force trace [5].

RESULTS: CT was similar between W and M (38.4 vs 36.9% of MVIC, $P>0.05$). W exhibited a longer time to task failure than M (1511±506 vs 1017±499 s, $P<0.05$). At POST, force loss was similar between W and M (-53.4 vs -55.6%, $P>0.05$). At PRE, CV was similar between W and M (3.2±1.1 vs 2.8±0.4%, $P>0.05$). During the fatiguing task, CV showed a time effect (+8.8% at half of task failure and +26.9% at POST, both $P<0.05$) with no sex effect or time x sex interaction. RMS amplitude throughout the task showed a time effect for both VL (+24.3% at half of task failure and +43.2% at POST, both $P<0.05$) and RF (+28.0% and +40.1% at half of task failure and POST, respectively, both $P<0.05$).

CONCLUSION: During the fatiguing KE intermittent isometric task, W were more fatigue-resistant than M. Force steadiness decreased comparably for W and M. Muscle activation in both VL and RF increased throughout the exercise without difference between sexes. These findings may suggest that sex-differences in force steadiness are task- and muscle-dependent.

POSTURAL ADJUSTMENTS OF A FATIGUING FINGER HANGING TASK IN CLIMBERS: JOINT COORDINATION AND MUSCLE SYNERGIES

EXEL, J., KAUFMANN, P., FROSCHAUGEN, O., BACA, A., KAINZ, H.

UNIVERSITY OF VIENNA

INTRODUCTION: So far, the neuromechanical strategies during sustained finger hangings – a common posture to be maintained while climbing – remain unclear. Therefore, the aim of this study was to assess changes in coordination patterns and muscle synergies during sustained isometric finger hangings in climbers.

METHODS: Eleven climbers (26±5 yrs) performed a hang on a 20 mm-depth edge until failure. Fingers were maintained at open crimp gripping and arms were fully extended. Upper body kinematics was obtained with a 12-camera 3D motion capture system (Vicon, UK). Coordination strategies adopted during the task were calculated by vector coding [1], which quantifies the variability in joint relative motion, among wrist, elbow, and shoulder angles in the sagittal plane. Surface EMG from 6 muscles per limb (flexor digitorium superficialis, extensor digitorium, brachioradialis, biceps, pectoralis major,

trapezius) were measured (Cometa, IT) and processed. We analyzed the first 20% (START) and last 20% (END) of the task. Mean activation over consecutive 100ms bouts were connected for START and END. After scaling to unit variance, muscle synergies were extracted via non-negative matrix factorization, initialized by non-negative-single-value-decompensation with low-rank-correction outputs. The number of synergies was determined by the knee point of the total-variance-accounted for curve, averaged over all participants [2]. For both needed synergies the activation coefficients (AC) were averaged for START and END individually.

RESULTS: Results (mean±std) showed the coordinative patterns (degrees) in START and END between wrist/elbow (START: 201.4±42.5; END: 108.3±40.6), wrist/shoulder (158.1±237.4; 36.7±75.4), and elbow/shoulder (169.1±241.8; 30.7±50.8) couplings to be significantly different ($p<0.05$). At START, wrist/elbow coupling showed dominance of the wrist extension over the elbow, which towards the failure point, progressed to an anti-phase relationship so the elbow tended to flex as the wrist maintained or increased extension. Wrist/shoulder and elbow/shoulder couplings showed similar behaviour. Wrist and elbow changed from an anti-phase coupling with the shoulder at START, where joints were extended while the shoulder was flexing, to a shoulder flexion domination at END. Synergies also differed its contributions across the task ($p<0.001$). Namely, Synergy 1, (mainly formed by finger flexor/extensor) was less activated in END (-0.08±0.07), while Synergy 2 (mainly formed by trapezius and pectorialis) had higher participation at END (0.24±0.08) due to the differences of mean AC.

CONCLUSION: Thus, postural adjustments of climbers while sustaining open crimp hangs demand changes in coordinative patterns of the upper body joint kinematics and muscle synergies in a proximal-to-distal fashion. This allows for a balanced body position and efficient gripping, thus compensating for the neuromechanical impairments caused by fatigue.

NEUROMUSCULAR FATIGUE ACCORDING TO INJURY HISTORY IN THE ACCELERATION PHASE OF A REPEAT SPRINT ABILITY TEST: PRELIMINARY RESULTS

ARMADA-CORTÉS, E., BENÍTEZ-MUÑOZ, J.A., SÁNCHEZ-SÁNCHEZ, J., SAN JUAN, A.F.

UNIVERSIDAD POLITÉCNICA DE MADRID

INTRODUCTION: Sprinting is a fundamental component of the professional soccer player's ability to achieve the highest performance in the sport (1) and the hamstrings muscles are crucial in sprint acceleration performance and maximal sprinting (2). The aim of this preliminary study was to analyze the influence of hamstring injury history on the neuromuscular fatigue in the acceleration phase produced by an RSA test in elite female football players.

METHODS: Ten female elite soccer players of the Second Spanish Soccer Division participated in the study. The participants were divided into: (1) a Control group who have not suffered previous muscular injuries and (2) a Hamstring group with previous hamstring injury at least one season prior to the protocol. The players performed a protocol consisting of a Repeat Sprint Ability Test (RSA) (6 × 40 m; 30 s rest). The different variables of the study were compared between groups with a two-way ANOVA for repeated measures.

RESULTS: The main findings from the present study were that, in subjects with previous hamstring injury, the performance was impaired compared with the control group in the initial meters of the sprint during an RSA, there was a higher percentage difference between SplitTT and ideal Split in 0–10 m compared to 0–20 m in the hamstring group ($p = 0.04$; ES = 0.48).

CONCLUSION: It seems that in elite female soccer players with previous hamstring injury, RSA-induced fatigue produces a greater decrease in the performance in the first 10 m of the sprint compared to the control uninjured players.

ETIOLOGY OF NEUROMUSCULAR FATIGUE IN HAMSTRING AND QUADRICEPS MUSCLES FOLLOWING SIMULATED SOCCER MATCH-PLAY

MASSAMBA, A., BARBI, C., KOUZKOUZ, N., GÉNY, B., FAVRET, F., HUREAU, T.J.

UNIVERSITY OF STRASBOURG

INTRODUCTION: Our previous study demonstrated greater fatigue resistance in hamstring compared to quadriceps muscles during isolated muscle exercise (1). However, the mechanisms of fatigue and recovery in hamstring vs quadriceps muscles during whole-body soccer match-play is currently unknown.

METHODS: Eleven male soccer players (18.7±1.6 years) from an elite French academy took part in this study and performed a simulated soccer match-play (2x45 min). Maximal isometric voluntary contraction (MVC) was used to assess neuromuscular fatigue before, during and immediately after exercise on quadriceps and hamstring muscles. Central and peripheral fatigue levels were quantified via changes in preexercise to postexercise voluntary activation (VA) and potentiated twitch force (Ptw), respectively, as evoked by supramaximal nerve (quadriceps) or direct muscle (hamstring) electrical stimulation. External load during the match was documented using GPS in order to estimate fatigue (2).

RESULTS: During the match, MVC decreased in a non-linear fashion. After 15 min of exercise, MVC already decreased ($P<0.01$) by 10±7% and 11±11% in quadriceps and hamstring muscles respectively. At the end of the match, MVC was reduced by 20±10% and -25±10% in quadriceps and hamstring muscles, respectively, compared to preexercise values ($P<0.001$). Specifically, peripheral fatigue was greater in hamstring (-28±23%) compared to quadriceps (16±8%, $P<0.01$).

Conversely, central fatigue was greater in quadriceps muscles (-20±12% vs -10±16%) compared to hamstring, P<0.01). No correlation was observed between neuromuscular fatigue (ΔMVC) and 'fatigue' metrics derived from GPS such as the Dynamic Stress Load (quadriceps: r^2=0.10, P=0.31; hamstring: r^2=0.06, P=0.48) or the Fatigue Index (quadriceps: r^2=0.09; P=0.38; hamstring: r^2=0.07, P=0.43) during the soccer match-play.

CONCLUSION: The present study documented substantial differences in neuromuscular fatigue etiology between quadriceps and hamstring muscles during a soccer match-play. Indeed, hamstring developed more peripheral fatigue, and less central fatigue, compared to quadriceps muscles. Moreover, 'fatigue' metrics provided by GPS were not correlated with our direct measurements of neuromuscular fatigue, which shows their irrelevance to estimate neuromuscular fatigue. These results might be relevant for practitioners involved in training prescription and muscle injury prevention in soccer.

Background

QE is defined as the final fixation on a specific location or object in the visuomotor workspace, for a minimum of 100 ms, that enables the athletes to gather relevant information before a critical movement. Several lines of research indicate that QE contributes to sports performance. However, its contribution to performance is derived mainly from research investigating isolated motor tasks. Therefore, little is known about its contribution in realistic competitional settings.

Methods

The present study determined whether QE contributes to table tennis performance obtained from matches played in a simulated competition. Athletes (N = 10) performed two matches, one against a difficult and one against an accessible opponent. Gaze behavior was captured using Tobii Glasses 2.

Results

We found that athletes made longer QE before winner balls (i.e., balls that scored a point), compared to forced and unforced errors (pBonferroni = 0.005, t = −4.45; pBonferroni <0.001, t = −6.45). Confirming that QE contributes to performance in a real match even in a competitional setting. We found no significant effect for the difficulty of the match, nor an interaction between the difficulty of the match and the type of shots Fs (1, 9) < 2.26, ps >0.16 0.70, η2ps < 0.20.

Conclusions

The present study provides evidence for QEs contribution to sports performance investigated in a "gold standard" ecological environment. More specifically, it provides evidence that QE gradually increases with the quality of the shot. Identical patterns were found regardless of the difficulty of the match.

THE EFFECTS OF PRESENTATION MODE ON GAZE BEHAVIOR BETWEEN 360VR AND 2D-VIDEO BROADCAST IN A BOXING SPECIFIC TASK.

LOISEAU TAUPIN, M.1,2,3, JUSTE, L.1,2, ROMEAS, T.3,4, LABBÉ, D.1,2

1. LABORATOIRE DE RECHERCHE EN IMAGERIE ET ORTHOPÉDIE, ECOLE DE TECHNOLOGIE SUPÉRIEURE, MONTREAL, CANADA
2. CENTRE DE RECHERCHE DU CENTRE HOSPITALIER DE L'UNIVERSITÉ DE MONTRÉAL, MONTREAL, CANADA.

Two-dimensional video broadcasts displayed on computer screens have been widely used and studied for perceptual-cognitive evaluation and training in sports. However, they have been criticized for their lack of representativeness compared to life-sized scenarios. With the development of new technologies, virtual reality (VR) is being introduced into the sporting environment because it is assumed to provide more ecological conditions, particularly due to its immersive effect, as well as stimulus and action correspondence. Specifically, immersive 360° VR (360VR) is a form of VR which is made from 360° videos and allows an advanced realism of the footage (e.g., 360° scanning of the environment). It has been

proposed as an enhancement of 2D-video broadcasts for perceptual-cognitive applications in sports. While some evidence has started to show an advantage of using 360VR over video broadcasts to assess and train anticipation and decision-making, it is still unclear how to explain the behavioral differences produced by both 360VR and 2D video broadcasts. One possible contributing factor is how both displays affect visual strategies. Therefore, the objective of this study was to compare the effects of the mode of presentation on gaze behavior between 3D-360VR and 2D-video broadcasts in a boxing specific task.

Fifteen novice participants were recruited for this study (including 5 women). The experimental design consisted of randomly presenting 24 single-punch sequences in a standalone VR headset (Pico Neo 3 Pro Eye), according to two randomly-presented viewing modes: 3D-360VR and on a 2D screen. Instructions for participants were to avoid unpredictable punches as accurately as possible by providing an appropriate motor response to the presented action. The action was voluntary not occluded to maintain ecological conditions. Four categories of punches were randomly presented (jab, direct, uppercut and hook) and were prerecorded from four different elite boxers (2 men and 2 women) using a 3D-360° VR camera (Insta360 Pro II). Gaze behavior was recorded using a Tobii eyetracker embedded in the VR headset. Fixation duration, number of fixations, saccades, and search rate were analyzed.

Results showed fewer fixations, fewer saccades and a lower search rate in the 2D-video broadcasts compared to 3D-360VR. There was no significant difference in gaze duration between presentation modes.

This study shows that the presentation mode had an impact on gaze behavior and offers new insights about the effect of 360VR and 2D-video broadcast on perceptual-cognitive behaviors in novices during a sport-specific task. Future studies should evaluate these behaviors during real-world conditions in both novices and experts to better understand the benefits of VR for perceptual-cognitive assessment and training.

BEHIND THE FENCING MASK: ATTENTIONAL AND EMOTIONAL PROCESSES OF ELITE LEVEL FENCERS

BRACCO, M.1, PETE, E.2, BAGOT, P.3, BERNIER, M.3, FOURNIER, J.4, DORON, J.2, MARTINENT, G.1

1.UNIVERSITY CLAUDE BERNARD LYON 1; 2. UNIVERSITY OF NANTES; 3.UNIVERSITY OF BRETAGNE OCCIDENTALE; 4.UNIVERSITY PARIS NANTERRE

Introduction

Fencing is a combat sport requiring a high attentional demand. According to Roi and Bianchedi (2008, p.474), fencers "must analyse and select the visual information provided by the opponent" in order to perform their own actions. Furthermore, as in any discipline, emotions are an integral part of the competitive experience, and the need for coping strategies is predominant in order to deal with stressful situations (Jones, 2003; Lazarus, 2000). This study aimed to identify attentional foci and coping strategies of elite fencers during bouts.

Methods

Twenty-two elite epee fencers (11 males and 11 females) from a senior national team took part in a simulated tournament. Retrospective video-recall interviews were held after their matches in order to ask fencers about their attentional foci and coping strategies. Inductive and deductive qualitative analyses were conducted on athletes' verbatims.

Results

Qualitative analysis of athlete's verbatims revealed three categories of attentional foci: (a) cues (i.e. focus on oneself and focus on the environment), (b) strategy and tactics (e.g. having one or more strategies, automatic performance, absence of planning effort) and (c) extraneous attention. In order to manage their emotions, fencers used different types of coping strategies: (a) task-oriented strategies (e.g. concentration effort, seeking solutions) and (b) disengagement strategies (e.g. mental or physical disengagement). They also mentioned, in a lesser proportion (d) deliberate absence of regulation effort and (e) automatic regulation.

Discussion

Results highlighted the value of an ecological approach to explore athletes' cognitions. The results expand those of previous naturalistic studies, which showed that experts' attentional foci were diverse in content as in characteristics, and dynamic along the different performance phases. In line with previous research, athletes could also combine several coping strategies in order to manage their emotional state. To conclude, fencers called upon numerous attentional foci and coping strategies during points, breaks, and across the bout as a whole, providing insights on how these athletes deal with competitive situations.

VISUAL SEARCH STRATEGIES OF ELITE FENCERS : AN EXPLORATORY STUDY IN ECOLOGICAL COMPETITIVE SITUATION

BAGOT, P.1, FOURNIER, J.2, BOSSARD, C.1, KERMARREC, G.1, KERIVEL, T.1, DORON, J.3, BERNIER, M.1

<1> UNIVERSITÉ DE BRETAGNE OCCIDENTALE ; <2> UNIVERSITÉ PARIS NANTERRE, <3> UNIVERSITÉ DE NANTES

Introduction

Visual search strategies (VSS) have been widely studied in sports (for a review, see Klostermann et al., 2020). Experts exhibit fewer fixations of longer duration and are superior at extracting perceptual cues than novice athletes (Martínez de Quel & Bennett, 2019). Fencing experts "must assess and select the visual information provided by the opponent" to perform their own action (Roi and Bianchedi, 2008), and focus particularly on their opponents upper torso to do so (Witkowski et al., 2018). Previous studies were conducted in laboratories or with predetermined outcomes, so we studied VSS during a real fencing bout. We hypothesised that expert fencers use different gaze behaviours and focus on their opponents upper torso to assess their situation in real-world duels.

Method

We monitored the gaze of 10 world-class French fencers (6 men and 4 women, epee, sabre, and foil) with an eye tracker during a bout. Frame-by-frame analysis specified VSS with gaze location, number of fixations, and fixation duration.

Results

Expert fencers, regardless of arm or gender, used visual pivot, to gather information from the central vision, and gaze anchor, to gather information from the peripheral vision. They focused on an area between the opponents elbow, lower torso, and hip joint. Experts use these VSS to gather information from nearby but distinct areas of interest (AOI).

Discussion

This study confirms that expert fencers VSS are mostly visual pivot and gaze anchor. This study is one of the first to show expert fencers real-world visual activity. However, we should proceed with caution because we can not be sure that attention was directed on the object the fencers were looking at. Hence, we advocate merging objective and subjective data with self-confronted interviews to analyse expert behaviour.

EFFECTS OF ACUTE COORDINATIVE AND AEROBIC EXERCISE ON DYNAMIC ELECTROPHYSIOLOGICAL MODULATION IN RESTING STATE: AN EEG STUDY WITH HOLO-HILBERT SPECTRAL ANALYSIS

CHEN, Y.L., LIN, M.P., CHEN, Y.H., FU, H.L., WANG, C.H., JUAN, C.H.

NATIONAL CENTRAL UNIVERSITY

Introduction

Recent research has suggested that the acute effect of exercise on cognitive function can be influenced by the complexity of motor movements involved, however, its underlying neural mechanism is yet to be fully understood. This study aims to examine the difference in the acute effect of coordinative and aerobic exercise on resting state electroencephalography (EEG). Specifically, we employed the Holo-Hilbert Spectral Analysis (HHSA) to reveal the dynamic patterns of neural activity, which may reveal the role of interareal communication for contributing the exercise effects.

Methods

Thirty college students were recruited and randomly divided into a coordinative exercise group (n=15, age=20.9 ± 1.5) and an aerobic exercise group (n=15, age=21.1 ± 1.8). Before and after the exercise intervention, the participants resting state EEG were recorded for 6 minutes with both eyes closed and open to evaluate the acute changes in electrical activity. Holo-Hilbert spectral analysis was used to analyze the EEG signals, which quantifies nonlinear and nonstationary signal characteristics to reveal full-dimension electrophysiological information. Specifically, the amplitude modulation is quantified and sheds light on the underlying mechanisms of specific exercise-induced changes.

Results

Prior to the intervention, the coordinative exercise group exhibited significantly greater frontocentral alpha (8-16 Hz) and beta (16-32 Hz) band power compared to the aerobic exercise group. However, no significant difference was observed between the groups after the intervention, indicating that these exercise types may affect neural dynamics during the resting brain state differently. Moreover, the coordinative exercise group showed a significant decrease in alpha (8-16 Hz)

amplitude modulated by slow waves of 0.5-4 Hz following the intervention, whereas the aerobic exercise group did not exhibit any significant changes.

Discussion

Using Holo-Hilbert spectral analysis of EEG, this study uncover differential patterns of non-linear brain modulation following different types of exercise interventions, as evidenced by the difference in delta AM modulating alpha/beta power. The results suggest that exercise interventions with higher levels of motor complexity may be more effective in activating the interareal communications associated with executive function, sensory perception, or motor triggering events. This emphasizes the advantages of including motor coordination in exercise regimes to improve brain function.

HIGH SCHOOL GIRLS' EXPERIENCES WITH BODY PRESSURE IN A PE CONTEXT

THORESEN, T.
UNIVERSITY OF SOUTH EASTERN NORWAY

ABSTRACT ECSS, PARIS JULY 2023

Title: Junior high school girls' experiences with body pressure in a Physical Educational (PE) context and possible effect on participation

Trine Thoresen

In this paper, young girls' experiences with body pressure in different PE contexts is looked at. Girls in 9th and 10th grade give different explanations for their interest-, or lack of interest in participating in physical education (PE). Some young girls express concern about body appearances and physical performance in the subject and are of this same reason hesitant to both participate and use the changing rooms. Previous research has questioned to what extend PE teachers should take into consideration students activity requests, as they sometimes may contribute to increased body pressure. PE teachers and fellow students' choices of communication about the body and performances in different PE contexts, such as the gym, the swimming pool or the changing rooms and content of the subject, all seem to affect both participation and experiences of body pressure differently. The purpose of the study is to shed light on possible challenges that can be seen in connection with changes in the subject, especially when it comes to topics about the body and body ideals and performances. The following question is asked;

Do junior high school girls' experience body pressure in and around a physical education context?

The results are based on two focus group interviews, one in 9th grade, where 8 girls participated and one in 10th grade, where 7 girls participated. The interviews were followed up with individual interviews with three girls in 9th grade and two girls in 10th grade. Results show that the context does affect experiences of body pressure differently. The swimming pool is an example of a context where body pressure was felt strongly. Also, the changing room and showering was experienced by more students to be challenging. They did not participate or chose not to shower as they were concerned about pictures being taken. They also experienced comments about their bodies from other school students and did feel pressure both on performances and body appearances and the way they dressed. The discussion focuses on school students' experiences with body pressure and if they take an active approach to avoid uncomfortable situations or not.

In conclusion, the purpose of this study was to investigate if a group of girls in 9th and 10th grade in junior high school experienced body pressure in connection with a physical education context. Some did not at all have this experience, whereas most of the girls expressed concern about their bodies, to dress and look in a specific way and that participation could be affected by the way the either looked or performed. Some chose to not participate as they felt strongly about bad performances.

THE ROLE AND IMPORTANCE OF PHYSICAL EDUCATION CLASSES FOR UNIVERSITY STUDENTS

SZÉPLAKI, I., RÉVÉSZ, L.
ESZTERHÁZY KÁROLY CATHOLIC UNIVERSITY

INTRODUCTION: Mental and physical wellbeing is an integral part of a health-conscious life, the importance of which has been proven by numerous national and international studies. In Hungary, after the completion of public education, the last formal stage of health awareness education for young people can be realized within the framework of university education. Increasing prevalence of physical inactivity and health risk behaviours in higher education (Martinez et al., 2020). This is a time of separation from their parents, a period of searching for their own way, which is full of challenges and stress. This developmental psychological phase, when young people no longer feel like adolescents but not yet adults, is referred to in the literature as the emerging adulthood phase (Arnett 2000).

METHODS: The study examined the mental and psychological well-being of some 435 first-year non-athletic students at Eszterházy Károly Catholic University (Hungary), asking them about their life goals (Purpose in Life Test), life satisfaction (Staisfaction with Life Scale), well-being (Well-being Index) and stress (Perceived Stress Scale), as well as their eating habits, attitude to exercise and satisfaction with their bodies. The intervention took place over one semester, with students attending one physical education class per week. The questionnaires were evaluated using the IBM SPSS Statistics 21 software.

RESULTS: At the end of the semester, a feedback survey with a minority of students (N=78) found that 67% of students had a positive change in their quality of life, feeling more active when they wake up and feeling more engaged and full of interesting things to do in their days. In this research, in terms of life satisfaction, almost a third of students feel that they dont always get everything they want and have moved somewhat away from fully agreeing that their lives are close to ideal in most respects. They pay less attention to their eating habits, but 17% have started a diet.Their physical activity has increased, largely due to transport between home and university and between university buildings.In the subjective assessment of posture, fitness and body awareness, the results are contradictory, with 24% of respondents experiencing a deterioration in this area, while 39% feel an improvement. There is a clear increase in the number of sedentary hours, which is also attributed to the writing of final papers, homework and the upcoming exam period, according to the responses.

CONCLUSION: The more important benefit of university physical education, with more than half (52.5%) of students feeling more responsible for their own health. The research also asked a number of other questions, for example, to what extent this was due to the physical education provided in the university setting. It would also be interesting to measure how intrinsic motivation develops and how well they are able to maintain and adapt it throughout their lives.

SPORT AND PARENTHOOD: PARENTAL ROLES IN HORSE RIDING ACTIVITIES FOR TODDLERS

ROSÉN, A., PALMQUIST, G.T., KÄLLÉN, E., HEDENBORG, S.

FACULTY OF EDUCATION AND SOCIETY

Sport and Parenthood: Parental Roles in Horse Riding Activities for Toddlers

Annika Rosén, Gabriella Thorell Palmquist, Ellinor Källén, Susanna Hedenborg.

Malmö University

Introduction

Parents play important and varying roles in sport activities for children. They provide transport, act as leaders, trainers and audience, work in cafeterias and offer care. To partake in children's leisure activities is even a middle-class norm for parenthood (Lareau 2011; Wheeler & Green 2014; Stefansen et al 2018). Research on parenthood in sports has primarily covered team sports (ball sports), and several studies have a psychological perspective including issues related parental pressure (or support) (Augustsson 2007, Woodcock et al 2011). There are few studies on parental roles in sport activities for young children. In this study, equestrian sports for toddlers are focused. The aim is to describe and analyze parental roles in horse riding activities for toddlers. Studies have shown that parental pressure is stronger in expensive sports (such as equestrian sports) (Idrottens pris 2015), whether this is true for activities for the very young is questioned. The theoretical framework is inspired by Goffman's dramaturgical theory (2020) and Skegg's concept respectability (1997). Goffman uses the metaphor theater to explain human behavior and in this study questions of how parents perform (front stage) in the stable, the indoor and outdoor arenas is analyzed.

Methods

Data consists of 10 participating observations at 6 different riding schools and 21 semi-structured interviews with riding school managers and parents of riding toddlers in Sweden and Norway. Interviews and observations are analyzed using a thematic content analysis.

Results and discussion

Parents play an essential role in horse riding activities for toddlers. They take care of the horses before and after the riding activities, they equipe the horse and during the lesson they side walk the horse and are constantly transferring/translating the commands of the riding instructor to the children. In difference from what previous research has showed for other sports and for parents to older children, where the concepts pressure and support have been used to explore the relationship between parents and children, parents and children form a team (cf., Goffman's concept collaborative teamwork) in the riding school activities. In addition, parenthood need to be understood through gender lenses as mothers and fathers perform and are expected to perform different roles. Mothers are respectable (to speak with Skeggs) when they perform as competent horse people, whereas fathers are expected to be incompetent. The incompetent mother provides an 'unacceptable other'. Parents act on a stage, the riding school, that has, since long been feminized, however providing femininities including strong and capable women (cf., Thorell et al 2015).

PHYSICAL ACTIVITY LEVEL OF CHINESE MIGRANT CHILDREN AND ITS ASSOCIATION WITH ENVIRONMENTAL FACTORS IN SCHOOL, FAMILY AND NEIGHBORHOOD SETTINGS

WANG, J., LI, M.

CHINA INSTITUTE OF SPORT SCIENCE

Objective: There are 20 million rural migrant children 14 years old or under in China, comprising 13% of the total student population for compulsory education. Chinese children and adolescents have shown the alarmingly low rate of engage-

ment in sufficient physical activity (PA). Environmental supports are important for creating changes in PA. However, there is scarcity of related research in migrant children due to the difficulty of accessibility. This study is of the first to examine the PA levels in Chinese migrant children in Beijing and to explore its association with environmental factors in three common settings for students- school, family, and neighborhood.

Methods: A cross-sectional study was conducted in 503 Chinese children and adolescent (51.3% males) aged 8-13 years from four primary and secondary schools. Children's PA was assessed by Children's Leisure Activities Study Survey (CLASS) Questionnaire. Three environmental settings related to PA were measured both with subjective and objective methods including the home, neighborhood and school. Subjective measures on environmental factors were collected by the questionnaires and reported by students themselves on presence, accessibility and utilization of sport facilities, traffic safety and others in different settings. Objective measure on neighborhood environmental correlates was assessed by ArcGIS V10.0. Proxy reports by parents and school Physical Education Teacher on environmental factors were considered as the objective measures in home and school setting.

Results: Moderate PA (MPA), vigorous PA (VPA), and moderate-to-vigorous PA (MVPA) in weekday were 59.3, 28.1, 39.0 mins, respectively. Students were more active in weekend than weekdays with MPA, VPA, and MVPA at 80.9, 58.2, and 107.3 min. The prevalence of meeting the PA guideline (≥ 60 min per day) was 35.3%. In the home environment, students with sports equipment at home generally had higher MVPA on both school days and weekends than those without sports equipment at home, and such difference was more significant on weekends ($P<0.05$). In the neighborhood setting, students who used community sports equipment had significantly higher MVPA on school days than those who used less. Students with more sports venues within the distance of 10–15-minute walk in the neighborhood had significantly higher VPA on weekdays than those with fewer sports venues. Two groups (remote vs. proximal group) was categorized by the GIS with 800m buffer distance from sport venues. Students in proximal group had longer MVPA than those in the remote group. However, no difference was found in the influence of school environment on students' PA, which may be due to the frequent online courses at home during COVID-19.

Conclusion: Findings suggest that PA is affected by several environmental correlates. This study provides a basis for further PA promotion and intervention strategy among migrant children.

OP-PN33 Metabolism

THE COMBINED EFFECTS OF GREEN TEA AND ECCENTRIC EXERCISE ON NUCLEAR FACTOR ERYTHROID 2-RELATED FACTOR 2 SIGNALING

THORLEY, J., THOMAS, C., MARTIN, N.R.W., BISHOP, N.C., BAILEY, S., CLIFFORD, T.

LOUGHBOROUGH UNIVERSITY

INTRODUCTION: Nuclear factor erythroid 2-related factor 2 (Nrf2) is a transcription factor that regulates cellular resistance against oxidative distress by coordinating the expression of endogenous antioxidants such as catalase (CAT) and glutathione reductase (GR). Both exercise and dietary (poly)phenol supplementation have been shown to increase Nrf2 signaling, ostensibly via oxidative or electrophilic cysteine modification of kelch-like ECH-associated protein 1 (Keap1). We hypothesized that combining exercise with 6-days of (poly)phenol (green tea) supplementation would lead to greater activation of Nrf2 than exercise alone.

METHODS: In a double blind, randomized design, healthy, recreationally active males (n = 24; mean [SD]; 23 [3] years, 179.6 [6.1] cm, 78.8 [10.6] kg)) consumed a 1 x 500 mg capsule of green tea (n = 12; 482 mg of (poly)phenols) or a 1 x 500 mg capsule of an inulin placebo (n = 12) for 6 days. On day 6, participants performed eccentric exercise (100 drop jumps, 20 reps x 5 sets, 20 seconds rest between jumps). Blood and urine were collected pre-, post-, 1 and 24 h post-exercise. Systemic Nrf2 levels were measured in plasma and Nrf2/ARE binding activity in peripheral blood mononuclear cells. Nrf2 gene targets CAT and GR, leukocyte counts, and 8-hydroxy-2'-deoxyguanosine (8-OHdG) were also measured. A 2 (supplement) x 4 (time) mixed model ANOVA was performed to detect time, supplement, and interaction effects.

RESULTS: Nrf2/ARE binding activity did not change over time ($p = 0.12$, $\eta2 = 0.10$) or between supplement groups ($p = 0.19$, $\eta2 = 0.08$) (fold change from rest: green tea = [POST] 0.78 ± 0.45, [1H] 1.37 ± 0.98, [24H] 1.09 ±0.57; placebo = [POST] 1.59 ± 1.68, [1H] 2.92 ± 3.73, [24H] 1.17 ± 0.57). There were no time ($p = 0.86$, $\eta2 = 0.01$) or group effects ($p = 0.88$, $\eta2 = 0.01$) for systemic Nrf2 concentration. Exercise increased mean GR activity by 36% (29.2 ± 2.6 vs 39.8 ± 3.5 nmol/min/ml-1, $p = 0.002$, $\eta2 = 0.20$); however, no differences were observed between groups ($p = 0.77$, $\eta2 = 0.01$). CAT activity and 8-OHdG excretion did not change after exercise (CAT: $p = 0.12$, $\eta2 = 0.10$; 8-OHdG: $p = 0.41$, $\eta2 = 0.05$) and did not differ between groups (CAT: $p = 0.79$, $\eta2 = 0.004$; 8-OHdG: $p = 0.67$, $\eta2 = 0.01$). Leukocyte (5.2 ± 1.2 vs 6.36 ± 1.91 x 109 cells/L-1) and neutrophil (2.89 ± 1 vs 4.01 ± 4.9 x 109 cells/L-1)) concentrations were only elevated post-exercise ($p < 0.001$).

CONCLUSION: Eccentric exercise did not increase Nrf2 activation, and this response was not altered by green tea supplementation. Despite the acute biochemical response, the low metabolic stress induced by eccentric exercise may not have been sufficient to trigger Keap1 modification and subsequently Nrf2 activation. The dose of green tea may have been too low to influence Nrf2 activation in vivo. Future research should experiment with different exercise models and (poly)phenol doses.

HEPCIDIN LEVELS DURING THE SEASON OF ELITE ROWERS – A USEFUL MARKER OF IRON NEED SUPPLEMENTATION

NOVÁKOVÁ, M.1, WORONYCZOVÁ, J.1,2, CÍSAROVÁ, K.1,3, BOLEK, E.1

1 - CASRI - SPORTS RESEARCH INSTITUTE OF THE CZECH ARMED FORCES, PRAGUE, 2 - 1ST FACULTY OF MEDICINE, CHARLES UNIVERSITY, PRAGUE, 3 - FACULTY OF BIOCHEMICAL INGINEERING CTU, PRAGUE

INTRODUCTION: Top sports performance and elite training make significant demands on an athlete´s iron metabolism. Iron deficiency is one of the most common nutrient deficiencies in athletes, especially females. Hepcidin emerges as a key regulator of iron metabolism. It regulates the absorption of iron in the intestine and the export of iron from macrophages. Although methods for hepcidin determination have become more available recently, hepcidin is not routinely used as a diagnostic parameter for assessing iron stores. The reason is also the unavailability of reliable reference values. In this study, the iron status is monitored in a group of elite female rowers throughout one year. The study aims to follow the hepcidin levels and correlate them with ferritin as the most commonly used diagnostic parameter for athlete´s iron stores. In addition, part of the results will be compared with a group of elite male rowers.

METHODS: In a group of elite female rowers (n=8, age=22.4±2,7 years), iron stores were monitored at 8 time points (F1-F8) during the one-year period (April – April). In a group of elite male rowers (n=9, age=21.4±1.4 years) iron stores were monitored at 4 time points during the pre-season training from November to April (M5-M8). The level of serum iron, transferrin, ferritin, hepcidin and C-reactive protein were measured in the morning fasting venous blood. Samples with CRP above 5 mg/L were excluded from further analysis. Female athletes with low iron stores supplemented 200 mg of iron (Fe2+) orally every day for three months (June-August). All female athletes supplemented with twice the daily recommended iron intake 7 days per month during the whole year to prevent iron loss due to menstruation.

RESULTS: In the female rowers, ferritin and hepcidin levels were initially 28.1±19.9 µg/L and 3.76±2.83 ng/mL, respectively. Both levels increase to the statistically significant maximum of 63.8±12.7 µg/L and 12.0±6.07 ng/mL after supplementation. Further, in the period F5-F7 ferritin keeps above 50 µg/L, while hepcidin fluctuates significantly (ANOVA, n=28, F=4.93, $p<0.01$). At the final time point F8 during the final pre-season training ferritin and hepcidin level decrease to a minimum. In comparison, in the male rowers there are no significant changes in ferritin and hepcidin levels between the time points M5-M7. Hepcidin correlates with ferritin, transferrin saturation and serum iron, but the strongest correlation is found for ferritin ($r=0.66$, n=94, $p<0.05$).

CONCLUSION: To our knowledge, this is the first study following hepcidin levels in elite athletes regularly on a long-term basis. We demonstrated that ferritin and hepcidin levels fluctuate significantly in female rowers during the season in comparison to male rowers. Our data suggest that hepcidin could be a useful additional marker for the need for iron supplementation in female elite athletes, especially when a history of individual ferritin levels is not available.

ACUTE AEROBIC EXERCISE INCREASES CIRCULATING IRISIN IN HEALTHY ADULTS

TOMMASINI, E.1, MISSAGLIA, S.1, VAGO, P.1, GALVANI, C.1, PECCI, C.2, RAMPININI, E.2, BOSIO, A.2, MORELLI, A.2, SILVESTRINI, A.1, MORDENTE, A.1, BONANOMI, A.1, TAVIAN, D.1

1 UNIVERSITÀ CATTOLICA DEL SACRO CUORE; 2 MAPEI SPORT RESEARCH CENTRE

INTRODUCTION: Irisin is a cytokine mainly secreted by muscle tissue via Ca2+–AMPK–PGC-1α–FNDC5 pathway. Physical exercise can increase its circulating level, inducing browning of white adipose tissue, promoting autocrine effects on muscle, maintaining glucose and bone homeostasis (1). However, previous studies reporting the effect of acute aerobic exercises on irisin secretion across adulthood are partially contradictory (2,3). Therefore, the aim of the present study was to evaluate the time course of circulating irisin level following a cycling incremental exercise to exhaustion in two age groups.

METHODS: 34 healthy male subjects were divided into two groups: young adults [YA] (N: 22; age, 24,6±3,6 yrs; BMI, 23,2±2,4 kg/m2; peak oxygen uptake [V'O2peak] 47,3±7 ml/kg/min) and middle-aged adults [MA] (N: 12; age, 54,6±5,7 yrs; BMI, 23,4±2,2 kg/m2; V'O2peak 44,8±5,1 ml/kg/min). Subjects completed the International Physical Activity Questionnaire [IPAQ] and performed an incremental cycling exercise test to exhaustion. V'O2peak via direct gas analysis was determined and blood samples were collected before the exercise, 15min and 24h post-exhaustion. Quantification of irisin levels in serum was performed using irisin-ELISA Kit (EK-067–29). Subjects were asked not to be engaged in moderate or vigorous physical activity [PA] during the 48h before the test. Level of significance was set at $p<0,05$.

RESULTS: A significant increase of serum irisin levels at 15min ($p<0,001$) and 24h ($p<0,001$) compared to baseline was found, with the greatest increase by 58% after 24h. Irisin levels at baseline, 15min and 24h post exercise were significantly higher in YA compared to MA (baseline: 9,5±1,5 vs 7,2±1,6 ng/ml, $p<0,001$; 15min: 10,9±1,7 vs 8,4±1,5 ng/ml, $p<0,001$; 24h: 14,5±2,2 vs 11,6±2,3 ng/ml, $p<0,001$, respectively). However, MA showed a similar percentage increment in serum irisin 15min and 24h post exercise to their younger counterparts. Irisin was negatively correlated with age at baseline, 15min and 24h ($r=-0,677$, $r=-0,711$, $r=-0,649$; all $p<0,001$). Moreover, a positive correlation was found between basal irisin and self-reported PA ($r=0,391$; $p<0,05$), while a negative correlation was observed with sedentary behavior ($r=-0,414$; $p<0,05$) only when adjusted with age.

CONCLUSION: Circulating irisin levels were elevated in response to acute exercise, with a greater increase after 24h post exercise. YA and MA showed a similar irisin response to acute aerobic exercise, nevertheless irisin levels were higher in YA than MA. Basal irisin seems to be positively influenced by PA and negatively by age and sedentary lifestyle.

HUMAN FIBER-SPECIFIC MUSCLE DIFFERENCES IN PROTEIN SYNTHESIS AND OXIDATIVE METABOLISM PATHWAYS BETWEEN OBESE AND HEALTHY INDIVIDUALS

CAMPOS, C., ARREDONDO, J., OYARZUN, S., FLORES-OPAZO, M., VALLADARES-IDE, D., CABELLO-VERRUGIO, C., PARADA, P., PINTO, P., PEÑAILILLO, L.

UNIVERSIDAD ANDRES BELLO

INTRODUCTION: Skeletal muscle demonstrates remarkable plasticity in response to different environmental and physiological stimuli such as energy availability and physical activity. Overfeeding and low physical activity may lead to obesity, which could affect skeletal muscle mass, metabolism, and fiber distribution (1). Skeletal muscle adaptations have shown to be fiber type-specific (i.e., type I or slow-twitch and IIa or fast-twitch)(2). Aim: to compare the protein content of the protein synthesis and oxidative metabolism proteins pathways in type I and IIa skeletal muscle fibers from obese and healthy individuals.

METHODS: Nine obese (OB; age=42.6±8.4 y; body mass index=33.7±4.5 kg/m2) and twelve healthy (HI; age=29.1±5.4 y; body mass index=24.9±1.6 kg/m2) individuals underwent a muscle biopsy from the vastus lateralis. Muscle specimens (10mg) were lyophilized for 48h after which muscle fibers were identified and isolated manually. Dot-blot technique was used to identify type I, IIa and IIx MHC isoforms, after which the same fiber-type fibers were pooled. Akt-1, mTOR, p70s6K, S6 ribosomal protein, COX-IV, ERK 1/2, AMPk total proteins from whole muscle and fiber-type pooled samples were quantified by Western blot. Two-way ANOVA and independent Student´s t-test were used to compare conditions and fiber types, and whole muscle samples, respectively.

RESULTS: Total levels of Akt-1, mTOR, p70S6K and S6RP protein were similar between muscle fiber types and between whole muscle homogenates from both OB and HI. Total levels of COX-IV were similar between OB and HI, with both groups showing greater (OB=35%, P= 0.04, HI 32%, P= 0.03) levels of this protein in type I muscle fibers. OB showed similar levels of total ERK (1/2) and AMPK proteins in both muscle fiber types. However, HI showed greater levels of total ERK (1/2) (70%; P= 0.003) and AMPK proteins (110%, P= 0.005) in type IIa muscle fibers compared to type I. There were no significant differences in total protein ubiquitination between muscle fiber types and between whole muscle homogenates from obese and healthy individuals (p=0.06).

CONCLUSION: These results suggest that healthy individuals seem to have greater machinery for protein synthesis in type IIa muscle fibers, particularly through a MAPK-dependent pathway. Greater COX-IV level in type I compared to type IIa muscle fibers was expected in both conditions as per the type I muscle fiber metabolism, which suggests a similar oxidative activity in both groups. In addition, the elevated levels of AMPK in type IIa fibers of healthy individuals suggest that AMPK may exert other roles rather than only increase oxidative metabolism, which needs to be explored further. Finally, we provide evidence that muscle adaptations occur specifically to muscle fiber type, and these changes could be masked when analyzed in whole muscle.

OP-SH20 Women in sport

A COMPARATIVE ANALYSIS OF THE MEDIA IMAGE PRESENTATION OF FEMALE ATHLETES BY CHINESE AND AMERICAN MEDIA: TAKE THE REPORTS OF PEOPLES DAILY AND THE NEW YORK TIMES DURING THE BEIJING WINTER OLYMPICS AS

CHEN, X., FAN, X.

SHANGHAI JIAO TONG UNIVERSITY

Introduction

There is explicit or implicit gender inequality existing in sports communication. The quantity, content, quality, and angle of media coverage of female athletes are affecting the visibility of female athletes. To study the image of female athletes in the mass media, the comparison of Chinese and American reports on female athletes during the Beijing Winter Olympics will help us understand how the mainstream official media of different countries reproduce the image of female athletes.

Methods

Using word frequency analysis, content analysis, tools such as the Divominer platform and LDA topic modeling were used to search the Peoples Daily (PD) and New York Times (NYT) databases with "Winter Olympics" and "Olympics " as keywords for full-text search, during the Beijing Winter Olympics. Finding 43 and 104 articles that met the criteria were selected as the samples. By counting the high-frequency words and doing quantitative statistical analysis, we understand the emo-

tional tendencies and themes of news reports, deconstruct the narrative discourse and explore how the two major media reproduce the images of female athletes.

Results

The study found that the number of female athletes reported by PD is significantly lower than that of the NYT, and the themes of the reports focus on positive and collective narrative discourse such as unity, glory, and struggle dream, and pay attention to showing the spirit of group cooperation of female athletes. It reports mainly on domestic female athletes. The NYT, however, focuses on positive personalized narrative discourse such as leadership, defeat, love, and overcoming, focusing on showing the individual competitive ability of female athletes. Moreover, a considerable number of articles show the narrative discourse of female athletes overcoming adversity, reporting both at home and abroad.

Discussion

The research shows that when Chinese and American mainstream media reported on female athletes during the Winter Olympics, there were significant differences in the number of reports, themes and inclinations. This phenomenon reflects the different cultural and educational backgrounds of China and the US: the Chinese Olympic culture focuses on the performance of individual female athletes in the country and the group. Individual success is largely due to the existence of the nation and group. The concept of nation permeates the growth of the athletes, and it is also reflected in the subconscious attachment of the Chinese official media to the nation and collective. However, the image of American female athletes remains at the individual level. In American society, individuals who succeed through hard work are respected and praised by society.

PROBABLY JUST SEXISM: GENDERED EXPERIENCES OF RESOURCE ACCESS IN RUGBY UNION

PETRIE, F., MACKINTOSH, K., STARBUCK, C., WILLIAMS, E., MCNARRY, M.

SWANSEA UNIVERSITY, WALES, UK

Introduction

Participation in women's rugby continues to grow, but it remains under-prioritised relative to the men's game, as evidenced by the dearth of women-specific research, the low visibility of the sport and limited access to resources for women in rugby. Indeed, whilst such gender inequalities are often anecdotally acknowledged, there is little rigorous research exploring gendered experiences within rugby, especially in non-elite settings. This study aimed to investigate the experiences of a diverse cohort of rugby players in relation to their navigation of the sport and availability of resources.

Methods

Twenty UK-based rugby players (10 men, 9 women and 1 non-binary person) from school, university, club, military and semi-professional environments took part in semi-structured interviews (mean length 36 ± 12 minutes) discussing their experiences of rugby in relation to their current gender identity and playing level. Interviews were transcribed verbatim, and a reflexive thematic analysis was undertaken.

Results

A widespread under prioritisation of women in rugby was highlighted. Specifically, gender biases were evident in access to changing rooms, pitches, quality coaches and referees, pitch-side healthcare, and opportunities to play rugby. A degree of positive change towards redressing these imbalances was acknowledged, but interviewees expressed that gender biases in rugby were embedded. Gender biases were more commonly propagated by those in decision-making managerial positions rather than by players themselves.

Irrespective of gender, amateur players reported difficulty accessing a suitable environment to play in and referenced rurality limiting access to development opportunities. Insufficient player numbers precluded the formation of second teams, meaning that inexperienced players were competing beyond their ability. This difficulty in accessing a suitable environment was cited as a reason for player attrition, alongside having to endure sexist treatment.

Discussion

This study highlights an urgent need to mitigate the gendered treatment experienced by rugby players and illustrates the detriment to player wellbeing, safety and growth of the game such inequalities produce. Increased representation of women in managerial positions in rugby unions and rugby clubs are recommended to enact meaningful change.

WOMEN'S FOOTBALL IN SOUTHERN AFRICA: AN EXPLORATORY STUDY OF THE CHALLENGES FACING INTERNATIONAL PLAYERS

BAHDUR, K.

LUNEX UNIVERSITY

Introduction

Governments and sports federations are prioritizing women's sport. The Federation Internationale de Football Association (FIFA) have made commitments and allocated resources to member associations (MA) to help them provide better support, better resources, and create an environment to enable more opportunities for female players. More MA are developing strategies for women's football. However, despite increased opportunities to compete, challenges still arise in creating the best environment for players to fulfil their potential.

Methods

This informal qualitative explorative study delved deeper into challenges facing Southern African footballers. Discussions which centered around individual player's development and the challenges facing them, were held with 70 English-speaking players from 5 senior women's national teams. Narrative analysis was used to analyse the data. During the discussions, information was clarified, and time was taken to ensure that the interpretation was correct. Consistent themes in the discussions were identified.

Results

Two main general themes were identified. These related to lack of resources and lack of support. Lack of resources extended to facilities, expertise, and financial resources. Lack of support centered around family, friends and extended to the broader community. A key point that was highlighted was that evidence-based solutions must explore both the homogenous and the heterogenous nature within an African women's context.

Discussion

The findings revealed that while progress in the women's game must be acknowledged, there remain challenges facing players within Southern Africa. The importance of training as well as the resources required for training and the holistic improvement of players are often not a focal area away from international tournaments. Players highlighted the difficulty in improving without enough exposure to high training stimuli. They also mentioned being required to work individually on training, which is challenging in a team sport often leads to often feeling isolated. Even players who seek new and better methods of training, recovery and conditioning tools, are often limited by socioeconomic constraints, or in the case of nutrition, solutions that are Eurocentric and not feasible in the African context.

The socioeconomic challenges facing the continent extend to football resources. These challenges are exacerbated due to the remaining gender stereotypes, cultural norms and firm opposition regarding women's involvement in football. The lack of support can sometimes extend to active critique and undermining of a player's football dreams. Balancing the expectations and venturing towards what community, family and friends see as an undesirable pathway, with one's own vision for their life adds feelings of conflict, guilt and greater conflict for players. More applied research is required to produce evidence-based solutions that are feasible within an African context.

MIDWIVES' AND PREGNANT WOMEN'S PERCEPTIONS OF PHYSICAL ACTIVITY PROMOTION PRACTICE DURING PREGNANCY TO IDENTIFY KEY DETERMINANTS TO PROMOTE AN ACTIVE LIFESTYLE.

HYVÄRINEN, M., WEGRZYK, J., DE LABRUSSE, C., VAN POPPEL, M.

1HESAV SCHOOL OF HEALTH SCIENCES, HES-SO UNIVERSITY OF APPLIED SCIENCES AND ARTS WESTERN, LAUSANNE, SWITZERLAND 2INSTITUTE OF HUMAN MOVEMENT SCIENCE, SPORT AND HEALTH, UNIVERSITY OF GRAZ, AUSTRIA

Introduction

Despite scientific evidence on health benefits of an active lifestyle during and after pregnancy for both women and children, healthcare professionals (HCPs) do not sufficiently promote physical activity (PA) during and after pregnancy. To address public health issues of rising rates of complications in pregnancy and non-communicable diseases in adulthood, HCPs, in particular midwives, need to inform women about PA recommendations and benefits for them and their children. Identifying the key determinants of PA promotion from the midwives and womens perspectives enables the development of an evidence-based strategy to integrate PA promotion in the health system.

Methods

Participants were recruited via the maternity department of the Lausanne University Hospital, Switzerland. Seventy-three pregnant women completed an extended version of the Pregnancy Physical Activity Questionnaire, of whom eight took part in semi-structured interviews. Nine midwives delivering prenatal consultations took part in semi-structured interviews. The Theoretical Domains Framework was used for qualitative data analysis. Descriptive statistics were performed on quantitative data. Then the data was combined by triangulation of viewpoints.

Results

Pregnant women were 4.6% in the first trimester, 21.1% in the second, and 74.2% in the third. 54.5% reported meeting PA recommendations before pregnancy and 56.2% were meeting it during pregnancy. 39.4% of pregnant women reported that HCPs did not address the topic of PA during pregnancy. 59.1% would have appreciated receiving more information. Interviewed women perceived a lack of knowledge and skills by HCPs and reported not having received clear information about recommendations and benefits. Because of lack of information from HCPs, women changed their PA practice during pregnancy due to negative emotions (fear and anxiety), beliefs about consequences (risk to harm the baby) and social influences (entourage advice to move less). Interviewed midwives confirmed that promoting PA is part of their professional role. They were aware of their lack of knowledge, skills, and noticed the absence of procedures at the maternity hospital. Women who do not ask questions about PA, who seem not interested in PA and from disadvantaged social groups are at higher risk not to receive information about PA.

Discussion

PA promotion is not systematically delivered during pregnancy. The implementation of new practices among HCPs is perceived as a complex process and depend on several key determinants such as environmental, interpersonal, and intrapersonal factors. Midwives identified advanced training, interprofessional collaboration and environmental resources

to be enablers to improve PA promotion practice, while pregnant women identified easier access to educational resources and clear, individualised, and repeated information from HCPs.

DAILY STEP COUNT AND LEISURE-TIME PHYSICAL ACTIVITY WITH THE PREVALENCE OF HYPERTENSION: A CROSS-SECTIONAL STUDY AMONG WORKERS IN JAPAN

TSUNEDA, U.1, SHIMIZU, S.1, ZHAI, X.1, SAWADA, S.S.1, KORIYAMA, S.1, DIMITROFF, S.A.1, HAMAYA, K.2

1> WASEDA UNIVERSITY, SAITAMA, JAPAN 2> JAPAN INDUSTRIAL SAFETY AND HEALTH ASSOCIATION, TOKYO, JAPAN

INTRODUCTION: Limited data are available on the joint relationship of daily step count and leisure-time physical activity with the prevalence of hypertension.

We conducted a cross-sectional study to investigate the joint relationship between DSC and leisure-time physical activity with the prevalence of hypertension among workers in Japan.

METHODS: Participants were 4,887 men [median age 45 years] and 1,161 women [median age 42 years] who completed a self-administered questionnaire on their health habits, including daily step count (< 6,000 steps/day, 6,000–7,999 steps/day, 8,000–9,999 steps/day, and ≥ 10,000 steps/day) and leisure-time physical activity excluding walking (never, only specific seasons, 1–2 times per month, once a week, more than twice a week) in 2017. Participants were classified into fourgroups based on their daily step count and leisure-time physical activity. Low daily step count and low leisure-time physical activity group (LL-G), low daily step count and high leisure-time physical activity group (LH-G), high daily step count and low leisure-time physical activity group (HL-G), and high daily step count and high leisure-time physical activity group (HH-G) were set, respectively. The prevalence of hypertension was obtained using a self-administered questionnaire. Multivariable-adjusted odds ratios and 95% confidence intervals for the prevalence of hypertension were obtained using logistic regression models while adjusting for age (continuous variable), sex (men, women), smoking (current-smoker, former-smoker, never-smoker, other), drinking (never, < 3 times/week, 3–5 times/week, ≥ 6 times/week, other), and sleep time (< 6 hours, ≥ 6 hours, other).

RESULTS: 1,052 participants (17.4%) had hypertension. Using the LL-G as a reference, the odds

ratios and 95% confidence intervals were 0.79 (0.63–0.98) for LH-G, 0.98 (0.81–1.18) for HL-G, and 0.69 (0.55–0.86) for HH-G, respectively.

CONCLUSION: In this cross-sectional analysis, the combination of high daily step count and high leisure-time physical activity group is associated with the lowest prevalence of hypertension among workers in Japan.

LOW INTENSITY STRUCTURED EXERCISE IS ASSOCIATED WITH HEMODYNAMIC CHANGES REVEALED BY INFRARED THERMOGRAPHY IN PEOPLE WITH INTERMITTENT CLAUDICATION

CARUSO, L.1, CREPALDI, A.2, PIVA, G.3, ZENUNAJ, G.4, GASBARRO, V.4, MANFREDINI, F.5, LOPEZ-SOTO, P.J.2, LAMBERTI, N.5

UNIVERSITY OF FERRARA

INTRODUCTION: In patients with peripheral artery disease (PAD) the assessment of perfusion of the lower extremity districts, of the foot in particular, enables patient's surveillance favoring the disease management and proving the effectiveness of interventions. Among the available techniques, non-invasive non-contact, infrared thermography (IRT) has been recently recognized as a promising method to screen different areas of foot perfusion. The study aimed to detect in PAD patients if at the end of an exercise program changes of foot temperature measured by IRT were observable and whether these variations were consistent with a validated hemodynamic measurement.

METHODS: In this prospective non-randomized trial we enrolled 76 PAD patients (72±4 years; 52 males) at Rutherford's stages 2-3 (claudication). All patients were enrolled in a structured in-home exercise program [1] composed of two daily 8-minute interval walking sessions (1:1 walk:rest ratio) at an initial slow speed, maintained at home by a metronome, and progressively increasing. Patients underwent four consecutive visits throughout the program. At week 0 (T0, baseline), week 5 (T1), week 12 (T2) and week 20 (T3), patients received program prescription and outcome measure assessment including foot temperature by IRT at selected points (anterior tibial, posterior tibial, dorsalis pedis and arcuate arteries [2]), lower limbs segmental pressures, ankle-brachial index (ABI) and 6-minute walk test.

RESULTS: All patients completed the exercise program, with a significant increase of 6-minute walking distance (+45 m; $p<0.001$) and of ABI of the worst limb (+0.10; $p<0.001$).

At baseline, a relationship was observed between mean foot temperature and ABI value ($r=0.33$ $p=0.022$). The foot temperature of both limbs showed a significant increasing trend with a mean variation of 1.3°C for the more impaired limb

and 0.9°C for the contralateral (t=8.88, p<0.001; t=5.36; p<0.001, respectively). Significant changes for all sampled districts were observed at T1 after only 5 weeks of training. At T3, changes in mean foot temperature and changes in ABI were significantly directly correlated (r=0.32; p=0.039).

CONCLUSION: In patients with PAD, a structured low-intensity exercise program significantly improved hemodynamics as assessed by ABI. Favorable correlated changes in foot temperature were also assessed by IRT. Infrared thermography, proved to be an effective method which rapidly displays the vascular adaptations occurring after exercise, also favoring adherence of patients to the exercise program.

VALIDATION OF A NOVEL ISOMETRIC RESISTANCE TRAINING BAND: A COMPARISON OF THE CARDIOVASCULAR RESPONSES BETWEEN EXERCISE MODES

WRIGHT, B.H., BAXTER, B.A., ANTROBUS, M.R., JONES, P.G.W., BAROSS, A.W.

THE UNIVERSITY OF NORTHAMPTON

INTRODUCTION: Short- to long-term isometric resistance training (IRT) can produce clinically meaningful reductions in resting blood pressure (BP) [1] but established methods are costly or require laboratory access, limiting wider application. An affordable home-based method could improve accessibility, however, there is a need to establish the efficacy, safety, and suitability prior to prescription as an alternative IRT method. The aims of this study were to determine if a novel isometric training band (ITB) can elicit cardiovascular (CV) responses (BP and heart rate [HR]) comparable with established IRT methods, and if the Category Ratio Scale (CR-10) can regulate isometric contraction intensity.

METHODS: Fifteen healthy normotensive participants (systolic [SBP]; 120 ± 3 mmHg, diastolic [DBP]; 71 ± 6 mmHg) reported CR-10 responses (T1-min & T2-min) to a single 2-min isometric handgrip (IHG) exercise at 30% of maximum voluntary contraction (MVC). Participants then completed 2-min contractions for four separate exercises using the ITB (chest fly, seated pull, seated lunge, bicep curl and tricep extension) with the aim of replicating localised sensations of exertion equivalent to the IHG contraction. Cardiovascular responses were measured following each 2-min isometric exercise with CR-10 values recorded on completion of each min. A further 15 normotensive participants (SBP; 118 ± 6 mmHg, DBP; 68 ± 7 mmHg) completed a bout of IRT (IHG, 4 x 2-min at 30% MVC; ITB, 4 x 2-min at pre-determined CR-10 values, [4, and 5 for T1-min & T2-min]) with mean CV responses compared between bouts. Repeated measures ANOVAs and pairwise comparisons were conducted to identify any significant (P <.05) differences, with additional analyses examining association, reliability, and agreement.

RESULTS: There was no difference in BP responses between IHG and all four ITB exercises (P >.05). CR-10 values and HR responses were comparable between IHG and three ITB exercises (P >.05) but were greater during the seated pull (T1-min, P <.05; T2-min, P <.05; HR, 96.8 ± 17.3 bpm·-1 vs. 81.1 ± 13.4 bpm·-1; P <.05). Between bouts, regulating contraction intensity through pre-determined CR-10 values resulted in comparable BP (P >.05) responses, although ITB elicited a greater HR response (91 ± 15.1 bpm·-1 vs. 79 ± 9.9 bpm·-1; P <.001). Between-bout CV responses were strongly positively correlated (r = 0.75-0.88, P <.05), alongside acceptable limits of agreement (bias = -11.13-3.38) and moderate-to-excellent reliability (ICC >0.65 and CoV <9.2%).

CONCLUSION: The CV demands reported during and after undertaking the novel ITB exercises are comparable with established IHG methods. Although the HR response was greater in the ITB bout, values did not exceed reported unsafe thresholds. The present study findings suggest the novel ITB, and associated protocol may serve as a versatile, cost-effective, and accessible alternative method of performing IRT.

EFFECTS EXERCISE ARM-CRANKING AND TREADMILL WALKING TRAINING ON AMBULATORY BLOOD PRESSURE OF PATIENTS WITH PERIPHERAL ARTERY DISEASE AND CLAUDICATION SYMPTOMS

CORREIA, M.A., KANEGUSUKU, H., COSTA, R.M., CASTELLARI, C.B., CUCATO, G.G., WOLOSKER, N., RITTI-DIAS, R.M.R.

UNIVERSITY NOVE DE JULHO

INTRODUCTION: Patients with peripheral artery disease (PAD) and claudication symptoms present walking impairment and increased cardiovascular risk. Although walking exercise training has been recommended to improve walking capacity and reduce blood pressure (BP) in these patients, pain during exercise is a main barrier to maintenance in practice. Arm-cranking (AC) exercise training has shown to improve walking capacity of these patients, however, whether this mode of training can improve blood pressure parameters remains unclear. Thus, the aim of this study was to compare the effects of walking and AC exercises on ambulatory BP in patients with PAD and claudication symptoms.

METHODS: Patients with PAD were randomized in arm-cranking (AC) and walking training (WT) groups. Both groups performed a supervised exercise program twice a week for 12 weeks. In both groups the volume of training progressed from 30 min of active exercise to 50 min of active exercise. Before and after 12 weeks of interventions, patients were submitted to a 24-hour ambulatory BP assessment. Mean 24 hr, awake and asleep BP were calculated.

RESULTS: Twenty-three patients finalized the intervention (AC: n=12, 70±8 yrs, 27±4 kg.m2, ankle-brachial index 0.68±0.23; WT: n=11, 70±4 yrs, 28±4 kg.m2, ankle-brachial index 0.72±0.24). At baseline groups were similar for all BP variables (p>0.05). Compared to WT, AC promoted greater decreases in 24 hr mean BP (-4±9% vs. +2±5%, p=0.05), 24 hr

diastolic BP (-5±8% vs. +4±7%, p=0.01), awake mean BP (-5±8% vs. +1±4%, p=0.03) and awake diastolic BP (-7±8% vs. +3 ±7%, p<0.01).

CONCLUSION: This preliminary data indicated that AC training promotes greater reductions in 24 hr BP compared to WT in patients with peripheral artery disease and symptoms of claudication.

WALKING EXERCISE INTENSITY PREFERENCES IN PATIENTS WITH PERIPHERAL ARTERY DISEASE

RITTI-DIAS, R., OLIVEIRA, M.D., KANEGUSUKU, H., FARIA, D.R.G., WOLOSKER, N., CORREIA, M.A.

UNIVERSIDADE NOVE DE JULHO

INTRODUCTION: Pain during walking exercise has been one of the main barriers for patients with peripheral arterial disease (PAD) and intermittent claudication symptoms (CI). Exercise with self-selected prescription (SSP) by the participant emerged as an alternative to increase the interest, since it has been shown to increase pleasure during exercise in other populations. However, whether similar responses are observed in patients with PAD and IC symptoms are unknown. The objective of this study was to compare exercise preferences, cardiovascular, perceptual and affective responses between the SSP and the prescription recommended by the guidelines (PRG).

METHODS: Nineteen patients (52.6% male, 69.1±7.9 years, 27.2±5.7kg/m², 0.59±0.15 ankle-brachial index) with PAD performed two experimental sessions (i.e., 30 minutes of walking on the treadmill) in random order: the PRG session (i.e., sets of 3-5 min of walking and 2-3 minutes of recovery, with intensity defined on a scale moderate in pain perception) and the SSP session (i.e., participants choose at which speed they preferred to walk, duration of sets and time of recovery between sets). Heart rate, systolic blood pressure, perceived exertion, subjective perception of pain and affective response were monitored every 5 minutes throughout the session.

RESULTS: The average duration of the sets (p<0.001) was higher for the SSP session. However, the number of the set (p<0.001), average walking speed per set (p<0.001), the total recovery time (p<0.001), and total distance covered in the session (p<0.001) were lower for the SSP session compared to PRG session. The intensity markers (i.e., heart rate and perceived exertion) and pain and affective responses were similar in both sessions

CONCLUSION: Patients with PAD and CI symptoms prefer few bouts with longer duration at slow walking speed and, with lower total time recovery compared to the PRG session. This prescription elicited similar cardiovascular and RPE, and pain perception affective responses than recommended by the guidelines.

LIFE'S ESSENTIAL 8 SCORE AND RISK OF ALL-CAUSE AND CARDIOVASCULAR MORTALITY IN SPANISH ADULTS: THE ENRICA STUDY

HERNÁNDEZ-MARTÍNEZ, A., DUARTE-JUNIOR, M.A., SOTOS-PRIETO, M., ORTOLÁ, R., BANEGAS, J.R., RODRIGUEZ-ARTALEJO, F., SORIANO-MALDONADO, A., MARTÍNEZ-GÓMEZ, D.

1 SPORT RESEARCH GROUP , UNIVERSITY OF ALMERÍA, ALMERÍA, SPAIN ; 2 DEPARTMENT OF PREVENTIVE MEDICINE AND PUBLIC HEALTH, SCHOOL OF MEDICINE, UNIVERSIDAD AUTÓNOMA DE MADRID.

INTRODUCTION: Cardiovascular diseases (CVD) continue to be the main cause of morbidity and death globally (1). Focusing on the primordial prevention, the American Heart Association (AHA) has recently updated its algorithm to quantify cardiovascular health, namely "Life's Essential 8" (LE8) (2). Recent evidence indicates that higher LE8 score is associated with lower risk of all-cause and CVD mortality in American population (3). However, little is known about the role of LE8 on mortality in Europe. Understanding the role of the LE8 score to predict mortality in European countries is of interest, particularly in Spain where the CVD mortality is rather low. This study aimed to examine the association of the LE8 score with all-cause and CVD mortality in a representative sample of noninstitutionalized adult population of Spain.

METHODS: Data from ENRICA cohort (4), comprising 11616 participants representative of Spanish population aged >18-years, recruited from 2008-2010 and followed up to 2022. LE8 (range 0-100) was assessed following the AHA definitions and was categorized as low (0-49), moderate (50-79), and high (80-100). The score components are diet habits, physical activity, nicotine exposure, sleep health, body mass index, blood lipids, blood glucose and blood pressure. Associations between the score and mortality were investigated using multivariable-adjusted Cox proportional hazard ratio (HR). Age, sex, social status, and education level were used as covariates.

RESULTS: The mean age of the sample was 47.4 years [95% confidence interval (CI), 47.0-47.7], and 6110 were female (50.5%). During a median follow-up period of 10.9 years (ranging from 0.47 to 13.6 years), 908 all-cause deaths occurred, being 207 (26.2%) due to CVD causes. The LE8 was associated with lower risk of all-cause (HR for per 10-score increase, 0.84; 95%CI, 0.78-0.89) and CVD mortality (HR for per 10-score increase, 0.76%; 95%CI, 0.66-0.89). Nonlinear dose-response relationship was observed for all-cause and CVD mortality.

In comparison with participants having low LE8, those having high LE8 had a reduction of 57% in the risk for all-cause mortality (HR, 0.43; 95% CI, 0.28-0.67). However, for CVD mortality the reduction was not significant (HR, 0.41; 95% CI, 0.14-1.19).

CONCLUSION: Higher LE8 score was associated with a lower risk of all-cause and CVD mortality in Spanish population. Interventions encouraging high levels of LE8 score should be promoted among the general population. Further research into the long-term and causal relationship of LE8 and mortality is needed.

ASSOCIATION OF ESTIMATED CARDIORESPIRATORY FITNESS AND INSULIN RESISTANCE IN KOREAN ADULTS: THE KOREA NATIONAL HEALTH AND NUTRITION EXAMINATION SURVEY (KNHANES 2020-2021).

HAN, Y., CHOI, Y.H., KIM, Y.S.

SEOUL NATIONAL UNIVERSITY

INTRODUCTION: Lower cardiorespiratory fitness is associated with various metabolic diseases. However, general physical fitness tests have limitations that require trained personnel and specialized measurements. Therefore, we use verified estimated CRF (eCRF) analysis to confirm the relationship with insulin resistance. The study aimed to examine the association between eCRF and insulin resistance (HOMA-IR) in Korean adults using data from the 2020 and 2021 Korean National Health and Nutrition Survey (KNHANES).

METHODS: This data is a cross-sectional study, and a total of 12,085 participants aged 19 and older were included in the analysis. The data were analyzed using regression models to assess the association between cardiorespiratory fitness and insulin resistance. eCRF was analyzed by dividing it into quartiles using the estimation equation verified by Artero et al. based on age, sex, body mass index, waist circumference, smoking status, resting heart rate, and self-reported physical activity level. Insulin resistance was measured to calculate the HOMA-IR. We used logistic regression to examine the relationship between the two variables after adjusting for potential confounders such as age, sex, body mass index (BMI), smoking, alcohol intake, hypertension, and family history of diabetes.

RESULTS: The study aimed to examine the relationship between cardiorespiratory fitness and insulin resistance by dividing the sample into quartiles. The results showed a clear association between fitness level and insulin resistance, with the highest fitness quartile having the lowest insulin resistance levels. The odds ratio of insulin resistance was calculated for each quartile, with the highest quartile having an odds ratio of 0.14 (95% CI: 0.11-0.17), the third quartile having an odds ratio of 0.27 (95% CI: 0.23-0.31), the second quartile having an odds ratio of 0.52 (95% CI: 0.45-0.59), and the lowest quartile serving as the reference. These results indicate a strong inverse relationship between cardiorespiratory fitness and insulin resistance, with the highest levels of fitness being associated with the lowest levels of insulin resistance. The results support the idea that increasing fitness levels can significantly impact insulin sensitivity and reduce insulin resistance risk.

CONCLUSION: The analysis results demonstrated a significant relationship between the two variables, indicating that higher levels of cardiorespiratory fitness are associated with lower levels of insulin resistance. These findings highlight the importance of maintaining good cardiovascular health for overall metabolic health and suggest that cardiorespiratory fitness may play a role in preventing insulin resistance and related conditions.

REFERENCE VALUES FOR ACCELEROMETER-ASSESSED PHYSICAL ACTIVITY AND ASSOCIATIONS WITH CARDIORESPIRATORY FITNESS: A CROSS-SECTIONAL STUDY OF HEALTHY ADULTS

SCHWENDINGER, F., WAGNER, J., KNAIER, R., INFANGER, D., ROWLANDS, A.V., HINRICHS, T., SCHMIDT-TRUCKSÄSS, A.

UNIVERSITY OF BASEL

INTRODUCTION: Accelerometers accurately quantify physical activity.[1] The traditional method of categorising acceleration using cut-points is inaccurate.[2] Average acceleration (AvAcc) and intensity gradient (IG) have been proposed as cut-point-free alternatives.[3] Yet, their interpretation is difficult and the association with cardiorespiratory fitness (CRF) is unclear. Thus, we aimed to compare the association between CRF and cut-point-free metrics to that with traditional metrics in healthy adults aged 20 to 89 years and 2) provide age- and sex-related reference values for healthy adults.

METHODS: In the COmPLETE study, 463 healthy adults underwent cardiopulmonary exercise testing and wore GENEActiv accelerometers on their non-dominant wrists.[4] Cut-point-free (IG: distribution of intensity of activity in a day; AvAcc: proxy of volume of activity in a day) and traditional (moderate-to-vigorous and vigorous activity) metrics were derived.[3,5]

RESULTS: IG and AvAcc provide a complementary perspective on PA with both IG ($p=0.009$) and AvAcc ($p<0.001$) independently associated with CRF in healthy individuals. The best cut-point-free model and the best traditional model exhibited comparable predictive value for CRF. However, IG and AvAcc are comparable among cohorts and the most widely-used accelerometers, contrary to traditional metrics. We created age- and sex-specific reference values for IG and AvAcc for healthy adults. Moreover, the newly developed R-package 'rawacceleration' will facilitate the transfer of our findings into practice.

CONCLUSION: IG and AvAcc have strong predictive value for CRF and indirectly for the risk of non-communicable diseases and mortality in healthy adults.[6] Our reference values will enhance the utility of AvAcc and IG and simplify their interpretation.

THE ACCURACY OF SMARTWATCH OPTICAL HEART RATE SENSOR, DURING THREE PROGRESSIVE INTENSITIES: A PILOT STUDY

LANOUX, L., LUCENA, E.G.P., OLIVEIRA, J.I.V., UCHIDA, M.C., SOUZA, T.M.F.

UNIVERSITY OF CAMPINAS

INTRODUCTION: Wearable-technology has been developed and investigated as a tool for health and well-being promotion. Along with, smartwatches have emerged with sensors to monitor daily activities and the practice of physical activity. However, the metrics provided by these technologies has been varied by user profile, protocol and sensors adopted [1]. Therefore, the aim of this study was to analyze the accuracy of heart rate by a photoplethysmography (PPG), optical sensor, adopted in the smartwatch, (Samsung Galaxy Watch4), during three different intensities.

METHODS: Eighteen (15 men and 3 women) physically active participants (age: 28.9 ± 7.3 years; height: 172.0 ± 7.0 cm; body mass: 74.6 ± 15.8 kg; BMI: 25.1 ± 4.1 kg/m2). They were informed about all procedures used during protocol. The participants were monitored during walking, jogging and running by two different heart rate monitoring devices. The intensity zones were determined by maximal heart rate percentage [2]: a) light [57-63%] = walking, b) moderate [64-76%] = jogging and c) vigorous [77-95%] = running. The each stage duration was 5-minute. The heart rate monitor Polar RS800-CX (Polar Electro®, Kempele, Finland) was used for a reference device, because of the electrical pulses reading method, and it works by a chest strap on the trunk. In parallel, the participants used a smartwatch (Samsung Galaxy Watch 4 [SGW4], Samsung®, South Korea) at the left wrist, the data was collected by a photoplethysmography (PPG) sensor, an optical one. For statistical analysis the average of values in each intensity zone by Polar and smartwatch was used and applied the Symmetric Mean Absolute Percentage Error (sMAPE, a percentage calculated from difference between actual and forecast values) for analyze the smartwatch accuracy [3], considering sMAPE < 10% as Good and sMAPE < 5% as Excellent. The analyses were performed in Microsoft Excel®, version 365 (Microsoft Office®).

RESULTS: Considering the comparison between SGW4 and Polar in the three intensity zones, it was observed an increase of smartwatch accuracy the greater the intensity according to sMAPE: 16,1% in light intensity; 8,9% in moderate intensity; 6,7% in vigorous intensity.

CONCLUSION: Considering the results of this study, the Samsung Galaxy Watch 4 is reliable for physical activity monitoring, especially in higher intensities, allowing the use of this device in physical exercise monitoring.

IMPACT OF CARBON-PLATED RUNNING SHOES ON RUNNING ECONOMY IN INTERMEDIATE RUNNERS

MEYER, M., HANAKAM, F., FERRAUTI, A.

RUHR UNIVERSITY BOCHUM

INTRODUCTION: Numerous sporting goods manufacturers advertise carbon-plated shoes as performance-enhancing products for runners. Some studies showed already a small effect for elite runners [1][2]. The aim of this study was to verify the influence of two types of carbon-plated running shoes on the running economy of intermediate runners like sports students at different percentages of the VO2peak velocity compared to the habitual footwear of the participants.

METHODS: Eight male sports students (mean ± SD 23.8 ± 2.3 years, 182 ± 7 cm, 75.0 ± 8.2 kg) first conducted an incremental treadmill running test until exhaustion wearing their habitual footwear (starting velocity 10 km/h increasing 1km/h per min, incline 1%) to determine their individual VO2peak (mean ± SD 58.13 ± 5.11 ml/kg*min-1). In the main part of the

study, each participant completed three treadmill sessions on three experimental days, each with different shoes (Adidas Adizero Pro 3, Nike Vaporfly 2, and their habitual Own shoes). The order of the three different footwear options was randomized and counterbalanced. During each treadmill session, every participant completed, after an individual moderate warm-up, three 5-minute stages at 60%, 70%, and 80% of their individual VO2peak velocity (mean ± SD 18.1 ± 1.5 km/h) interrupted by a one-minute break to collect the RPE values. Comfort values of the three different conditions were evaluated by a visual analog scale (VAS from 0 to 10). 2-Factor ANOVA was used to verify the impact of intensities and footwear on outcome parameters.

RESULTS: Oxygen consumption [ml/kg*min-1] increased significantly with higher intensities (main effect intensity $p<0.001$) while no effect of footwear ($p=0.364$) and no interaction intensity x footwear ($p=0.992$) was found. Running economy tended to be lower with Own shoes (mean ± SD):

Adidas: 39.0 ± 5.0 [60%], 45.0 ± 4.6 [70%], 50.4 ± 4.8 [80%]

Nike: 39.5 ± 4.3 [60%], 46.6 ± 5.6 [70%], 50.9 ± 5.9 [80%]

Own: 40.6 ± 3.5 [60%], 47.0 ± 4.1 [70%], 52.8 ± 5.2 [80%]

Energy expenditure corresponded to oxygen consumption and reached the highest values during running with the habitual own shoes at 80 % of VO2max (1167 ± 99 kcal/h). RPE post-exercise ratings increased significantly with higher intensities (main effect intensity $p<0.001$) while no effect of footwear ($p=0.193$) and no interaction ($p=0.753$) was found. RPE values tended to be higher with Own shoes at higher intensities. Comfort values were 8.6 ± 1.0 (Adidas), 7.8 ± 2.2 (Nike), and 7.1 ± 1.9 (Own). Overall, there were no significant footwear effects except for the VAS comfort between Adidas and the Own footwear (p-value: 0.024*).

CONCLUSION: We conclude that carbon-plated running shoes have only small positive effects on running economy in intermediate runners. Future studies should include larger and more homogenous samples and longer running distances under more ecologically valid field conditions.

DO SUPER SHOES OFFER AN ADVANTAGE TO RECREATIONAL RUNNERS?

PARADISIS, G., HANLEY, B., BISSAS, A., ZACHAROGRANNIS, E.
NATIONAL & KAPODISTRIAN UNIVERSITY OF ATHENS

INTRODUCTION: Research shows a lower energy cost in athletes using Advanced Footwear Technology (so called "super shoes"), but this has mainly focussed on well-trained runners. It is not clear whether such super shoes benefit recreational marathon runners at slower paces. The aim of this study was to compare physiological and biomechanical variables between a model of super shoes (Saucony Endorphin Speed 2) and regular running shoes (Saucony Cohesion 13) in recreational athletes.

METHODS: Ten participants (1.66 ± 0.04 m, 57.1 ± 3.8 kg, 23.3 ± 1.1 y) began an incremental treadmill test at a running speed corresponding to 50-60% VO2 max. Speed increased by 1 km/h every 2 min until exhaustion. Gas collection was performed during the last 60 s of each stage to attain steady state VO2. The VO2peak was calculated with the speed at VO2peak (vVO2peak) determined as the lowest running speed that elicited a VO2 equivalent to VO2peak. Participants subsequently ran four times in a randomly ordered cross-over design for 5 min (super or normal shoe, at 65% or 80% vVO2 max). Video data were recorded (Casio EX-F1 camera, 300 Hz) during the last 30 s of the 1st and 5th min, with VO2 measurements collected during the 5th min. Averaged contact and flight times during 10 consecutive steps were used to calculate step rate and step length. Vertical and leg stiffness were calculated using the methods of Morin et al. (2005) [1]. Two-way ANOVA ($\alpha < 0.05$) was used to identify differences between shoes and running speeds for O2 consumption and heart rate (HR), and three-way ANOVA (shoes x speed x time elapsed) was used for spatiotemporal and stiffness variables.

RESULTS: O2 consumption in the Endorphin was 3.9% and 5% lower than the Cohesion shoe at 65% vVO2 max (~9.4 km/h) and 80% vVO2 max (~11.2 km/h) accordingly ($P < 0.001$). HR was lower (1.8%) in the Endorphin shoe ($P < 0.001$), although there was no shoe-speed interaction for this variable. The Endorphin condition had shorter step lengths (0.7 - 1.0%), higher step rates (0.7 - 1.4%), shorter contact times (2.0 - 2.7%) and longer flight times (4.8 - 7.9%) ($P < 0.001$). All these variables changed with increased speed ($P < 0.001$). For global stiffness characteristics, vertical stiffness and leg stiffness were greater in the Endorphin shoes (1.6 - 3.3% and 4.6 - 6.3% accordingly, $P < 0.001$). Peak vertical force and vertical stiffness both increased with speed ($P < 0.001$).

CONCLUSION: There was a physiological benefit to running in the super shoes as O2 consumption and heart rate were lower than in the regular shoe. The difference in O2 consumption did increase at the faster speed (5%), but nonetheless there was still a 3.9% advantage at the slower speed. The physiological benefits were accompanied by spatiotemporal and global stiffness benefits to wearing the super shoes, indicating that recreational runners gain a mechanical advantage by using this kind of footwear.

EFFECTS OF WEARING COOLING TROUSERS ON SKIN TEMPERATURE AND SKIN PERFUSION IN HEALTHY MALES.

WILDMOSER, J.1, HOHENAUER, E.1,2,3,4, CLIJSEN, R.1,2,4

1 THIM UNIVERSITY OF APPLIED SCIENCES; 2 UNIVERSITY OF APPLIED SCIENCES AND ARTS OF SOUTHERN SWITZERLAND; 3 UNIVERSITY OF FRIBOURG; 4 VRIJE UNIVERSITEIT BRUSSEL

INTRODUCTION: Cold-water immersion (CWI) is a commonly used recovery modality with the aim of positively affecting subjective recovery parameters and reducing inflammatory reactions [1]. The main mechanisms of cryotherapy for recovery enhancements can be attributed to its vasoconstrictive effects, which reduce skin temperature and skin perfusion. However, the use of CWI is sometimes unpleasant and can be a logistical challenge. For this reason, alternatives to CWI, such as cooling trousers by Icebein™, have been developed. Due to their novelty, there exists a lack of scientific research on the basic physiological and perceptual responses to these cooling trousers. Therefore, this pilot study aims to investigate the effects of cooling trousers on i) lower leg skin temperature, skin perfusion, and ii) thermal perception.

METHODS: In this pilot study, 12 healthy males (26±4.2 years old) volunteered to wear the Icebein™ cooling trousers for a duration of 20 min with the water temperature set at 5°C. Lower leg skin temperature (FLIR, A655, Kent, UK), skin perfusion of the m. quadriceps femoris vastus lateralis (moor VMS-LDF-1, Millwey, UK) and thermal perception (ISO 10551) were assessed at baseline, every 4 min during the intervention (except skin temperature) and every 4 min post-cooling up to 20 min follow-up time.

RESULTS: Skin temperature significantly decreased from baseline to post-cooling (–12.4±5.63°C, $p<.001$) and remained lower than baseline until the 20 min follow-up time (all: $p<.001$). Skin perfusion showed an overall significant decrease when compared to baseline ($p=0.038$). Perfusion was decreased by 19.9±23.7% immediately post-cooling and by 22.1±26.4% at the end of the 20 min follow-up time. Wearing cooling trousers induced a significant perception of cold ($p<.001$) compared to baseline values.

CONCLUSION: The present study shows that the cooling trousers from Icebein™ elicit i) significant skin cooling on the legs, reduce skin perfusion and ii) induce a significant perception of cold. These preliminary results demonstrate the physiological effects of this novel cooling strategy for potential performance recovery usage. Future studies should aim to directly compare the effects of cooling trousers and CWI with a larger sample size.

IDENTIFICATION OF SPATIAL COGNITION FOR MULTIPLE SOUNDS IN BLIND FOOTBALL PLAYERS USING A VIRTUAL ACOUSTIC SYSTEM

TANAKA, S., AIHARA, S., TAKAZAWA, S., TORIYA, S., LIU, C., IWATA, H.

WASEDA UNIVERCITY

INTRODUCTION: Although spatial cognition based on auditory information, or sound source localization ability, is important in blind football, there is no simple, and quantitative method for evaluating it. Therefore, this study aimed to develop a virtual acoustic system for identifying the unique sound source localization ability of blind football players.

METHODS: A. Development of the system

Using stereophonic technology, we developed a virtual acoustic system that can generate three types of sound sources at arbitrary locations in a virtual space: the sound of the ball, the players vocalizations, and the sound of the guide hitting the goalposts, and simulate the sound on a blind football pitch simply by putting on headphones. Comparing the system and real space shows that the spatial resolution of the sound sources that the system can reproduce is approximately 0.42 m.

B. Evaluation of sound source localization ability

The subjects were six clear-sighted, inexperienced players and six visually impaired blind football players. First, as a single task, a stationary sound source (ball sound) was generated in a virtual space, and the subjects responded verbally to the sound source location (azimuth and distance) when they heard the sound. Twenty-four positions were generated, with each being generated 5 times, i.e., 120 times in total. Because various audio information was heard simultaneously during the competition, the ability to simultaneously grasp the positions of multiple sound sources was evaluated. Then, as a double task, two types of sound sources were generated at two points in the virtual space. Next, as a triple task, three types of sound sources were generated, and the above procedure was repeated. Considering the systems spatial resolution, the minimum distance between the generated sounds was approximately 1 m.

RESULTS: In the single-task test, the mean percentage of correct responses was 67.4% (SD 9.25) for experienced players and 57.9% (SD 17.2) for inexperienced players, indicating that experienced players had a significantly higher percentage of correct responses. In the double- and triple-task tests, the percentage of correct responses for all sound sources was significantly higher for the experienced players.

CONCLUSION: The correct response rate for inexperienced players significantly decreased as the number of tasks increased, whereas experienced players showed no significant difference between single and double tasks. Therefore, sound source localization ability for multiple sound sources is considered important in blind football.

As an application of this research, it is possible to iteratively train sound source localization ability by focusing on the type of sound source, distance, and direction that each user has difficulty with. In the future, we plan to develop a training system and verify its effectiveness.

COMPARING THE EFFICIENCY OF DIFFERENT KAYAKING PADDLE LEAVES.

ESPOSITO, G., SCHMID, M., GUERRA, B.M.V., BRONZINI, D., RAMAT, S.
UNIVERSITY OF PAVIA

INTRODUCTION: Flatwater kayaking performance was revolutionized following the introduction of the "wing" paddle in 1986, which was significantly more efficient than the traditional "drag" one. Since then, many sports equipment manufacturers have proposed several new designs based on the "wing" paddle leaf concept, in an attempt to further improve performances. Yet, to our knowledge, no quantitative comparison of the efficiency of such new designs was carried out so far. Here we set out to experimentally compare two popular new paddle shapes and determine whether the different designs do have an effect on performance.

METHODS: We used two Kayak Power Meters and a GPS smartwatch to record 8 college-level athletes each performing four 200m runs with each one of the two tested leaf models, at a predefined, sub-maximal stroke rate while focusing on the correct stroke technique and on maximizing the exerted power. The collected data were analyzed both in terms of individual strokes and as overall means, focusing on stroke power trace morphology, peak stroke power, and time-averaged stroke power. The two latter parameters were individually normalized on each participant's performance and then compared through statistical analysis.

RESULTS: The morphological analysis of the power exerted during individual strokes showed that the main characteristics of right and left strokes are independent of the paddle blade as they are preserved across each subject's runs. On the other hand, more subtle parameters of the stroke morphology as its initial slope and the time of peak power relative to the stroke duration are influenced by the shape of the leaf and were higher and occurred sooner, respectively, with one model compared to the other.

Also the value of the normalized mean peak stroke power and that of the normalized mean time average power of each stroke were found to be higher with one paddle design compared to the other.

Finally, the comparison of completion times taking into account the direction of the trial with respect to the weak current flow was also in favor of a statistically significant difference related to the paddle leaf used.

CONCLUSION: Here we set out to perform a comparison of the biomechanical efficiency of two different paddle blade designs, and we devised an experimental study on a group of college-level athletes to answer such question. Although the differences in power delivery and boat speed were subtle, an accurate data analysis and statistical comparison highlighted a consistently better performance obtained with one model over the other, in spite of the several confounding factors involved. Future developments will attempt to further reduce such factors and their influence to simplify and promote quantitative analyses of performances.

REDUCING HEAD INJURY IN WRESTLING: A BIOMECHANICAL AND IMPACT TESTING STUDY USING POLYUREA-COATED FOAMS AS WRESTLING MATS

TOMIN, M.1, KMETTY, Á.1,2, MOLNÁR, SZ.3, MANÓ, S.4, CSERNÁTONY, Z.4
1 BUDAPEST UNIVERSITY OF TECHNOLOGY AND ECONOMICS, 2 ELKH–BME RESEARCH GROUP FOR COMPOSITE SCIENCE AND TECHNOLOGY, 3 MEDICAL CENTRE HUNGARIAN DEFENSE FORCES, 4 UNIVERSITY OF DEBRECEN

INTRODUCTION: Wrestling is a sport that involves various moves, including throws and takedowns, which can cause the athletes to hit the mat with significant force. The impact of such falls can lead to various injuries, with head injuries being the most dangerous due to their potential negative consequences, including Chronic Traumatic Encephalopathy (CTE) or Second Impact Syndrome (SIS). These injuries may have severe, long-lasting effects on the athletes health, including permanent neurological damage and impaired cognitive functions. Therefore, developing wrestling mats that can reduce the risk of these injuries is crucial for ensuring the safety and well-being of athletes.

METHODS: Three Hungarian male wrestlers were involved in a biomechanical study to determine the typical loads on wrestling mats. A BTS Smart DX400 system with six infrared cameras and two regular video cameras was used to analyze the motion of the athletes during the seven most typical wrestling movements. The maximum velocity of the head was determined from the collected data, which was then used as input data in the subsequent impact testing. An impactor equivalent to an average human head (Triax Touch E-Missile) was used to investigate the shock-absorbing capacity of a traditional (30 kg/m3 density, 50 mm thick cross-linked polyethylene foam) and a polyurea-coated wrestling mat. Head Injury Criterion (HIC) was calculated, and the probability of different severity head injuries was determined.

RESULTS: The comparison of different wrestling movements showed that executing the forward bridge technique had the highest possible head impact velocity with 5.94 m/s. The impact tests conducted from a 180 cm drop height indicated a greater injury-preventing effect for the polyurea-coated mat, with a significant reduction in Head Injury Criterion to 793±1 compared to 1347±39 for the traditional foam. The probability of severe head injuries (associated symptoms: skull fracture, loss of consciousness, and neurological damage) decreased from 42.1% to 8.6% with the polyurea-coated mat. Compared to the traditional mat, the polyurea-coated mat also had a lower probability of minor (96.6 vs. 99.9%), moderate (74.7 vs. 97.9%), serious (33.3 vs. 81.3%), critical (0.9 vs. 10.1%), and fatal (0.0 vs. 0.8%) injuries.

CONCLUSION: The use of polyurea-coated foam structures as wrestling mats significantly reduces head injury probability, making the sport safer for its athletes. The coating provides four times higher protection against severe injuries with neurological damage, decreasing potential long-term negative effects such as CTE. Moreover, the longer lifetime of the polyurea-coated mats suggests their implementation may be economically viable in the long term. However, further studies are necessary to evaluate the practicality of this technology in competitions.

A PROPOSAL FOR A HIGHLY EFFICIENT RECEIVING PRACTICE METHOD IN VOLLEYBALL USING VIRTUAL REALITY ENVIRONMENTS: ESTIMATION OF LOW-RETURN RATE SPIKE COURSES BY DEEP LEARNING BASED ON RECEIVER POSE

TAKAZAWA, S., TANAKA, S., TORIYA, S., AIHARA, S., IWATA, H.

WASEDA UNIVERSITY

INTRODUCTION: Among the many volleyball skill types, improvement of spike-receiving skills have been considered critical [1]. Therefore, we have developed a volleyball spike receive-training system using 3D-VR [2]. Although focusing practice on courses that have appeared difficult to receive individually was effective, thereby enhancing receiving skills, it remained hard to judge the course's position because it changed with time, depending on the receiver's posture. Hence, this study used the previously proposed VR training system to develop a deep-learning model that would be able to predict challengingly receiving courses based on the receiver's time-varying posture.

METHODS: A. Dataset creation

The player wears a HMD and stands at the center of the court within the VR space. Spikes were continuously hit from the net's center of the opponents court at regular time intervals. Then, a male subject (age 24) performed 538 spike receives within the VR. We recorded the spike course, the receivers time-varying posture information before receiving, and the success or failure of the receive for each trial. For the posture information, we attached trackers at seven points (waist, left thigh, right thigh, left ankle, right ankle, arm and ball contact point, and head) to obtain the 3D coordinates and three-directional rotation angles for each point.

B. Development of the deep learning model

Subsequently, we developed a model that could predict whether a receiver will be able to receive a spike based on their posture information up to the moment the spike is hit. Remarkably, the model should make it possible to instantly determine low-return rate spike courses according to the receivers current posture. We constructed the model using LSTM since it is superior to others in extracting features from time-series data.

RESULTS: Applying our model to the test dataset, we obtained an accuracy of 69 %. It is important for this study to predict low-return rate spike courses precisely and the precision that the model predicted a receiver would fail and that the receiver actually failed was 79%.

CONCLUSION: Although this study developed a model using deep learning that could predict low-return rate spike courses with high precision (79%), we only investigated one subject. Therefore, future studies must increase the sample size to consider individual differences. For future prospects, this model should be integrated into the VR system, which can hit a specific course as many times as needed to enable repetitive practice by hitting only low-return rate spike courses determined by the model. It would greatly contribute to the improvement of receiving skills in real space.

AN INNOVATIVE COMPLEX SPORTS LIGHTING SYSTEM AND THE RELATED OPTIONS FOR THE ENHANCEMENT OF SPORTS PERFORMANCE

VÁRHELYI, T.1, BOROS, Z.2, LACZA, ZS.2, AMBRUS, M.2

GET LTD, HUNGARIAN UNIVERSITY OF SPORTS SCIENCE, BUDAPEST, HUNGARY

INTRODUCTION: The significance of the impact of light on human activity and performance has been well known for a long time. Nowadays new LED light sources and the state of the art computerised control options can be utilised for the enhancement of sports performance. Said developments result in a complex sports lighting system. This integrated and innovative product simultaneously responds to the current pandemic-related challenges and makes use of the latest lighting technology and control features while providing an optimal environment for even the indoor activities of athletes.

METHODS: The theoretical foundations of the project were established via secondary research and analysis performed by the Hungarian University of Sports Science. The experimental development effort and the construction of the prototype took place within the framework of an innovation support project at the GET Ltd. The given effort resulted in the elaboration of the experimental lighting of the sports hall at the University of Sports Science hosting the respective performance assessments as well. Twelve basketball players performed 100 free throws and 100 three-point shot in low (cc. 600 lux, lack of 483 nm) and strong (over 800 lux, rich in 483nm as the midday natural light) light. The statistical analysis was done by R (version 4.2.2) statistical program.

RESULTS: The theoretical findings resulted in the development of a unique prototype facilitating the realization of the respective goals. The prototype included individually controlled LED lights and an UV-C fluorescent tube.

The regulation of colour temperature implies the ability of LED lights to provide lighting with a wavelength similar to that of the midday sunlight. Such light capable of influencing the melatonin system of the human body can increase the activity of athletes as well.

Our study introduces the forms and results of the initial comparative assessments performed in three point shot and free throw in basketball. Regarding the three point shot, there was a singnificant association between the two types of illumination $x2(1)=7.1$; $p=0.008$. However, there was no singnificant association between the two types of illumination $x2(1)=3.62$; $p=0.057$ during the free throw.

CONCLUSION: By now, the lighting technology industry has reached a level of development facilitating the construction of a complex indoor lighting system capable of improving sports performance along with protecting the health of athletes via the elimination of viruses and other pathogens. Said progress can revolutionize indoor lighting and provide quantifiable and assessable assistance to athletes in achieving better performance. The results are truly encouraging and regarding the initial assessment results we could highlight that the players performed significantly better at the strong, blue light session during the three point shot.

THE PLAY HABITS OF CHILDREN DURING THE EARLY YEARS – EXPLORING ETHNIC DIFFERENCES IN THE BORN IN BRADFORD COHORT STUDY.

LINDSAY, R., BINGHAM, D., COSTA, S.

ANGLIA RUSKIN UNIVERSITY AND LOUGHBOROUGH UNIVERSITY

Background: Play is an integral component of the physical activity (PA) children engage in during the early years (0-4 years). PA levels differ between White British and South Asian populations during childhood and adulthood. However, there is contradictory evidence regarding different types of activity behaviours (e.g., PA and screen time) during the early years, and ethnic differences in play during the early years have not yet been investigated.

Methods: Questionnaires were administered to children's parents/carers when their child was 24 and 36 months. Differences in time spent in different play behaviours, the frequency of play behaviours, who children played with, and the use of indoor play facilities and parks/playgrounds, were analysed.

Results: The final sample included 311 White British and 509 Pakistani children. Pakistani children engaged in active play and outdoor play less frequently and for lower durations than White British children. Boys from both ethnic groups engaged in active play more often and for longer than girls. There were also significant variations between ethnic groups in who children frequently played with. There were no significant interactions with mother's education on any of the outcome variables.

Conclusion: Findings suggest interventions to increase active and outdoor play may need to be tailored to account for ethnic differences in play habits.

RESEARCH ON THE RELATIONSHIP BETWEEN PHYSICAL ACTIVITY CONSCIOUSNESS AND INTENTION: A SURVEY OF CHINESE COLLEGE STUDENTS

WANG, Y., ZHAO, Y., FUJISHIMA, R., YAMAHIRA, Y., SAITO, K.

HIROSHIMA UNIVERSITY

Background

Physical inactivity and fitness decline have been significant issues among college students, becoming a major concern in most nations. Specifically, in China, which now has the worlds largest higher education system, more than 60% of college students feel inadequate in physical activities (PA). The issues root was indicated as they have a low rate of PA consciousness and implementation. PA consciousness promotes an understanding of perception and attitude towards PA including sports. The stronger an individuals consciousness, the more active one is in PA. Additionally, behavioural intention demonstrates that people tend to act in favour of a specific item; so, PA intention must link awareness to implementation. However, despite numerous inquiry studies aimed at elucidating the consciousness position of college students, previous studies indicated that empirical research on the relationship between PA consciousness and intention in China is insufficient. Thus, this study aimed to discuss the relationship between PA consciousness and intention among Chinese college students after identifying their PA consciousness.

Method

Four universities from the north, south, east, and west of China participated in a questionnaire survey. 508 valid questionnaires were gathered. The sports awareness scale developed by Tokunaga et al. (1984) served as the foundation for the questionnaires content. The questionnaire also includes two items about PA intention based on Qu et al. (2012). By using Data SPSS 28.0, factor analysis correlation coefficients, cluster analysis, Chi-squared test and one-factor analysis of variance were performed to analyse the data.

Results and Discussion

Three factors: Positive Perception, Negative Attitudes and Peripheral Expectations, were extracted in Chinese college students consciousness. PA intention showed a high positive correlation ($r = .779$, $p < .001$) with Positive Perception; a low significant negative correlation ($r = -.285$, $p < .001$) with Negative Attitude; a high positive correlation ($r = .640$, $p < .001$) with Peripheral Expectations. Three factors showed significant group differences. Four clusters were discovered, which means four consciousness styles were categorised according to the characteristics of each cluster through multiple comparisons. In addition, the four types of PA consciousness scored differently for PA intention, and significant between-group differences in scores were identified. This demonstrated the significant connection between PA consciousness and intention.

This study concludes that improving students' PA consciousness based on their traits increases their intention efficiently, which may successfully encourage college students in China to participate in PA and sports. This study will also help address the problem of physical inactivity among college students on a global scale.

PHYSICAL EDUCATION TEACHERS AND THEIR STATUS: WHY ARE THEY NOT SEEN AS PROFESSIONALS?

SEBELIUS, S.

MALMÖ UNIVERSITY

Introduction

Physical education (PE) teachers express that their professional status is lower than that of teachers in theoretical subjects. Studies shows that it might be because the subject is not a core subject and of the uncertainty about the subjects goals (James, 2011). Nonetheless, there is a lack of knowledge about PE teachers' status which both can be negative for the reputation of the subject and the recruitment of new PE teachers. Using concepts of social closure when analyzing historical texts about PE teachers and physical education teacher education (PETE), the aim of the study is to contribute with new knowledge about how claims have been produced and reproduced over time and maintained an animated debate about PE teachers' lack of status.

Method

An analysis of ten historical texts about PE teachers and PETE was done, to identify how PE teachers negotiate about their occupation and how that negotiation results in the use of certain social closures. The texts are written by PE teachers (n=5) and government officials (n=5). They range from the beginning of the 19th century to present day and describe partly the PETE and PE teachers of that time and partly make suggestions on how to make changes in PETE to acquire higher status for PE and PE teachers. The analysis is made in two steps: first using thematic analysis to identify relevant themes and then distinguish how the concept of social closure is used. Social closure is divided into two types, exclusionary and usurpationary closure, and is derived from theories of profession (Parkin, 1979).

Result

The study shows that PE teachers try to create a higher status profession for themselves by using exclusionary closure on nearby occupations. They also use usurpationary closure on higher standing professions, partly through the monopolization of education and professional titles, and partly by trying to imitate the education systems of other professions.

Discussion

By using the concept of social closure we can identify PE teachers attempts to create a high status occupation, which might lead to benefits as a higher salary and a better reputation. An example is the ambition to create an expert education with a specialist degree through which they can gain a monopoly over PE teaching positions in schools. However, they still have difficulties distinguishing their occupation from other closely related occupations and can therefore not create a sufficiently exclusionary closure in relation to competing occupations. This can be seen in PE´s strong relation with sports, which results in difficulties for PE teachers making exclusionary closure against sport coaches. They also use usurpationary closures when they imitate educational systems of professions that are considered having higher status.

TEACHERS' PERCEPTIONS ON PHYSICAL EDUCATION IN ITALIAN SCHOOL: A MIXED METHODS APPROACH

MAULINI, C., FEDERICI, E., DANNA, C.

UNIVERSITY OF NAPLES - PARTHENOPE

After a long legislative process, the educational offer of physical and sports education in Italian primary schools will be able to make use of the specialized physical education teacher as of this school year (Low n. 234/2021). With the aim of understanding the state of the art of the quality of physical education teaching (UNESCO, 2015), highlighting training needs and perceived strengths and weaknesses, an exploratory survey was conducted with a mixed methods approach.

Through the administration of a specially constructed semi-structured questionnaire, a sample of 691 participants in the support teacher course took part in the research, 59% of whom are currently employed teachers.

Some of the results show that PE is for 69% of the sample an extremely (69%) and for 30% a very important vehicle for promoting biopsychosocial well-being and an active lifestyle. The discipline is considered to be extremely (56%) and very (41%) important for promoting the development of life skills and for 56% and 41% respectively extremely and very important for promoting the acquisition of life skills; for 68% and 30% extremely and very important for promoting healthy lifestyles. Whereas for only 34% PE is an extremely important tool for promoting learning and memorizing other subject content (51% very and 14% moderately important). The same applies to the acquisition/development of key competences for lifelong learning where only 36% consider it extremely important and 49% and 14% very and moderately important respectively.

With regard to the possibility of improving the quality of teaching, 69% and 28% respectively consider it extremely and very important to have adequate spaces and facilities; 45% and 47% of the sample consider economic resources to be allocated to extracurricular projects to be extremely and very important; finally, 59% and 31% indicated the presence of a teacher with a degree in motor sciences as extremely and very important. In addition to the quantitative analysis of the data, the contents of the open answers in the questionnaire were analyzed starting from two general theoretical categories generated by the questions themselves, namely: Critical points and Strong points of inclusive teaching in PE in schools.

The didactic and organizational scenario of PE in primary schools needs a change that can enhance corporeity in its multiple expressions as a personal right and a cognitive learning tool. It is necessary to take note of the balance that emerged from the survey, which highlights the need for a review of the curriculum and a strong investment in terms of organization, structure and human resources.

ASSESSMENT TOOLS IN PHYSICAL AND SPORTS EDUCATION IN SCHOOL CONTEXT: AN OVERVIEW.

FORTE, P., PUGLIESE, E., ALI, L., D'ANNA, C.

UNIVERSITY OF CAMERINO - PEGASO UNIVERSITY

Introduction: During the developmental age the acquisition of skills is a priority objective in all learning contexts. The student will be competent when he will be able to use knowledge, skills, attitudes, emotions to effectively face the situations that everyday reality proposes to him in relation to his potential and attitudes. In motor-sports contexts this affirmation is declined in the ability to use ones personal, social and methodological resources in the expressive, sports, well-being and leisure fields. In the design of learning environments aimed at the development of competences it is essential to consider the following dimensions of competence: cognitive, operational-motor, social, metacognitive. The aim of this paper is to identify the different assessment tools available in the literature that are able to detect the different dimensions of competence and the complex relationships between them that manifest themselves in the context of physical and sports education.

Methods: We reviewed the assessment tools that have been used to measure motricity, cognition and emotion in young people/youth aged between 6 and 18 years old. We identified assessment tools more functional in the educational field. In order to identify them we used the keywords "motor/cognitive/emotional/social-dimension" "children" "scales" "questionnaire" "school" "assessment tools" "competence" in scientific platforms like Google scholar, PubMed, ResearchGate, Scopus, Web of science.

Results: The scientific literature analysis has identified assessment tools for motor development cognitive, emotional and psychosocial development. We selected tools that are more suitable for use in the school environment to provide an overview summarising the specific evaluation domains of the most appropriate tools for understanding the specific assessment.

Discussion: The evaluation of competence in the field of motor sports in the school context is very complex. The study shows strong interconnections between the different dimensions of competence (1), highlighting the need to use different evaluation tools that, integrating with each other, can give us the information and feedback useful to act effectively in the design of educational interventions.

COMMERCIAL RUNNING APPS: HOW MUCH DO THEY SUPPORT USERS' PSYCHOLOGICAL NEEDS?

GOMES FERNANDES, G., MARTIN, J.C., SANCHEZ, X.

UNIVERSITÉ PARIS-SACLAY; UNIVERSITÉ DORLÉANS

Physical inactivity and sedentary lifestyles are major health-related risk factors. Running is quite relevant when studying the design and implementation of interventions aiming at increasing PA levels, as it is a very popular activity. A growing strategy to promote PA is to design interventions using "motivational technology."

Several commercial apps are specifically designed for running, but it remains unclear how much they rely on motivational theories and support users' needs. The purpose of the present study was twofold; firstly, to identify relevant apps available to the running community and secondly, to gain knowledge on how much they support three fundamental psychological needs: autonomy, competence, and relatedness (Self-Determination Theory; SDT [1]).

We extensively reviewed the top 8-ranked commercial running apps' features for 2022, using "best/most used/top-ranked running apps" as keywords in search engines. We included those with a clear running goal (e.g.: activity tracking, proposing training programs) and that systematically appeared in different ranks of most used apps. We compared eight running apps, and analysed five other applications and web services with interesting features, even if they were not con-

sidered the most used apps. To examine how these apps supported the above-mentioned psychological needs, we considered the following: Competence – applications offered articles on running to increase users' knowledge and tips to improve performance; Autonomy – freedom in the choice of functions, training programs, location, or time of the sessions; Relatedness – offered some interaction between users.

Findings showed that none of the apps explicitly considered any psychological need in their design. However, we can rate these apps according to SDT dimensions. All the apps satisfied autonomy to some extent. Six out of eight also included features allowing for competence satisfaction. Relatedness was present in every app but in different forms; some had an interface mimicking social networks, whereas others merely let the users share photos. Personalisation is another critical option to guarantee program adherence–only one of the eight apps produced personalized motivational messages.

To conclude, findings suggest that researchers may use existing commercial running apps when designing interventions. However, further research is warranted to fully understand what aspects are critical when using motivational technology to encourage long-term adherence and establish a common framework valid for different runners' profiles—ranging from health to performance.

BARRIERS AND FACILITATORS TO PHYSICAL ACTIVITY FOR YOUNG ADULT WOMEN: A QUALITATIVE SYNTHESIS

PENG, B., NG, Y.Y.J., HA, S.A.

THE CHINESE UNIVERSITY OF HONG KONG

Introduction: Physical activity (PA) promotion for women of all ages is needed, especially for young adult women, who have remained at a lower level of PA than men for the past two decades and have not been extensively studied than other age groups. Moreover, young adult women generally face a sharp decline in PA from transition into adulthood, possibly due to societal and cultural impact. Thus, the current review aimed to synthesize the qualitative studies of young adult womens self-perceived barriers and facilitators to PA and provide some contextual implications for future research.

Methods: The review followed the PRISMA guideline. Medline, Pubmed, Scopus, SPORTDiscus, and Web of Science were searched to identify qualitative studies published between January 2000 and February 2022. Studies examined the barriers and facilitators of healthy young adult women's PA between ages 18 and 40 were included. Research quality was appraised using the Critical Appraisal Skills Programme tool. Data were extracted and thematically analyzed based on the social-ecological model (SEM) tenets.

Results: Twenty-three studies were included, and four themes with sub-themes were identified: 1. Body image, health, and beauty (body dissatisfaction & health, weight stigma & social embarrassment, body image & beauty standards); 2. Multiple roles, social support, and PA (multiple roles & patriarchal family, motherhood & children's needs); 3. Religious identity, cultural identity, and PA (Muslim identity and PA, embodied cultures); 4. Safety issues and women's fears.

Discussion: The results showed that barriers and facilitators of young adult women's PA were intertwined and integrated between SEMs intrapersonal, interpersonal, organizational, community, and environmental levels. At the intrapersonal level, PA was closely linked to health and women's body. Two discourses predominated and were seen as facilitators: the health discourse, which served as the primary justification for PA engagement; the beauty discourse, which was closely related to womens bodies and self-improvement. Beyond the individual level, young womens narratives tended to emphasize more on barriers at the interpersonal, organizational, and community levels. Young womens multiple social roles mostly drove these barriers within and across organizations after they entered adulthood, namely mother, employee, and self. In addition, gender norms and expectations were deeply ingrained in womens identities and shaped their lives, which extend to PA. Overall, young womens PA is a multilevel experience and multifaceted decision largely influenced by social relationships, cultural norms, and the societal environment. Future studies targeting the social-cultural level rather than merely individual behavior change could pave the way for successful interventions in this population. Additionally, qualitative research is critical and indispensable for comprehending the context and effects of implementations.

DUAL–TASK TRAINING EFFECTS ON THE COGNITIVE-MOTOR INTERFERENCE IN INDIVIDUALS WITH INTELLECTUAL DISABILITY

REBAI, H., BORJI, R., HAMMAMI, R., KASMI, S., GABBOUJ, M., FENDRY, T., LAATAR, R., SAHLI, S.

NATIONAL CENTER OF MEDECINE AND SPORT SCIENCES CNMSS

INTRODUCTION: Individuals with intellectual disability (ID) present both cognitive (Spaniol, & Danielsson, 2022) and postural balance (Enkelaar et al., 2012) impairments. Recent studies showed that they are more prone to cognitive-motor interference during dual task (DT) condition when performing postural and cognitive tasks simultaneously compared to those with typical development (Van Biesen et al., 2018; Kachouri et al., 2020). The cognitive-motor interference (CMI) refers to a decline in the performance of a motor or/and cognitive task when executed concurrently relative to when each task is performed separately (Woollacott & Shumway-Cook 2002). Since it has been documented that DT training could reduce the CMI (Tait et al., 2017), it is particularly relevant to explore the effect of such training program in individuals with ID. This study explored the effect of DT compared to single task (ST) training program on the CMI in adolescents with ID.

METHODS: training group (DTTG) performed the same physical exercises with the STTG but simultaneously associated with cognitive tasks whereas the control group (CG) was not involved in any intervention. Motor and cognitive DT costs (DTC) were calculated as DTC=[(DT-ST)÷ST]×100 and then analyzed.

RESULTS: Before training, both CoPVm and cognitive performance were significantly higher in the DT condition compared to DT one in all groups. After training CoPVm values were significantly higher in the DT condition compared to the ST one only in the STTG and the CG. CoPVm values decreased significantly in both trained groups during DT and ST conditions. The cognitive performance increased only in the DTTG. After training the motor DTC was lower compared to before training only in the DTTG whereas no change was observed in the STTG or the CG. The cognitive DTC did not vary after training in any group.

CONCLUSION: Both ST and DT training programs improved postural balance whereas only the DT training enhanced cognitive performance and reduced the effect of CMI on postural balance during DT condition in these individuals.

CP-SH11 Physical activity promotion for children and youth

THE EFFECT OF COVID-19 ON PHYSICAL FITNESS PERFORMANCE AMONG UNIVERSITY STUDENTS

LIN, M.S., WU, Y.T., WU, H.F.
SOOCHOW UNIVERSITY

Introduction: In recent years, physical education in school has been decreasing year by year, and the trend is deteriorating. Studies have found that physical exercise showed beneficial for individuals mental and physical health. (Gust & Bryan, 2021). In 2019, the new coronavirus (COVID-19) started spreading in many countries around the world. According to UNESCO, nearly 90% of students around the world have been out of school due to the new Corona Virus and have been affected by the suspension of classes and are unable to attend school. Moreover, most classrooms have been moved online, and implemented distant learning using online classes.

Method: A total of 64659 students were recruited to participate in the study which they were enrolled in the physical education program from 2017 to 2020. This study assessed the cardiorespiratory endurance, muscular power, muscular endurance, flexibility, and body composition. The physical fitness assessment for these items was assessed using the standardized assessment method developed by the Department of Physical Education, Ministry of Education in Taiwan (MOE, 2015) This study was conducted to investigate the impact of the new coronavirus epidemic on physical fitness performance before and after the epidemic from year 2017 to 2020.

Result: From the study 30,088 males and 34,571 females, the result showed that physical fitness during 2017 -2018 prior to the epidemic had a pass rate of (80.8%, and 79.7%) However, during the COVID-19 epidemic there was a significant impact leading to 77.4% in 2019 and 71.5% in 2020.

Discussion: Exercise was significantly reduced during the COVID-19 epidemic, both in terms of frequency and duration of exercise. Similar results have been found in studies from other countries, with reduced exercise frequency occurring not only in young adults, but also in children, adolescents, middle-aged adults, and older adults (Qi et al., 2020). This study found significant decline for all assessment from 2017 to 2020, this is all due to the suspension of the opening of sports fields, students can only do home exercises and unassisted fitness activities (such as gymnastics, yoga, dance, martial arts, etc.) The epidemic prevention measures and social distance will affect human life, behavior patterns and psychological states, thus facing new challenges in body, mind and spirit. Schools are encouraged to organize more physical activity and health activities in the post-epidemic era, and to encourage students to exercise more and change their lifestyle habits to increase physical activity. The best way to prevent the epidemic is to maintain good physical fitness and to develop regular exercise habits.

DEVELOPMENT OF A MODEL FOR AFTER-SCHOOL EXERCISE PROGRAM IN ELEMENTARY SCHOOLS IN JAPAN, ITS EFFECTIVENESS AND CHALLENGES

KOKUDO, S.
CHUKYO UNIVERSITY

Objectives

There is a need to make effective use of public facilities such as schools to ensure that children have time for exercise. The purposes of this study are to provide a model of an after-school exercise program for elementary school students, to build and implement the system, to design a system to support the instructors from outside of the school, and to examine its effectiveness and issues.

Methods

An after-school exercise program was designed and implemented for a public elementary school (714 students and 25 teachers) from October 2021 to January 2022in Kobe City. Nineteen different exercise programs were created 5 days a week from Monday to Friday: 5 review-type programs of physical education, 9 physical manipulation-type programs and 5 game-type programs. Thirteen external exercise instructors provided guidance and 167 children, 512 in total, participat-

ed in the program. A private-tutoring school management website was applied for child registration, attendance management, and communication with parents. A questionnaire survey was administered to the children and their parents at the beginning and at the end of the program.

Results and Discussion

The overall attendance rate for the program was 83.1%, with the highest rate of 91.6% for mat exercise for grades 1 and 2, and the lowest rate of 73.6% for basketball. By week, the highest attendance was 93.0% in the first week and the lowest was 73.8% in the twelfth week.

Among children, satisfaction with the exercise program was more than 70% positive. For 5th-6th grade girls, 35.7% of the responses were positive and 28.6% of the responses were negative. The desire to continue the program was high among 3rd-4th grade boys (85.3%) and girls (69.6%), and among 5th-6th grade boys (72.0%) and girls (35.7%). 93.5% of the parents/guardians wanted the exercise program to continue.

The following issues were identified in implementing the exercise program.

1) School facilities are not available when there are club activities that are regular school classes for 5th and 6th graders. 2) School events that did not appear on the plan often took place, and programs had to be canceled on short notice. In order to solve these problems, it is necessary to share information closely in advance. 3) The gymnasium could not be used for long periods (about a month) due to other annual school events. The annual plan to use the gymnasium should be reviewed for events other than athletic purposes during long periods. 4) If the system is independent from the school, the school infirmary cannot be used when a child is injured. In fact, children were confused by the unavailability of the school nurses room. 5) A management system dedicated to after-school exercise programs needs to be developed. 6) Although instructors from universities and private clubs could be utilized in this model, the actual recruitment and securing of instructors is an issue.

ASSOCIATION OF PARTICIPATION ON SPORTS VIDEO GAMES AND REAL-LIFE SPORTS INVOLVEMENT OF UNIVERSITY STUDENTS

WAI KEUNG, H.

CHINESE UNIVERSITY OF HONG KONG

28th Annual ECSS Congress Paris, July 4-7 2023

Association of participation on sports video games and real-life sports involvement of university students

Ho, W.K., Sum, K.W., Tang, D.

Chinese University of Hong Kong

INTRODUCTION: Playing video games is one of the most popular entertainments in adolescents. Particularly, sports video games are the main genres which stimulate the real sports training and competition. Most of the past research related to video games has focused on its sedentary nature, it often has been characterized as a predictor of physical inactive and obesity [1]. However, recent research demonstrated that playing sports video game predicted higher involvement in real-life sports clubs over time among adolescents [2]. Sports video games may be used as a tool to create and enhance peoples' interest in sports [3]. The aim of this study is to examine the association of sports video games playing and involvement in real-life sports among university students. We will further investigate the link between involvement in sports team and sports video game play.

METHODS: Participants were 1625 undergraduate students (F = 58.6%). An online questionnaire about the video game playing habit and exercise habit was distributed to the participants (M = 18.72 years, SD = 1.71).

RESULTS: Within students who played video games, for those participated in sports video games (M=2.13, SD=1.10) had an average daily exercise time 1.13 hour more than those did not participate in sport video games (M=1.01, SD=1.20), 95% CI [.94, 1.32], t(266.83)=12.31, p<.001. The Cohen's d = .97 indicated a large effect. The odds ratio of sports team members who participated in sports video game is 3.38 times, 95% CI [2.28, 5.08], compared with that of non-sports team.

CONCLUSION: The findings revealed that there is a strong association between participation on sports video games and involvement in real-life sports. There is a higher probability that a sports team member would also participate in sports video games.

SOCIO-STRUCTURAL DETERMINANTS OF PHYSICAL ACTIVITY BEHAVIOR IN CHILDREN AND ADOLESCENTS: THE RELEVANCE OF SOCIAL SUPPORT

WOLBRING, L., JEKAUC, D., BURCHARTZ, A., KOLB, S., SCHMIDT, S.C.E., WOLL, A., WÄSCHE, H.
KARLSRUHE INSTITUTE OF TECHNOLOGY

INTRODUCTION: The purpose of this study is to look in more detail at the socio-structural determinants of physical activity behavior in children and adolescents. We expected that socioeconomic status, social support, and physical environment influence physical activity directly while socioeconomic status also has an indirect influence via social support and physical environment. In addition, we hypothesized that social support shows an indirect effect through the perceived physical environment.

METHODS: Cross-sectional data from the German Motorik-Modul study (MoMo) were used (Wave 2, 2014-2017). The sample consisted of N = 2525 children and adolescents aged 6-17 years. Socioeconomic status (parental education, occupational status, and net income), perceived social support, and perceived physical environment were measured by questionnaires. To measure physical activity, children and adolescents were instructed to wear ActiGraphGT3X+/wGT3X-BT accelerometers for seven consecutive days. Path analysis was used to analyze the direct and indirect effects separately for children (6-10 years) and adolescents (11-17 years).

RESULTS: Goodness-of-fit statistics showed satisfactory model fit for both models (children and adolescents). The analysis revealed similar effects for both age groups. Among the socio-structural determinants, only social support had a direct effect on physical activity behavior. Socioeconomic status did not have a direct but an indirect effect on physical activity via social support. Furthermore, social support showed a direct effect on the perceived physical environment. Physical environment had no significant influence on physical activity in both models. Overall, the analysis revealed rather small to moderate effects.

CONCLUSIONS: The results of this study emphasize the relevance of social inequalities and social capital, as a source social support, for health-related behavior such as physical activity in young age groups. Interventions to increase children and adolescent physical activity levels should thus focus on components of social support from family and peers.

GAIT ANALYSIS USING POSE ESTIMATION - BASIC RESEARCH FOR DEVELOPMENT OF INTERACTIVE HEALTH PROMOTION SYSTEM-

INOUE, Y., KOBAYASHI, T., YASUTOME, S.
OSAKA INSTITUTE OF TECHNOLOGY

Introduction

We are considering using digital signage to interactively display feedback on gait with the aim of promoting exercise. In this study, we investigate what kind of gait analysis is possible to make using a webcam to show instant feedback. In previous studies, it has been reported that differences in gait with age tend to appear in stride length and walking speed, but stride length does not seem to be appropriate for instant computational feedback. In this study, we set three gait pitch conditions and examine whether changes in gait can be analyzed instantaneously using pose estimation, and what kind of differences they make.

Methods

Fifteen university students participated in the experiment. They walked for 10 steps, and the fourth and fifth steps were captured from the side by a webcam. Three walking pitch conditions were set: 70-bpm (elderly people), 130-bpm (20 or 30–year-olds), and free walking. They were instructed to adjust their walking pitch to the metronome sound on the 70-bpm and 130-bpm conditions.

Body positions were estimated using MediaPipe. From the estimated skeleton, we calculated the minimum values of the hip joint angle and knee joint angle during the gait cycle, the ankle joint angle when the toes left the floor, the stride length, and the maximum distance at which the toes were lifted off the floor.

Results

The knee and hip joint angles were the smallest on the 130-bpm condition, followed by the free walking condition. Both conditions showed significant differences from 70-bpm ($P<0.01$). The ankle joint angle was larger on the 130-bpm and free walking conditions ($P<0.01$). Stride length decreased in the order of 130-bpm, free walking, and 70-bpm, with significant differences between 130-bpm and 70-bpm, and between free walking and 70-bpm. Significant correlations were found between stride length, knee joint angle and hip joint angle ($P<0.01$).

Discussion

The significant correlations suggested that a faster gait pitch results in a wider stride length because the toes kick the floor with greater force, which in turn results in smaller knee and hip joint angles. Previous studies have reported that stride length varies with age but estimating stride length with a single webcam is computationally demanding and not suitable for providing interactive gait feedback on digital signage since the calculation of stride length requires taking into account the depth and tilt of the image. In contrast, joint angles do not need to take into account such factors as distance from the webcam, so the load of computation is relatively small and joint angles are estimated to play a significant part in age estimation. In the future, these results help to develop a better system capable of providing interactive gait feedback.

TRAINING INTENSITY DISTRIBUTION CONSIDERING SPORTS SPECIFICITY, QUANTIFICATION METHODS AND TIME OF SEASON IN ELITE TO WORLD CLASS ENDURANCE ATHLETES – ANALYSIS OF CURRENT SCIENTIFIC LITERATURE

MATZKA, M., SPERLICH, B.

JULIUS-MAXIMILIANS UNIVERSITY WUERZBURG

INTRODUCTION: The current review examined the literature about retrospective analyses of training intensity distribution (TID) in elite to world class endurance athletes by clustering the different sport disciplines, quantification methods (QM) and time of season.

METHODS: TID data was obtained from PubMed, using varying combinations of the search terms "training intensity distribution", "TID", "training intensity", "endurance training", "training characteristics, "endurance," "training" and "athletes". Inclusion criteria: peer-reviewed English articles of endurance athletes categorized as Elite Level (Tier 4) or World Class (Tier 5) with internal (e.g., heart rate [HR]), external (e.g., velocity, power) and/or subjective (e.g., rating of perceived exertion [RPE]) QMs. All different QMs were categorized. The TID data expressed in percentages or in absolute numbers was included.

RESULTS: 33 reports quantified the TID of 425 athletes (67 females) from different endurance sports. 162 different TIDs could be extracted from all studies and clustered according to the sport, different seasonal phases, and different QMs. The TIDs derived from cycling (9 studies), rowing (n=7), running (n=6) skiing (n=6), swimming (n=2), hand cycling, triathlon and ice speed skating (each n=1). 69 (42%) TIDs were based on single-case reports of which 44 TIDs stemmed from cross-country skiing. 45 TIDs reported an entire season, n=7 mean values for multiple seasons, n=65 preparatory periods and n=54 competition periods. TIDs were categorized in 9 different QMs: HR time-in-zone (HR-TiZ), HR session goal – number of sessions (SGSession), HR session goal – total time/session (SGTime), HR session goal/time-in-zone (HR-TiZ/SG), session RPE (sRPE), RPE time-in-zone (RPE-TiZ), velocity time-in-zone (V-TiZ), power time-in-zone (PO-TiZ), race pace time-in-zone (RP-TiZ). 7 studies directly compared different QMs in their reports. 66 TIDs (41%) showed a polarized TID with 34 (52%) of these reported by single case analysis in cross-country skiing. 72 TIDs (44%) showed a pyramidal TID. Analysis of the most comparable TID QMs (HR-TiZ,V-TiZ, PO-TiZ) show proportion ranges for the moderate (Z1), high (Z2) and severe (Z3) intensity domain of 20-96%, 0-70% and 0-19%, respectively. Independent of the QM and time of season 91% (n = 147) of all analysis report Z1 proportions ≥65%, whereas 70% of all analyses report Z2 and Z3 proportions < 10%.

CONCLUSION: Current evidence on TID in Tier 4 and 5 athletes is equivocal and influenced from a high number of single case reports. The QM influences the TID pattern which must be recognized in the TID debate in endurance sports. The number of reports considering pyramidal and polarized TIDs are approximately equal. The most comparable QMs using the TiZ-approach highlight high variation in proportion ranges in the different intensity zones. Most noticeable, high volume of low intensity training zones (≥ 65%) is applied across all sports, seasonal phases, and quantification methods.

POSITION-SPECIFIC EXTERNAL WORKLOAD OF PROFESSIONAL RUGBY UNION PLAYERS DURING TACTICAL PERIODIZATION TRAINING

HU, X.P., BOISBLUCHE, S., REN, X.Y., PHILIPPE, K., MAURELLI, O., LI, S.C., XU, B., PRIOUX, J.

EAST CHINA NORMAL UNIVERSITY; RENNES 2 UNIVERSITY; ÉCOLE NORMALE SUPÉRIEURE DE RENNES; RUGBY CLUB VANNES; UNIVERSITY OF PAU AND PAYS DE L'ADOUR; UNIVERSITY OF MONTPELLIER.

INTRODUCTION: Tactical periodization (TP) is a training strategy that emphasizes the tactical aspect of the game. It originated in soccer and is quickly gaining traction in other team sports, particularly rugby union (RU) [1]. RU differs in external workload (EWL) response during training and matches depending on player position [2]. A greater understanding of the external workload of TP for different positions within three acquisition days (strength, StD; endurance, EnD; and speed SpD) would support coaches in planning loads for specific positional groups. Therefore, the purpose of this study was to shed light on the effect of TP acquisition days on different positions of RU players and apply the knowledge gained to the training environment.

METHODS: Twenty-six professional RU players (27.0 ± 3.5 years; 185.6 ± 7.1 cm; 101.7 ± 15.7 kg) were recruited from the French second-division rugby club by playing position: forwards (n = 15) and backs (n = 11). EWL was measured using a global positioning system and accelerometer microtechnology throughout 10 weeks of in-season home games. The following global positioning system (GPS) metrics were studied: arbitrary units of PlayerLoadTM (AU; extracted from all triaxial accelerometers in each unit); PlayerLoadslow (AU; extracted from all triaxial accelerometers when speed was below 2 m/s) ; total distance (TD) covered; distance covered in different intensity zones: > 15 km/h (D15), > 21 km/h (D21), and > 25 km/h (D25); the number of repeated high-intensity efforts (RHIE); and the number of low (> 2 m/s2; [A-D]2) and medium (> 2.5 m/s2; [A-D]2.5) speed accelerations/decelerations. A total of 780 observations were analysed, and differences between positions were assessed using Cohen's d effect size (ES) and magnitude-based inferences.

RESULTS: There were different EWL profiles for each position under each acquisition day. Mean PlayerLoadTM, TD, D15, D21, D25, RHIE, [A-D]2, and [A-D]2.5 were significantly higher ($p \leq 0.01$; ES = 0.41 to 1.93) for backs compared with forwards for all acquisition days. However, forwards experienced greater PlayerLoadslow than backs on EnD (152.59 ± 27.39

vs. 133.10 ± 28.03 AU; $p < 0.001$; ES = 0.70). Furthermore, the difference between positions in PlayerLoadslow was unclear on StD and SpD ($p = 0.23$ and 0.22, respectively).

CONCLUSION: PlayerLoadTM combined with PlayerLoadslow demonstrated acceptable reliability for EWL and provided different information between positions. Validating EWL characteristics on TP acquisition days enables extensive analysis of training load data, which can then be utilised to discover the unique characteristics of each position and design position-specific acquisition days to improve performance.

EFFECTS OF AN 8-WEEK OF BRIEF MINDFULNESS MEDITATION COMBINED WITH A RUNNING PROGRAM ON THE PERFORMANCE AND HEALTH OF TRAINED RUNNERS.

BARBRY, A.

UNIV. LILLE, UNIV. ARTOIS, UNIV. LITTORAL CÔTE DOPALE, ULR 7369 - UREPSSS - UNI

INTRODUCTION: The impact of Mindfulness Meditation (MM) during Physical Activity (PA) have been well documented.1 However, these studies2,3 have often focused on the response of MM when the intensity of PA was low. Interventions addressing the influence of MM when PA intensities are typically experienced by athletes in sports club are lacking in the literature.1 The main goal of this study was to evaluate the influences of brief MM in trained runners on Intermittent Maximum Speed (IMS), Ratings of Perceived Exertion (RPE), Heart Rate Variability (HRV), Fat Mass (FM) and Physical Fitness (PF) level.

METHODS: Fifty-four trained athletes were randomized in a control group or a brief MM group following the same running training program including high intensities. They performed at 3 times: baseline (T0), 4 (T4) and 8 weeks (T8) after baseline IMS test (i.e., 45"- 15" of Gacon).4 The RPE scale of Borg (RPE6-20) was documented at each stage of the IMS test. As an indicator of HRV, the Root Mean Square of Successive R-R interval Differences (RMSSD) was measured using the Polar® V800 (Polar® Electro OY; Kempele, Finland) during 5 minutes in a supine position before the IMS test. The FM using the Biody Xpert® (Aminostats Bio-ZM II, Aminogram, La Ciotat, France) and PF level with the Diagnoform® Actif (IRFO, Loos, France) were measured at T0 and T8. A 2-way repeated measures ANalysis Of VAriance (ANOVA) was conducted for each outcome. A Bonferroni post-hoc test was realized when significant differences were noted.

RESULTS: A decrease of IMS was reported for the control group between T0 and T8 ($p = 0.004$) whereas a stagnation was observed for the brief MM group ($p = 0.056$). The speed reached at RPE13, RPE15 and RPE17 decreased with time ($p \leq 0.05$). No statistical differences were detected for RMSSD ($p = 0.681$). FM and PF level increased between T0 and T8 ($p \leq 0.01$).

CONCLUSION: Brief MM combined with a running program does not seem to have an impact on RPE, HRV, FM and PF level in trained runners. According to speed performance, the decrease observed for the control group on IMS could be partly explained by the high training load at this time of year for athletes. The stagnation of IMS for the brief MM group might be illustrated by the development of psychological skills (e.g., awareness of one's sensations, acceptance and refocusing) allowing the athletes to regulate their speed during the training according to his own sensations. More studies with a larger sample size need to be conducted to confirm our

results.

ACKNOWLEDGEMENT: The authors are grateful to Alycia BACHA, Marie BOCHUN, Raymond BARBRY and Amandine DAUBRESSE.

LIFESTYLE AS A MODULATOR OF THE EFFECTS ON FITNESS OF AN INTEGRATED NEUROMUSCULAR TRAINING IN PRIMARY EDUCATION: A RANDOMIZED CONTROLLED TRIAL

PRATS-PUIG, A., ROMAN-VIÑAS, B., VASILEVA, F., LÓPEZ-ROS, V., FONT-LLADÓ, R.

EUSES UNIVERSITY OF GIRONA

INTRODUCTION: Being fit as a child increases the likelihood of being active as an adult and reduces the risk of having several cardiovascular risk factors. The objective of this study was to evaluate changes on fitness after an integrated neuromuscular training (INT) intervention designed to improve motor competence in primary school children and to evaluate how lifestyle behaviours and parental education modulate those changes.

METHODS: One hundred and seventy children (7.45±0.34 years; 52% girls) were included in this randomized controlled trial. Cardiorespiratory fitness (½ mile run test), 10 × 5 m shuttle run test, standing broad jump (SBJ), handgrip dynamometer, body mass index (BMI) and fat mass percentage (FM%) were assessed before and after the 3 months intervention (20 minutes of INT in the physical education class, twice per week). Mediterranean Diet (MD), sleep time and parental education level (PEL) were evaluated by questionnaires and adherence to physical activity (PA) recommendations was measured with an accelerometer before the intervention.

RESULTS: After the intervention, there were improvements in the 10x5 test and the SBJ. Only girls had improvements in the handgrip test, BMI SDS and FM%. After correcting for confounding variables only BMI was significantly improved whereas strength improved in the participants non-compliant with the PA recommendations or pertaining to families of high PEL.

CONCLUSION: The INT produced improvements in fitness in a brief period and in different subgroups of pupils (inactive and with diverse sociocultural environments).

ATTEMPTING TO THRIVE DURING THE OLYMPIC QUALIFICATION WINDOW: A NARRATIVE ANALYSIS

BROWN, D.J., WAGSTAFF, C.R.D.

UNIVERSITY OF PORTSMOUTH

Background. The desire to succeed at the highest levels of sport has resulted in vast investment and, with it, greater scrutiny and accountability for performance. Consequently, this 'need' to succeed has fostered a 'win-at-all-costs' mentality and led to some environments that prioritize results and performance at the expense of athlete welfare. Although the existence of such 'performance-narratives' may be prominent in elite sport, there is growing recognition that such narratives need not be at the cost of welfare, and that more should be done to create and maintain environments that promote both high performance and athlete well-being.

Purpose. Our purpose for the present study was to better understand track cyclists' experiences of attempting to thrive (i.e., experience high levels of performance and well-being concurrently) during the Tokyo Olympic qualification window. In so doing, we hoped to shed light on the prevailing narratives underpinning their accounts, and to reflect the dynamism and complexity in experience inherent with competing for high-performance sporting organizations.

Methods. Underpinned by ontological relativism and epistemological constructionism, a longitudinal design was employed with interviews conducted with eleven international track cyclists on three occasions over a six-month period. At the time of the first interview, the cyclists had competed in 126 major sporting events (e.g., World Championships, Olympic Games) and won 36 medals at these events. We adopted a storyanalyst stance and used thematic narrative analysis to understand the narrative themes that underpinned the cyclists' stories as they attempted to thrive during the Olympic qualification window.

Results and Discussion. Our results comprise four realist tales that reflect narratives of family dynamics, labor of love, discovery, and redemption that we believe were embodied in the cyclists' experiences during this time. These tales are the first representation of athletes' attempts to thrive during a critical part of their Olympic journey and offer a unique insight into how these experiences evolved over time. Moreover, they highlight the complexity, variety, and dynamism in athlete experience, and provide direction to allow us to proactively support people (e.g., by developing adaptability and acceptance, and ensuring a sense of safety) and systems (e.g., to raise organizational awareness of how and when friction may occur) to thrive sustainably at the highest level of sport.

Funding. This research was supported by a grant from the International Olympic Committee's Olympic Studies Centre.

USING NETWORK SCIENCE TO IDENTIFY THE PROMINENT COURT ZONE OF TENNIS LONG RALLY

ZHOU, Y., CUI, Y., CAO, R.

BEIJING SPORT UNIVERSITY

INTRODUCTION: In the process of the tennis match, the interaction between two competing players involves the decision-making of stroke, positioning and ball direction and rotation. To unveil the playing pattern within such interaction and to interpret player performance, a recent study has applied network science to the analysis of rallying in other racquet sports such as badminton. However, little has been done in tennis given it contains more constraints like ball location and wider court space. Therefore, this study aimed to construct a tennis stroke network that considers the consecutive ball placement during long rallies and to identify the prominent court zone within the network.

METHODS: The study randomly selected 15 rallies that ended with nine and more strokes from 12 mens singles main-draw matches of the 2019 Australian Open, which contains 163 strokes, excluding the serve and return strokes. All included players are right-handed. The tennis stroke network is a paradigmatic example of a bipartite network, where nodes are grouped into two disjoint sets, with nodes of the same set devoid of a direct link between them. The size of nodes was proportional to their importance in the network, with the links' width proportional to the number of times a specific path was repeated. Therefore, a 40*40 adjacency matrix was established, with 20 zones on each player's side of the court. Finally, the centrality of each node (after transforming the corresponding nodes on both sides of the court into the same half) and frequency of all the network edges were calculated in order to evaluate zone importance and ball direction.

RESULTS: Zone_7 (Zone_34) has the greatest degree centrality of 2.3, representing the most frequent zone where players made the strokes. It is followed by Zone_8 (Zone_33), Zone_11 (Zone_30) and Zone_5 (Zone_36), with values of 1.85, 1.75 and 1.65, respectively. Considering the zones of the baseline, the highest degree centrality is shown at Zone_4 (Zone_37) with a value of 1.2, where players used more backhand strokes. Considering the network edges, Zone_31 (Zone_10) and Zone_5 (Zone_36) are most frequently connected for forehand strokes, while Zone_7 (Zone_34) and Zone_33 (Zone_8) are most frequently connected for backhand.

CONCLUSION: The current study provides preliminary knowledge about tennis long rally performance considering the evolution of the shot information. The findings reveal that hitting the ball to the backhand side of the opponents is the most frequent tactical choice during the long rally, given that there are more related zones of high centrality degree. Nonethe-

less, the edge between forehand Zone_31 (Zone_10) and Zone_5 (Zone_36) is also highly connected, probably indicating a preferred ball direction to end the point. The results explored the stroke patterns of professional tennis and the most favorable zone for players. Future researchers and analysts could adopt the method to analyze tactics and specific striking styles of individual players.

DIFFERENCES BETWEEN TIME-MOTION CHARACTERISTICS AND SERVING VELOCITY IN WINNING AND LOSING MATCHES OF ELITE MALE TENNIS PLAYERS – A PILOT STUDY

TÓTH, P.J.1,2, HORVÁTH, D.1,2, DOBOS, K.1, GYORI, T.1,2, NÉGYESI, J.1,2, ÖKRÖS, CS.1

1 HUNGARIAN UNIVERSITY OF SPORTS SCIENCE, BUDAPEST, HUNGARY; 2 FIT4RACE, BUDAPEST, HUNGARY

INTRODUCTION: Tennis is a game characterized by physical activities such as running at different speeds, accelerations, decelerations, changes of direction, slides and different strokes [1]. Therefore, mechanical loads (e.g., accelerations and decelerations) are more relevant to the dimensions of the court than the locomotive loads (eg. total distance, running at different speeds). Besides time-motion characteristics, it is useful to measure serving velocity (SV) because it is one of the most important performance determinants in both gender's tennis in the junior age [2], and serves are the most repeated strokes in the game that directly influences the outcome of points [3]. The aim of this study was to examine differences in time-motion characteristics, including mechanical load and SV, between winning and losing match conditions of elite male tennis players.

METHODS: Four elite male tennis players (one of them ATP world-ranked) played simulated matches on an indoor clay court in a round robin system, resulting in a total of six matches. To determine the time-motion characteristics, mechanical load-related parameters were measured using portable micro-sensors (Catapult OptimEye S5, Catapult Sports, Melbourne, Australia) which sampled at a frequency of 10 Hz for the GPS and 100 Hz for the tri-axial accelerometer, gyroscope and magnetometer. Regarding the SV, the peak velocity of the first- and second serves was measured with a radar gun (Pocket Radar Ball Coach, model PR1000-BC, Pocket Radar Inc., Santa Rosa, CA). Descriptive statistics were used to present mean and standard deviation results, and Mann-Whitney U test was used to determine the differences between winning and losing match conditions. Significance level was set at $p<0.05$.

RESULTS: Only one significant difference between the two conditions was found for the mechanical load in the high deceleration/minute parameter ($U=5$, $Z=-2.08$, $p=0.037$, $r=-0.60$). Regarding the SV, we found significant difference in favor of winning matches for both the first ($U=1$, $Z=-2.72$, $p=0.006$, $r=-0.79$) and second serve ($U=2$, $Z=-2.56$, $p=0.010$, $r=-0.74$). Apart from these, there was no significant difference for the other variables.

CONCLUSION: Overall, the results suggest that the velocity of the first and second serves is an important factor in the success of tennis matches. With a high SV, players can hit more aces and win points more efficiently. Therefore, serving speed training is important because SV seems to be a fundamental predictor of match results.

CP-MH18 Obesity/Weight loss II

THE EFFECT OF UNIVERSITY PHYSICAL EDUCATION CLASSES ON BODY COMPOSITION

BARKA, N.1,2, NAGY, V.3

1 BUDAPEST BUSINESS SCHOOL, 2 EÖTVÖS LORÁND UNIVERSITY, 3 GITLAB INC

INTRODUCTION: Up to 5 million deaths a year could be prevented if the world population were more active. Inactive people have a 20-30% higher risk of dying than sufficiently active people (1). Weight problems and obesity are increasing rapidly with age in most EU Member States (2). The causes can be traced back to lifestyle, including physical inactivity. Schools are important places to promote physical activity, as students spend much of their lives in schools. They, therefore, play an essential role in promoting healthy lifestyles (3).

METHODS: 340 people enrolled in the 14-week programme, of whom 100 (61 women, 39 men) participated in the before and after programme surveys. 187 only at the beginning of the semester and 53 only at the end of the semester. Body composition and waist and hip circumferences were measured before and after the intervention. The survey aimed to determine whether and how the students values changed due to physical education at university.

RESULTS: The results are for the 100 people surveyed twice. The average age was 19.62 years. After the 14-week program, we observed significant changes in Total Body Water ($p=0.003$, $d=0.344$), Protein ($p=0.00008$, $d=0.127$), Minerals ($p=0.0007$, $d=0.05$), Skeletal Muscle Mass ($P=0.0007$ $d=0.328$), InBody Score ($p=0.03$, $d=0.52$), Waist-Hip Ratio ($p=0.002$, $d=0.006$). The BMI index showed a significant but negligible change ($p=0{,}00001$, $d=0{,}243$).

CONCLUSION: The programme effectively improved various body composition values, contributing to a healthy lifestyle. To better understand the relevance of the results another study with a control group is recommended.

THE EFFICACY OF THE WEIGHT LOSS PROGRAM ON GUT MICROBIOTA AND METABOLIC HEALTH IN PATIENTS WITH OBESITY

KUBÁNOVÁ, L.1,2, PENESOVÁ, A.2, HRIC, I.2,3, TKACIKOVÁ, M.1, BARANOVICOVÁ, E.4, BIELIK, V.

1 FACULTY OF PHYSICAL EDUCATION AND SPORT, 2 BIOMEDICAL CENTER SLOVAK ACADEMY OF SCIENCES, 3 FACULTY OF NATURAL SCIENCES, 4 BIOMEDICAL CENTER MARTIN

INTRODUCTION: Obesity has spread from Western countries to third-world countries and has become a global pandemic. Weight loss programs containing regular physical activity and lower calorie intake became an effective non-pharmacological approach to treat and prevent metabolic diseases in patients with obesity. In addition to body composition (body fat, BMI), cardiovascular variables (blood pressure), and common blood characteristics (glycemia, cholesterol), the results from the last decade point to changes in gut microbiota composition in individuals with obesity. Therefore, the purpose of this study was to investigate whether the 3-month weight loss program can affect gut microbiota composition and metabolic health in patients with obesity.

METHODS: We conducted a randomized controlled trial in 23 patients with obesity. From the group of recruited patients, 12 participants completed a 3-month combined nutrition-physical exercise program 2-times a week (EP), and 11 participants were controls. The fecal microbiota was classified using specific primers targeting the V3–V4 region of 16S rDNA, whereas biochemical parameters were analyzed in a certified hospital laboratory.

RESULTS: As expected, we observed a significant decrease in serum concentration of glucose, uric acid, and liver enzymes (AST, ALT, GMT) in EP compared to controls. However, we detected a significant increase in relative abundance of beneficial bacteria (e.g., Akkermansia muciniphila, Parabacteroides merdae, Alistipes finegoldii) and a significant decrease in pathogenic bacteria (e.g., Erysipelatoclostridium ramosum, Clostridium spiroforme). Notably, a significant inverse correlation was recorded between A. muciniphila and body weight, body fat, BMI, waist and hip circumference, visceral fat, uric acid, and creatinine. However, a significant positive association was found between pathogenic E. ramosum and body weight, body fat, BMI, waist and hip circumference.

CONCLUSION: The main findings of our study were a positive shift in body composition, gut microbiota, and serum metabolomics after a 3-month weight loss program in patients with obesity. We believe that even a short 12-week non-pharmacological treatment is effective to stimulate changes in bacteria linked to health or illness.

IMPACT OF SUPERVISED EXERCISE ON HEART RATE VARIABILITY, BLOOD PRESSURE, AND ARTERIAL STIFFNESS FOLLOWING BARIATRIC SURGERY: EFIBAR STUDY

MARTÍNEZ-ROSALES, E., HERNÁNDEZ-MARTÍNEZ, A., LÓPEZ-SÁNCHEZ, L., TORRENTE-SÁNCHEZ, M.J., FERRER-MÁRQUEZ, M., SORIANO-MALDONADO, A., ARTERO, E.G.

SPORT RESEARCH GROUP , CERNEP RESEARCH CENTER, UNIVERSITY OF ALMERÍA, SPAIN

INTRODUCTION: Obesity is associated with type 2 diabetes, dyslipidemia, and cardiovascular disease (CVD), among others [1]. Bariatric surgery has been proposed as an effective method to reduce weight. This study aimed to determine the impact of a 16-week concurrent exercise program on heart rate variability (HRV), blood pressure, and arterial stiffness in participants undergoing bariatric surgery [2].

METHODS: 80 individuals with severe obesity (body mass index ≥35 kg/m2) were randomized to an exercise group (n=40) or a control group (n=40) following bariatric surgery. At baseline (before the surgery), week 16 and 12 months, heart rate variability was measured using a heart rate monitor (Polar V800) with the participant seated for 10 minutes. Blood pressure and arterial stiffness parameters (i.e., Augmented index at 75% of heart rate) were assessed using an oscillometer-based pulse wave analysis system (Mobil-O-Graph). The exercise program consisted of 48 sessions (three times per week over 16 weeks) of 60-min sessions that include (1) warmup [light aerobic activity at 50–65% of HR reserve (HRR)], (2) compensatory training (i.e., core stability and stabilizer muscle exercises), (3) strength training (whole-body exercises progressing from 1 to 3 sets, from 12 to 6 repetitions per set, from 24 to 10 repetitions maximum (RM) (≈50 to 75% of 1RM), (4) aerobic training (on a treadmill, progressing from 15 to 25 min, from 65 to 85% of HRR), and (5) cool down.

RESULTS: Although both groups improved HRV following bariatric surgery, there were no between-group differences in any HRV-derived parameters. The mean changes (95% Confidence Interval [CI]) in systolic blood pressure from baseline to 16 weeks were -14.1 (-18.8 to -9.4) in the exercise group and -7.9 (-12.6 to -3.3) in the control group (between-group difference -6.7 mmHg, 95%CI [-12.8 to -0.4], $p < 0.05$) although this difference disappeared at 12 months. In contrast, the mean change (95% CI) in Aix75 from baseline to 12 months were 0.3 (-6.8 to 7.5) in the exercise group and -9.1 (-14.6 to -2.4) in the control group (between-group difference 9.4 %, 95%CI [2.3 to 16.5], $p = 0.011$).

CONCLUSION: In this randomized controlled trial involving participants with severe obesity who undertook a 16-week concurrent exercise intervention immediately after bariatric surgery, exercise did not significantly improve HRV-derived parameters compared to a control group following usual care after surgery. However, we found that the exercise group

decreased their systolic blood pressure at 16 weeks more than the control group and that the control group had their Aix75 increased at 12 months. Further research using different exercise configurations is needed.

RELATIONSHIP BETWEEN GUT MICROBIOTA COMMUNITY AND SHORT-CHAIN FATTY ACID PRODUCTION IN TLR5 KNOCK-OUT MICE AFTER VOLUNTARY EXERCISE

HIROMI, Y., WATANABE, H., HAMADA, H., KAWASHIMA, H., AOKI, T., KREMENIK, M.J., OYANAGI, E.

KAWASAKI UNIVERSITY OF MEDICAL WELFARE

INTRODUCTION: Immunometabolism is that the impact of immune cells on metabolism and, conversely, the metabolic needs of immune cells during homeostasis and pathological settings. In recent years, it has been known that the gut microbiota may be a factor in the induction of immunometabolism. Exercise is well known as an improvement factor for metabolism such as obesity, but it is not clear whether the exercise habit itself has a preventive effect on obesity through changes in the intestinal microbiota. In this study, we aimed to investigate the preventive effect of voluntary exercise on obesity in Tlr5 gene knockout mice via the gut microbiota.

METHODS: Tlr5 gene-deficient (Tlr5-/-: KO5, n=15) and wild-type (Wild Type: WT, n=16) mice (C57BL/6J, 4 weeks old) were used in this experiment, and mice were lorded to voluntary wheel running (W: individually housed in a cage with a rotating wheel with 24-hour access), or rest (C) for 20 weeks. Fasting blood glucose levels and tissue weights were measured. Collected fresh feces were used for analysis of microbiota, and organic acid analysis was performed using cecum contents. This study was conducted with the approval of the Recombinant DNA Experimental Committee (19-44) and the Animal Experimentation Committee of Kawasaki Medical School (21-103).

RESULTS: A significant increase in body weight due to gene deletion ($p<0.01$) and its suppression by exercise ($p<0.01$) were observed. Also, a high epididymal fat weight in KO5 mice ($p= 0.05$) was inhibited by exercise ($p<0.01$). Moreover, high level of fasting blood glucose in KO5 mice was improved by voluntary exercise ($p=0.057$, $p<0.01$). The α-diversity of the gut microbiota was observed to be significantly higher in Tlr5 gene deficiency. β-diversity was classified into two populations, differing between KO5 and WT. Mucispirium showed a positive correlation with propionic acid and succinic acid, while Parasutera showed a positive correlation with propionic acid. Furthermore, we observed a positive correlation between Anaeroplasma and succinic acid.

CONCLUSION: The increased weight gain and fat accumulation induced in KO5 mice, as well as impaired glucose metabolism, may be prevented by voluntary exercise. The involvement of the gut microbiota in the prevention of obesity and abnormal glucose and lipid metabolism by exercise was demonstrated. Our results suggest that changes in the gut microbiota via exercise may have preventive effects against abnormal immunometabolism.

EFFECT OF DIFFERENT EXERCISE MODES ON FAT LOSS IN RECESSIVE FEMALE UNIVERSITY STUDENTS

ZHANG, P.

BEIJING SPORT UNIVERSITY

INTRODUCTION: In recent years, the physical fitness of university students has been declining, and the recessive obesity has become one of the most easily ignored health problems, among which recessive obesity in female university students is the more prominent. High-intensity interval training is one of the popular exercise and fitness methods in recent years, but there are few empirical studies on recessive obesity in female university students. This paper probes into the effect of different modes of exercise training with equal amount on weight loss in female university students with recessive obesity, and to provide a reference for the formulation of exercise prescription.

METHODS: Forty-five university students (21.6±2.1yrs) with recessive obesity were recruited and participated in the study that was approved by IRB at Beijing Sport University. They were randomly divided into three groups, a moderate-intensity continuous training(MIT) group, a high-intensity interval training(HIT) group and a blank control(COL) group. The MIT and HIT groups completed exercise on the cycle ergometer. The HIT group performed an interval cycling session consisting of 4×4 min bouts (4 min of cycling at 85%-95%HRmax followed by 3 min of cycling at 50%-60%HRmax). The MIT group did equal amount of cycling with HIT group at 60%-75%HRmax. The exercise intervention last eight weeks. Body composition was determined before and after the exercise intervention to explore the effect of different modes of exercise training on recessive obesity in female university students.

RESULTS: (1) After eight-week intervention, participants in the MIT group and HIT group had significant reductions in the body weight (1.50kg, 1.52kg) and body mass index(BMI) compared with COL group ($P<0.01$). There was no significant difference in changes of body weight and BMI between the MIT group and HIT group. (2) The MIT group and HIT group demonstrated significantly decreased level of waist-to-hip ratio(WHR) compared with COL group (-2.4% & -3.6% vs +1.2%, $P<0.01$) after eight-week intervention, and the decrease of WHR in the HIT group was significantly greater than that in the MIT group ($P<0.05$). (3) After eight-week intervention, compared with the COL group, participants in the MIT and HIT groups had significant declines in percentage of body fat(PBF) and body fat content, and the decline of PBF (2.7% vs 3.6%) and body fat content (5.7% vs 6.6%) in the HIT group was significantly greater than that in the MIT group ($P<0.05$). (4) There was no significant change in skeletal muscle mass in the MIT, HIT and COL groups. There was also no significant change in body weight, BMI, WHR, PBF and body fat content in the COL group.

CONCLUSION: Both high-intensity interval training and moderate-intensity continuous training could reduce fat of female university students with recessive obesity, which were beneficial to prevent obesity and related diseases in early life. It was suggested that high-intensity interval training may be advantageous in reducing the accumulation of abdominal visceral fat in female university students with recessive obesity when compared to moderate-intensity continuous training.

INVOLVEMENT OF EXTRACELLULAR VESICLES IN EXERCISE-RELATED INFLAMMATION REDUCTION IN LEAN AND OBESE SEDENTARY ADULTS

WARNIER, G., VAN DOORSLAER, S., LANNOY, C., ANTOINE, N., COPINE, S., FRANCAUX, M., DELDICQUE, L.

UCLOUVAIN

INTRODUCTION: Obesity prevalence has dramatically increased in the last 50 years worldwide. This abnormal fat accumulation has serious consequences as it increases the risk to develop cardiovascular diseases, diabetes, musculoskeletal disorders or some cancers. In addition, obesity is characterized by a low-grade systemic inflammation related to multiple health issues. To reduce this systemic inflammation, endurance exercise appears to be an effective method, but the underlying mechanisms are not fully understood. Recently, growing interest has emerged around the extracellular vesicles (EVs) and their role in inter-organ cross talk and exercise adaptations. By transporting exercise factors ("exerkines"), EVs could participate in the inflammation reduction observed after a training period. Here, we investigated if inflammation reduction in obese people could be related to acute and chronic change in EVs content.

METHODS: Thirteen lean (CTRL) and ten obese (OB) sedentary adults (30–55 years old) were recruited to participate to a 3-month endurance program (30min at 60-80% of VO2peak, 3 sessions/week). Fitness level and body composition were evaluated prior and at the end of the program. Venous blood samples were taken before and after the first endurance session and after the training period. Plasma EVs were isolated by size exclusion chromatography and their content was analyzed by mass spectrometry.

RESULTS: After 12 weeks training, VO2peak increased in the two groups (CTRL: +10%; OB: +17%; p=0.016) whereas body weight and fat mass remained unchanged. Respiratory exchange ratio (RER), reflecting substrate utilization, decreased at submaximal intensities (100, 130 and 160W, p≤0.001) in both groups. Fasting glucose, HOMA-β, QUICKI, HDL and LDL did not change while insulin (-21%, p=0.087) and HOMA-IR (21%, p=0.098) tended to be reduced after the program only in the obese group. Additionally, CRP levels decreased in obese participants (-57%, p=0.045). Preliminary results from EVs content analysis reveal the presence of several proteins involved in inflammation process such as complement C proteins, serum amyloid A proteins, alpha-2-macroglobulin, histidine-rich glycoprotein or CD5 antigen-like protein.

CONCLUSION: The present study shows that a 3-month low intensity endurance training is efficient to attenuate systemic inflammation and insulin resistance in obese sedentary adults. This reduction of inflammation is not statistically related to fat mass loss suggesting that other mechanisms as change in EVs content might be involved.

HIGH-FREQUENCY BIO-IMPEDANCE EQUATION FOR APPENDICULAR SKELETAL MUSCLE MASS IN OLDER PEOPLE

KIM, C., SONG, K., JEON, K., JIANG, F., KIM, H.

SOONCHUNHYANG UNIVERSITY1,2, SALISBURY UNIVERSITY3, HUNAN NORMAL UNIVERSITY4, KOREA NATIONAL UNIVERSITY OF EDUCATION5

INTRODUCTION: Whole-body bioelectrical impedance analysis (BIA) has been accepted as a doubly indirect method to estimate appendicular skeletal muscle mass (ASMM) comparable to dual-energy X-ray absorptiometry (DXA). Single or limited frequencies currently used for these estimates may over or under-estimate ASMM. Accordingly, there is a need to measure the impedance parameter with appendicular muscle-specific across multiple frequencies to more accurately estimate ASMM. Therefore, we aimed to validate the appendicular muscle mess-specific frequency BIA equation for ASMM using multifrequency BIA (MF-BIA) with DXA as the reference.

METHODS: 195 community-dwelling Korean older people (94 men and 101 women) aged 70~92y participated in this study. ASMM was measured by DXA and bioimpedance measures at frequencies of 5kHz~3MHz were assessed for independent predictive variables. Regression analyses were used to find limb-favorable frequencies of bioimpedance, to develop the ASMM equations and to conduct the internal cross-validation. The six published equations and the final equation of MF-BIA were externally cross-validated.

RESULTS: 195 participants completed the measurements of MF-BIA and DXA. Using bivariate regression analysis, the 2MHz impedance index explained R2 = 91.5% of variability (P < 0.001) in ASMM and predictive accuracy of standard error of estimate (SEE) was 1.0822kg ALM (P < 0.001). Multiple stepwise regression analysis obtained in the development group had an adjusted R2 of 9.28% (P < 0.001) and a SEE of 0.97kg ALM. The cross-validation group had no significant difference between the measured ASMM and the predicted ASMM (17.8±3.9kg vs. 17.7±3.8kg, P=.486) with 93.1% of R2 (P < 0.001) and 1.00kg ASMM of total error. The final regression equation was as follows: ASMM = 0.247ZI@2MHz + 1.254SEXM1F0 + 0.067Xc@5kHz + 1.739 with 93% of R2 (P < 0.001), 0.97kg ASMM of SEE (Subjective Rating as "excellent" for men and "very good" for women). In the analysis of the diagnostic level for sarcopenia of the final regression, the overall agreement was 94.9% (k = 0.779, P < 0.001) with 71.4% of sensitivity, 98.8% of specificity, 91.3 of positive prediction value and 95.3% of negative prediction value.

CONCLUSION: The newly developed appendicular muscle mass-specific high-frequency BIA prediction equation has high predictive accuracy, sensitivity, specificity, and agreement for both individual and group measurements. Thus, the high-

frequency BIA prediction equation is suitable not only for epidemiological studies but also for the diagnosis of sarcopenia in clinical settings.

EVALUATION OF THE CHARACTERISTICS OF BEHAVIORAL CHANGE IN THE FACE OF PHYSICAL ACTIVITY IN SCHOOLCHILDREN IN BOGOTÁ, COLOMBIA.

TRIANA-REINA, H.R., MENDOZA-ROMERO, D.
SANTO TOMAS UNIVERSITY

INTRODUCTION: The acquisition of a healthy lifestyle entails a series of behaviors that the person can develop from their first years of life. The school is a scenario where these mechanisms can be evaluated based on different models and theories, such as the Transtheoretical Model developed by Prochaska & DiClemente. The studys objective was to assess the characteristics of behavioral change in the face of physical activity in schoolchildren from educational institutions in Bogotá, Colombia. [2].

METHODS: A cross-sectional analytical study was carried out with 348 students of both sexes between 8- and 17 years old belonging to 5 district educational institutions (IED), in whom the Behavior Change Questionnaire (CCC) was applied in a self-filled manner [1]. Additionally, information on grip strength, blood pressure, and the calculation of the Body Mass Index (BMI) were recorded, and the data were compared according to sex between the groups of children 8 to 13 years old (211; 60.6%) and adolescents 13 to 17 years (137; 39.3%).

RESULTS: Significant differences were found in the categories of behavioral change compared to contemplation physical activity (p=0.003) and maintenance action (p=0.021) between the sexes in the entire sample. In the group of children, these differences were maintained (contemplation, p=0.02; maintenance action, p=0.039), but in adolescents only in the contemplation category (p=0.03), these differences were held between the groups. Sexes. A higher proportion of overweight and obese children and adolescents was found compared to girls and adolescents (24.5% versus 4.3%, p<0.001). In grip strength, men achieved better results, 22.8 kg (S.D.=7.08) compared to 19.73 kg (S.D.=4.18) for women, p<0.001. No significant differences were found in blood pressure measurements between the sexes.

CONCLUSION: Although a higher proportion of overweight and obese boys was found compared to girls, the latter is located in a lower ratio in the category of action and maintenance compared to physical activity. This situation evidences the potential risk of a healthy lifestyle for both sexes in educational institutions in Bogotá, Colombia.

CP-AP05 Monitoring

TELEMEDICAL MONITORING FOR SAFE HOME-BASED EXERCISE TRAINING OF SENIORS

SLOBODOVÁ, L.1,2, ONDICOVÁ, K.3, LEHOCKI, F.4, TIRPÁKOVÁ, V.1
SLOVAK MEDICAL UNIVERSITY; 2> BIOMEDICAL RESEARCH CENTER OF SAS; 3> FACULTY OF MEDICINE, COMENIUS UNIVERSITY; 4> SLOVAK UNIVERSITY OF TECHNOLOGY IN BRATISLAVA;

INTRODUCTION: The number of seniors gradually increases worldwide; by 2030, 1 in 6 people will be 60 years or over. With an increasing number of seniors arises the question of how to help seniors reach healthy ageing and enhance their quality of life. There is plenty of papers on the beneficial effect of regular exercise training on both, quality of life and healthy ageing. However, many seniors refuse to exercise due to fear of the potential deterioration of their health.

METHODS: Our project aims to create safe home-based exercise training supervised by telemedical monitoring. For the purpose of the monitoring, we use telemedical monitoring already in use at the National Institute of Cardiovascular Diseases in Bratislava (Slovakia) for patients with cardiovascular diseases. The telemedical monitoring kit consists of the web and mobile application connected with sensor devices: chest strap with ECG sensors (BioHarness 3, Zephire, USA), oximeter (Nonin 3230, USA) and blood pressure monitor (OMRON M7 Intelli IT, Japan). Data recorded to the mobile application can be checked immediately by the user or delivered to the medical specialist (e.g. cardiologist), who can work with the data on the web page both online or offline.

RESULTS: The first step in our project is to adapt the ECG measurement for the senior exercise training. The ECG measurement is realized during exercise training and the oximetry and blood pressure measurement before and immediately after the exercise. The main goal is to adapt ECG, blood pressure and oximetry measurements for real-time analysis. In case of unexpected heart arrhythmia, fibrillation or an increase/ drop in blood pressure, the application will alert the senior with the recommendation to stop the exercise. It also allows to set up sending this alert information to a doctor or other assigned person to provide medical assistance if necessary.

CONCLUSION: Telemedical monitoring should be attractive for patients with cardiovascular diseases and should also help increase the number of seniors practising home-based training. The continual availability of data related to a health status of senior through the web application is the next benefit. It enables a senior to be under the doctor´s supervision without the need for a personal visit to the health facility.

INDIVIDUALIZED INTERPRETATION OF RAW VALUES IN TRAINING LOAD AND RECOVERY MONITORING - ROBUST SCALING AS A POTENTIAL ALTERNATIVE TO ACWR (AND BEYOND)

HECKSTEDEN, A., MEYER, T.
UNIVERSITÄT INNSBRUCK

INTRODUCTION: Load and recovery monitoring aims to support decision making in daily practice. This regularly calls for an indication of how high or low a current value is for the individual player (rather than in absolute terms). Considering the substantial interindividual variation in the habitual levels of common indicators even within professional and elite teams, standard group-based reference values are therefore inappropriate. Rather, individualized interpretations takeing into account the distribution of previous observations in the same player (what is "normal" for him / her) are warranted. For such "scaled" indicators, a specific value means the same for every player, thereby allowing for a uniform interpretation across individuals which is particularly important for routine use in team sports.

In recent years a variety of approaches has been proposed ranging in sophistication from individual means to Bayesian methods. Regarding training load, the acute-to-chronic workload ratio (ACWR) is a widespread "scaled" indicator, that puts current (acute) load in relation to what the player is used to (chronic load). However, while ratio-based indicators are intuitive, they are associated with severe limitations which have recently been demonstrated specifically for ACWR. We therefore propose robust scaling of acute training load as an alternative to ACWR including a proof-of-concept application to monitoring data from professional soccer. Of note, robust scaling can also be applied to other monitoring parameters e.g. questionnaire results.

METHODS: Robust scaling is a standard method used for engineering informative features in machine learning. In its simplest form (as applied here) it is calculated as the difference of the respective value from the individual median in inter-quartile-range units. Robust scaling was applied to acute training load (sessionRPE method, linearly weighted 3-day trailing average) and subjective recovery needs (short recovery and stress scale, SRSS). Data of 82 outfield players from 4 professional soccer teams collected during the 2019-2020 season were included.

RESULTS: Substantial interindividual variation was present for acute training load (mainly reflecting interindividual variation in RPE rather than time) as well as for daily responses to the SRSS. As intended, after scaling the median was 0 for all individuals and measures. Interindividual variation in the range of scaled values was minor and independent from the median of raw values.

CONCLUSION: Robust scaling may be a simple, well-understood alternative to ACWR which can also be applied to monitoring parameters beyond training load.

INVESTIGATING THE INFLUENCE OF REPRESENTATIVE SCALING IN FOOTBALL PRACTICE GAMES VIA POSITIONAL DATA

DEUKER, A.1, WITTKUGEL, J.1, KLEMP, M.2, JAKOBS, J.1, VOGT, T.1
GERMAN SPORT UNIVERSITY

INTRODUCTION: One major problem in football practice is defining the scaling of the field size when a chosen practice game reduces the number of players unlike the formal 11 vs. 11 game (FG11vs11) [1]. In common practice, the frequency of actions per player increases due to a much smaller area per player in sub-task designs (e.g. 5 vs.5) [2]. Whereas the emergence of individual and collective skills is constrained by the ambient information of the learning environment [3]. Thus, the representative (RP) interpersonal layout given in training remains to be elucidated, particularly on how collective behaviors change when the area per player is reduced in sub-task designs.

METHODS: 22 male football players (age: 23 ± 5 years) of a professional German U21 football team are separated into two teams, competing in five different field conditions: One FG11vs11 and two practice game conditions (RP7vs7, RP5vs5) are played with an area per player that represents an official match scaling (296m²/player). In contrast, two practice game conditions are played with a commonly smaller (S) area per player [2] (S7vs7, 174m²/player; S5vs5, 184m²/player). Each team plays six attacks per condition in a crossover study design (60 attacks total). Players' positional data are computed using a GPS unit (10Hz, Catapult®). The data is processed to calculate the parameters distance-to-nearest-opponent, convex hull, and relative convex hull.

RESULTS: Results from the repeated-measures ANOVA revealed significant differences between the played conditions for distance-to-nearest-opponent, $F(4, 55) = 14.76$, $p < 0.0001$, $\eta2 = 0.52$, convex hull, $F(4, 55) = 275.07$, $p < 0.0001$, $\eta2 = 0.95$, and relative convex hull, $F(4, 55) = 53.41$, $p < 0.0001$, $\eta2 = 0.80$. Tukey's post-hoc pairwise comparisons revealed that merely the RP7vs7 showed a similar distance-to-nearest-opponent as the FG11vs11. Furthermore, the convex hull differed notably between the sub-tasks S5vs5 compared to the RP5vs5 and S7vs7 compared to the RP7vs7.

CONCLUSION: Data show, that the space occupied by both teams and thereby their collective behaviour, is highly influenced by the available space surrounding them. Moreover, smaller field scales as well as fewer players tend to reduce the representativeness of the interpersonal layout in practice tasks. Further investigation of RP field scales might be fertile ground to improve the effectiveness of practice designs.

CONTEXTUAL FACTORS INFLUENCING EXTERNAL AND INTERNAL LOAD IN COLLEGIATE WOMEN'S BASKETBALL

SAVLA, R., SAVE, R., ANDERSEN, J.C.
THE UNIVERSITY OF TAMPA

INTRODUCTION: Basketball is a physically demanding sport that requires repetitive high intensity efforts. Monitoring training load (TL) metrics- external (eTL) and internal (iTL), are vital to maximize performance and minimize the risk of injury/illness (1,2). These TL metrics are known to vary based on contextual factors like player role (starter, reserve), game (G), and training days relative to game (e.g. the day before a game (G-1)) in other sports (1); little investigation has been done in women's basketball. The primary purpose of this study was to examine the influence of player role on eTL and iTL during games among female collegiate basketball athletes. Secondarily, we investigated the relationship between G and G-1 on performance metrics for starters.

METHODS: Sixteen G and 12 G-1 during the 2022-23 season were monitored. Data were collected from 11 players (21.9±1.45 years; 177±9.39 cm) of the university women's basketball team. Player role and minutes played were retrieved from the box score for each G. Player load (PL), PL/min, and heart rate exertion (HRE) were captured using Catapult® S5 IMU sensors (version 2, indoor) with integrated HR devices and OpenField Console version 2.5.2. The data were visualized using Catapult OpenField Cloud 4.7 and exported to excel for data quality analysis resulting in 79 observations from starters and 56 observations from reserves. For our secondary aim, 4 G were excluded due to lack of G-1 data, resulting in 12 G and 12 G-1 sessions for analysis. There were 59 G and 60 G-1 observations. Jamovi 2.3.16 was used to calculate descriptive statistics for each variable. Relative TL metrics for role and days relative to the game were also calculated.

RESULTS: Starters played a mean of 31.8±7.9 mins, while reserves played 12.5± 8.2 mins. For G eTL, mean PL for starters was 474±152 and reserves was 191±117, while PL/min for starters was 7.75±1.2 and reserves was 7.08±1.3. For G iTL the mean HRE was 9665±5076 for starters and 4160±3294 for reserves. In games, reserves accumulated 40.3% of starter PL, 91.4% of starter PL/min and 43% of starter HRE. For our second aim, 12 G and 12 G-1 showed starters had a mean PL 495±149, PL/min 7.74±1.2; mean HRE was 9664±5252 for G and for G-1 PL 404±135, PL/min 4.62±1.3; mean HRE was 6531±1608. In G-1 starters accumulated 81.6% of G PL, 59.9% of G PL/min and 65.5% of G HRE.

CONCLUSION: Our results indicate reserves accumulated less G specific PL and HRE than starters, which is consistent with past literature in football (1). However, reserves PL/min was over 90% of starters suggesting they maintained similar game intensity as the starters. Starters accumulated high G-1 PL relative to G, with a low to moderate PL/min and HRE suggesting G-1 was high volume with low to moderate intensity. These results contrast with the suggestions for tapering TL volume before games (1,2). Further work exploring TL programming and contextual factors in women's basketball is needed.

DEEP NEURAL NETWORK-DRIVEN TIME SERIES ANALYSIS OF POSTERIOR LEGS SURFACE RADIATION DURING CARDIOPULMONARY EXERCISE TESTING AND ASSOCIATIONS WITH CORE TEMPERATURE AND INTERNAL LOAD

HILLEN, B., ZENTGRAF, S., WEBER, V., OCHMANN, D.T., ANDRÉS LÓPEZ, D., NÄGELE, M., SCHÖMER, E., SIMON, P.
INSTITUTE OF SPORTS SCIENCE | JOHANNES GUTENBERG UNIVERSITY MAINZ

INTRODUCTION: Infrared Thermography (IRT) measures the surface radiation of the skin (Tsr [°C]). Specific Tsr variations are proposed to be associated with individual acute thermoregulatory and cardiopulmonary responses to exercise [1]. Recently, deep neural network-driven automatic thermal image analysis was developed and enabled reproducible time-series data analysis during running for the first time [2]. This study investigated the relationship between continuous Tsr data, internal load, and core temperature during cardiopulmonary exercise testing (CPET).

METHODS: Twelve endurance-trained subjects [6=male; 6=female; age=24.83y (±2.17); body mass=67.9kg (±8); height=173.8cm (±6)] completed a CPET on a treadmill (start 6 km/h; 3 min per stage; 2 km/h increase per stage at 1.5% slope). Thereby, we measured Tsr, oxygen uptake (VO2), heart rate (HR), rated perceived exertion (RPE), core temperature (Tcore) and blood lactate (LA). We performed descriptive data analysis, bivariate correlation analysis, and repeated measures ANOVA (significance level: $p<0.05$).

RESULTS: The Tsr decreased during stages and immediately increased during standing breaks, which is directly inverse to variations in HR and VO2. Furthermore, Tsr and Tcore showed a significant difference between all relevant levels of the CPET (rest; ventilatory thresholds one and two; maximum load; recovery) ($p<0.05$). The gradient (TG) between Tsr and Tcore increased by 2.6°C (±1) from pre to post. Global correlation analyses revealed statistically significant correlations for TG with VO2 ($r = .402$), HR ($r = .504$), LA ($r = .449$), and RPE ($r = .533$) $p<0.001$. Further analyses revealed high interindividual differences, such as correlations ranging from $r = .43$ to $r = .97$ for TG and VO2.

CONCLUSION: The direct inverse relation of Tsr and cardiopulmonary parameters confirm the association with acute stress response and reveal the high value of the enabled time series analysis. Synchronous measurement of cardiopulmonary and thermoregulatory exercise response allows a comprehensive view of the individual acute physiological adaptation. The origin of interindividual differences requires further analysis. Classification algorithms will be implemented to may enable the non-invasive and contact-free IRT quantification of internal load or the identification of individual training zones.

COMPARISON BETWEEN BODYWEIGHT LUNGES AND SQUATS ON MUSCLE OXYGEN SATURATION, HEART RATE AND PERCEIVED EXERTION

AMARAL, A., TEIXEIRA, A., MACHADO, I., SANTARÉM, D., SAMPAIO, J., ABRANTES C.

UNIVERSIDADE DE TRÁS-OS-MONTES E ALTO DOURO

INTRODUCTION: Squat and Lunges exercises are strongly focused on lower limbs, differing among them in the symmetry of the movement. Several commonly different task constraints related to technical variations or training targets, such as type of surface, type of contraction and range of motion, can promote different acute physiological responses. This study aimed to compare the effect of 6 Lunge and Squat variations on the muscle oxygen saturation (SmO2) of the vastus lateralis (VL) muscle, on the heart rate (HR) response and on the cardio and muscle perceived exertion (RPEc and RPEm, respectively) [1].

METHODS: Ten healthy adults participated in this study (age=26.1±3.1yrs; body mass=74.8±7.9kg; height=173±7cm; BMI=25.0±3.1kg/m2; VL skinfold=14.2±4.8mm). A familiarisation session for each exercise was conducted followed by two sessions, on separate days, where the 6 variations were held in random order for 90sec and 5min rest (cadence 40-60bpm). Variations were chosen so there were unstable (squat Terracore | side-lunge Terracore), reactive (squat Jump | Jumping lunge), single leg (Pistol squat | Bulgarian) and isometric (Wall squat | lunge) and range of motion (Deep squat | Walking lunge and Uneven squat | Cross lunge). Both VL SmO2 percentage (Moxy Fortiori Design, Hutchinson, USA) and HR were collected continuously (last 30sec data was used) and RPE (Borg 6-20) after each variation [2].

RESULTS: Repeated measures ANOVA with Bonferroni's correction revealed no differences on the VL SmO2 in exercise variations (F[11.66]=0.765, p=0.673, n2=0.055). HR (F[11.66]=4.83, p=0.001, n2=0.237) was lower in Isometric lunge vs Walking lunge (p=0.05), and no differences between exercises. Higher RPE were found in reactive Jumping lunge and Jump squat (RPEc 15.1±3.0 and 15.5±1.3 and RPEm 18.6±1.0 and 18.6±0.9). Unstable variations Lateral lunge and squat Terracore, reported lower RPEc (11.1±1.5 and 11.9±2.0) and RPEm (12.9±1.3 and 13.1±2.1) with slightly higher SmO2. Lunge vs squat isometric variations revealed no difference on SmO2 and reported similar RPEc (13.1±3.0 and 12.9±2.6) and RPEm (16.2±1.8 and 16.8±3.2). Both reactive variations revealed higher RPEm compared to unstable ones (F [11.77] =10.2, p=0.001, n2=0.517), squat Jump vs side-lunge Terracore (p=0.003) and vs squat Terracore (p=0.011), Jumping lunge vs side-lunge Terracore (p=0.002) and vs squat Terracore (p=0.025).

CONCLUSION: Squat and lunge variations promoted a similar response in VL SmO2, and the isometric lunge promoted lower HR. Despite no differences in SmO2, reactive variations were perceived by participants with higher RPEm, and unstable variations with lower RPEm regardless the exercise.

WORK!: AN EXTERNAL LOAD FRAMEWORK FOR TENNIS MATCHES

KEMPE, M., BROUWER, M., HOEKSTRA, A.E.

UNIVERSITY OF GRONINGEN

INTRODUCTION: Electronic performance and tracking systems (EPTS) are already very common in some team sports like football and the play a vital role in the monitoring of athletes and match analysis. In tennis the use of tracking systems is still sparse. One of the main reasons for this is that players were not allowed to play with wearable technology (like GPS Sensors) and video tracking is by now only feasibly via Hawk-Eye system, which is rather expensive. We therefore created a tracking approach using a one low-cost camera-system and a Deep-Neural Network algorithm for player tracking using YOLOv5 via Pytorch. To evaluate this system, we compared it´s accuracy on typical external load variables with a reference system (Xsens).

METHODS: Ten experienced tennis players took part in the study. They performed 5 different basic exercises (5m, 10m, 20m sprint, a sport specific sprint test, & Pendle sprint) and a short test match. Performance of the participants was recorded with Xsens and video on both sides of the pitch to account for differences in the resolution of the tracked players. To evaluate the new tracking approach (WORK!), distance covered, mean velocity, max velocity, max acceleration and number of accelerations above 3 m/s^2 were extracted from both systems. For synchronisation, start and end times of the exercises were annotated in Dartfish. Statistical analysis was performed with SPSS. Accuracy of fundamental XY-position data was estimated by means of the root mean square error (RMSE). Inter-system differences in accuracy levels on the output variables were tested using an independent t-test.

RESULTS: There was strong agreement between WORK! and three-dimensional motion capture across each activity undertaken. The root mean square difference for speed was 0.55 $m \cdot s{-}1$ and for position was 4.2 m .

CONCLUSION: WORK! had strong agreement with the criterion three-dimensional motion capture system three-dimensional motion capture for football-related movements tested in typical tennis court environments. WORK! can thus be used to monitor tennis players during training and matches. This could spark future research on physiological factors in top tennis and injury prevention.

HOW TO MAXIMIZE PERFORMANCE DURING PARALYMPICS BY ANALYZING THE HUMAN-WHEELCHAIR-ATHLETIC TRACK INTERACTIONS ?

MICHEL, M., LOUBET, J.L., MAZUYER, D.
LABORATOIRE DE TRIBOLOGIE ET DYNAMIQUE DES SYSTÈMES

INTRODUCTION: Sciences2024 is a collaborative French research project between sport federations and academic researchers aimed at improving athletics and para-athletics performance for the Paris Olympic and Paralympic Games. Thus, for instance, maximizing the velocity of the wheelchairs during competitions requires to increase the grip between gloves and handrims during the propulsion phase as well as to understand the friction dissipation between the wheelchair tire and the athletic track during the rolling phase.

METHODS: A lab-field approach was carried out. From experiments with French national athletes in real conditions, an analysis of the kinematics was performed and force sensors, strapped on the athlete glove, provided additional data on the glove/handrim interface.

The propulsion phase kinematics was experimentally simulated in LTDS by means of the LORRY tribometer that allows one to control both the contact and release times of the glove/handrim interface. The rolling/sliding phase between the wheelchair tire and various tracks was experimentally investigated thanks to the LUG tribometer. It allows us to realize contacts between a rubber barrel sample, representative of the tire, versus various tracks, from smooth transparent glass discs to real athletic tracks. The contact kinematics was controlled with each solid velocity ranging from 50 □m/s to 1 m/s and the contact forces were measured up to 10 N. The composition of rubber samples (both handrim and tire) provided by Hutchinson was varied in terms of fillers, keeping the elastomer matrix constant.

RESULTS: Our first results on the model glass/rubber contact in rolling/sliding conditions helped us to identify the relative influence of adhesive and viscoelastic contributions of the rubbers. When investigating more realistic scenarii with rolling-sliding conditions on athletic tracks, friction depended on the sliding-rolling ratio (SRR): at low SRR, a levelling of friction was observed and at higher SRR, the friction level did not correlate directly with the rubber bulk properties. These results highlighted the influence of track viscoelasticity and roughness, confirming field experimental results focusing on the coefficient of rolling resistance.

The contribution of adhesion was marked during the propulsion phase and this will be confronted to field results.

CONCLUSION: The methodology proposed here was based on the analysis of the interactions of the wheelchair with either the Human athlete or the track, during rolling-sliding and propulsion phases. Confronting measurements on field to lab experiments, we were able to discuss the role of the roughness, adhesion and viscoelasticity, defining a promising way to enhance athletic performance.

HOW IS SPORTS INJURY PREDICTION PERCEIVED BY ELITE SPORTS STAKEHOLDERS? AN ONLINE SURVEY DURING THE MUNICH 2022 EUROPEAN CHAMPIONSHIPS.

DANDRIEUX, P.E.1,2, NAVARRO, L.2, CHAPON, J.1, TONDUT, J.1, ZYSKOWSKI, M.3, HOLLANDER, K.4, EDOUARD, P.1
1UNIVERSITÉ JEAN MONNET SAINT-ETIENNE; 2MINES SAINT-ETIENNE; 3TECHNICAL UNIVERSITY MUNICH; 4MSH MEDICAL SCHOOL HAMBURG

INTRODUCTION: The development of artificial intelligence and machine learning techniques may enable measuring an individual athlete's own risk of injury occurrence and can also be used to further investigate the relative importance of risk factors related to sports injuries. In the near future, elite stakeholders (athletes, coaches, health professionals) could have the opportunity to access to the injury risk estimation provided by predictive algorithms in order to manage training and injury risk as an additional injury risk reduction measure. The aim of this study was to explore the perception and beliefs of elite sports stakeholders towards the use of injury prediction as an injury risk reduction measure.

METHODS: During the 2022 European Championships in Munich (Germany), a multi-sports event, all registered athletes, coaches and health professionals from the nine sports disciplines (i.e., athletics, beach volleyball, canoe sprint, cycling, gymnastics, rowing, sports climbing, table tennis, triathlon) were asked to complete an online questionnaire on their perception and beliefs of the use of injury prediction as an injury risk reduction measure. The interest, intent to use, perceived help, potential stress and dissemination scores were assessed using an analogic scale from 0 (not at all) to 100 (totally).

RESULTS: There were 79 participants: 35 athletes, 14 coaches, 29 health professionals, from 23 countries and from 8 sports disciplines (54 athletics, 8 canoe sprint, 4 cycling, 2 gymnastics, 2 rowing, 2 sports climbing, 5 table tennis, 1 triathlon). They all expressed a high level of agreement regarding the interest (86±15), intent to use (84±16), and perceived help (85±16) of injury prediction as an injury risk reduction measure. Regarding potential stress induced by injury prediction, the level of agreement was moderate (41±33), and there was an important inter-individual variability in each stakeholder group (athletes, coaches, health professionals) with scores ranging from 0 to 100. They expressed a high level of agreement regarding the dissemination for athletes (85±17), coaches (84±20) and health professionals (86±18).

CONCLUSION: This innovative study shows that regardless of the stakeholder group (athletes, coaches, health professionals), there was a high level of acceptance of injury prediction as injury risk reduction measure. In contrast, potential stress induced by injury prediction seems to be more nuanced and affected by individual factors. Our results provide new insights into how elite stakeholders may respond and apply to this preventive measure. This is an important step for properly defining implementation strategies and may have implications for future research and practice in the use of sports clinical prediction modelling as an injury risk reduction measure in elite sports field.

IRISIN AND BONE REMODELING REGULATORS AFTER HIGH-INTENSITY INTERVAL EXERCISE OF HIGH AND LOW IMPACT IN YOUNG ADULT FEMALES

KLENTROU, P., BORZOOEIAN, G., KOTTARAS, S., KOUVELIOTI, R., WARD, W., TSIANI, E.

BROCK UNIVERSITY

INTRODUCTION: Recent evidence indicates that exercise leads to increased secretion of irisin, a muscle-derived cell signalling protein, which, in turn, seems to play a major role in bone homeostasis. Moreover, while high-impact activities such as running are known for their beneficial effects on bone remodelling, the evidence on whether low-impact activities have similar effects on bone cell processes appears contradictory. Thus, the purpose of this study was to investigate potential changes in irisin, and several upstream and downstream regulators of bone cell signalling in young adult females following high-intensity interval exercise of high and low impact.

METHODS: Healthy, recreationally active, young adult females (n=18; 22.5±2.7 years) performed two exercise trials in random order; high-intensity interval running on a treadmill and high-intensity interval cycling on a cycle ergometer. The exercise trials involved eight intervals of 1-minute running or cycling at high intensity (≥ 90% of maximal heart rate, with 1-minute passive recovery breaks in between. In both trials, blood samples were taken before the exercise (resting), and three times after exercise (5 minutes, 1 hour, and 24 hours). The myokine irisin, the bone-modulating parathyroid hormone (PTH), and three Wnt signalling-related osteokines, including sclerostin, osteoprotegerin (OPG), and receptor activator nuclear factor kappa-β ligand (RANKL), were analyzed in serum. Post-exercise concentrations were corrected for exercise-induced changes in plasma volume.

RESULTS: Irisin did not increase immediately following either the running or cycling trial but was 20% higher 24 hours post-exercise compared to pre-exercise in both trials (6.2±0.5 versus 5.±0.3 ng/ml; time effect p=0.005). PTH, sclerostin, and RANKL were higher 5 minutes post-exercise compared to pre-exercise (18%, 37%, 83% and 33%, respectively; time effect p<0.05), returning to pre-exercise 1 hour after exercise irrespective of exercise mode. Specifically, compared to pre-exercise, 5 minutes post-exercise, PTH increased from 76.2±10.6 to 163.0±12.1 pmol/L (p<0.001), sclerostin increased from 99.0±7.6 to 134.5±10.4 pg/ml (p<0.001), and RANKL increased from 89.8±10.0 to 118.9±16.5 pg/ml (p=0.017) with no differences between trials. OPG showed a time effect (p<0.05), reflecting an overall increase from pre-exercise to 5 minutes and 1 hour post-exercise (525.7±31.7 versus 579.0±39.9 and 565.2±41.4 pg/ml, respectively), which was not significant after the Bonferroni adjustment for three comparisons.

CONCLUSION: This study found that high-intensity interval running and cycling produce similar responses in the circulating levels of irisin and regulators of bone cell signalling in young adult females. This finding suggests that when performed at high-intensity, high and low-impact exercises seem to have similar effects on muscle and bone cell signalling pathways.

BONE (RE)MODELLING MARKER CONCENTRATIONS THROUGHOUT MENSTRUAL CYCLE PHASES IN RESPONSE TO AN ECCENTRIC RESISTANCE TRAINING PROTOCOL

GONZÁLEZ-MATEOS, A.1, GUISADO-CUADRADO, I.1, PEINADO, A.B.1, ROMERO-PARRA, N.1,2

1. UNIVERSIDAD POLITÉCNICA DE MADRID; 2. UNIVERSIDAD REY JUAN CARLOS.

INTRODUCTION: Bone remodelling may be altered by sex hormone fluctuations during the menstrual cycle [1]. Bone formation determined by procollagen type 1 N propeptide (P1NP), and bone resorption measured by carboxy-terminal cross-linking telopeptide of type I collagen (β-CTX-1), can reflect changes in bone metabolism. Although there is evidence suggesting that resistance training could have positive effects on bone health [2], it is unknown how these sex hormone fluctuations may affect the acute response to this modality of training/exercise. Thus, this study aimed to observe the impact of resistance training on bone (re)modelling markers throughout the menstrual cycle.

METHODS: Seven eumenorrheic resistance-trained females (age: 23.7±2.86years; weight: 61.1±3.93kg; height 162.2±4.2cm; body fat: 28.3%±6.93%; BMI: 23.3±2.49kg/m2; 1RM: 65.1±11.31kg) performed an eccentric-based resistance training protocol [3], in which participants performed 10x10 of parallel back squats at 60% of 1RM. P1NP and β-CTX-1 serum concentrations were measured pre- and 0h post-exercise in the early-follicular phase (EFP), late-follicular phase (LFP) and mid-luteal phase (MLP). Menstrual cycle phases were determined by the 3-step methodology [4]. A mixed linear model was conducted, where phase and time were set as fixed effect and subjects as random effect.

RESULTS: Significant differences were found in P1NP values between the EFP (73.0±17.24 ng/ml) and MLP (82.1±26.4 ng/ml; p<0.035). Moreover, higher β-CTX-1 values were observed in the LFP (0.6±0.07 ng/ml) compared to the EFP (0.5±0.07 ng/ml; p<0.045) and MLP (0.5±0.07 ng/ml; p<0.003). Furthermore, significant differences were also found in P1NP/β-CTX-1 ratio when comparing the LFP (126.4±31.71) with the MLP (154.9±34.4; p<0,004). Additionally, higher post-exercise P1NP/β-CTX-1 ratio value (176.7±16.56) was obtained compared to pre-exercise values (142.9±10.17; p<0.007).

CONCLUSION: The observed higher bone formation and lower bone resorption, determined by P1NP and β-CTX-1 respectively, could lead to increased resistance training-induced bone anabolism during the MLP. Therefore, these findings may

indicate that menstrual status may influence the resistance exercise response of bone metabolism, highlighting its importance for proper menstrual health. Nevertheless, the long-term implications of the higher P1NP/ β-CTX-1 ratio observed during the MLP remain unknown, as well as the potentially greater bone health benefits derived from resistance training during this phase.

INFLUENCE OF EXERCISE MODALITY (ENDURANCE VERSUS RESISTANCE) ON BONE (RE)MODELLING MARKERS IN ORAL CONTRACEPTIVE USER WOMEN

PEINADO, A.B.1, GUISADO-CUADRADO, I.1, ALFARO-MAGALLANES, V.M.1,2, CUPEIRO, R.1, ROMERO-PARRA, N.1,3

1. UNIVERSIDAD POLITÉCNICA DE MADRID; 2. PUBLIC UNIVERSITY OF NAVARRA; 3. UNIVERSIDAD REY JUAN CARLOS.

INTRODUCTION: The osteogenic effects of exercise depend on its nature and features. Previous results have shown that multidirectional sports (e.g. volleyball or gymnastics) are more beneficial for bone health in comparison to endurance sports (e.g. running, cycling or swimming) (1). Moreover, given the effects of oestrogen on the regulation of bone metabolism and the high prevalence of oral contraceptive use, the different hormonal profiles of women of reproductive age should be considered. However, there is limited evidence about the effect of the exogenous hormones on bone (re)modelling markers. This study aimed to analyse the influence of the exercise modality (resistance vs. endurance) in OC users.

METHODS: Fifteen OC users exercising women participated in this study (25.6±3.5 years; 27.1±7.2% fat mass). Eight women performed an interval running exercise (8 bouts of 3 min at 85% of the maximal aerobic speed) while seven participants performed an eccentric-based resistance training session (10x10 of barbell parallel back squats at 60%1RM) (2). Volunteers were evaluated in the withdrawal phase (WP) and the active pill-taking phase (APP). Procollagen type 1 N-propeptide (P1NP) and carboxy-terminal cross-linking telopeptide of type I collagen (β-CTX-1) serum concentrations, representing bone formation and resorption respectively, were analysed pre-exercise and just (0h) post-exercise and delta values were calculated (units: ng/ml).

RESULTS: Delta values of P1NP were significant affected by the exercise modality (Endurance: 12.4±5.03; Resistance: -1.79±3.05; $p<0.001$) showing higher delta values of P1NP during the endurance exercise. There was a significant phase*protocol effect ($p=0.018$). Delta values of P1NP were significantly higher ($p<0.001$) at WP (14.74±4.71) and APP (10.06±4.42) during the endurance exercise compared to the WP (-2.6±3.25) and APP (-0.98±2.85) during the resistance exercise. Delta values of β-CTX-1 were also significant affected by the exercise modality (Endurance: 0.016±0.052; Resistance: -0.110±0.124; $p<0.001$) with higher delta values during the endurance training.

CONCLUSION: Exercise modality affects bone formation markers, showing a large increase after the endurance exercise in both OC phases. On the contrary, P1NP and β-CTX-1 showed a decrease after the resistance exercise. Further investigation of the mechanism on microdamage repair in bone tissue is necessary to explain this increase in P1NP with the endurance training since it seems inconsistent with the classical remodelling theory (3). On the contrary, the direct repair theory (4), demonstrated in vitro models, could be supported by these results.

INCREASED PHYSICAL LOADING ON AND OFF THE PITCH: DEMANDS OF FULL-TIME ACADEMY PROGRAMMES AND IMPLICATIONS FOR GROWTH, MATURATION AND BONE HEALTH.

STABLES, R., HANNON, M., COSTELLO, N., HAMBLY, C., BODDY, L., CLOSE, G., MORTON, J.

LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: We have previously reported that male academy soccer players from the English Premier League (EPL) complete training loads [1] and exhibit daily energy expenditures [2] that are comparable to (and in some cases exceed) their first team counterparts [3]. Given the implications of "under-fuelling" upon growth and maturation, such data demonstrate the necessity of consuming sufficient energy intake. However, the extent to which being enrolled on a full-time academy programme increases the total daily energy expenditure (TDEE) and physical loading (PL) patterns of adolescent soccer players compared with non-academy players is not yet known. Accordingly, the aim of this study was to test the hypothesis that the TDEE of male academy soccer players is significantly greater than players not enrolled on a formalised academy programme.

METHODS: In a cross-sectional design, eight male soccer players from an EPL academy (ACAD: 13 years, 51±8 kg, 89±3% predicated adult stature (PAS) and six aged-matched non-academy players (NON: 13 years, 53±12 kg, 89±3% PAS) were

assessed for TDEE (using the doubly labelled water method) during a 14-day in-season data collection period. External loading was evaluated during soccer training sessions (ACAD: n=8, NON: n=2) and competitive games (ACAD: n=2, NON: n=2) via GPS technology whilst daily physical activity (PA) was also evaluated using triaxial accelerometery sampling at 30Hz.

RESULTS: In accordance with a greater frequency of training and games, academy players completed a greater accumulative duration of soccer activity (ACAD; 975±23min, CON; 397±2min, 95%CI 557 to 599, p<0.01) and distance covered (ACAD; 54.2±8.3km, CON; 21.6±4.7km 95%CI 24.3 to 40.8, P<0.05) during the 14 day-period. Additionally, academy players also spent more time engaging in daily moderate-to-vigorous (ACAD; 124±17min, CON; 79±18min, 95%CI 25 to 65, p<0.001) and high intensity PA (>600 mg; ACAD: 13±3mins, NON: 7±3mins, 95%CI 2 to 10, P>0.05). In considering higher physical activity levels, both absolute (ACAD; 3380±517kcal.d-1, CON; 2641±308kcal.d-1, 95%CI 218 to 1258, P<0.05) and relative TDEE (ACAD; 66±6kcal.kg.d-1, CON; 52±10kcal.kg.d-1, 95%CI 5 to 24, P<0.05) was also greater in academy players versus non-academy players.

CONCLUSION: We report for the first time that the daily energy requirements of male adolescent soccer players engaged in a formalised academy program are significantly greater than age matched non-academy players. Our data demonstrate the necessity for academy players to consume sufficient daily energy intake to support the energetic demands of growth and maturation alongside the enhanced energy cost associated with the training and competition academy programs. The present data form the basis of stakeholder (e.g. governing bodies, coaches and parents) and player education and behaviour change strategies that promote sufficient daily energy intake, contributing to long-term player development.

DETERMINANTS OF RESTING CEREBRAL BLOOD FLOW AND ARTERIAL TRANSIT TIME IN HEALTHY OLDER ADULTS

FERON, J., RAHMAN, F., FOSSTVEIT, S.H., JOYCE, K.E., GILANI, A., LOHNE-SEILER, H., BERNTSEN, S., SEGAERT, K., MULLINGER, K.J., LUCAS, S.J.E.

UNIVERSITY OF BIRMINGHAM, UNIVERSITY OF AGDER, SIR PETER MANSFIELD IMAGING CENTRE

INTRODUCTION: The relationship between fitness and cerebrovascular health in older adults remains unclear. Previous research using pseudo-continuous arterial spin labelling (pCASL) shows that resting grey matter cerebral blood flow (CBF) declines with age, is lower in males than females, and is inversely associated with body mass index (BMI) (4). However, fitness has been shown to be both a positive and negative determinant of CBF (1,2). Disparities in results may be because few studies use multiple post-label delays to correct CBF values for differences in arterial transit time (TT) between groups that possibly accompany the changes in CBF. This study aims to establish the key determinants of CBF in healthy older adults, measured using pCASL with multiple post-label delays.

METHODS: On separate days, 79 healthy older adults (65±5 yrs, 39 females) completed a modified Balke fitness test, and an MRI scan to measure CBF and TT using pCASL with a 3D GRASE readout (6). 8 post-label delays (200, 975, 1424, 1850, 2025, 2150, 2250, 2300 ms) were used (7) to enable CBF and TT to be measured. ASL data were analysed using BASIL toolbox, FSL. Separate linear regressions were performed with CBF and TT as dependant variables, both including age, sex, education level, Montreal Cognitive Assessment (MoCA) score, systolic and diastolic blood pressure, BMI, handgrip strength, and fitness as independent variables.

RESULTS: For CBF, BMI was the only significant determinant (β = -0.44, p = 0.001), while fitness was a non-significant negative determinant (β = -0.29, p = 0.077). For TT, BMI (β = 0.27 p = 0.031), age (β = 0.38, p = 0.011), and handgrip strength (β = -0.47, p = 0.030) were all significant determinants. For CBF and TT, all other independent variables were non-significant (p > 0.100).

CONCLUSION: The CBF-BMI and TT-age associations observed in the current study were consistent with previous research, as was the lack of association between TT and fitness in older adults. Further, our data indicate that fitness may be negative determinant of CBF (though p = 0.077). Previous research has shown both a negative (2) and a lack of (3) association between CBF and fitness in older adults. The tentatively negative relationship between fitness and CBF may be a compensatory response to neurovascular inefficiency (5).

GRIP STRENGTH CORRELATES WITH BODY COMPOSITION AND BASAL METABOLIC RATE IN OLDER ADULTS WITH LOW APPETITE

GONNELLI, F.1, PRATT, J.1, VALLI, G.1, FRANCHI, M.1, DE VITO, G.1,2

1) DEPARTMENT OF BIOMEDICAL SCIENCES, UNIVERSITY OF PADOVA, PADOVA, ITALY; 2) CIR-MYO MYOLOGY CENTER, UNIVERSITY OF PADOVA, PADOVA, ITALY

INTRODUCTION: Grip strength (GS) and lean mass have been identified as robust indicators of functional impairment, morbidity, and mortality (1) throughout the lifespan (2,3). Although, GS is widely used in clinical settings its relationship with lean mass, anthropometric measurements and cross-sectional area of the thigh is still unclear. In the present study we examined this relationship in healthy older adults with low appetite a population at risk of developing undernutrition and a plethora of pejorative health outcomes including sarcopenia. Thus, the aim of this study was to establish the efficacy of both GS and maximal voluntary contraction (MVC) of knee extensors (KE) in predicting body composition, anthropometric measurements, and KE cross-sectional area (CSA) in healthy older adults with low appetite.

METHODS: Prior to enrollment in the study, eight healthy older adults (>65 yrs.) underwent appetite assessment using the Simplified Nutritional Appetite Questionnaire (SNAQ) where low appetite was defined as SNAQ score <16. Waist-Hip Ratio (WHR) was measured with a tape. Bioelectrical impedance analysis was used to assess fat free mass (FFM_kg) and to estimate basal metabolic rate (BMR). A hand dynamometry measured GS of both arms and the highest value among the two limbs was retained for analysis. A custom-made knee dynamometer was used to measure MVC of KE. Vastus lateralis and rectus femoris CSA were evaluated using extended-field-of-view ultrasonography imaging.

RESULTS: The non-dominant arm expressed the highest GS value in 2 out of 8 subjects. Analysis revealed that in older adults GS is correlated with WHR (r2=0.496; p=0.034), FFM_kg (r2=0.646; p=0.009) and BMR (r2=0.814; p=0.002). No correlations were found when considering muscle CSA or MVC (KE). At the same time, MVC is not a predictor for the other dependent variable.

CONCLUSION: GS confirms to be a good indicator in evaluating body composition and metabolic rate in older adults but it is not specific in predicting muscle mass and strength of lower limbs. Moreover, assessment of GS has proven to be an effective screening tool for predicting both BMR and total energy expenditure, which are crucial factors in maintaining an adequate level of physical activity in older adults. The potential of MVC to predict general fitness and body composition variables in this particular population has yet to be evaluated, and thus, remains unclear.

THE ETIOLOGY OF AGE-RELATED FATIGABILITY REVISITED

LUNEAU, E.

UNIVERSITÉ JEAN MONNET

INTRODUCTION: Aging is associated with a decline in muscle mass and force/power. These alterations can exacerbate fatigability, defined as an exercise-induced reduction in force/power, and reduce autonomy. The mechanisms underlying fatigability are insufficiently known, especially at very old age (> 80 years). The aim of this study was to further investigate the causes of fatigability with the ultimate goad to adjust exercise intervention to prevent the age-related fatigability and thus maintain autonomy and improve quality of life.

METHODS: Thirty young (YM; 19-35 years), 28 old (OM; 65-80 years) and 16 very old (VOM; >80 years) men performed an incremental fatiguing task on a validated cycle-ergometer that allows to block instrumented pedals at 90° for the right knee. The fatiguing test consisted of 3-min stages with incremental workload based on the subjects' body weight. Before, at the end of each stage and at exhaustion, subjects performed a neuromuscular evaluation consisting of a maximal isometric voluntary contraction (MVC) of the knee extensors and single-pulse stimulations during MVC and on relaxed muscles to evaluate voluntary activation (VA) and resting twitch amplitude (Tw). Perceived exertion (RPE) was rated at the end of each stage on a 6-20 Borg scale. In a second session, subjects realized a VO2max ramp-test on a similar ergocycle.

RESULTS: The total number of stages completed decreased with age (YM: 9.5±1.3, OM: 7.4±1.4, VOM: 4.7±1.0; p<0.001). At exhaustion, the decrease in MVC was lower for VOM (21.4±12.7%; p<0.001) than YM (34.7±12.4%; p<0.001) and was 27.0±23.0% for OM (not significantly different from YM and VOM). The decrease in Tw was greater in YM (44.1±18.1%; p<0.001) than both OM (27.0±23.0%; p<0.05) and VOM (15.6±17.9%; no significant), and there was no age-related difference in VA. RPE at exhaustion was higher for YM (17.8±1.3) than OM (16.2±1.8) and VOM (14.4±1.5; p<0.01). However, the mean RPE for the first three stages was higher for VOM (14.3±1.6) than both OM (13.0±1.8) and YM (9.7±1.0; p<0.001) whereas MVC loss after stage 3 was similar for the 3 groups. RPE at last stage and VO2max were positively correlated (r=0.59; p<0.001).

CONCLUSION: The age-related decreases in MVC and Tw suggest that the increase in fatigability at exhaustion is mainly due to peripheral mechanisms (i.e. within the muscle). In VOM, despite a ~ 20% decrease in MVC, neither Tw nor VA declined significantly. This could be due to the fact that the task ended before maximum effort, as shown by the relatively low RPE at the last stage. Interestingly, the correlation between VO2max and RPE at the last stage indicated that participants who had a high VO2max could sustain higher levels of perceived effort. Therefore, a low VO2max and RPE at exhaustion, together with a higher RPE for a given submaximal workload could contribute to limit VOM performance when compared to OM. These results suggest that the targeted level of RPE during rehabilitation programs should be adjusted for VOM.

GENDER DIFFERENCES IN THE EFFECTS OF SARCOPENIA ON COGNITIVE FUNCTION, DEPRESSION, AND PHYSICAL FUNCTION IN THE ELDERLY: A SYSTEMATIC REVIEW AND META-ANALYSIS

LEE, C.

INCHEON NATIONAL UNIVERSITY

INTRODUCTION: Sarcopenia is defined as an age-related loss of skeletal muscle mass and functional impairments. Further, critical symptoms of the disease in the elderly include impaired cardiopulmonary performance and unfavorable metabolic effects, decreased physical capabilities such as falls and motor disability, and cognitive deficits and depression. Although age-induced sarcopenia often appeared in both elderly men and women, the symptoms of sarcopenia may differ depending on gender. However, common findings on the differences caused by sarcopenia in men and women are still lacking and have not been clearly presented. Therefore, the purpose of this meta-analysis was to identify potential effects of sarcopenia on cognitive function, physical function, and depression in the older adults based on gender, respectively.

METHODS: Our systematic literature search was conducted in the electronic databases of PubMed and Web of Science from March 1, 2010 to February 15, 2022 by two independent authors (CL, NK). We used the following search terms for each searching engine: (Cognition OR Cognitive) AND (Sarcopenia) AND (Elderly OR Older People). A total of 17,054 participants (7,680 women and 9,374 men) from the 29 qualified studies was examined in this meta-analysis.

RESULTS: Sarcopenia had significant negative effects on (a) cognitive function assessed by mini-mental state examination for women: SMD (standardized mean difference) = -0.714, p<.0001 and for men: SMD = -0.505, p<.0001, (b) body composition assessed by body mass index for women: SMD = -0.630, p<.0001 and for men: SMD = -0.570, p<.0001, and (c) appendicular skeletal muscle mass index for women: SMD = -1.119, p<.0001 and for men: SMD = -0.832, p<.0001 indicating relatively greater effects for women than those for men. In contrast, sarcopenia revealed significant negative effects on depression assessed by geriatric depression scale for women: SMD = -0.186, p<.0001 and for men: SMD = -0.261, p<.0001) and (b) physical function assessed by gait speed for women: SMD = -0.725, p<.0001 and for men: SMD = -1.018, p<.0001 indicating relatively greater effects for men than those for women. Finally, sarcopenia showed a significant negative effect on muscle strength assessed by handgrip strength for women: SMD = -1.271, p<.0001 and for men: SMD = -1.231, p<.0001 with minimal gender difference.

CONCLUSION: The current meta-analytic findings showed that sarcopenia had greater negative effects on cognitive function and body composition for women, whereas greater negative effects of sarcopenia for men were found in depression and physical function. No gender effect of sarcopenia appeared in muscle strength. These results suggested basic guidelines for preventing sarcopenia according to men and women in the elderly.

THE COMBINED TREATMENT OF ACETIC ACID SUPPLEMENT AND EXERCISE INTERVENTION ALLEVIATES SKELETAL MUSCLE MITOCHONDRIAL DYSFUNCTION IN OVARIECTOMIZED MICE

PARK, K.1, YOON, H.1, TAN, Y.1, PARK, S.1, RYU, B.1, SO, B.2, JANG, J.2, PARK, J.2, LEE, K.2, YEOM, D.2, KWAK, D.3, KANG, C.2, PARK, Y.1

1. INCHEON NATIONAL UNIVERSITY, 2.INHA UNIVERSITY, 3.HANYANG UNIVERSITY

INTRODUCTION: Menopause is a major factor causing negative changes in body composition and metabolic function in women. The present study aimed to investigate whether, using ovariectomized mice, acetic acid supplement and exercise intervention effectively alleviate the adverse effects of ovariectomy in terms of metabolic function including mitochondria.

METHODS: Female C57BL/6J wild-type mice (n=40, 8 weeks old) were randomly assigned to sham (SHM, n=8), ovariectomy (OVX, n=8), ovariectomy with exercise (OVX-E, n=8), ovariectomy with acetic acid (OVX-A, n=8), and ovariectomy with acetic acid and exercise (OVX-AE, n=8) groups. Following a 1-week recovery from ovariectomy, acetic acid supplement (5% in chow diet) and voluntary wheel running exercise intervention were administered according to group assignment for 13 weeks. Body composition, whole-body metabolic rate, and glucose tolerance were analyzed via DXA, indirect calorimetry, and intraperitoneal GTT, respectively. Mitochondrial function and pAMPK protein content in soleus and gastrocnemius were measured by OROBOROS-O2k and Western blot.

RESULTS: Ovariectomy significantly increased total body weight and fat mass, and decreased whole-body metabolic rate and glucose tolerance. Acetic acid supplement or exercise intervention failed to alleviate the ovarietomy-associated negative changes in body composition, whole-body metabolic rate and glucose tolerance. There was no significant difference between groups in mitochondrial respiration of soleus muscle. Interestingly, in gastrocnemius, ovariectomy significantly decreased mitochondrial respiration (53.079 ± 5.03 vs. 35.31 ± 4.13 pmol*sec-1*mg-1, P=0.003, SHM vs. OVX), which mitochondrial dysfunction was rescued by the combined treatment of acetic acid and exercise (35.31 ± 4.13 vs. 50.94 ± 5.17 pmol*sec-1*mg-1, P=0.015, OVX vs. OVX-AE). In addition, the combined treatment increased the activity of AMPK, the ratio of phosphorylated to total AMPK (2.35 ± 0.56 vs. 10.53 ± 1.65 AU, P=0.040, OVX vs. OVX-AE).

CONCLUSION: These findings suggest that single treatment of acetic acid or exercise cannot alleviate the ovariectomy-associated metabolic problems, but there was a synergetic effect on mitochondrial function when acetic acid supplement and exercise intervention were combined. The underlying mechanism by which the effect of the combined treatment differs between soleus and gastrocnemius muscle should be investigated in the future studies.

GETTING THE MOST OUT OF IT - DOES MEMORY BENEFIT FROM SYNERGIES OF SLEEP AND TRAINING?

FRISCH, N.1, HEISCHEL, L.1, WANNER, P.1, KERN, S.2, ROIG, M.3, FELD, G.2, STEIB, S.1

<1> HEIDELBERG UNIVERSITY; <2> CENTRAL INSTITUTE OF MENTAL HEALTH, MANNHEIM; <3> MCGILL UNIVERSITY, MONTREAL

INTRODUCTION: There is emerging evidence that high-intensity interval training (HIIT) may affect procedural and declarative memory consolidation as well as nocturnal sleep. Roig et al. (2022) postulated a theoretical framework of synergistic effects of exercise and sleep on memory. Recently, it has been shown for the first time that exercise followed by a day nap enhanced declarative memory formation. There was a positive correlation between performance and sleep spindle density, a sleep parameter associated with memory consolidation, only in the combined exercise and nap group (Mograss et al., 2020). Whether these effects can also be transferred to other memory systems, and in particular to nocturnal sleep, has not yet been studied. Therefore, the aim of this study was to investigate the potential influence of HIIT on sleep-dependent memory consolidation.

METHODS: 19 healthy subjects (23.7, ±4.0, m: 9, w: 10) were tested in a within-subject design. In counterbalanced order, two experimental nights with either (i) a HIIT (90%/25% Wmax) or (ii) a control condition (documentary) were performed immediately after the encoding of the memory tasks (7pm). The memory tasks were a finger tapping task (FTT) and a paired-associate learning task (PAL). Subsequent nocturnal sleep was recorded by polysomnography (N=13). Retention tests were carried out the following morning (8am). Consolidation was measured by the percentage change between encoding and retention. Differences between the conditions and associations between memory and sleep parameters were analysed using paired t-tests and Pearson correlations.

RESULTS: After encoding, there was no significant difference in performance between the two conditions (FTT: $t(18)=-1.899$, $p=.074$; PAL: $z = 1.844$, $p = .065$). HIIT had a small non-significant positive effect on procedural consolidation ($t(18)=1.324$, $p=.101$, $d=0.304$) and a significant small positive effect on declarative consolidation ($t(18)=1.767$, $p=.047$, $d=0.405$). HIIT also increased N2 sleep ($t(14)=1.857$, $p=.042$, $d=0.480$) and decreased REM sleep ($t(14)=-2.893$, $p=.006$, $d=0.747$). Notably, the exercise-induced change in N2 correlated significantly with the change in procedural memory consolidation ($r=0.475$, $p=.037$). Exploratory analyses of oscillatory brain rhythms revealed non-significant small effects on sleep spindle count in N2 and slow wave activity (SWA) in N3 ($t(12)=1.590$, $p=.138$, $d=0.441$; $t(12)=1.296$, $p=.219$, $d=0.359$).

CONCLUSION: The results confirm previous findings of increased N2 and reduced REM sleep after HIIT. The expected increase in memory consolidation was partially confirmed. The correlation between exercise-induced changes in N2 and FTT consolidation suggests that HIIT may favour procedural memory formation by lengthening relevant sleep stages. Exploratory analyses of oscillatory brain rhythms revealed no significant differences. However, we can gain some insight in exercise-induced changes, as small effect sizes indicate an increased spindle count in N2 and an increased SWA in N3.

EFFECTS OF CONCURRENT SPRINT INTERVAL TRAINING AND VELOCITY-BASED RESISTANCE TRAINING ON MUSCLE STRENGTH AND VO2MAX: A PILOT STUDY

KIKUCHI, S., MOCHIZUKI, Y., HOMMA, H., KIKUCHI, N.

NIPPON SPORT SCIENCE UNIVERSITY

INTRODUCTION: This study aimed to examine the effects of concurrent sprint interval training (SIT) and velocity-based resistance training using two different velocity loss cut off (VLC) on muscle strength and VO2max in three weeks.

METHODS: Eight trained subjects (two women and six men) participated in this study. The subjects characteristics were as follows; age; 24.2 ± 3.9 years, height; 168.7 ± 5.7 cm, body mass; 68.5 ± 9.7 kg, one repetition maximum (1RM) of parallel squat; 107.8 ± 26.1 kg, VO2max; 44.2 ± 6.3 mL/kg/min. Subjects performed two training sessions per week for three weeks and randomly divided into three groups; 10% of VLC resistance training and SIT (VLC10; n = 3), 40% of VLC resistance training and SIT (VLC40; n = 3), and only SIT (SIT; n = 2). Parallel squats at 80% 1RM (four sets, rest intervals; 4 min) was performed before SIT in VLC10 and VLC40. SIT was performed using a bicycle ergometer, with six bouts of 10 s sprint pedalling with 80 s rest intervals. Body composition, maximal oxygen uptake, 1RM test, countermovement jump (CMJ), and Wingate test were measured before and after the training session.

RESULTS: All groups improve in a VO2max after the three-week training session (SIT; 6.8%, VL10; 5.7%, VL40; 3.9%). Only the group with the resistance training had changed more 1RM (VL40; 10.6%, VL10; 7.3%, SIT; 1.7%). Similar results were observed for CMJ (VL40; 5.1%, VL10; 2.7%, SIT; -2%). There were no changes in peak and mean powers in the Wingate test in all groups.

CONCLUSION: Our results showed increased 1RM and CMJ only in the resistance training group. Conversely, in VO2max, there were high individual differences in effectiveness in the resistance training group. Therefore, increasing the number of subjects eventually is necessary.

ASSOCIATION BETWEEN ACTN3 R577X POLYMORPHISM AND MUSCLE STRENGTH AND POWER PERFORMANCE: A SYSTEMATIC REVIEW AND META-ANALYSIS

SAITO, M.1, ZEMPO, H.2, DE ALMEIDA, K.Y.1, HOMMA, H.1, MOCHIZUKI, Y.1, DEGUCHI, M.1, KOZUMA, A.1, SAITO, A.1, TASHIRO, S.1, KIKUCHI, N.1

1> NIPPON SPORT SCIENCE UNIVERSITY, 2> TOKYO SEIEI COLLEGE

INTRODUCTION: R577X polymorphism in the α-actinin-3 gene (ACTN3) is associated with muscle strength and power performance (Kikuchi et al. 2015, Yang et al. 2017). A previous study suggests that there is an additive relationship in muscle performance, which increases in the following order: RR, RX, and XX (Garton et al. 2016). However, there is no meta-analysis on the association between ACTN3 R577X polymorphism and muscle strength and power performance. Therefore, through a systematic review and meta-analysis study, we examined the effect of the ACTN3 R577X polymorphism on strength and power performance.

METHODS: Relevant studies published before July 27th, 2022 were identified from the PubMed database using the following keywords and Boolean operators: ("muscle strength" OR "muscle function" OR "muscle force" OR "power") AND ("α-actinin 3" OR "ACTN3 R577X genotype" OR "ACTN3 polymorphism" OR "ACTN3" OR "alpha-actinin 3"). Studies that met the following criteria were included: (1) published in English, (2) included human participants, (3) included healthy participants, (4) provided muscle function measurements, and (5) analysed the ACTN3 R577X genotype. Measurements were divided into maximum voluntary contraction (MVC), 1 repetition maximum (1RM), and jump and sprint performance and examined for association with ACTN3 R577X polymorphism. All analyses were conducted using R (version 4.1.3) and its "meta" package. The additive genetic model was assessed using a meta-regression model.

RESULTS: A total of 101815 participants from 33 studies were included in the meta-analysis (MVC: 19 studies, n=7419, 31 measurements; 1RM: 4 studies, n=657, 7 measurements; jump performance: 18 studies, n=3594, 44 measurements; sprint performance: 6 studies, n=1701, 7 measurements). Additive relationships in MVC, 1RM, and jump were observed and increased in the following order: RR, RX, and XX (MVC $p=0.005$, 1RM $p=0.005$, jump $p<0.0001$). There was no significant association between ACTN3 R577X polymorphism and sprint performance (sprint $p=0.168$).

CONCLUSION: MVC, 1RM, and jump performance had additive relationships with ACTN3 R577X polymorphism among muscle function measurements in the meta-analysis.

Further investigation is needed to determine whether the effects of ACTN3 R577X polymorphism on muscle strength and power performance differ by sex, ethnicity, and age.

THE RELATIONSHIP BETWEEN INDIVIDUAL MRI-DERIVED MUSCLE GROWTH AND STRENGTH GAINS AFTER RESISTANCE TRAINING

MARQUES, E.A.1,2,4, BALSHAW, T.G.1, FUNNELL, M.P.1, MCDERMOTT, M.1, MADEN-WILKINSON, T.M.3, ABELA, S.1, QUTEISHAT, B.1, EDSEY, M.1, JAMES, L.J.1, FOLLAND, J.P.1,4

1 LOUGHBOROUGH UNIVERSITY, LEICESTERSHIRE, UK; 2 CIDESD, UNIVERSITY OF MAIA , PORTUGAL; 3 ACADEMY OF SPORT AND PHYSICAL ACTIVITY, FACULTY OF HEAL

INTRODUCTION: Resistance training (RT) is well-recognised as an effective intervention to elicit profound improvements in neuromuscular strength and power. Although the muscle size-strength relationship has been extensively documented over decades, the contribution of muscle hypertrophy to strength changes following RT is still under debate (1,2). In addition, several methods to assess the size changes are available (such as anthropometry, biopsy, various imaging techniques), which may influence the consistency of previously reported relationships. Thus, only a few studies have assessed the relationship between individual muscle growth and strength gain after RT using high-resolution magnetic resonance imaging (MRI), the gold standard method of determining muscle size. This study aimed to explore the relationships between firstly, muscle hypertrophy and strength change, and secondly the hypertrophic response of different muscle groups. We hypothesised that in response to a standardised RT regime (1) quadriceps (Q) hypertrophy would be the biggest predictor of knee extensor (KE) strength gains rather than changes in neuromuscular activation or pre-training strength, (2) their would be a positive relationship between the hypertrophic response of different muscle groups.

METHODS: This study was a secondary analysis of longitudinal data from a randomised controlled trial, a two-arm 15-week RT intervention (3 times/week) study in young, healthy males (n = 39, mean age 25.7 ± 4.3 y) (3). Measurements pre and post-RT included: KE isometric maximum voluntary torque (MVT); KE one repetition maximum (1RM); Q, hamstrings (H) and gluteus maximus (GM) volume (VOL) with MRI; and Q neuromuscular activation (QEMGMVT and QEMG1RM).

RESULTS: Percentage changes (Δ) in Q VOL and QEMGMVT were correlated to ΔKE MVT ($r = 0.593$, $P < 0.001$, and $r = 0.347$, $P = 0.035$, respectively), while only ΔQ VOL correlated with ΔKE 1RM ($r = 0.334$, $P = 0.05$). Pre-training KE strength was not correlated with muscle strength changes (KE MVT and KE 1RM). Also, muscle hypertrophy of the different muscles were associated (All $r > 0.4$; $P<0.05$). The linear stepwise regression analysis only retained change in QVOL which explained 27.5% of the variance in KE MVT change and 11.8% of the variance in KE 1RM change.

CONCLUSION: The individual changes in quadriceps muscle volume were the biggest predictor of changes in KE strength after RT. However, this association differed in magnitude, depending on the measure used to capture muscle strength change (KE MVT vs 1RM). Also, the observed positive relationship between the hypertrophic response of different muscle groups indicates a significant contribution of systemic factors.

ACUTE STRESS RESPONSE IN HUMAN SKELETAL MUSCLE AFTER LOW-LOAD BLOOD FLOW RESTRICTED COMPARED TO HIGH-LOAD RESISTANCE EXERCISE IN TRAINED INDIVIDUALS

TANABE, Y., LANDER, E., DAVIDS, C., PAULSEN, G., VIKMOEN, O., CUMMING, K.T., ROBERTS, L., RAASTAD, T.

NORWEGIAN SCHOOL OF SPORT SCIENCES

INTRODUCTION: Low-load resistance exercise with blood flow restriction (LL-BFR), has been shown to induce similar increases in muscle mass and strength as high-load resistance exercise (HL-RE) (1). However, it remains unclear whether the cellular stress induced by LL-BFR in human skeletal muscle is different from that of HL-RE in trained individuals (2). Small heat shock proteins, such as αB-crystallin, are known to translocate from the cytosolic to cytoskeletal structures upon exercised-induced stress and damage (3,4). Therefore, the aim of the present study was to compare αB-crystallin translocation to cytoskeletal structure between LL-BFR and HL-RE.

METHODS: Eighteen strength-trained males and females (24±3 years) performed 9 weeks of lower body strength training (2-3 exercises, 3/week) with either LL-BFR (30-15-15-15 reps, 30-60% of 1RM, n=10) or HL-RE (4 x 8 reps, 75-90% of 1RM, n=8). Five days after the last session, participants performed an additional LL-BFR or HL exercise session to assess acute responses. Biopsies from vastus lateralis were collected before and after 9 weeks of training and at 2, 24, and 48 hours after the acute exercise sessions. The αB-crystallin levels in the cytosolic and cytoskeletal fractions were analyzed by Western blotting and immunohistochemistry on cross-sections. The cross-sections were counterstained for fiber type.

RESULTS: The αB-crystallin staining intensity in type I and II fibers did not change from before to after the training period. In the acute experiment, staining intensity of αB-crystallin was increased 2 hours after exercise; similarly in both groups in type II fibers (50-90% $p<0.05$), but in type I fibers staining intensity tended to increase more in LL-BFR than in the HL-RE group (92±72% vs 34±43% respectively, $p=0.08$). The αB-crystallin levels increased in the cytoskeletal fraction 2 hours after exercise in both groups ($p<0.05$), and this was mirrored by non-significant reductions in the cytosolic fractions (3-11%). The αB-crystallin levels in both the cytosolic and cytoskeletal fractions were not different between groups at any time point. Two hours after exercise, the increased αB-crystallin staining intensity correlated with the increase of αB-crystallin in the cytoskeletal fraction ($r=0.69$, $p<0.05$).

CONCLUSION: Acute resistance exercise with both LL-BFR and HL-RE induced translocation of αB-crystallin from the cytosolic to cytoskeletal structures and subsequent accumulation in the cytoskeletal structure. However, αB-crystallin accumulation in type I fibers tended to be higher with LL-BFR than HL-RE. Our results suggested that LL-BFR can yield muscle cellular stress comparable to that elicited by HL-RE in trained individuals. Finally, the αB-crystallin levels did not seem to be up-regulated by either LL-BFR or HL training for 9 weeks.

EFFECTS OF STEPWISE LOAD REDUCTION RESISTANCE TRAINING ON POWER PERFORMANCE AND MUSCLE STRENGTH: A PILOT STUDY

MOCHIZUKI, Y.1, KIKUCHI, S.1, OZAKI, H.2, HASHIMOTO, T.3, HOMMA, H.1, KIKUCHI, N.1

1) NIPPON SPORT SCIENCE UNIVERSITY, 2) TOKAI GAKUEN UNIVERSITY, 3) TOKYO UNIVERSITY OF SCIENCE.

INTRODUCTION: A previous study described a new training concept, "stepwise load reduction training", which starts at high and gradually decreases the exercise load (Ozaki et al. 2022). However, fatigue levels may be high due to the stepwise-to-exhaustion protocol. Therefore, it is possible that reduction in load without repetition to failure may improve power. The present study examined the effects of stepwise load reduction (SLR) resistance training on power performance and muscle strength.

METHODS: Nine participants (six men, two women, one drop-out) were randomly assigned to one of three training groups: high-load (HL [n = 3]); SLR [n = 3]); or low-load (LL [n = 2]). Exercise training was performed twice per week for three weeks. Resistance training for each group comprised the following: HL, three sets of five repetitions (rep[s]) at 85% one-rep maximum (1RM); SLR, three sets of two reps at 85% 1RM, two reps at 75% 1RM, and two reps at 55% 1RM; and, LL, three

sets of eight reps at 55% 1RM. The rest interval between sets for all groups was 3 min. The exercise consisted of free weight bench press. Participants performed a bench press 1RM test, bench press maximal isometric muscle strength (maximal voluntary contraction [MVC]), and bench-press throw (50% 1RM) at baseline and after each training program. Total exercise volume was matched across the three groups.

RESULTS: MVC increased by 0.4% in the LL, 6.8% in the HL, and 5.3% in the SLR groups. Bench throw demonstrated higher improvement in the SLR compared to the LL and HL groups (SLR = 9.9%; LL = 1.1%; HL = 2.1%).

CONCLUSION: Results suggested that three weeks of SLR resistance training was effective in improving muscle strength and power for bench press exercise.

EFFECTS OF DIFFERENT EXERCISE DURATION ON SALIVARY IGA SECRETION AND SECRETORY REGULATING FACTOR

UCHINO, T.1, UCHIDA, M.1, ITO, R.1, FUJIE, S.1, IEMITSU, K.1, INOUE, K.1,2, SHINOHARA, Y.1, IEMITSU, M.1

1> RITSUMEIKAN UNIVERSITY, 2> RESEARCH FELLOW OF JAPAN SOCIETY FOR THE PROMOTION OF SCIENCE

INTRODUCTION: Prolonged exercise such as marathon induces a transient decrease in oral immune function through reduced salivary immunoglobulin A (IgA) secretion, leading to an increase in the risk of developing upper respiratory tract infections. Saliva flow rate decreased by sympathetic nervous activity is involved in the reduction of salivary IgA secretion rate after an acute exercise bout. However, the effects of different exercise duration on salivary IgA secretion and secretory regulating factor remain unclear. We aimed to investigate the changes in salivary IgA secretion and secretory regulating factor before and after an acute exercise bout at different exercise duration.

METHODS: Twelve healthy young males with no exercise habits participated in this study. Subjects performed three exercise durations in a randomized crossover order: moderate-intensity continuous cycle exercise (55% maximal oxygen uptake [VO2max]) for 30 min, 60 min, and 90 min. Saliva samples were collected at baseline, immediately after, and 60 min after each exercise duration. The salivary IgA secretion rate was calculated from saliva flow rate per minute and salivary IgA concentration measured by ELISA. As a regulating factor for the reduction of saliva flow rate by acute exercise, salivary levels of cortisol released via the regulation of the adrenocortical system was measured by ELISA. The effect of different exercise duration was determined by using two-way repeated measures ANOVA. The relationship between change in salivary IgA secretion and change in salivary cortisol concentration was determined using Pearson's correlation coefficient. A significance level in statistics set at $P < 0.05$.

RESULTS: The significant changes in saliva flow rate and salivary IgA concentration were observed as the main effect of time (respectively, $P < 0.05$). The change in salivary IgA secretion rate immediately after exercise in an exercise duration for 90 min was significantly lower than that of 30 min ($P < 0.05$). The change in salivary cortisol concentration did not change significantly at the time course of each exercise duration. However, there was a significant negative correlation between the change in saliva flow rate and the change in salivary cortisol concentration before and immediately after exercise ($r = -0.63$, $P < 0.01$).

CONCLUSION: These results suggest that the salivary IgA secretion rate is reduced by exercise at 55% VO2max exercise intensity for longer than 90 min, and hence the decreased saliva flow rate via the increase in cortisol secretion may be a related factor of the decrease in salivary IgA secretion rate.

DOES MENTAL FATIGUE AFFECT REACTION TIME IN ATHLETES?

MIGLIACCIO, G.M.1, ORGIANA, T.1, DE PASCALIS, P.1, RUSSO, L.2, PADULO, J.3

<1> SPORT SCIENCE ACADEMY, ROMA, ITALY - <2> IUL UNIVERSITA TELEMATICA FIRENZE, ITALY - <3> DEPARTMENT OF BIOMEDICAL SCIENCES FOR HEALTH, UNIVERSITÀ DEGLI STUDI DI MILANO, MILAN, ITALY

INTRODUCTION: Mental fatigue (MF) has been defined as a psychobiological state caused by prolonged periods of demanding cognitive activity and characterized by subjective sensations that are felt with the semantic expression of "fatigue" or "lack of energy" (Boksem & Tops, 2008; Van

Cutsem et al., 2017)). However, mental fatigue plays a role in endurance athletes (Meeusen et al., 2021), while the impact of mental fatigue in motor task as reaction time (RT) to visual stimuli remains largely unknown.

METHODS: For this aim, 45 athletes (age 29.18±3.25 y) took part in this study. MF was induced by a routine of 15 minutes of Stroop Task (PsyTool),

with 600 tasks and 5 different colors choice. Heart rate (HR) was recorded with Cardio-Polar H7 in pre-Stroop-Test, during Stroop-Test

(every 5'), post-Stroop-Test and 1', 3', and 5' after post Stroop-Test. While RT was evaluated in pre and post Stroop-Test with a Cognitive

Fun software. The variables considered were HR (bpm), RT on Pre-Stroop-Test (RTPR), RT on Post-Stroop-Test (RTPO). Univariate ANOVA

and Bonferroni Post-hoc were used to compare HR in-between conditions and t-test to compare the RT performance before/after StroopTest. The significance level was fixed at priori as $\alpha < 0.05$

RESULTS: Analysis of variance (ANOVA) for HR showed a Fischer value of 6.051 and $\eta 2 = 0.101$ with $p<0.001$; while the post-hoc showed a significant

difference (p<0.05) during the Stroop-Test (HR was 36.58±5.40, 40.31±6.36 and 42.87±7.36 %HRMAX at the 1st 2nd 3rd point, respectively) compared to the other conditions. RTPR and RTPO was 310.29±38.34 and 334.12±38.79 ms, with p=0.0029, respectively

CONCLUSION: The present findings suggest that the parasympathetic branch of the autonomous nervous system functioning as a relaxation system tends

to be activated under increasing mental fatigue with a decreased performance (RT). Therefore, the athletes could use MF induced during

the training to improve the time delay related to the motor task.

These data have numerous implications. In the first place, it suggests how MF has a direct relationship to the RT and how its alteration can

become a determining factor in sports performance. Secondly, it suggests that the detection of HR can be used as a verification marker of

mental fatigue, in the absence of physical fatigue.

DOES PRIOR MENTAL FATIGUE AFFECT SUBJECTIVE MEASURES DURING AND AFTER A CYCLING TIME TRIAL?

ARENALES ARAUZ, Y.L.1, HABAY, J.1., OCVIRK, T., MARUSIC, U., DE PAUW, K.1, ROELANDS, B.1

1. HUMAN PHYSIOLOGY AND SPORTS PHYSIOTHERAPY RESEARCH GROUP, FACULTY OF PHYSICAL EDUCATION AND PHYSIOTHERAPY, VRIJE UNIVERSITEIT BRUSSEL, BELGIUM

INTRODUCTION: Mental fatigue (MF) can manifest itself in a subjective, physiological and a behaviorally manner, and can negatively impact physical performance [1]. A multitude of studies have investigated perceived effort during exercise in a mentally fatigued state [1]. However, investigating additional subjective measures of fatigue during exercise is essential to understand how MF affects performance. Therefore, we aim to examine how MF affects perceived effort, mental and physical fatigue during a 15-minute cycling time trial in a mentally fatigued state.

METHODS: Current results are part of an ongoing randomized cross-over trial. 51 participants (M/F=26/25; MeanAge =30 ± 8 y; BMI; 22.6 ± 2.5) visited the lab for three trials (familiarization, intervention and control). MF was induced with a 45-minute individualized STROOP task while the control trial consisted of watching a documentary. Directly after each condition, participants completed a 15-minute cycling time trial. The rate of perceived effort (0-100 RPE scale), physical fatigue and MF (0-100 scale) were monitored at the start, during (every 3 minutes) and at the end of the time trial. A two-way repeated measures (2x7) ANOVA was employed to test changes between conditions over time of each measure separately. Significant interaction effects were followed-up with paired T-tests.

RESULTS: For perceived MF, an interaction between condition and time (F=15.5, P<0.001, effect size=0.237) and a main effect of condition (F=19.4, P<0.001, effect size=0.280) were found. At the start of the time trial, perceived MF was significantly higher in the MF condition vs. control condition (MF=36.5 ± 23.9; CON = 18.4 ±15.3; t=5.664; P<0.001). Between the start and 12th minute, perceived MF decreased in the MF condition (MeanDifference= -7.29) whereas an increase was found in the control condition (MeanDifference = 7.22). Perceived physical fatigue and effort increased over time for both conditions, but only physical fatigue revealed a main effect of condition with higher scores in the MF condition (F=4.2, P=0.046, effect size=0.820).

CONCLUSION: Preliminary results show that a 45-min individualized Stroop task induced a higher MF perception before, during and after a 15-minute cycling time trial. In the MF condition, exercise decreased perceived MF over time, which reflects positive effects of exercise on MF. Physical fatigue was negatively affected by MF, possibly reflecting a separate working mechanism of MF on effort and physical fatigue perception. Future studies should further explore the underlying mechanisms of MF during exercise by relating subjective to physiological fatigue measures.

DO GENDER DIFFERENCES IN PERFORMANCE FATIGABILITY EMERGE AFTER NEUROMODULATION WITH THETA BURST STIMULATION?

MARTIGNON, C., BARBI, C., VERNILLO, G., EMADI ANDANI, M., SCHENA, F., VENTURELLI, M.

UNIVERSITY OF VERONA

INTRODUCTION: Sex-based differences in performance fatigability have been observed frequently, with females generally showing a greater fatigue resistance than males, but the responsible mechanisms are not completely understood. This study aimed to examine the events that might underlie the effect of biological sex on the neuromuscular components of

fatigue and corticospinal excitability elicited by elbow flexion task after different protocols of theta burst stimulation (TBS) applied on the motor cortex of the biceps brachii.

METHODS: During three experimental sessions, one for each TBS protocol (facilitatory, i.e. intermittent: iTBS; inhibitory, i.e. continuous: cTBS, and sham TBS), participants performed maximal and submaximal isometric contractions. Performance was measured with time to task failure (TTF). Changes in maximal voluntary contraction (MVC), voluntary activation (VA, central fatigue), and potentiated twitch force at rest (Qtw,pot, peripheral fatigue) from pre to post-exercise were determined via the interpolated twitch technique in thirty young healthy subjects (15 males; 15 females). Corticospinal excitability, reflected by the area and silent period (SP) of each motor-evoked potential (MEP), was assessed before and after both TBS, and the isometric sustained TTF (35% MVC).

RESULTS: More fatigue resistance in females than in males during the fatiguing task was detected (F:~233±40 vs M:~159±38 s; $P<0.05$), although the duration of TTF after the three TBS protocols changed equally in both groups ($P>0.05$) Moreover, after verifying the effectiveness of the three TBS protocols within each group, no sex differences were observed in VA, MEPs, and SPs ($P>0.05$). Similarly, MVC and Qtw,pot were not influenced by any TBS protocols, nor sex differences were observed ($P>0.05$).

CONCLUSION: Comparable alterations during the TTF emerged due to TBS protocols in both groups, although confirming greater fatigue resistance in females than males. Furthermore, iTBS and cTBS seem to influence central fatigue and corticospinal excitability, reducing and increasing them respectively, in males and females equally. Thus, this study suggests the possibility to alter fatigue and performance in both males and females, enhancing neuromuscular adaptations or offsetting them in both groups.

THE IMPACT OF EXHAUSTIVE EXERCISE ON BRAIN ACTIVATION AND EXECUTIVE FUNCTION

AKAZAWA, N., NAKAMURA, M.

WASEDA UNIVERSITY, JAPAN INSTITUTE OF SPORTS SCIENCES

INTRODUCTION: Elite athletes are thought to exhibit superior visual processing and executive control. To ensure high performance, athletes should have a high level of executive function such as attention, judgment, and information processing during exercise. However, little is known the effect of exercise-induced fatigue on brain function. The aim of the present study was to investigate the impact of exhaustive exercise on executive function and brain activation.

METHODS: Nineteen young men participated in this study (30 ± 3 yrs). The participants conducted incremental exercise until exhaustion. The brain activation during Stroop task using functional magnetic resonance imaging (fMRI) before and after exhaustive exercise. We evaluated the Stroop interference as an index of executive function. Visual analog scales (VAS) of fatigue and arousal as an index of subjective condition before, immediately after exhaustive exercise, and after MRI task. The participants were divided into two groups: impaired executive function with prolonged interference time group (impaired group) and enhanced executive function with shortened interference time group (enhanced group).

RESULTS: The Stroop interference time was significantly prolonged in the impaired group and shortened in the enhanced group. There is no difference in maximal oxygen consumption, ventilation, heart rate, and time to exhaustion during exercise between the impaired and enhanced group. The impaired group exhibited a significant increase activation of meddle frontal gyrus region, whereas brain activation did not change before and after the exhaustive exercise in enhanced group. The VAS of fatigue score increased immediately after exhaustive exercise in both groups and decreased after MRI task only in the enhanced group. The VAS of arousal score decreased after MRI task in the impaired group, whereas it did not change in the enhanced group.

CONCLUSION: We demonstrated that delay of fatigue recovery and decrease in arousal status induced by exhaustive exercise increased activities of the middle frontal gyrus and slowed executive response. The findings of the present study suggest that the changes in subjective conditions including fatigue and arousal status and brain activation pattern may be contributed to impair executive function.

PERFORMANCE ANALYSIS OF AN ELITE-LEVEL E-CYCLING COMPETITION

MILLOUR, G., DOREL, S., VARESCO, G.

UNIVERSITÉ DE NANTES

INTRODUCTION: E-cycling is an emerging discipline that became particularly popular during the COVID-19 pandemic [1]. Despite the increasing interest of national and international federations, the performance-specific characteristics of a high-level E-cycling competition remain to be elucidated. In the present study, we evaluated the performance and characteristics of athletes competing in the first French national championship of E-cycling.

METHODS: The competition took place in February 2023 in an indoor stadium with 46 participants, which was the largest face-to-face E-Cycling event ever organized. The event was performed on the Zwift platform (https://www.zwift.com). The

cyclists used their own bike and the same power trainer (Wahoo KICKR V6, Wahoo Fitness, Atlanta, United States). They were divided into categories A, B or C based on their past performance, and competed in two races (22 km and 21 km), separated by 15 min. For the present study, we analyzed the performance of seven male athletes competing in the first category (A, 66 ± 6 Kg, 1.75 ± 0.03 m, 31 ± 12 years old) and seven male athletes competing in the second category (B, 72 ± 5 Kg, 1.77 ± 0.05 m, 45 ± 11 years old). We compared personal best records of 15 s, 5 min and 20 min over the last 3 months (virtual) and the percentage of their personal bests during the races.

RESULTS: Personal best records normalized to body mass were greater for category A than category B athletes (15 s: 12.7 ± 2 vs. 9.8 ± 1.9 W/kg; 5 min: 5.5 ± 0.6 vs 4.6 ± 0.4 W/kg; 20 min: 4.8 ± 0.4 vs 4.1 ± 0.3 W/kg; all $p < 0.05$). Work was greater in race 1 (7.3 ± 0.7 kJ/kg) than race 2 (5.4 ± 1.6 kJ/kg, $p < 0.001$) and in category A (7.0 ± 1.0 kJ/kg) than category B (5.8 ± 1.7 kJ/kg, $p = 0.03$). Performance that was expressed as percentage of the personal best showed no effect of category for all time intervals considered. Lower performance was systematically observed in race 2 over a period of 5 min (95 ± 8% vs 85 ± 8%, $p = 0.004$) and 20 min (92 ± 9% vs 83 ± 6%, $p = 0.001$) but not 15 s (83 ± 14% vs 74 ± 11%, $p = 0.09$).

CONCLUSION: Overall, performance during the second competition was lower compared to the first one. This was probably due to the effect of fatigue cumulated in the first competition which can affect the ability to produce high levels of power output. Athletes in category A were younger and showed better performance than category B athletes, both in terms of personal bests and performance during the race (work). However, the two groups showed a similar performance during the races when expressed in percentage of their personal bests measured in similar conditions (E-cycling). These results could be useful to inform coaches and E-cycling race organizers.

PERFORMANCE ANALYSIS OF WOMENS EPEE IN THE 2017-2019 WORLD FENCING CHAMPIONSHIPS

HSU, J.T., CHEN, Y.H.

NATIONAL TAIWAN SPORT UNIVERSITY

INTRODUCTION: Various factors can impact how fencers score, including the use of techniques in different locations of the piste, and different rounds and status (leading, even, or losing) of the match. Performance analysis in sports, especially on elite players, could provide insights on how to win a match as well as how to design the training to improve the performance.

METHODS: This study examined the performance of elite female epee fencers during the matches from top 16 to final in 2017-2019 world fencing championships (including 1840 scoring events from 90 fencers in 45 matches) using notational analysis on videos downloaded from official website of the International Fencing Federation (FIE) in YouTube. Three- or two-way repeated measures ANOVAs were used to investigate the effects of aforementioned factors and their interactions, and three- or two- way mixed-design ANOVAs were used to further examine these effects of winners and losers respectively.

RESULTS: Fencers scored the most at the 2nd round during the match, replicating the previous findings. This might reflect that they became more aggressive only after they were familiar with the profile of the opponent that they obtained from the 1st round. When the winner was Whereas in the end area, attack, counterattack, and defensed were all used more often than other skills. Conversely, there were no specific techniques used at any area of the piste for loser no matter in leading or losing status. These results show that winners had their own strategies to use specific techniques on specific location of the piste for specific situations to achieve the final victory. leading in the match, the piste of her own side was the main area she moved and scored. Specifically, in the central area, attack was used more often than defense and other skills. In the middle area, attack and counterattack were used more often than defense and other skills.

CONCLUSION: In sum, our findings provide empirical evidence of how elite fencers manipulate their techniques on the piste to create and maintain leading status till the final victory. Such information could be useful to coaches for designing training program and giving suggestions to fencers during the match.

SINGLE AND MULTI-PUNCH PERFORMANCE ANALYSIS IN BOXING

CHENG, S.H., LIU, Y.T.

NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: Boxing is a combat sport where hitting the opponent with quality blows and demonstrating fight dominance is key to claiming victory. Research has shown that in boxing, though the total number of punches were similar, winners had a higher ratio of effective punches and a lower ratio of air punches than losers [1]. Attacks can be performed as a single- or a multi-punch combination. Due to the high fitness demand of the multi-punch combinations, we hypothesized that the number of multi-punch combinations would be reduced over the progression of the rounds, and winners would have more multi-punch combinations than the losers. The study was to examine the effects of the round and outcome of the bouts on the attacking performance.

METHODS: Eight bouts of the quarterfinals of the 71kg division from 2021 AIBA (Association Internationale de Boxe Amateur) Men's World Boxing Championships were analyzed. Two observers used the Simi Scout notational analysis system to record timing of all punches for each boxer. All recorded punches were further separated into single punch and multi-punch based on the recorded intervals between punches. Cohen's Kappa for the average inter- and intra-observer relia-

bility tests were 0.74 and 0.77. The total number of attacking movement, single punch, and multi-punch combinations were analyzed using round (3) × outcome (2) repeated measure ANOVA.

RESULTS: There was a significant round effect on the number of single punches F(2,14)=4.05, p=.04, with decreasing values over the 3 rounds, (24.19, 19.50, 18.88). The outcome effect on the number of single punches was not significant, F(1,7)=7.48, p=.06, with a lower mean value for the winners (17.2) than the losers (24.5). For the number of the multi-punch combinations, the outcome effect was not significant either, F(1,7)=4.83, p=.06, with a higher mean value of 22.2 than the loser's 17.3. The round effect was not significant, F(2,14)=2.23, p=.14. For the total number of attacking movement, although the effect of the round did not reach the significant level, F(2,14)=3.10, p=.08, the mean values showed a decreasing trend over the 3 rounds (44.3, 41.3, 36.3). There was no outcome effect on the total number of attacking movements, F(1,7)=0.38, p=.56.

CONCLUSION: Boxers performed fewer single punch attacks as rounds progressed, whereas multi-punch combinations did not vary significantly. Although the statistical analyses for the outcome variable did not quite reach the significant level (ps = 0.6), with the large effect size (partial eta squared ≥ 0.41), the results seem to suggest that winners had more multi-punches and less single punch attacks than losers. More data from boxing bouts should be recorded and analyzed to substantiate the current findings.

DETECTING PUNCHES FROM MULTI-VIEWS VIDEOS DATA FOR PERFORMANCE ANALYSIS IN ELITE BOXING

VITEL, V., TALBI, I., SCHORTGEN, A., GOYALLON, T., SAULIERE, G., MOUSSA, I., REVERET, L., BREZEPHIN, L.

IRMES - INSEP - UNIVERSITÉ DE PARIS, INRIA - LJK - LOKI - ZENITH, FÉDERATION FRANCAISE DE BOXE

INTRODUCTION: The quantification of punches thrown and received by a boxer is a key performance indicator to assess boxing activity [1]. More than a scoring factor, hit quantification allows to evaluate the physical load endured, which is essential for injury prevention [2]. Manually counting punches is a tedious and time-consuming annotation workload. To overcome this challenge, we have developed an automatic method for punch recognition from videos.

METHODS: To build our training dataset, we recorded 21 rounds of 3 min between elite boxers with 11 synchronized and calibrated cameras (Qualisys Miqus 60 fps, Full HD) distributed around the ring. For each point of view, we used a 2D pose estimator [3] to extract the body joint positions of both boxers at each frame in image coordinate system. The 2D skeletons are tracked and triangulated to avoid 2D issues (i.e. occlusions, depth estimation). In addition, 2508 punches were manually annotated at the exact frame of impact. We designed a temporal Convolutional

Neural Network [4] with Long Short Term Memory architecture to integrate spatial and temporal features tied to the action. The model outputs a hit probability for each frame throughout the video which allows to identify punch events with a 25 frames buffering sequence.

RESULTS: We obtain an accuracy of 93.2% and an F1-score of 93.3% on our validation set. Our model's predictions showed a significant impact of parameters like the number of joints and the sequence length. For each boxer, our model creates a playlist containing video clips of all the detected punches. It can be used for a first analysis by coaches, and will help us to expand our dataset. Based on fist speed, we also identify which of the boxer's arms is used to deliver the punch which gives additional qualification of the punches (unknown beforehand).

CONCLUSION: Our model quantifies punches thrown and received by a boxer with a good accuracy from multi-views feed. However, some detection errors persist due to specific gestures such as feints and combinations. Future work will focus on enriching our analysis by performing strike classification (i.e feints, hooks, jabs, uppercut), improving the model accuracy and deploying this approach inside the French Boxing training center. We aim to couple this automatic strike detector with more features such as impact zone or fist acceleration magnitude.

YOUNG PERFORMANCE DETERMINES THE ADULTHOOD PERFORMANCE ? A PARAMETRIC AND NON-PARAMETRIC MARKOVIAN MULTI-STATE DEVELOPMENT MODEL IN FRENCH ALPINE SKIING

DELAROCHELAMBERT, Q.

IRMES

INTRODUCTION: Estimating the potential of alpine skiers is an unresolved question, especially because of the complexity of sports performance. Yet, an unsolved question is : the best performers at young age will be the best ones when they get older ? Our study aims to objectify this problem and to determine the influence the rate of progression on skier's future performance.

METHODS: The population studied included all French alpine skiers having participated in at least one competition in Slalom (GS), between the age of 10 up to 30 from the 2004/2005 season up to the 2020/2021 season. We categorized the states of the model by five Performance Lanes (PL), defined as a categorisation of performances by age group .We modelled and estimated the probabilities of performance progression among French alpine skiers in slalom using parametric and non-parametric multi-state Markovian models and a time-inhomogeneous Markov chain to calculate future PL probability. , We calculated the rate of individual performance progression based on a Bayesian nonlinear mixed model and we estimated the impact of this rate of progression on the skiers future PL.

RESULTS: The probability to be the first PL (PL1, i.e highest performance by age) at 20 years old is rather similar among the skiers who were at the first or the last PL at 10 years old. These probabilities are more heterogeneous with age. The probability to reach the PL1 at 20 years old according the PL 1,2,3,4 and 5 at 15 years old are 0.13, 0.07, 0.04, 0.02, 0.01 respectively. At 12 years old, the rate of progression is a better estimator of future performance at 20 years old than the PL the skier is.

CONCLUSION: We show that at the youngest age , the probability difference for reaching the highest PL according to the starting PL are rather similarMeaning that performance at the youngest age are not a good predictor of future performance. Yet, such difference increases with age. We also showed that the rate of progression among the youngest is a better predictor of future performance than the skiers PL.

INFLUENCE OF NEUROMUSCULAR ACTIVITY AND TECHNICAL DETERMINANTS ON ROWING PERFORMANCE

PITTO, L., ERTEL, G.N., SIMON, F.R., GAUCHARD, G.C., MORNIEUX, G.

UNIVERSITÉ LORRAINE

INTRODUCTION: Studies (1) have described the relationships between technical determinants and rowing performance (defined as cycle-average boat velocity and power transferred to the oar), as well as activation patterns of upper body muscles (2,3). However, the dependence of rowing performance to muscle coordination has not yet been investigated. Knowing how muscle activity influences rowing performance could provide valuable information to trainers. The purpose of this study was to correlate rowers' performance i) with the neuromuscular activation of upper body muscles and ii) with the main technical determinants of rowing on water.

METHODS: Eleven male rowers performed three bouts of 15 strokes on a single scull at their own competitive stroke rate (32.8±2.3spm). Boats were equipped with Peach system (Peach Innovations, UK), collecting oar's forces and angles as well as boat velocity. Subjects were equipped with surface EMG (Trigno, Delsys, USA) to measure 13 trunk and arm muscles. Normalized EMG RMS were calculated over eight equal intervals of the drive phase. Linear mixed effect models were fitted to investigate the effects (i.e. the amount of performance explained by the linear model using the group average value of the predictor) of technical determinants and the neuromuscular activity in each interval of the drive phase on the rowers' performance.

RESULTS: All intervals in the drive phase had at least one muscle whose activity was significantly correlated to boat velocity and oar power. For example, during the first interval after catch, 11 muscles had a significant effect on velocity (highest effect: 0.11m/s flexor carpi; average trunk flexors (TF): 0.08m/s; average trunk extensors (TE): 0.04m/s); and six with oar power (highest effect: 39.1W biceps brachii; TF: 22.6W; TE: not significant). For the interval between 50 and 62.5% of the drive phase, i.e. during the peak power interval, 8 muscles had a significant contribution to boat velocity (highest effect: 0.07m/s brachioradialis; TF: 0.06m/s; TE: -0.05m/s) and 9 to oar power (highest effect: 34.2W gluteus maximus; TF: -22.0W; TE:24.4W). The largest effects of technique on boat velocity were: 2.4 m/s for the oar stroke min-to-max angle; 1.0 m/s for oar power and -0.4 m/s for time to peak oar power.

CONCLUSION: We evaluated the relationship between muscle activity and boat velocity for 13 muscles in the upper body. Increased activations in arm muscles and trunk flexors immediately after catch had a positive effect on boat velocity and oar power, indicating a more efficient power transfer to the oars. On the other hand, at mid drive phase, increased trunk flexors and reduced extensors activations were associated to higher velocities, but lower oar powers. This might indicate that techniques that maximize power production might not be the ones that maximize velocity.

CLASSIFICATION OF MIDDLE- AND LONG-DISTANCE RUNNERS BASED ON THEIR COMPETITION RESULTS

ILJUKOV, S.

UNIVERSITY OF HELSINKI

INTRODUCTION: The scientific literature lacks consensus on classification of middle- and long-distance runners. Many terms are used to describe the proficiency level of athletes. This creates situations where the sample studied may not represent the target population and could produce misleading results. Thus, we present an approach for a data-driven classification of middle- and long-distance runners according to their competition results.

METHODS: The best annual results of middle- and long-distance track runners participating at major (Olympics, World and European Championships) and national championships (Denmark, Sweden, Finland, Norway) were gathered for the

2012–2018 period. The results were grouped accordingly. Quadratic discriminant analysis was applied to define the limits between the groups.

RESULTS: Three basic categories could be proposed for classification: world class, international and national. The performance-based approach for classification provide value necessary for population descriptions in scientific research and elsewhere. Classification provides a realistic overview on performance standards and the number of athletes for different categories in middle- and long-distance track running in real-world settings.

CONCLUSION: The developed classification has the potential to improve the quality of scientific research and has applications in the effective planning of anti-doping testing. The present classification may further require regular upgrades to meet the demands of the constantly changing sport.

PACE STRATEGY IN THE 1500M SWIMMING IN TOKYO 2021

RUSSOMANNO, T.

TECHINICAL UNIVERSITY OF MUNICH / UNIVERSITY OF BRASILIA

INTRODUCTION: The ideal pace strategy (PS) in competitive long-distance swimming is not widely known in the literature but in generally is represented by U-shaped curve(Lara and Del Coso, 2021), indicating that professional long-distance swimmers have a fast pace in the first 100m and again another fast pace in the final meters of the race, while most of the entire race they keep the speed constant with small fluctuations. Nevertheless, there is no agreement on how the pace strategy determines the winners in a 1500 m competition, thus, the aim of this study is to analyze the performance of Olympic Games finalists in the mens 1500-meter freestyle race over the last Olympic games in Tokyo 2021 and identify the pace strategy most used by the best swimmers in the 1500 m.

METHODS: The sample of the study was collected from public data files available at FINA (Fédération Internationale De Natation) website(www.fina.org). Lap times (every 50 m) of the athletes (n = 8) finalists of the Olympic Games Tokyo 2021 were used in this study. To evaluate the athletes pace strategies, descriptive statistical analysis of the laps was done (mean, standard deviation, coefficient of variation) together with boxplots of the laps. T-test evaluate the difference from the first third of the race to the second and final third of the race (500m splits), Wilcoxon-Signed Ranks test was performed when the data did not present a normal distribution. The times at each 250 m were also compared with the following split times (250, 500, 750,1000,1250, and 1500 m), to assess which sections of the race were statistically different. The Friedman test with Bonferroni post hoc correction was used for $p < 0.003$. These tests were run on SPSS 27 software.

RESULTS: The results found were a parabolic race strategy (U-shaped) performed by all athletes, where the partial velocities as a function of time show an acceleration at the beginning of the race (250 m) followed by a maintenance of the speed in the middle part of the race (250 to 1250 m) and finally an increase in their accelerations in the final part of the race (1250 to 1500 m) characterizing a final sprint.

CONCLUSION: From the data analyzed it was identified U-shaped curve pace strategy profile used by all the athletes analyzed in this study. Most likely the fast pace in the beginning is related to the use of starting Blocks (diving start). A plausible explanation for athletes to assume a slower rhythm after some meters is related to a model of tele-anticipation, where the swimmer wants to save energy so that afterwards a final sprint can be performed.

From the practical aspect the U-shape PS is the best strategy so far (as we know) and should be used in training to improve performance of young athletes.

Some limitations of the study, only finalist were analyzed, so maybe different PS can be adopted in other heats before the finals.

Stroke rate and stroke length was not measured, this may help to understand whats within the PS in long distance events.

CP-MH20 Health and Fitness II

LONGITUDINAL DATA ANALYSIS INVESTIGATING THE INTERELATIONSHIP BETWEEN AIR POLLUTION, LUNG FUNCTION, AND THE ROLE OF PHYSICAL ACTIVITY AND ASTHMA STATUS IN CHILDREN AGED 5 - 18 YEARS.

GUDZIUNAITE, S.

SWANSEA UNIVERSITY

INTRODUCTION: Children are more susceptible to air pollution due, at least in part, to their less developed respiratory systems and higher respiratory rates. Whilst the health benefits associated with physical activity are indisputable, there is considerable debate regarding whether the increased exposure to, and deeper inhalation of, air pollution while being physically active negates such health benefits. The purpose of this study was to explore the relationship between air pollution and lung function, and the role of asthma status and physical activity in this relationship, in children and adolescents across different seasons throughout the year.

METHODS: A 9-month longitudinal study was conducted with 18 children (7 boys), 6 with a history of asthma. Seven-day, device-based physical activity levels were measured alongside spirometry and 30 day air pollution levels. Specifically,

outdoor air Pollution data (PM2.5 - PM10, NO2, and O3) was gathered from the Automatic Urban and Rural Network (AURN) whilst indoor air pollution data was collected using Dylos monitors (PM2.5 - PM10). Time series analysis were used to assess the temporal associations between lung function, physical activity and air pollution.

RESULTS: Children's physical activity levels were greatest during rush-hour and break-times, therefore, amplifying their exposure to air pollutants. However, no relationship between air pollution and lung function was found, irrespective of physical activity levels or timing.

CONCLUSION: The current results contrast previous findings of a three day lag in the relationship between air pollution and lung function. This may indicate that the influence of air pollution is lower in youth populations, or that the exposure to air pollution in the current study was relatively low. The lack of influence of physical activity is encouraging, suggesting that the benefits of physical activity are unabated by air pollution exposure, at least in terms of lung health.

EFFECTS OF NORDIC WALKING TRAINING ON FUNCTIONAL STATUS, PERCEIVED FATIGUE, AND QUALITY OF LIFE IN PEOPLE WITH MULTIPLE SCLEROSIS

LIBERALI, G.1, PEYRÉ-TARTARUGA, L.A.2, CORREALE, L.1, MARTINIS, L.1, DELL'ANNA, S.1, PASSOS-MONTEIRO, E.3, FEIJÓ-MARTINS, V.2, MACHADO, F.A.4, TAVAZZI, E.5, BERGAMASCHI, R.5, BUZZACHERA, C.F.

1 UNIVERSITY OF PAVIA, ITALY; 2 FEDERAL UNIVERSITY OF RIO GRANDE DO SUL, BRAZIL; 3 FEDERAL UNIVERSITY OF PARÁ, BRAZIL; 4 STATE UNIVERSITY OF MARINGÁ, BRAZIL; 5 IRCSS C. MONDINO, ITALY.

INTRODUCTION: Multiple sclerosis (MS) is a chronic neurologic disease of the central nervous system. The clinical manifestations of MS are well documented and include sensory, motor, cerebellar, or visual system abnormalities. Pharmacologic approaches are commonly used to manage such symptoms experienced by persons with MS. Non-pharmacologic interventions, such as exercise training, are also helpful as behavioral approaches for managing clinical manifestations of the disease with minimal side effects. Nordic Walking (NW) has recently emerged as a safe and effective non-pharmacologic intervention for patients with neurologic disease and consists of walking with hand-held poles. Despite their growing popularity, the effects of NW have not been examined in the MS population. Therefore, the aim of this study was to investigate the effects of an 8-week NW training intervention on measures of functional status, perceived fatigue, and quality of life in people with MS.

METHODS: A group of men (n = 4; mean age: 40 ± 10 yrs.; mean BMI: 22.9 ± 2.7 kg.m2) and women (n = 5; mean age: 38 ± 4 yrs.; mean BMI: 24.4 ± 2.7 kg.m2) with definite relapsing-remitting MS participated in this quasi-experimental study. Key eligibility criteria included age 18-60 yrs. and EDSS score <4. All participants trained twice a week for 8 weeks, and before and after the intervention period, measures of aerobic endurance (two-min walk test), upper- (handgrip) and lower-body (30-sec chair stand test) muscle strength, gait speed (10-m walk test), and overall functional mobility (timed up and go test) were tested. Fatigue perceived and quality of life were also assessed using the Italian versions of the Modified Fatigue Impact Scale (MFIS) and the MS Quality of Life Questionnaire (MSQOL-29). Data were analyzed using paired t tests with the alpha level set at 0.05.

RESULTS: All participants completed the training program, with an adherence rate > 80%. Following the NW training regimen, upper-body muscle strength, gait speed, and overall functional mobility remained unchanged from baseline values ($P > 0.05$). However, significant improvements were observed for both lower-body muscle strength ($t8 = -4.919$; $P < 0.01$) and aerobic endurance ($t8=-4.944$; $P < 0.01$). A trend for improved perceived fatigue was also noted ($P = 0.09$), while the quality of life did not change over time ($P > 0.05$).

CONCLUSION: According to the results of this study, it seems that an 8-week NW training intervention may have positive effects on aerobic endurance and lower-body muscle strength, with plausible benefits on perceived fatigue. Although preliminary, such findings might have important clinical implications for the management of MS.

EFFECTS OF 3-MONTH AEROBIC EXERCISE AND TAI-CHI CHUAN EXERCISE INTERVENTIONS ON MOTOR AND NON-MOTOR FUNCTIONS IN PARKINSONS DISEASE: A PRELIMINARY STUDY

CHANG, C.L., TSAI, C.L., WANG, T.C.

NATIONAL CHENG KUNG UNIVERSITY

INTRODUCTION: Parkinson's disease (PD) is a progressive, neurodegenerative disease with the characteristic of movement disorder (e.g., balance and gait problems) and non-motor symptom (e.g., cognition impairment). Exercise plays an important role in PD management and the improvement in motor status and cognition function through physical activity has been highlighted in recent studies [1, 2]. The aim of this study was to compare the different effects of Tai-chi chuan and aerobic exercise on the clinical motor status and neurocognitive performance in patients with PD.

METHODS: Twenty-eight participants with early-stage PD were recruited and randomly divided into three groups: aerobic exercise (AE), Tai-chi chaun exercise (TE), and control (C) groups. During the 3 months of the intervention period, participants in the AE group attended three 30-minute exercise sessions per week, with the exercise intensity corresponding to 50-65% of the individual target heart rate reserve. The TE group were trained in a series of 60-minute sessions that took place two times per week. The C group maintained their sedentary lifestyle. Participants' clinical motor performance was examined using Unified Parkinson Disease Rating Scale (UPDRS). Neuropsychological [e.g., accuracy rate and reaction times (RTs)] and neurophysiological [e.g., event-related potential (ERP) P3 latency and amplitude] parameters were to assess their neurocognitive functions when performing a delay matched S1-S2 paradigm. To minimize the potential for a medication cycle bias, all assessments were performed during their "on" state.

RESULTS: Compared to the pre-test, the control group showed significantly smaller ERP P3 amplitude in the post-test (p=.04). Compared to pre-test, the TE group exhibited faster RTs (p=.02) while the AE group scored lower UPDRS scores (p=.006) after 3 months of exercise interventions. The ERP P3 amplitudes only approached pre- and post- intervention significance (p=.06) in the TE group.

CONCLUSION: The motor status and neuropsychological (e.g., RTs) performance could be enhanced through different regular exercise modes in patients with PD. However, the neurophysiological performance (e.g., ERP P3 amplitude) might be deteriorated when they maintained sedentary lifestyle. The present findings suggested that the neuroplasticity could still be ameliorated by chronic exercise interventions in patients with PD with stages I and II.

ASSESSMENT OF AEROBIC CAPACITY AND MUSCLE STRENGTH OF CHRONIC KIDNEY DISEASE, HEMODIALYSIS PATIENTS AND AFTER KIDNEY TRANSPLANT

DZIUBEK, W.1, ROGOWSKI, L.2, GOLEBIOWSKI, T.3, KUSZTAL, M.3, PAWLACZYK, W.4

1. WROCLAW UNIVERSITY OF HEALTH AND SPORT SCIENCES,WROCLAW; 2.THE WITELON COLLEGIUM STATE UNIVERSITY,LEGNICA; 3.WROCLAW MEDICAL UNIVERSITY,WROCLAW; 4. LOWER SILESIAN ONCOLOGY CENTER, WROCLAW

INTRODUCTION: Chronic kidney disease (CKD) is a disease process in which the function of the kidneys is impaired and leads to renal failure due to progressive nephrons destruction. The progression of this disease leads to end-stage renal disease (ESRD) and renal replacement therapy: hemodialysis (HD) or kidney transplant (KTX). The complicated clinical state of those patients strongly impacts their physical activity and exercise tolerance. Information about changes in physical capacity in CKD and KTX patients are limited, hence interventions to improve exercise tolerance are not standard care. Therefore there is a need to establish "easy to carry out" tests for health professionals and expand the knowledge of physical status in this group of patients. The study aimed to assess aerobic capacity and muscle strength in CKD and TKX patients with selected tests.

An additional aim of the study was to determine the dependence of the obtained results from the stage of kidney failure and after kidney transplantation in the examined patients.

METHODS: The study included 333 patients: 111 hemodialysis patients (stage V) - group 1; 120 patients with CKD in stages I–IV - group 2; 102 patients after a kidney transplant - group 3. The mean age was 54.7 +/- 15.6 years, divided into groups according to the stage of progression of the disease and patients after kidney transplant. In three groups, the following tests were performed: evaluation of physical activity tolerance using a six-minute walk test (6MWT), 2-Minute Step in Place Test (2MSPT), hand grip strength test (HG), sit-to-stand test (STS), timed up and go test (TUG), the assessment of subjective fatigue was determined by the Borg scale. Hemodynamic parameters were measured before and after those tests (6MWT, 2MSPT, STS, TUG). Statistical significance was determined at the level of $p<0.05$. The Statistica 13.1 was used.

RESULTS: Kidney transplant patients have a higher exercise tolerance than patients with end-stage renal disease. KTX patients have a lower tolerance for physical activity based on a 2-MSPT than patients with CKD in Stages I-IV, but contrary higher physical activity tolerance based on 6MWT. Patients in Stages I-IV of CKD have a higher tolerance for exercise than ESRD patients. There is a correlation between hand grip strength, lower limb strength and exercise tolerance in CKD and KTX patients. However, in HD patients, those results do not show any significant relationships.

CONCLUSION: A two-minute walk-in-place test can be used as an alternative to the six-minute walking test to assess exercise tolerance in CKD and KTX patients. In all groups (I, II, and III) the correlations of results of 2MSPT and 6MWT were statistically highly significant.

TEST-RETEST RELIABILITY OF CARDIOPULMONARY EXERCISE TESTING IN PATIENTS WITH ATRIAL FIBRILLATION

TERADA, T., REED, J.L.

UNIVERSITY OF OTTAWA HEART INSTITUTE

INTRODUCTION: Cardiopulmonary exercise testing (CPET) is the gold-standard measure of cardiorespiratory fitness (CRF). In patients with cardiovascular disease, CPET has been used to assess the risk of morbidity and mortality, prescribe individually tailored exercise interventions, and determine the effectiveness of exercise interventions. In patients with atrial fibrillation (AF), however, the complex presentation of disabling AF-related symptoms (e.g., palpitations, dyspnea, and dizziness) combined with medications to control heart rate (HR) may influence day-to-day exercise performance. This study evaluated the test-retest reliability of symptom-limited CPET in patients with AF.

METHODS: A subset of patients with persistent and permanent AF completed two baseline CPETs on a cycle ergometer as part of a clinical trial (OPPORTUNITY). The first CPET (CPET1) was completed by cardiac stress technologists in the Department of Cardiac Imaging, whereas the second CPET (CPET2) was completed by the research team. The intraclass correlation coefficient (ICC) based on a two-way mixed-effects model was used to examine the degree of consistency between the two tests, and minimal detectable difference was calculated. The ICC was classified as follows: <0.5 as poor, ≥0.5 and <0.75 as moderate, ≥0.75 and <0.9 as good, and ≥0.9 as excellent. Paired t-tests were used to determine the systematic bias between the two CPETs.

RESULTS: Data from 27 individuals with diagnosed persistent or permanent AF (persistent: 44.4%, mean age: 69 ± 7 years, female sex: 29.6%, beta-blockers: 70.4%) were analyzed. CPETs were conducted on two separate occasions within 14 ± 11 days. The peak VO2 (VO2peak) were 18.5 ± 5.7 and 18.3 ± 5.4 mL/kg/min for CPET1 and CPET2, respectively (p=0.774). The ICC for VO2peak was excellent (ICC=0.907, 95% CI 0.792-0.958). The minimum detectable difference for VO2peak was 4.6

mL/kg/min. The ICC for peak power output (PPO, ICC=0.796, 95% CI 0.545-0.909) and highest rating of perceived exertion (RPE, ICC=0.795, 95% CI 0.389-0.931) were good but CPET2 showed significantly greater PPO (135 ± 37 vs. 174 ± 41 Watts, P<0.001) and RPE (16 ± 4 vs. 18 ± 2 points, p<0.001). Peak HR, power output and HR at ventilatory threshold showed poor ICC (i.e., <0.5).

CONCLUSION: Our result showing excellent ICC (i.e., > 0.9) of VO2peak supports the use of this measure to capture changes in CRF over time in patients with AF. When CPETs are completed by different testers, changes in CRF of 4.6 mL/kg/min may be needed to be 95% confident that observed changes in VO2peak is beyond test-retest variability. PPO is often used for exercise prescription. However, our results showed a significant difference between the two tests. Caution is warranted when prescribing exercise intensity to patients with AF based on PPO. The high variability in HR and RPE observed in this study may be due to a condition unique to AF.

EFFECTS OF INTRADIALYTIC COGNITIVE AND AEROBIC EXERCISE TRAINING IN HEMODIALYSIS PATIENTS: RANDOMIZED CONTOLLED STUDY

BOGATAJ, S., KURNIK MESARIC, K., KREN, A., PAJEK, M., PAJEK, J.

UNIVERSITY MEDICAL CENTRE LJUBLJANA

INTRODUCTION: Hemodialysis (HD) patients have lower cognitive functioning and reduced physical fitness compared to age-matched healthy individuals [1,2]. Clinicians typically do not recognize the declining cognitive performance in these patients; therefore, cognitive impairment is greatly underestimated and not appropriately treated [3]. This study aimed to evaluate the impact of combining cognitive training with physical exercise on cognitive function and physical performance in HD patients.

METHODS: Using a randomized, single-blinded control design, forty-four HD patients were recruited from University Medical Centre Ljubljana. Participants were randomly assigned to either an intradialytic physical exercise and cognitive training program (EXP group; n = 22; age = 65.7 ± 9.7 years) or a standard care control group (CON group; n = 22; age = 67.2 ± 12.5 years). The EXP group performed intradialytic aerobic exercise (approximately 30 minutes of cycling) and cognitive training three days per week for 12 weeks. Cognitive training was performed on the CogniFit platform on tablets. The primary outcome of the study was performance on the Alertness subtest of the computerized Test of Attentional Performance. Secondary study outcomes were: Symbol Digit Modalities Test (SDMT), Montreal Cognitive Assessment (MoCA), 10-repetition sit-to-stand test (STS10), Timed Up and Go test (TUG), and TUG dual task.

RESULTS: At baseline, Alertness scores were 391.23 ± 117.39 ms in the EXP group and 424.41 ± 211.65 ms in the CON group (p=0.067). Alertness score decreased in the EXP group after 12 weeks (347.95 ± 93.5 ms) and increased in the CON group (454.86 ± 235.99 ms), with a significant group x time interaction (p=0.017). In addition, the results showed a significant interaction effect for SDMT (p < 0.001), MoCA (p < 0.001), TUG (p = 0.005), and TUG dual task (p = 0.006) in favor of the EXP group. Moreover, no interaction was observed for STS10 (p = 0.530).

CONCLUSION: Our findings suggest that incorporating intradialytic cognitive and physical exercise training could help to improve functional status of HD patients. The innovative, nonpharmacological, bimodal intervention is cost-effective, safe, and easy to implement during the intradialytic period and has a potential impact on patients quality of life and well-being.

A SINGLE CHEMOTHERAPY ADMINISTRATION IS SUFFICIENT TO INDUCE MITOCHONDRIAL ALTERATIONS IN SKELETAL MUSCLE OF EARLY BREAST CANCER PATIENTS

MALLARD, J., HUCTEAU, H., BENDER, L., MOINARD-BUTOT, F., SCHOTT, R., PFLUMIO, C., TRENSZ, P., KALISH-WEINDLING, M., CHARLES, A.L., GÉNY, B., FAVRET, F., PIVOT, X., HUREAU, T.J., PAGANO, A.F.

INSTITUT DE CANCÉROLOGIE STRASBOURG EUROPE / UR 3072

INTRODUCTION: Breast cancer is mainly treated with chemotherapy (CT). This treatment induces severe side effects including skeletal muscle deconditioning, characterized by structural and functional alterations that impair exercise capacity. In a recent study (1), we identified that mitochondrial homeostasis was severely impaired in patients after the whole CT treatment completion (~4 months). However, studies conducted in preclinical models also reported major acute alterations following only one CT administration (2). Identifying these acute muscle alterations in patients is necessary to provide tailored preventive strategies. Thus, this study aimed to investigate acute mitochondrial alterations in skeletal muscle of breast cancer patients after a single CT administration.

METHODS: Ten early breast cancer patients undergoing epirubicin-cyclophosphamide-based CT treatment were included. Muscle biopsies from the vastus lateralis muscle were performed before and four days after the first CT administration. Mitochondrial respiratory capacity recording and western blotting analyses were performed.

RESULTS: Four days after the first CT administration, a large decrease in mitochondrial content markers was observed, as evidenced by a decrease in both citrate synthase (-49%; p=0.04) and VDAC (-41%; p=0.02) protein levels. We also found alterations in key markers of mitochondrial dynamics. Indeed, we reported a decrease in OPA1 protein levels (-70%; p=0.02) as well as an increase in DRP1 protein levels (+139%; p=0.03), reflecting potential alterations in fusion and fission processes, respectively. We then explored the mitophagy process through the quantification of PINK1 and Parkin proteins and found substantial reductions in their expression (-63%; p=0.02 and -58%; p=0.02, respectively). As a possible consequence of these alterations, mitochondrial respiration capacity was also reduced, as evidenced by a reduction in the complex I (CI) linked substrate state (-32%; p=0.02), the oxidative phosphorylation by CI (-33%; p=0.04) and by CIV (-23%; p=0.02). Finally, apoptosis pathway might be upregulated as we documented a large increase in the Bax/Bcl-2 ratio (+3786%; p=0.03).

CONCLUSION: A single CT administration substantially decreased mitochondrial content and function in skeletal muscle of breast cancer patients. Our study emphasizes the need to implement specific preventive strategies early (i.e., from the initiation of the treatment), such as exercise training and/or nutritional supplementation.

EFFECT OF ACUTE AEROBIC EXERCISE BEFORE IMMUNOTHERAPY AND CHEMOTHERAPY INFUSION IN PATIENTS WITH METASTATIC NON-SMALL-CELL LUNG CANCER: ERICA FEASIBILITY TRIAL

GOUEZ, M., PIALOUX, V., PEROL, M., PEROL, O., DELRIEU, L., CAUX, C., WALZER, T., FERVERS, B.

UNIVERSITÉ DE LYON / CENTRE LÉON BÉARD

INTRODUCTION: Data suggest that exercise could improve immune responses against cancer cells by increase immune cell infiltration to the tumor and potentially having an impact on disease progression. Additionally, there are data to suggest that infiltration of T and NK cells into the tumor microenvironment is correlates with response to immune checkpoint inhibitors (immunotherapy) in patients. We have therefore initiated the clinical trial ERICA to investigate if an aerobic physical exercise performed just before immuno-chemotherapy can increase treatment efficacy in metastatic lung cancer patients.

METHODS: ERICA (NCT04676009) is a randomized controlled trial (30 patients, 2:1) for patients with metastatic non-small cell lung cancer. Patients in the intervention arm, receive a 3-month program consisting of a supervised acute physical exercise session less that 15min prior to immune-chemotherapy infusion, and an unsupervised home-based walking program with an activity tracker. All patients will also receive standard oncological treatments; checkpoint inhibitors combined with chemotherapy and physical activity and nutrition recommendations. Primary outcome is feasibility of this innovant pre-treatment physical exercise administration. Secondary outcome is muscular strength and aerobic capacity measured by VO2 sub-max test, physical activity levels and quality of life measured by questionnaires, clinical outcomes and immune, inflammatory, metabolic, oxidative stress biomarkers and molecular profiling.

RESULTS: For now, 24 patients with metastatic non-small cell lung cancer (age 63±9 years, men 71%) was included, 16 in exercise group and 8 in control group. Of the 15 patients who ended the pre-treatment exercise program, 46% (7/15) completed all the exercise session planed and 87% completed > 85% of the program. All the data will be available in April 2023 (clinical, physical and biological data).

CONCLUSION: The ERICA study will provide clinical and physiological insights into feasibility of acute exercise prior immune-chemotherapy infusion in exercise in patients with metastatic non-small cell lung cancer. Data from ERICA geared to be informative regarding immune cell mobilization after an acute physical exercise.

BREAST CANCER PATIENTS WITH CANCER-RELATED FATIGUE PRESENT SPECIFIC ELECTROMYOGRAPHIC FEATURES DURING A FATIGUING EXERCISE FROM THE TIME OF DIAGNOSIS

CHATRENET, A., LECLERCQ, A., BOURGEOIS, H., COJOCARASU, O., RAHMANI, A., MOREL, B.

UNIVERSITÉ DU MANS

INTRODUCTION: Cancer related fatigue (CRF) is one of the most burdensome symptoms along cancer treatments. From a clinical point of view, CRF management remains challenging. At diagnosis, CRF concern about 50 % of patients suffering from breast cancer. At this time, anticancer treatments cannot be responsible of this symptom, and other etiologies remain to identify. It was established that performance fatigability may be a determinant of CRF. Electromyographic (EMG) dynamic (i.e., evolution of temporal or frequency domains) during fatiguing exercise can provide useful information regarding possible neuromuscular etiology. For example, mental load at cancer diagnosis could reduce motivation and/or increased central limitations in muscle recruitment. Thus, this study investigated the effect of CRF at diagnosis on EMG content during repeated isometric contractions of plantar flexor muscles.

METHODS: Neuromuscular fatigability was quantified on maximal force decrease of right plantar flexor muscles along with EMG recording of Gastrocnemius Lasteralis, Medialis and Soleus. A 5-min all-out exercise were realized, composed of 60 4-s maximal isometric contractions interspersed by 1-s recovery. EMG signals were analyzed in the time-frequency domain using a continuous wavelet transformation (CWT). Each CWT matrix was normalized using the total activity of the

first contraction, allowing analysis frequency changes independently of the EMG amplitude modifications. The mean of the first (PRE) and last (POST) 3 contractions was performed. Then, CWT matrices PRE-POST differences, i.e. fatigability effect, were compared between CRF (FA12>22) and non-CRF patients (FA12≤22) using a 2-dimensional statistical non-parametrical mapping (SnPM) analysis.

RESULTS: The study included 54 patients at cancer diagnosis, before chemotherapy treatments. In those included, the prevalence of CRF was 50% at baseline. No difference of fatigability was observed between CRF and non-CRF groups (47±14 % vs. 49±12 %, respectively). The SnPM analysis of relative CWT matrices reveals differences between groups. Patients presenting CRF symptoms manifested less spectrum energy in the frequency band 50-120 Hz during the first second of contraction. It was associated with a significantly reduced instantaneous median frequency on the same time-period.

CONCLUSION: Results showed that despite no difference in plantar flexors fatigability, CRF patients presented specific EMG features. Time-frequency transformation reveals a relative decrease in the energy spectrum content in the first second of contraction. This, associated to the reduced instantaneous median frequency in the fatigued group, may suggest an impairment in muscle activity at the initiation of the contraction. These results participate in understanding etiology of CRF at different step of anticancer treatments which remains challenging and worst of investigation.

THE IMPACT OF NUTRITION-PHYSICAL INTERVENTION ON GUT MICROBIOTA IN CHILD CANCER SURVIVORS

TKACIKOVÁ, M., KUBÁNOVÁ, L., HRIC, I., SMAHOVÁ SARVASOVA, S., KOLENOVÁ, A., BIELIK, V.

FACULTY OF PHYSICAL EDUCATION AND SPORT, COMENIUS UNIVERSITY IN BRATISLAVA

INTRODUCTION: The impact of changes in gut microbiota on etiology of acute lymphoblastic leukemia (ALL) in children has not been fully clarified. However, many researchers have dealt with this area in recent years. Considerable decrease in diversity of gut microbiota can last many years after the treatment is finished. The aim of this study was to evoke shift in gut microbiota in child cancer survivors by healthy diet, physical activity and supplementation of probiotics drinking fermented milk beverage with Lactobacillus Casei CNCM I-1518 and yogurt cultures and evaluate effectiveness of intervention.

METHODS: This study is focused on analysis of gut microbiota in child cancer survivors with ALL. Patients who participated in this study (n = 16) completed a program comprised of physical activity and nutritional changes lasting 8 weeks. The fecal microbiota was categorized using specific primers targeting the V3–V4 region of 16S rDNA.

RESULTS: We found a significant positive shift in the Shannon index ($p = 0.04$) after nutrition-physical intervention in child cancer survivors. Moreover, we evaluated a significant increase in relative abundance of genus Lactobacillus after drinking the milk beverage with probiotic cultures (Lactobacillus Casei CNCMI-1518).

CONCLUSION: The main findings from our study were positive changes in gut microbiota after 2-months exercise-nutrition intervention in child cancer survivors. We assume that the implementation of intervention can have a positive impact on the gut microbiota and the overall clinical state in child cancer survivors.

INFLUENCE OF COACHING ON EFFECTIVENESS, PARTICIPATION, AND SAFETY OF AN EXERCISE PROGRAM FOR POSTMENOPAUSAL WOMEN WITH OSTEOPOROSIS: A RANDOMIZED TRIAL

BRAGONZONI, L.1, BARONE, G.1, BENVENUTI, F.1, RIPAMONTI, C.2, LISI, L.2, BENEDETTI, M.G.2, MARINI, S.1, DALLOLIO, L.1, MAIETTA LATESSA, P.1, ZINNO, R.1, AUDINO, G.1, KEMMLER, W.3, PINELLI, E.1

1 UNIVERSITY OF BOLOGNA; 2 RIZZOLI ORTHOPAEDIC INSTITUTE; 3 FRIEDRICH-ALEXANDER-UNIVERSITY ERLANGEN-NÜRNBERG

INTRODUCTION: We compared two different strategies providing professional coaching to administer an exercise program for women with postmenopausal osteoporosis (POP): individual training (IT) at home with trainers supervision provided by telephone contacts at regular time-intervals or group training (GT) with trainers live supervision. Our working hypothesis was that IT is a valid alternative to GT when GT is not feasible.

METHODS: This was a single-blind, randomized study. We recruited 52 women with POP, without significant comorbidity, and no participation in any structured exercise program within the previous 6 months. They were assigned randomly to IT or GT groups (n = 26 each). Distribution of age (IT: 68±4, GT: 67±8 years) and body mass index (IT: 23.0±2.5, GT: 21.4±5.1) was similar between groups. Each group performed the exercise program in two 1-hour sessions per week for 18 months. Primary outcome measure was Health-Related Quality of Life (HRQoL), as measured by the Short Osteoporosis Quality of Life Questionnaire. Secondary outcome measures focused on domains acknowledged to influence HRQoL (disability, fear of falling, weekly physical activity, physical function) or the effectiveness of the exercise program (retention, adherence, and safety). Significance level was set at $p < 0.05$.

RESULTS: No significant differences were observed between IT and GT groups for any domain. Retention, adherence, and safety were also similar. HRQoL, disability and fear of falling did not change between baseline and follow-up for either

group. However, for both groups, physical function (knee flexion, shoulder mobility) and functional capacity (6-minute walking test) improved. Weekly physical activity levels increased from moderate range at baseline to intense at final assessment for both groups.

CONCLUSION: IT and GT supervised exercise programs for women with POP provide similar effectiveness, participation and safety. Hence, both modalities should be considered for future translation in clinical practice of exercise recommendations for POP.

COMPARISON OF BODY COMPOSITION AND BONE MINERAL DENSITY IN UNTRAINED ELDERLY AND MASTER ENDURANCE RUNNERS

STRELECKÝ, M.1, ORESKÁ, L.1, BUZGÓ, G.1, CERNÁCKOVÁ, A.1, HAMAR, D.1, CVECKA, J.1, KERN, H.2, PAYER, J.1, KILLINGER, Z.1, SEDLIAK, M.1

1 COMENIUS UNIVERSITY IN BRATISLAVA, BRATISLAVA, SLOVAKIA, 2 INSTITUTE FOR PHYSICAL MEDICINE, PHYSIK UND RHEUMATHERAPIE, ST. PÖLTEN, AUSTRIA

INTRODUCTION: Age-related loss of lean mass and increase in adipose tissue lead not only to decline in strength and to functional limitations but also to inflammaging and immunosenescence. Changes in body composition (BC) and bone mineral density (BMD) may thus lead to the initiation of various bone conditions. Long-term exercise training could therefore reduce the risk outcomes of osteoporosis and other metabolic pathological processes. The purpose of this study was to assess multiple anthropometric variables in relation to the amount of physical activity in elderly men.

METHODS: Subjects were divided into two groups: a master endurance runners (MER) (n= 9, 68.58 ± 3.01 yrs, body mass index (BMI) 24.18± 2.56 kg.m-2) and 'active less than recommended' group (ALTR) (n= 8, 70.73 ± 3.13 yrs, BMI 28.19± 2.12 kg.m-2) according to their long-term sports history anamnesis. MER were defined by a training volume of minimum 150 minutes of running activity per week and active participation in endurance running competitions and ALTR were defined as individuals with no history of regular physical activity training and no more practice than 150 minutes of moderate or 75 minutes of vigorous intensity per week. All subjects underwent a dual energy X-ray absorptiometry (DXA) where all the necessary anthropometric BC and BMD variables were estimated. Group differences were calculated using Mann-Whitney U-tests with significance level of $p< 0.05$. All data are expressed as means ± SD.

RESULTS: Total body mass (71.73 ± 9.63 vs 84,73 ± 5,05 kg, $p< 0.05$), BMI (24.18 ± 2.56 vs 28.19 ± 2.12 kg.m-2, $p< 0.01$) and total fat mass percentage (22.76 ± 3.08 vs 28.74 ± 3.45 %, $p< 0.01$) were significantly lower in MER compared to ALTR. On the contrary, lean mass percentage was significantly higher in MER (73.59 ± 2.95 vs 68.13 ± 3.20 %, $p< 0.01$). No significant differences were found in android/gynoid ratio and when analysing BMD, in none of the two standardly evaluated body parts (neither in T-score nor in Z-score) were detected significant differences.

CONCLUSION: Even though no significance was found in between BMD variables, a higher prevalence of osteopenia threshold values were noticed in the ALTR. Additionally, MER showed significantly more favourable BC values within the healthy population range what indicates the positive effect of endurance running on musculoskeletal health.

THE EUROPEAN "HAPPY BONES" PROJECT: HEALTH PROMOTION IN MENOPAUSAL WOMEN.

MORETTI, E.

UNIVERSITÀ DEGLI STUDI DI ROMA

INTRODUCTION: Menopause is a condition that can lead to several side effects such as a decrease in Bone Mass Density, muscle loss and fatigue which negatively affect the women's Quality of Life (QoL). Adapted exercise can provide psycho-physiological adaptations which improve bone health, mental health and prevent falls by improving lower limb strength and balance. In addition, Physical Activity (PA) increases cardiorespiratory fitness, strength, flexibility and QOL in PostMenopausal Women (PMW) [1]. Therefore, it is essential that PMW practice regularly PA to preserve bone, muscle, physical fitness and QoL. Unfortunately, PMW do not reach minimum PA levels recommended, thus it is necessary to implement strategies to promote regular PA in this population. The WorkPlace (WP) might be the better place to implement a healthy lifestyle in PMW, because it can reduce the typical barriers to the regular PA practice. therefore, firstly, study aims to compare if compliance and dropout rate to the "Happy Bones" (HB) protocol are the same when offered in the WP or in a Sports Centre (SC). Secondary, it aims to evaluate the effects of the protocol on womens bone health, QoL and fitness in PMW.

METHODS: 73 PMW were enrolled in 5 European countries (Italy, Romania, Bulgaria, Spain and Turkey) and performed 6 months of HB training, three times a week. The HB training protocol was structured to positively affect bone health. 39 women performed the protocol at the WP (Italy, Romania and Turkey) while 34 at the SC (Bulgaria, Romania and Spain). To monitor the compliance and drop-out of the HB intervention attendance registers were used; to assess the effect of the protocol on osteoporosis prevention and the risk of falls 1RM test, star balance test, single leg stance test, were performed; to evaluate women's QoL the QUALEFFO-41 questionnaire was administered.

RESULTS: 5 of the PMW trained at WP (12.8%) drop the program due to Covid-19 restrictions. While, 14 of the women exercised at SC (41.2%) did not complete the program for reasons unrelated to the protocol. This evidenced a lower dropout for PA practice at the WP comparing to SC. Results showed 47% of PMW trained at WP and 85% at the SC recorded high

compliance. At the end of 6 months of intervention, the whole group showed improvements in strength and balance. Greater cognitive functions, general health perception and ability to move independently were evidenced after the protocol.

CONCLUSION: The HB protocol, when it was proposed at the WP seems to demonstrate a lower dropout rate but less compliance when compared to SC. Results on strength and balance suggested the efficacy of this protocol in preventing osteoporosis and risk of falls, improving general health in PMW.

ATHLOME: GENETIC PREDISPOSITIONS TO OUTSTANDING ATHLETIC PERFORMANCE

DIEDHIOU, N., HEYER, V., ALOUANE, T., SIMON, A., OHANA, M., LAPORTE, J.

IGBMC

INTRODUCTION: There is a link between genetic predispositions, diseases and exceptional physiological and athletic abilities. As an example, a mutation of the HFE gene, encoding a protein involved in iron homeostasis, leads to hemochromatosis when present in two copies in the genome, while the presence of a single copy was found enriched in top-level athletes engaged in sports which require either a large capacity for oxygen transfer or high muscular performance. With the present ATHLOME project, we aim to discover new genes and genetic variants modifying neuromuscular and respiratory performances, that would be potential therapeutic targets for diseases affecting these physiological functions.

METHODS: A first international cohort of thirty-one freedivers with a national or international level was recruited based on their high abilities in comparison to the common population (more than 6 min static apnea for women and 7 min for men, lung vital capacity >110%). Physiological (lung vital capacity, glossopharyngeal respiration…) and biological (blood cell counts and protein levels) data were gathered. Saliva samples were collected allowing DNA extraction and genome sequencing after anonymization. Also, lung MRI was performed to decipher mechanisms of the glossopharyngeal breathing.

RESULTS: For the analysis of the DNA sequencing raw data, benchmarking of several in-house and commercial pipelines was performed before optimization of the most efficient pipeline. As a first approach, a list of candidate genes implicated in the physiology of breathing, oxygen transport and muscle function was screened and both novel genetic variants as well as known variants were found enriched in the freedivers cohort compared to the control population. A second approach aimed to screen for very rare variants with a high predicted impact on the encoded protein leading to a modification of its expression or function. Two hits with a statistically relevant frequency were found and require further functional investigations. Lung area and height evolution were measured during glossopharyngeal breathing from MRI data from one athlete, documenting a consequent lowering of the diaphragm during this process.

CONCLUSION: The study design and pipeline of analysis were validated by those first results as variants already reported linked to athletic performance were identified in our cohort. However, validation of implicated genes or genetic variants at the statistical and molecular levels may require a larger cohort. In addition, other athletes whose field necessitates resistance to hypoxia and high muscular performance may be recruited and investigated. Also, enrollment of families of athletes would be an asset allowing genetic segregation.

A STUDY ON THE RELATIONSHIP BETWEEN SOCIAL ADAPTATION AND FINE MOTOR SKILLS IN AUTISM

CHEN, Y., LIANG, A.

BEIJING CHILDRENS HOSPTIAL CAPTIAL MEDICAL UNIVERSITY

INTRODUCTION: Autism spectrum disorders (ASD) is a kind of complex neurodevelopmental disorder. Previous studies have focused on social disorders. The aim of this study is to understand the relationship between social adaptation and fine motor development in children with autism, and to provide scientific direction for the follow-up intervention treatment.

METHODS: A retrospective study was conducted to collect data on social adaptability and developmental level of children with autism diagnosed in the Child Development Behavior Clinic, and the control group was children with normal developmental level.

RESULTS: The results showed that there was no significant difference in sex and age distribution between ASD Group and control group ($P > 0.05$),but there was significant difference in social adaptation and fine motor skills between ASD Group and control group ($P > 0.05$).There was a certain correlation between each dimension of childrens development level and social adaptation (fine motor $P< 0.006$, $OR = 3.98(1.5 \sim 10.54)$.

CONCLUSION: there is a certain relationship between the developmental level of autistic children and their social adaptation. In the course of intervention therapy, fine movement can be used as an important point of entry, and it is of great significance to improve their social adaptation.

THE CONVERGENT VALIDITY OF THE CALF CIRCUMFERENCE TO PREDICT MUSCLE MASS COMPARED TO A BIOELECTRICAL IMPEDANCE ANALYSIS IN ADULTS WITH INTELLECTUAL DISABILITIES.

DE OUDE, K.I., BONNET, R., ELBERS, R.G., MAES-FESTEN, D.A.M., OPPEWAL, A.

ERASMUS MC

INTRODUCTION: Intellectual disability (ID) is defined as a deficit in cognitive and adaptive functioning, originated before 22 years of age [1]. In people with ID there is a high prevalence of sarcopenia (14.3%), at a relatively young age [2]. Sarcopenia is characterized by the loss of muscle mass and strength, and a decrease in quality of the remaining tissue [3]. In the European consensus on the definition and diagnosis of sarcopenia, CC is proposed as a non-invasive measurement for muscle mass [3]. However, it is not certain if CC is a valid screening tool in adults with ID. The aim of this study was to investigate the convergent validity of CC compared to bioelectrical impedance analysis (BIA) in assessing muscle mass in adults with ID.

METHODS: Muscle mass was measured using CC (Seca 200, Seca, Hamburg, Germany) and BIA (Tanita Body Composition Analyzer MC-780, Tanita, Tokyo, Japan) in 27 adults (mean age 56.15 ± 12.9 SD) with mild to moderate ID and at least two cardiovascular risk factors, who participated in a Progressive Resistance Exercise Training study [4]. All measurements were conducted by the same researcher. We used the Spearman's rho correlation to estimate the association between CC and skeletal muscle mass (SMM), segmental muscle mass of the legs (SegMM), and skeletal muscle index (SMI; SMM/height2).

RESULTS: A moderate correlation was found between CC and SegMM (rs= 0.49, p= 0.01, 95% CI: 0.10-0.76), and between CC and SMI (rs= 0.55, p=0.006, 95% CI: 0.17-0.78). No statistical significant correlation was found between CC and SMM (rs= 0.30, p= 0.13, 95% CI: -0.11-0.62).

CONCLUSION: The moderate correlation for SegMM and SMI indicates that there is a relationship between CC and muscle mass in adults with ID. The CC might be used as a tool for assessing muscle mass in adults with ID, but further research is necessary. Firstly, to investigate the validity in a larger and more heterogeneous sample of adults with ID. Secondly, to investigate the reliability of using CC as a screening tool for sarcopenia in adults with ID.

THE RELEVANCE OF TENSIOMYOGRAPHY-DERIVED SKELETAL MUSCLE CONTRACTILE PROPERTIES IN SARCOPENIC AND NON-SARCOPENIC PARTICIPANTS

PUŠ, K., PESKAR, M., ŠLOSAR, L., TERAŽ, K., PIŠOT, S., KALC, M., ŠIMUNIC, B.

SCIENCE AND RESEARCH CENTRE KOPER

INTRODUCTION: The original operational definition of sarcopenia was based solely on low muscle mass; however, in 2010 European Working Group on Sarcopenia in Older People (EWGSOP) issued guidelines that classified sarcopenia based on three consecutive criteria: low muscle quantity; low muscle strength; and low muscle performance. In 2019 the same group revised the guidelines and rearranged the consecutiveness of criteria: low muscle strength; low muscle quantity or quality; low muscle performance. Important, in 2019 the EWGSOP recognised muscle quality as the primary biomarker to confirm sarcopenia where the muscle quality should be used to describe micro- and macroscopic aspects of muscle architecture and composition. Since muscle contractile properties estimated from tensiomyography (TMG) reflects muscle fibre type composition and muscle architecture we aimed to investigate the prevalence of sarcopenia according to latest EWGSOP protocol in Slovenian population and compare TMG-derived contractile parameters of three leg skeletal muscles between non-sarcopenic and (pre)sarcopenic participants.

METHODS: A randomized sample of 345 individuals (31 % males) aged over 60 was recruited through Slovenian health centres and assessed according to EWGSOP protocol (grip strength, gait speed, chair stand and timed-up-and-go tests) and classified into two groups: non-sarcopenic (nonSARC; n = 298), pre-sarcopenic or sarcopenic (preSARC; n = 47). TMG was used to assess contraction time (Tc) and response amplitude (Dm) in vastus lateralis (VL), biceps femoris (BF), and gastrocnemius medialis (GM). Non-parametric Mann-Whitney and Spearman correlation tests were used due to non-normality of data distributions.

RESULTS: Prevalence of pre- and sarcopenia among Slovenian population was 13.1 %. PreSARC have lower Dm in all three muscles ($p < .05$) and shorter Tc in GM ($p = .032$). BF Dm correlated with chair stand ($\rho = -.168$), grip strength ($\rho = 0.151$), timed-up-and-go ($\rho = -0.147$) and gait speed ($\rho = .125$). GM Tc correlated with chair stand ($\rho = -.150$). GM dm correlated with chair stand, timed-up-and-go and gait speed GM Dm correlated with chair stand ($\rho = -.292$), timed-up-and-go ($\rho = -.238$) and gait speed ($\rho = .174$). VL Tc correlated with chair stand ($\rho = .166$), timed-up-and-go ($\rho = .150$) and gait speed ($\rho = -.153$).VL Dm correlated with chair stand ($\rho = -.171$), grip strength ($\rho = .299$) and timed-up-and-go ($\rho = -.215$).

CONCLUSION: Preliminary results of our study confirmed sensitivity of TMG-derived skeletal muscle contractile parameters to sarcopenia groups and sarcopenia classification tests. Although the correlations are weak, TMG parameters are promising biomarkers to be used in sarcopenia classification. By investigating the contractile properties of skeletal muscle in older adults, this study aims to shed light on the mechanisms underlying sarcopenia and contribute to the development of more effective interventions to prevent or treat the condition.

THE COGNITIVE AND PHYSICAL DEMAND OF A COMMERCIAL HIGH-ALTITUDE EXPEDITION

FAIRBAIRN, P., NEAL, R., BERKOFF, D.

BOURNEMOUTH UNIVERSITY AND UNIVERSITY OF NORTH CAROLINA

INTRODUCTION: Laboratory and field studies have demonstrated the detrimental effect of hypoxia on cognitive function. Commercial expeditions to high altitude are becoming more accessible to a wider variety of individuals resulting in greater health and performance risks. The combination of hypobaric hypoxia and the additional demand of an expedition may augment impairments in cognitive function and be associated with perceived and physiological markers of altitude illness in healthy, although relatively unprepared, visitors to high-altitude. This study aimed to understand the effect of a commercial high-altitude trek to Everest Base Camp on fatigue, cognitive function, acute mountain sickness (AMS) and optic nerve size in healthy sojourners.

METHODS: A total sample of 20 international athletes completed a 14-day return trek to Everest Base Camp interspersed with a battery of tests at four different altitudes: 1) 1400 m (day 1); 2) 3340 m (day 4); 3) 4240 m (day 7); 2860 m (day 12). Multiple cognitive domains were assessed including reaction time tests, spatial working memory and task load (n=10). Fatigue and AMS (n=18) were determined by surveys and optic nerve sheath diameter (n=20) was measured using ultrasound of the eye. Mixed model one-way ANOVA (four altitudes) with Tukey's test for multiple comparison was employed with a 0.05 alpha level.

RESULTS: During a high-altitude trek there were no changes in spatial working memory (P=0.783), simple reaction time (P=0.590) or formula reaction time (P=0.247). Focus reaction time did not change (P=0.115) but errors increased (P=0.033, from 1.5±2.4% at 1400 m to 28.3±26.6% at 2860 m; 8.34±7.1% at 3340 m, and; 12.0±15.5% at 4240 m). Task load parameters did not change except for perceived physical demand (P=0.025; from 18.5±23.9% at 1400 m to 43.3±30.5% at 2860 m, and 33.9±21.8% at 4240 m). There was no significant effect of altitude on fatigue (41±23 to 61±22, P=0.187) or AMS score (P=0.0618, although pairwise comparisons suggest greater AMS scores on day 7 and 12 compared with 4 and 1, respectively) and optic nerve sheath diameter was unchanged (to P=0.054).

CONCLUSION: Participant adherence in this applied study, in a remote and austere environment, was challenging and highlighted individual variation among athletes. Attrition was due to expedition evacuation on two occasions as well as expedition time-limits and participants' self-citing extreme fatigue. Participants maintained their reaction time but at the cost of accuracy during the focus reaction time task that involved distracting stimuli. Increased error rate at lower altitude, but later during the expedition, may indicate that fatigue had greater influence on performance than altitude. Further data analysis will explore the relationship between AMS, optic nerve diameter and task load index to explore whether monitoring trekkers with these tools may offer expedition providers information to determine high-risk participants prior to emergency evacuation for altitude illness.

CP-AP08 Statistics and Analyses

HOW CAN MACHINE LEARNING HELP PREVENT KNEE INJURIES OF EXPERIENCED ATHLETES?

LIPPS, C., FRÈRE, J., WEISSLAND, T.

UNIVERSITY OF BORDEAUX, GRENOBLES-ALPES UNIVERSITY

INTRODUCTION: Risk prediction of anterior cruciate ligament (ACL) injuries is highly multifactorial. As machine learning (ML) algorithms have the ability to understand complex relationships in large datasets, they seem appropriate to predict at-risk athletes based on a large number of features [1]. Thus, we compared two artificial intelligence models that can help prevent knee injuries including ACLs of experienced athletes.

METHODS: 50 athletes, 24 healthy and 26 with a medical history of severe knee injuries in the last 3 years took part in our experiment. They completed an informative questionnaire with physical, psychological (KOOS, SAS), and sports questions and performed a horizontal force-velocity test on a ballistic device [2]. From each push phase, we extracted a vector containing 60 biomechanical and psychological features (force peak, velocity, KOOS Pain score, …). Thus, we obtained a 519 vectors database. To train our machine learning algorithms to classify athletes correctly, we split the database into a train set of 405 vectors (39 athletes) and a test set of 114 vectors (11 athletes). For interpretability reasons, we chose to train nearest-neighbors (kNN) and decision tree (DT) classifiers with and without principal component analysis (PCA). Metrics used for model evaluation were accuracy and the area under the receiver operating characteristic curve (AUC).

RESULTS: The test of our models on the 114 test vectors led to an accuracy of 79% with an AUC of 0.77 for the kNN, while the DT accuracy was 64% with an AUC of 0.61. With the use of a PCA before training, the results were lower for the kNN

(accuracy of 72%, AUC of 0.71), but were higher for the DT (accuracy of 77%, AUC of 0.77). Finally, the first kNN classified correctly ten out of the eleven test athletes.

CONCLUSION: Unlike the kNN, the DT is sensitive to small variations in data which may explain the differences in performance as our features were highly person dependent. Our best model achieved an AUC of 0.77, surpassing the Jauhiainen model's [3]. The results of the PCA might be better as the size of our database would increase. Finally, the results suggested that ML could help identify at-risk athletes and be useful in predicting knee injury risk.

INJURY PREDICTION USING MACHINE LEARNING BASED ON THE MONITORING OF SPRINTING ATHLETES' PERCEPTION OF PHYSICAL AND MENTAL STATES

TONDUT, J.1, NAVARRO, L.2, GIROUX, C.3, CAUMEIL, B.3, RUFFAULT, A.3, GUILHEM, G.3, EDOUARD, P.1,4

INTER-UNIVERSITY LABORATORY OF HUMAN MOVEMENT BIOLOGY, EA 7424, F-42023

INTRODUCTION: To estimate the risk of sports injury occurrence is an important challenge in sport science and medicine [1]. Sports injuries are multi-faceted issues, as athletes can be considered as complex systems exposed to inter-related physical, psychological, and physiological influences [2]. From these observations, machine learning (ML) techniques offer an opportunity to identify patterns leading to injuries [3]. The aim of this study was to predict injury risk over time by monitoring athletes' perceptions of physical and mental states using ML models [3].

METHODS: A total of 122 athletes practicing sports involving repetitions of sprints from three sports federations (athletics, bobsleigh and rugby) were included in the study. 16 features corresponding to their perceptions of physical and mental states, were assessed throughout a mobile app each morning and evening. The injury status of the athlete (either injured or not) was collected in the evening. Two ML models (a logistic regression LR [4] and a Decision Tree DT [5]) were trained and then tested on collected data over a follow-up period of 532 days. Data were preprocessed in a time window of 1.5 days composed of successive evening - morning - evening data. An internal validation strategy was used to assess model performances [6]. The test set was composed of the last 30% days of each athlete monitoring data in order to keep a chronological timeline in the validation process.

RESULTS: On a total of 3688 time-window observations, 171 injuries were recorded. This constitutes a case of serious class imbalance between injured and uninjured. The model was validated on test set of cases unused during models training. The accuracy (mean (SD)) (LR:0.64 (0.02)), specificity (LR:0.65 (0.02) – DT:0.92 (0.008)), recall (LR:0.55 (0.06) – DT:0.17 (0.05)), precision (LR:0.06 (0.02) – DT:0.16 (0.05)) and ROC AUC (LR:0.63 (0.03) – DT:0.56 (0.02)) were computed over 50 runs.

CONCLUSION: This preliminary analysis highlights the ability of ML models to estimate injury risk by monitoring athletes' perceptions of physical and mental states which are usually not considered in ML models [3]. Our ML model gives a good estimation with high true negative rate. However, the precision (i.e., the ability to detect true injury) is low and could be improved by increasing the sample size and particularly if class imbalance can be mitigated, or by using ensemble methods [7,8]. Moreover, prediction performances could be improved ML techniques seem to be a promising tool to help athletes and stakeholders in the management of injury risk by adopting some preventive behaviors and should require further investigation on the data collection, and mathematical formulations to manage the imbalanced class problem [9].

THE EMERGING TRENDS AND KNOWLEDGE STRUCTURE OF SPORTS PERFORMANCE: A SCIENTOMETRICS ANALYSIS

LUO, H., NASHARUDDIN, N.A., TENGKU KAMALDEN, T.F., ZHU, X.L.

UNIVERSITI PUTRA MALAYSIA, COLLEGE OF SPORT AND ART, SHENZHEN TECHNOLOGY UNIVERSITY, SHENZHEN, GUANGDONG, CHINA

INTRODUCTION: Sports performance involves research in several fields and disciplines. As research in these areas advances rapidly, it is critical to keep abreast of emerging trends and critical turns in the development of collective knowledge. Not only because discoveries emerge from a diverse range of areas but also because new findings may fundamentally alter the collective knowledge as a whole. Scientometrics is a branch of informatics that quantitatively analyzes patterns in the scientific literature to understand emerging trends and the knowledge structure of a research field.

METHODS: The database selected for the scientometric analysis in this study was the Web of Science Core Collection. The search formula was TS=("sport* performance" OR "athletic performance" OR "exercise performance"). Citation indexing was limited to SCI-E and SSCI. The document types were Article or Review Article. The period was from the start to 31 December 2022. No language restrictions. Duplicates were eliminated with CiteSpace and the final 16,279 documents were obtained and imported into CiteSpace (5.7.R5) for analysis.

RESULTS: The most cited references were IOC Consensus Statement: Dietary Supplements and the High-Performance Athlete, Position of the Academy of Nutrition and Dietetics, Dietitians of Canada, and the American College of Sports Medicine: Nutrition and Athletic Performance, ISSN exercise & sports nutrition review update: research & recommendations. The top 2 citations with the highest citation bursts were consistent with the top two most cited references. The 3 journals with the most references were The Journal of Strength and Conditioning Research, Journal of Sports Medicine and Physical Fitness, and Medicine and Science in Sports and Exercise. Medicine and Science in Sports and Exercise, Journal of

Applied Physiology and Sports Medicine were the top 3 most cited journals. The USA was the country with the most total publications and citation count, followed by the UK and Australia. The top 3 cited institutions were the University of California, Udic French Research Universities, and Universidade De Sao Paulo, which has the most recent and strongest citation burst. The institution with the most centrality was the University of Colorado. The top 3 most co-cited authors in the last 5 years were Anonymous, Cohen J, and Hopkins WG. The top 3 authors with the highest centrality were Beedie CJ, Amann M, and Burke LM.

CONCLUSION: This study identified the most influential references, journals, countries, institutions, and authors. The retrieved co-citation reference network describes coherent links between 31 different clusters and identifies three distinct major research trends, namely advances in disease prevention and treatment, improvements in sports performance, and enhancements in healthy diets and sleep quality. The last five years research trends were: dietary supplementation and performance enhancements. These findings can inform funding agencies and research groups' future directions.

INVESTIGATING THE TEACHING OF QUANTITATIVE DATA ANALYSIS IN UNDERGRADUATE SPORT AND EXERCISE SCIENCE-RELATED DEGREE PROGRAMMES IN UK UNIVERSITIES

TIDMARSH, G., ABT, G., MCERLAIN-NAYLOR, S., MYERS, T.

UNIVERSITY OF BIRMINGHAM, THE UNIVERSITY OF HULL, LOUGHBOROUGH UNIVERSITY, NEWMAN UNIVERSITY

INTRODUCTION: A large proportion of research findings may be false [1]. Underpowered studies [2], inappropriate research designs, and questionable research practices are at the heart of the problem, including within sport [3]. Many researchers misunderstand fundamental aspects of statistics [4] and it is important to consider how this affects the teaching of undergraduates who will enter the academic or industry workforce.

METHODS: To examine this, we surveyed 94 academics from 60 UK institutions on aspects related to the teaching of research methods and statistics on undergraduate sport and exercise science courses.

RESULTS: Topics 'covered in depth' on average included null-hypothesis significance testing, p-values, statistical significance, and assumption checks. This was at the expense of 'not covered' topics such as the Neyman-Pearson approach, the Fisherian approach, Bayesian approaches, open science, pre-registration, and Registered Reports. Students were mostly assessed via written assessments (54%), although individual research projects (29%), multiple choice tests (29%), and computer-based assessments (27%) were also common. Most courses used SPSS (76%) and Microsoft Excel (64%), although there was evident use of open-source software such as JASP (20%) and JAMOVI (10%), as well as greater referral to online videos and tutorials (73%) than textbooks (68%) and journal articles (64%). The median response 'strongly agreed' that modules effectively developed the practical ability to conduct data analyses, 'agreed' they prepared students effectively for a dissertation and developed conceptual understanding, and 'slightly agreed' that they prepared students effectively for data analysis within both sporting and industry settings. Content analysis of open responses indicated that participants judge the effectiveness of their teaching based on aspects relating to feedback (students, other staff), assessment (formative, summative), industry (preparedness for work), and future study (preparedness for dissertations/postgrad). The usefulness of student module evaluations was debated. There were also contrasting views on relative effectiveness for students passing tests compared to developing conceptual understanding. There were some collaborative projects with industry, but responses generally suggested students weren't prepared to work in industry and that many participants weren't even sure what that would require.

CONCLUSION: Our study suggests that academics in our discipline are mostly taking a 'well-worn path' to teaching statistics. Although some alternative approaches are being used, staff are focussing on the 'doing' of statistics in preference to developing conceptual understanding. Our study also suggests that particular emphasis should be given to the constructive alignment between academia and industry.

THE ASSOCIATION BETWEEN MENTAL HEALTH AND PARTICIPATORY SPORTS CONSUMPTION IN KOREANS: A CROSS-SECTIONAL STUDY

HUANG, Y.C., SU, Y.Q., PARK, J.H., WANG, L., KIM, S.H.

KOREA UNIVERSITY

INTRODUCTION: Mental wellness protects against aging and chronic physical conditions, while mental disorders increase the risk of diseases and injury. Participating in sports activities is an effective way to improve mental health. With the successful development of the sports industry, participatory sports consumption as the core of sports consumption has a higher proportion in our leisure expenditure. Although participatory sports consumption is a concept in sports economics, consumption may allow us to have a more comfortable experience when participating in sports activities. Studying the relationship between the emergence of participatory sports consumption and mental health is necessary and meaningful.

METHODS: In the Korea Health Panel Annual (KHPS) data provided by the Institute of Health and Social Affairs & National Health Insurance Service (2020), we included 11268 participants over 19 years old in the analysis for this study. We per-

formed a logistic regression analysis to evaluate the relationship between participatory sports consumption and mental health. Adjustments were made for sex, age, education level, household income, and chronic disease. Subgroup analyses were also conducted based on sex, age, and exercise habits.

RESULTS: In Korea, there are significant differences between participation in sports consumption and the various factors of the study subjects, including gender, age, education level, annual income, number of chronic diseases, depression, anxiety, suicidal thoughts, subjective health status, and regular exercise habits($p<0.05$). Furthermore, even without a consistent exercise habit, study subjects who had participated in sports consumption showed significantly better results in terms of suicidal thoughts and subjective health status compared to other groups($p<0.05$). The presence or absence of participation-based sports consumption had a significant impact on stress , anxiety , suicidal thoughts , and subjective health status . Subgroup analysis also showed that the impact of participating in sports consumption on "feeling stressed" was significantly higher for women, the elderly, and regular exercisers compared to other subgroups. Additionally, the elderly showed a significant difference in the impact of participating in sports consumption on feelings of anxiety and subjective health status compared to other age groups.

CONCLUSION: The emergence of participatory sports consumption can positively influence our mental wellness. Despite potential variations in impact based on factors such as age, gender, and athletic inclinations, however, access to sports is more accessible than any other intervention method, and the costs associated with it are relatively low. Furthermore, the advantages derived from sports activities extend beyond mere mental health benefits. Therefore, encouraging the growth of participatory sports consumption is crucial to enhancing mental health.

ARE GYMNASTICS COMPETITIONS A SELF-FULFILLING PROPHECY?

LECOCQ, T.1, TORDI, N.1,2

UNIV. BOURGOGNE FRANCHE-COMTÉ, 25000, BESANÇON, FRANCE.

INTRODUCTION: In artistic gymnastic international competitions, access to All Around, Apparatus and Team finals are established based on the qualification round results. For a nation who aims for medals in all three finals, the composition of the qualification round's team is a major strategic choice. Coaches may find themselves facing the following question: which gymnasts will maximize the chances of individual and/or team finals. The purpose of this study is to see if it is possible to predict gymnastic result.

METHODS: To answer this question, we collected results of international gymnast over a period of six months. Two predictions were calculated for each athlete: "Max", corresponding to his/her best score and "Mean" corresponding to the average of all the score collected over the 6-month window. Those 2 predictions were then compared to the results obtained on each apparatus during the 2022 European Championship at Munich. A total of 547 Junior and Senior competed in Women's and Men's Artistic Gymnastics (WAG and MAG). Several statistics were used to quantify the validity of our prediction: Pearson's Coefficient, RMSE, Paired Sample T-Test and Bland & Altman's Limits of Agreements.

RESULTS: Systematic error is higher for Max than for the Mean prediction. Junior WAG Floor (+0,055), Senior WAG Uneven Bar (0,015), Junior MAG Parallel (-0,037) and High Bar (-0,051), Senior MAG Parallel Bar (0,017) and Floor (-0,078) present the smallest bias while Senior Balance Beam (0,331) Junior and Senior Pommel Horse (0,286 and 0,304 respectively) are among the highest. Random errors are very similar between Max and Mean predictions. Junior and senior WAG Floor (0,447 and 0,360 respectively), Junior and Senior MAG Still Rings (0,382 and 0,651 respectively) display the smallest dispersion while Junior and Senior WAG Balance Beam (0,921 and 1,256 respectively) and Junior and Senior Pommel Horse (0,932 and 1,113) show the highest. RMSE results follow the same trend. All correlation between prediction and results are moderate, large, or very large ranging between 0,409 and 0,867. Larger correlations correspond to Senior WAG Floor (0,867), Senior MAG Vault (0,786), Junior MAG Still Rings (0,779) and Junior WAG Uneven Bars (0,757). Percentages of prediction contain within our Limits of Agreement range between 90,164% and 97,826% for every apparatus. Max predictions are systematically significantly superior to the event final score while mean prediction are significantly different on some apparatus.

CONCLUSION: Considering all our indicators, Junior WAG Vault, Junior MAG Floor and Senior MAG Still Rings seem to be predictable based on their high validity and small dispersion. Other apparatus such as Pommel Horse or Balance Beam seems harder to predict due to their high variability. The validity of our predictions are in agreement with previous study interested in inter-day apparatus reliability [1].

EFFICACY OF PRESSURE MANIPULATION TECHNIQUES IN DARTS PLAYERS - AN EXPLORATORY STUDY

FREY, S., BÄCHINGER, M., WEIJS, M.L., WENDEROTH, N.

ETH ZÜRICH

INTRODUCTION: Being able to perform at a top level is of major importance for professional athletes. Therefore, it is essential to prevent a performance decrease under the pressure of competition which often leads to an over-aroused state of the athlete. However, it is difficult to (i) simulate mental pressure in laboratory or training settings and (ii) provide objective markers of the athlete's arousal state. Previous research has shown that the activation of the locus coeruleus-noradrenergic (LC-NA) system, a key regulator of arousal in humans, causes the eye's pupil to dilate particularly in situations that are perceived as stressful. Here we assessed the effectiveness of pressure manipulation via self-reported state anxiety, performance, and pupil measures in skilled dart players. Based on previous studies, we hypothesized that exper-

imentally induced pressure will cause an increase in self-reported anxiety and pupil diameter and a reduction in darts performance.

METHODS: Skilled darts players (N=39) completed two counterbalanced rounds with 15 specific targets on the dartboard, one round without pressure and a second round with experimental pressure manipulation techniques. The techniques used were: audience, camera, fake ranking, and monetary incentive, which were all implemented simultaneously. In addition to darts performance (number of attempts), pupil size and self-reported state anxiety (questionnaire) were measured pre and post each round. The anxiety questionnaires were analyzed using linear mixed effects models including the factors pressure (non-pressure vs. pressure) and time (pre vs. post playing). For pupil size, a 2-way repeated measures ANOVA time series analysis with the factors pressure and time was applied. The performance was analyzed using a dependent t-test.

RESULTS: Participants reported significantly higher state-anxiety in the pressure than in the non-pressure rounds (pre non-pressure 25.41±13.55, post non-pressure 21.24±12.83, pre pressure 27.88±14.78, post pressure 30.35±17.62; pressure x time interaction $p<.05$). We also found a significant decrease of mean performance (M non-pressure = 88.13±28.94, M pressure = 96.28±30.02; $p<.05$) and a significant increase of mean pupil size from 3.45mm to 3.61mm (SPM1D pressure main effect $p=.005$, $F^*=9.97$) for the pressure compared to the non-pressure condition.

CONCLUSION: Our pressure manipulation had a significant effect on self-reported state anxiety. This was accompanied by a significant increase in pupil size which is considered a physiological marker of elevated arousal levels, and by a significant decrease in performance. Our results provide the basis for experimentally testing new mental strategies and interventions for coping with pressure and associated over-arousal. One particularly interesting strategy is to train athletes in self-regulating their arousal state by combining mental strategies with pupil-based neurofeedback which has been shown help participants with gaining volitional control of their LC-NA system.

DROPOUT AMONG FRENCH SWIMMERS: GENDER, RELATIVE AGE EFFECT AND PERFORMANCE LEVEL INFLUENCES

DIFERNAND, A.

INSEP

INTRODUCTION: Dropout can be seen as someone who had competed in one particular sport and stopped but has not completely stopped participating in sport in general . This study investigates the dropout rate among French swimmers according to performance levels, sex and relative age.

METHODS: Using data from 160 861 swimmers under the age of 21, the distribution of birth quarters as well as the dropout rate by performance level is studied. Chi-squared statistical tests will be performed to attest to the significant effect of birth quarter variables on performance level. In addition, to determine and analyze the impact of sex and relative age on dropout, Kaplan Meier survival curves are realized.

RESULTS: For female, the most likely age to dropout is 13 while for male, it is 17 years old. At these ages, there is a significant effect of birth quarters on performance levels: the proportion of first birth quarter increases with the level of performance. A significant effect of performance levels on dropout is also measured: dropout rate increases as the performance level decrease. The Kaplan Meier dropout curves as a function of age, with sex as a discriminant variable, show that the dropout trends for both sexes are similar before age 13. However, from this age onwards, the dropout rate increases more rapidly for females than for males, with a maximum difference (4.8%) at 17.89 years old. The maximum difference in dropout trends for swimmers born in the first and last quarters is 10% for females at 12.71 years and 8.1% for males at 14.67 years with the dropout rate increasing more rapidly for swimmers born in the last quarter.

CONCLUSION: This study shows the importance of sex, relative age and performance level on the dropout of French swimmers. Female swimmers' present higher dropout rate than their males' counterparts. The highest dropout rate occurs during respective puberty. Dropout is potentiated by the level of performance.

WHAT DO STRESS-ESTIMATION MODELS REALLY SHOW?

SCHRANZ, C., JUNG, O.

SALZBURG RESEARCH

INTRODUCTION: Recent advancements in wearable technology have enabled continuous and non-invasive monitoring of physiological responses, providing opportunities to estimate stress levels.[1] Stress intensity plays a critical role in the ability to stay alert, focussed and enthusiastic.[2] However, it is important to distinguish between stress intensity and its perception ranging from positive eustress to negative distress[3]. In particular in sports, wearables shall not reduce stress intensity, but support a more positive perception. The aim of this study is to characterize the stress intensity and its perception based on the SWELL-dataset[4].

METHODS: Two male participants, approx. 30 years of age, wore a Movisens EcgMove4[5] device for seven consecutive days to measure heart-rate peaks. Concurrently, every two hours from 8 am to 10 pm, they completed brief self-report questionnaires assessing their stress intensity and perception on a 7-point Likert scale.

A multi-layer perceptron (MLP) was trained using the Movisens-dataset, which consists of 118 stress events and 12 generated heart-rate features based on 60-second frames. The MLP was trained for 120 epochs to map the selected features onto the normalized stress intensity and perception scores, obtained from the assessment. The models hyperparameters were optimized using a 10-fold cross-validation. Subsequently, the trained model was applied to data from the SWELL-

dataset, which contains similar heart-rate data from 25 participants, exposed to different stressors such as interruption, time pressure and no stress.

RESULTS: During the model's pre-training using the Movisens dataset, a root mean square error (RMSE) of 0.2288 for the stress intensity and 0.3009 for the stress perception was achieved. In the downstream task of estimating the stress intensity and perception for the SWELL-dataset, different intra-class means were found. The normalized differential vectors in the 2D-target space between the center of the no stress class and the interruption class was (0.9627, 0.2706), and the differential vector between the center of the no stress class and the time pressure class was (0.8108, 0.5853).

CONCLUSION: The results of this study approves an increase in estimated stress intensity for both stress conditions. The perception was more positive in the time pressure condition as well as (but lesser) in the interruption condition. The artificially induced stress situations in an experimental setting might led to a motivational and therefore positive stress response. The higher RMSE for the stress perception compared to the intensity may be due to the higher complexity of the first aspect. This insight is crucial for the design of future stress studies, particularly those that incorporate stress feedback from wearables in sports, where it is essential to distinguish between stress intensity and the perception of stress.

LITERATURE SCREENING OF GENETIC VARIANTS WITH RELEVANCE FOR ERGOGENIC POTENTIAL OF NUTRITIONAL SUPPLEMENTS

VANDECAUTER, J., MISPLON, L., VAN DE LOOCK, A., DERAVE, W.

GHENT UNIVERSITY

INTRODUCTION: Dietary supplements are frequently used in sports to enhance performance, yet a high interindividual variability in response exists that can be partly assigned to genetic factors. We screened the scientific literature for genetic variants that can or could influence the response to the five most commonly accepted ergogenic supplements (caffeine, creatine, beta-alanine, sodium bicarbonate and nitrate) in sports performance.

METHODS: We conducted a thorough literature search for common genetic variants demonstrated to affect one or more of the main processing steps in the human body: absorption, distribution, metabolization, physiological effect and excretion. We also explored whether they have been linked to exercise performance studies.

RESULTS: Common genetic variants in a total of 46 relevant genes were identified for the five ergogenic supplements. Seven genes were described for caffeine, mainly involved in the metabolization and physiological effect. The breakdown of caffeine into paraxanthine is crucial as this metabolite has a higher affinity for the adenosine receptor than caffeine and therefore, has a prominent biological use. The CYP1A2-gene is the most researched gene in sports performance since it regulates the essential metabolization step. The rs762551 SNP of this gene slows this step down and therefore, decreases the ergogenic aid of caffeine in athletic performance. Five genes code for key proteins engaged in the creatine distribution to the skeletal muscle, but it is currently unclear as to whether genetic variants in these genes affect responsiveness to creatine loading. Beta-alanine is the rate-limiting precursor of carnosine, a proton buffer, and eleven genes were defined to be involved in the carnosine distribution and metabolization in skeletal muscle. Regarding the plasma pH buffer, sodium bicarbonate, nine potential genes, mainly active in the absorption of this supplement, were noticed. The final supplement nitrate, with fourteen target genes, becomes functional after conversion to nitric oxide, so the metabolization proteins have probably the highest impact on the usage of nitrate.

CONCLUSION: Multiple genes code for proteins that control important steps of the accumulation and ergogenicity of dietary supplements, but very little is known about potential SNPs that can alter this and there is a lack of sport specific research, except for caffeine. Thus, our screening can steer and inspire more research, which is definitely required to identify genetic variants that can form the future basis for sport nutrigenetics.

ACUTE EFFECTS OF CAFFEINE ON PHYSICAL PERFORMANCE AND LEVEL OF TECHNICAL AND TACTICAL SKILLS IN ELITE JUDO ATHLETES

KASZUBA, M.1, KRAWCZYK, R.1, MICHALCZYK, M.1, KOSTRZEWA, M.1, KOMAREK, Z.2, KRZYSZTOFIK, M.1, FILIP-STACHNIK, A.1

1 INSTITUTE OF SPORT SCIENCES, THE JERZY KUKUCZKA ACADEMY OF PHYSICAL EDUCATION IN KATOWICE, 2 INSTITUTE OF SPORT SCIENCES, UNIVERSITY OF PHYSICAL EDUCATION IN KRAKOW

INTRODUCTION: Several previous investigations assessed the effect of pre-exercise caffeine ingestion on judo-specific performance. However, the effects of caffeine on repeated technical-tactical skills and physical tests related to judo performances are unclear. Therefore, the aim of this study was to explore the effect of acute oral caffeine intake on physical performance tests and indicators of activeness, efficiency, and effectiveness of athletes during repeated judo combats.

METHODS: Nine elite judo athletes of the Polish national team (4 men and 5 women, age: 22 ± 4 years, body mass: 70.7 ± 11.7 kg) habituated to caffeine (2.2 mg/kg/day) participated in a randomized, crossover, placebo-controlled and double-blind experiment. Each participant performed two identical experimental sessions after ingestion of (a) 3 mg/kg body mass of caffeine (CAF); b) a placebo (PLAC). After 60 min for substance absorption, the athletes performed the following 4 sets of tests: a) maximal isometric handgrip strength test; b) countermovement jump (CMJ) which were separated by three 4 min judo combats, on the basis of which indicators of activeness, efficiency, and effectiveness of attack and defense of the athletes were assessed. Additionally, blood lactate (LA) concentration was also measured before the testing, after each combat, and 30 minutes after the testing.

RESULTS: A two-way repeated measures ANOVA indicated no significant substance × time interaction effect ($p=0.940$) as well as no main effect of a substance ($p=0.054$) but indicated a significant main effect of time ($p<0.001$) for LA concentration. Post-hoc analysis for time effect showed a significant increase in LA concentration at points II, III, and IV compared to points I and V ($p<0.02$ for all). No significant differences between a substance x time interaction effect, the main effect of a substance, and the main effect of time were observed in CMJ ($p=0.587$; $p=0.162$; $p=0.117$, respectively), handgrip test with the dominant hand ($p=0.684$; $p=0.150$; $p=0.295$, respectively) and with non-dominant hand ($p=0.242$; $p=0.324$; $p=0.479$, respectively). In addition, t-tests showed no differences in the Overall Activeness ($p=0.558$), Attack Activeness ($p=0.736$), Defense Activeness ($p=0.233$), and Final Effectiveness ($p=0.860$) between PLAC and CAF trials in judo combats. In turn, the Wilcoxon signed rank test showed no differences in the Attack Efficiency ($p=1.000$), Defense Efficiency ($p=0.779$), Attack Effectiveness ($p=0.575$), Defense Effectiveness ($p=0.326$) between PLAC and CAF trials.

CONCLUSION: The present study indicates that 3 mg/kg body mass of caffeine is not an effective dose to improve physical performance and indicators of activeness, efficiency, and effectiveness during repeated judo combats in elite judo athletes habituated to caffeine.

PRELIMINARY RESULTS CONCERNING EFFECTS OF ACUTE CAFFEINE SUPPLEMENTATION ON PHYSICAL PERFORMANCE AND SLEEP IN HANDBALL PLAYERS. DOES IT DO MORE HARM THAN GOOD?

KOMAREK, Z., SPIESZNY, M., KASZUBA, M., WIECEK, M., KRZYSZTOFIK, M., HOLDA, M., FILIP-STACHNIK, A.

UNIVERSITY OF PHYSICAL EDUCATION IN KRAKOW; ACADEMY OF PHYSICAL EDUCATION IN KATOWICE; SECTION OF SLEEP PSYCHOLOGY, INSTITUTE OF PSYCHOLOGY, JAGIELLONIAN UNIVERSITY, KRAKOW

INTRODUCTION: Although acute caffeine intake may improve sports performance, its increases the likelihood of sleep disturbance, particularly when consumed in the evening. Therefore, the aim of this study was to analyze the effects of low and moderate caffeine doses ingested before late evening sessions on physical performance and sleep in male handball players

METHODS: Twelve male handball players (age: 21.6 ± 3.4; body mass: 87.3 ± 11.6 kg; height: 183 ± 6 cm; habitual caffeine intake: 1.1 ± 0.9 mg/kg/day) participated in a randomized, counterbalanced, and crossover experiment. Each athlete performed three identical trials after the ingestion of a) placebo (PLAC) b) 3 mg/kg of caffeine (CAF-3) and c) 6 mg/kg of caffeine (CAF- 6), administered 60 min before the evening session and completed: a) agility T-test; b) countermovement jump; c) isometric handgrip test; d) the throwing velocity test e) sprint test (5, 10, 20 m). Sleep was assessed using wrist actigraphy and a Karolinska Sleep Diary (KSD).

RESULTS: One-way ANOVA showed no significant differences between conditions in any physical tests ($p > 0.05$ for all, ES: PLAC – CAF-3: 0.00 – 0.35, ES: PLAC – CAF-6: 0.00 – 0.41). Significant differences were observed in the following sleep actigraphy sleep measures: a) time between substance intake and sleep onset between CAF-3 and CAF-6 (464 ± 76 vs 492 ± 80 min, respectively; $p = 0.03$, ES: 0.35) and b) sleep duration between PLAC and CAF-6 (439 ± 69 vs 357 ± 72 min, respectively; $p < 0.001$, ES: 1.16). Results of sleep assessment on KSD showed a statistically significant difference in sleep quality between PLAC and CAF-6 (4.0 ± 0.7 vs 3.2 ± 0.7, respectively; $p = 0.24$, ES: 1.14) and calm sleep between CAF-3 and CAF-6 condition (3.9 ± 0.5 vs 3.5 ± 0.8, respectively; $p = 0.04$, ES: 0.59. In addition, sleep duration (5 :56 ± 0:05 h:min) and sleep latency (33 ± 35 min) during the CAF-6 condition were shorter than sleep recommendations.

CONCLUSION: The present study indicates that acute caffeine intake of 3 and 6 mg/kg has no significant impact on physical tests associated with handball performance. However, acute caffeine intake substantially interferes with some objective and subjective sleep parameters. Thus, when considering caffeine use in the evening, athletes need an individual approach and estimate potential profits and losses. However, future studies using a larger sample size and including genetic analysis will be required to confirm these findings

EFFECT OF DIETARY NITRATE SUPPLEMENTATION ON SKELETAL MUSCLE MITOCHONDRIAL RESPIRATION PRIOR TO AND FOLLOWING SEVERE-INTENSITY EXERCISE IN HEALTHY ADULTS

ALSHARIF, N.

LOUGHBOROUGH UNIVERSITY

INTRODUCTION: Dietary supplementation with nitrate (NO_3^-), which can undergo a stepwise reduction to nitrite and then nitric oxide, has been reported to improve exercise economy and performance during continuous endurance exercise. While these effects might be linked to improved mitochondrial function, the extent to which NO_3^- supplementation can improve mitochondrial respiration in human skeletal muscle is currently conflicting. Moreover, all studies assessing the effect of NO_3^- supplementation on mitochondrial respiration to date have obtained resting skeletal muscle samples prior to exercise. There is evidence that acute exercise can modulate skeletal muscle respiratory variables, but the extent to

which such variables may be impacted after exercise following NO3- supplementation has yet to be investigated. The purpose of this study was to assess the effect of short-term NO3- supplementation on mitochondrial respiratory variables from skeletal muscle sampled prior to and following severe-intensity cycle exercise.

METHODS: In a randomised, double-blind, cross-over study design, 5 recreationally active adults males consumed NO3rich (BR, 13 mmol of NO3-) or NO3depleted (PL, <0.1 mmol of NO3-) beetroot juice for 7 consecutive days. Muscle biopsy samples were collected on day 7 of supplementation at rest (Pre) and after (Post) attaining 80% of task failure during a constant work rate severe-intensity cycling test, which was established during a preliminary severe- intensity performance test. Mitochondrial respiratory variables were assessed in permeabilised muscle fibre bundles. Specifically, uncoupled leak respiration through complex I (CIL), saturating adenosine diphosphate stimulated respiration through complex I (CIP) and complex I+II (CI+IIP), and maximal electron transfer system activity through complex I+II (CI+IIE), complex II (CIIE) and complex IV (CIVE) were assessed using high-resolution respirometry. In addition, coupling control ratio (CIL/CI+IIP; 1/RCR) was used as a marker of oxidative phosphorylation coupling efficiency. Data were analysed with two-way (supplement x time) repeated-measures ANOVAs.

RESULTS: There were main effects for time for CIL (PL-Pre: 4 ± 2, BR-Pre: 8 ± 3, PL-Post: 7 ± 2, BR- Post: 9 ± 5 pmol/s/mg), CIP (PL-Pre: 53 ± 11, BR-Pre: 58 ± 18, PL-Post: 66 ± 10, BR-Post: 70 ± 21 pmol/s/mg), CI+IIP (PL-Pre: 98 ± 21, BR-Pre: 100 ± 14, PL-Post: 115 ± 14, BR-Post: 114 ± 12 pmol/s/mg) and CI+IIE (PL-Pre: 106 ± 21, BR-Pre: 108 ± 15, PL-Post: 124 ± 13, BR-Post: 124 ± 13 pmol/s/mg; all $P<0.05$). There were no main effects for supplement ($P>0.05$) or no supplement x time interaction effects ($P>0.05$) on any of the mitochondrial respiratory variables.

CONCLUSION: Short-term NO3- supplementation did not alter skeletal muscle mitochondrial respiratory variables prior to or following severe-intensity cycle exercise in healthy adults.

ACUTE EFFECT OF BEETROOT JUICE ON PHYSIOLOGICAL RESPONSES OF WOMEN TO EXERCISE

KOSKOLOU, M.D., TZIKA, A., MILIOTIS, P.G., STERGIOPOULOS, D.C., YANNAKOULIA, M., GELADAS, N.D.

NATIONAL AND KAPODISTRIAN UNIVERSITY OF ATHENS

INTRODUCTION: Beetroot juice has emerged as a widespread ergogenic dietary supplement with its natural nitrate content playing a key role in modifying normal responses to exercise. Research on the effects of even a single dose of a beetroot supplement to exercise performance is ample in men but scarce in women, despite the biological sex differences that exist in nitric oxide metabolism (Wickham & Spriet, 2019). The purpose of this study was to examine the acute effect of beetroot juice on physiological exercise responses in young physically active women.

METHODS: Six young (24.2±5.7 yrs) physically active (VO2max 31.1±3.1 ml/kg/min) females participated in the study. The participants performed a protocol with three types of exercise (submaximal work, sprinting, and incremental exercise to exhaustion) in two conditions, conducted between mean luteal and the beginning of the next ovarian phase of their menstrual cycle, 150 minutes after ingesting an acute dose of: a) a beetroot juice containing 6-7 mmol nitrate, and b) a placebo drink of similar color and taste with beetroot juice. Blood pressure (at rest, before and after drink administration, and post-exercise), heart rate, oxygen consumption (VO2), and power output were measured. Statistical analysis was performed using paired t-test.

RESULTS: Resting mean blood pressure was maintained 150 min after the intake of beetroot juice, whereas it was marginally increased ($p=0.068$) after the placebo drink. The mean VO2 during submaximal work was similar after the ingestion of beetroot juice and placebo. Peak power at the sprint also did not differ significantly. In the exercise test of gradually increasing intensity to exhaustion, both maximal VO2 and maximal power output did not differ significantly between conditions, but maximal heart rate was higher after beetroot than after placebo ingestion ($p=0.015$). Post-exercise systolic blood pressure was lower at the 10th min of recovery in the beetroot compared to the placebo condition ($p=0.029$).

CONCLUSION: In the present study, no significant differences were found in oxygen consumption at submaximal and maximal work, as well as in power output produced at 10-sec maximal sprint and at VO2max. The effect of beetroot ingestion on maximal heart rate and on resting blood pressure values pre- and post-exercise could suggest a compensatory reaction of the body against a reduction of total peripheral resistance elicited by nitric oxide acting as a vasodilator. It is possible that beetroot ingestion led to improved baroreceptor sensitivity increasing the range of positive heart rate response during exercise (Wehrwein & Joyner, 2013).

EFFECTS OF 12 WEEKS OF OMEGA-3 FATTY ACID SUPPLEMENTATION IN LONG-DISTANCE RUNNERS

TOMCZYK, M.

GDANSK UNIVERSITY OF PHYSICAL EDUCATION AND SPORT

INTRODUCTION: Omega-3 index (O3I) has been recognized as the best marker of omega-3 PUFA status. O3I is positively associated with many health indicators and outcomes in the general population. However, it's relation with physical performance indicators in athletes is poorly understood. We determined the effects of 12 weeks of omega-3 PUFA supple-

mentation compared with medium-chain triglycerides (MCT) as placebo during endurance training on O3I and physical performance indicators in amateur runners.

METHODS: 40 participants were randomly assigned to OMEGA or MCT groups providing either omega-3 PUFA (2234 mg·d−1 of EPA and 916 mg·d−1 of DHA) or MCTs as placebo (4000 mg·d−1). All participants completed a 12-week progressive endurance training programme supervised by a track and field coach, consisting of 3 four-week phases, together with simultaneous supplementation. A graded exercise test to exhaustion with assessment of VO2 peak, running economy and a 1500-m run trial were carried out before and after completion of the exercise training programme.

RESULTS: From the 40 participants enrolled, 26 completed the entire study (14 in the OMEGA and 12 in the MCT group). Twelve weeks of omega-3 fatty acid supplementation during endurance training increased O3I in the OMEGA group to the target range (from 5.8% to 11.6%, $P < 0.0001$) without significant changes in the MCT group. There was no significant difference between groups in change in VO2peak over the 12-week intervention period ($P = 0.6764$). However, a significant increase in VO2peak from pre- to post intervention in OMEGA group was observed (from 53.6 ± 4.4 to 56.0 ± 3.7 mL·kg−1·min−1, $P = 0.0219$) with no significant change in MCT group (from 54.7 ± 6.8 to 56.4 ± 5.9 mL·kg−1·min−1, $P = 0.1308$). Increase in VO2peak was seen in 13 (93%) out of 14 participants in the OMEGA group, whereas in the MCT group, improvements were visible in 9 (75%) out of 12 runners. When results pre- and post- 12-week intervention from all participants were combined, correlation highlighted the relationship between O3I and oxygen cost of submaximal running ($P = 0.0338$). No difference between groups in completion of the 1500-m run trial was seen (pre- to post-intervention between groups, $P > 0.9999$).

CONCLUSION: Twelve weeks of omega-3 PUFA supplementation at a dose of 2234 mg of EPA and 916 mg of DHA daily during endurance training resulted in the improvement of O3I and running economy and increased VO2peak without improvement in the 1500-m run trial time in amateur runners. Compared with previous studies in which performance indicators were assessed, our supplementation protocol was a higher dose over a longer supplementation period. However, what values of O3I are sufficient for amateur and competitive athletes to optimize athletic performance remains a question to be answered in future studies.

INCREASED SKELETAL MUSCLE NITRATE CONCENTRATION FOLLOWING 3 DAYS OF NITRATE SUPPLEMENTATION IS NOT INFLUENCED BY PRIOR NITRATE AVAILABILITY

BLACK, M.I.1, KADACH, S.1, PIKNOVA, B.2, PARK, J.W.2, WYLIE, L.J.1, STOYANOV, Z.1, VANHATALO, A.1, SCHECHTER, A.N.2, JONES, A.M.1

1> UNIVERSITY OF EXETER MEDICAL SCHOOL, UNIVERSITY OF EXETER, EXETER, EX1 2LU, UK; 2> MOLECULAR MEDICINE BRANCH, NIDDK, NATIONAL INSTITUTES OF HEALTH, BETHESDA, MD, 20892-1822, USA.

INTRODUCTION: Skeletal muscle nitrate (NO_3^-) concentration is increased following NO_3^- ingestion, and its decline during exercise is associated with enhanced performance. Rodent models have shown that muscle [NO_3^-] can be augmented by consuming NO_3^- following a period of low dietary NO_3^- availability, i.e., there is a 'supercompensation' response. The purpose of the current study was to assess whether, in humans, muscle [NO_3^-] was increased and exercise performance was improved to a greater extent following NO_3^- supplementation when preceded by 7-d low compared to 7-d normal dietary NO_3^- intake.

METHODS: Nine participants (8 males1 female; age: 22 ± 1 y; body mass: 76.2 ± 8.8 kg) were assigned in a randomized, crossover design to a calorie and macronutrient matched: i) 7-d low (<50 mg NO_3^- per day), or; ii) 7-d normal (~180 mg NO_3^- per day) NO_3^- diet, that was immediately followed by 3-d high NO_3^- intake. At baseline (i.e., prior to the 7-d prescribed diet), and at completion of the dietary interventions, participants completed a 10-s all-out sprint and a ramp incremental cycle test. Saliva, plasma and skeletal muscle samples were collected for determination of [NO_3^-] and nitrite ([NO_2^-]) using ozone-based chemiluminescence.

RESULTS: Saliva, plasma, and skeletal muscle [NO_3^-] and [NO_2^-] were not different between diets at baseline. Skeletal muscle [NO_3^-] was significantly increased when high NO_3^- intake was preceded by both the 7-d normal or 7-d low NO_3^- diets, but no difference was observed in the absolute or percentage increase between the conditions. Skeletal muscle [NO_2^-] was not changed from baseline for either diet. Ramp incremental exercise performance and 10-s sprint performance were not changed from baseline and were not different between conditions. No significant correlations were observed between absolute or percentage change in skeletal muscle [NO_3^-] and absolute or percentage changes in exercise performance variables.

CONCLUSION: This study shows, for the first time, that skeletal muscle [NO_3^-] is increased to a similar extent following 3-d high NO_3^- intake irrespective of dietary NO_3^- availability during the previous 7-d, i.e., there was no 'supercompensation' response. Under the conditions of the present study, neither ramp incremental nor 10-s sprint performance were enhanced.

EFFECT OF ARGININE-CITRULLINE SUPPLEMENT ON SKIN-GAS NITRIC OXIDE CONCENTRATION AND PERFORMANCE FOLLOWING MAXIMAL RUNNING EXERCISE

MATSUDAIRA, H.1, YAMADA, K.1, TAKEHARA, K.1, IWATA, Y.1, ITO, R.1, SATO, T.1, HAGINO, Y.1, HASHIMOTO, R.1, ONO, F.1, TAKEUCHI, A.1, MIYAZAKI, M.2, TSUDA, T.1, ITOH, H.1

NAGOYA INSTITUTE OF TECHNOLOGY

INTRODUCTION: The combination of oral L-arginine and L-citrulline immediately and synergistically increases plasma arginine and nitrite/nitrate (NOx) concentrations more than either citrulline or arginine alone (1,2). Nitric oxide (NO) is the most important endothelium-derived relaxing factor, which plays a pivotal role in modulating smooth muscle tone (3). During exercise, increasing NO production facilitate blood flow in muscle tissues, muscle energy metabolism, and mitochondrial respiration, therefore previous human study has reported that oral arginine-citrulline supplement improved exercise performance due to increased NO bioavailability (1). However, there is no data concerning with the effect of arginine-citrulline supplement on skin-gas NO concentration during exercise. The present study examined to confirm the effect of arginine-citrulline supplement on skin-gas NO concentration and performance following maximal running exercise.

METHODS: A double-blind randomized placebo-controlled 2-way crossover study was employed. Ten healthy male students (23.0 ± 1.5 years; mean ± SD) consumed arginine-citrulline supplement (VELOX Charge: Kyowa Kirin Co., Ltd., Japan) or placebo orally 1 h before incremental maximal running exercise exhausting within 30 min. The skin-gas samples were obtained from the dominant hand by covering with a polyethylene bag in which pure nitrogen gas (250mL) was introduced for 100 sec, and collected in a sampling bag at rest and 0, 5, 10, 15, 30 min recovery of the exercise. The skin-gas NO concentration was measured by a chemiluminescence analyzer (Pico-Device Co., Ltd., Japan). Blood flow measured using a laser tissue blood flow meter from the non-dominant index finger belly and leg thigh skin surface (Omegaflo, Omega Wave, Japan).

RESULTS: The arginine-citrulline supplement significantly ($p<0.05$) increased running time and distance compared to the placebo. Maximal exercise in this study significantly increased skin-gas NO concentration ($p<0.05$) and blood flow ($p<0.001$) after the exercise compared to the resting values. Significant higher levels were observed in skin-gas NO concentration ($p<0.001$) and blood flow ($p<0.001$), thus there was a significant interaction in skin-gas NO concentration ($p<0.05$) and blood flow ($p<0.001$) between the arginine-citrulline supplement and the placebo.

CONCLUSION: Significantly higher levels of skin-gas NO concentration has indicated that the arginine-citrulline supplement increased NO production and NO bioavailability in the whole body during the maximal exercise. As a result, blood flow in muscle tissues, muscle energy metabolism, and mitochondrial respiration during exercise facilitated by the arginine-citrulline supplement, consequently improved exercise performance (1).

INFLUENCE OF MUSCLE SIZE GROUP ON THE ERGOGENIC EFFECT OF CAFFEINE ON MUSCULAR STRENGTH, POWER AND ENDURANCE

MONTALVO-ALONSO, J.J., VALADÉS, D., DOMÍNGUEZ, R., FERRAGUT, C., PÉREZ-LÓPEZ, A.

UNIVERSIDAD DE ALCALÁ

INTRODUCTION: There is a consensus that caffeine improves muscular strength-power-endurance performance; however, we did not entirely understand the mechanism of action of this substance. If the caffeine ergogenic effect occurs in the CNS, a higher increase in force production should occur in larger muscle groups by eliciting a higher increase in motor unit recruitment and firing rates than in small muscle groups. While if caffeine has a direct effect on muscle, the ergogenic effect of this substance should occur to a similar extent across muscle groups. Previous studies support the central effect hypothesis by observing a more pronounced improvement in mean isokinetic peak torque of larger than smaller muscle groups. However, the ergogenic effect of caffeine according to muscle size group has been scarcely investigated in isotonic exercises. Thus, this study aimed to examine the effects of acute caffeine intake on upper and lower-body muscular strength-power-endurance performance at different loads.

METHODS: Twenty resistance-trained athletes (male/female: 10/10; age: 23±4 yr; body mass: 71±15 kg) participated in a double-blind, placebo-controlled, cross-over and randomized study. Participants were provided with either 3 mg/kg of body mass of caffeine or maltodextrin (placebo). Sixty minutes after ingestion, they performed muscular strength and power assessment for bench press and back squat exercises at 25%, 50%, 75% and 90% 1-repetition-maximum (1RM), performing 3, 2, 1 and 1 repetitions, respectively. Then, muscular endurance was assessed for both exercises at 65% and 85% 1RM performing one set until task failure.

RESULTS: Compared to placebo, caffeine improved mean velocity (Vmean, ANOVA effect, P=0.045), mean power (Wmean, ANOVA effect, P=0.049) and rate of force development (RFD, ANOVA effect, P=0.032) in muscular strength and power test, particularly in back squat exercise at 75% and 90% 1RM where Vmean increased by 5-7% (P=0.48-0.038), Wmean by 6-8% (P=0.050-0.032) and RFD by 17-97% (P=0.042-0.046). No differences were found in the bench press exercise. In muscular endurance, caffeine improved the number of repetitions in all exercises and loads (ANOVA effect, P=0.003), but only

in back squat exercise at 85% 1RM, caffeine increased Vmean and Vpeak (8-9%, P=0.006-0.004), Wmean and Wpeak (10-13%, P=0.006-0.003) and force peak (3%, P=0.009).

CONCLUSION: This study compared back squat and bench press exercises, where the quadriceps and pectoralis are the main muscles involved, respectively. The results show a more pronounced ergogenic effect of low doses of caffeine on muscular strength-power-endurance performance by increasing Vmean, Wmean and RFD according to muscle size group. Therefore, this study reinforces the central effect hypothesis that caffeine improves force and power production by stimulating the CNS through increasing motor unit recruitment and firing rates in isotonic tasks.

CO-SUPPLEMENTATION WITH NITRATE AND RESVERATROL PREVENTS HIGH-FAT-DIET MEDIATED REDUCTIONS IN BRAIN BLOOD FLOW, BUT SURPRISINGLY DECREASES MITOCHONDRIAL RESPIRATORY CAPACITY IN THE CORTEX OF MALE MICE

DESORMEAUX, G.J., DOWLING, J., HANDY, R.M., BARBEAU, P.A., HOLLOWAY, G.P.

UNIVERSITY OF GUELPH

INTRODUCTION: Mitochondrial biology affects neurological health, as oxidative phosphorylation (OXPHOS) influences action potential conductance and dendritic growth, while excessive reactive oxygen species (ROS) production has been linked to atrophy. Dietary nitrate (NIT) and resveratrol (RSV) are two nutraceuticals that may optimize mitochondrial biology within the brain as they can cross the blood-brain barrier and coordinate blood flow. In the present work, we aimed to characterize the effects of a high-fat diet (HFD) on mitochondrial bioenergetics within the cortex, as well as determine if supplementation with NIT and RSV could prevent HFD-mediated changes in blood flow and mitochondrial biology within this region of the brain in an independent and/or additive manner.

METHODS: C57Bl/6N male mice consumed a low-fat diet (LFD; 10% fat) or a HFD (60% fat) for eight weeks (n=9-10/group). Blood flow to the brain was measured via carotid ultrasonography and following the intervention period, the cortex was permeabilized to determined mitochondrial respiratory capacity, and homogenized for analysis of various protein targets. These experiments were repeated with nutraceutical interventions where mice consumed one of four HFD variations (n=12/group): un-supplemented (HFD), supplemented with +NIT (4mM sodium nitrate via drinking water), + RSV (172mg RSV/kg diet), or combined +NIT+RSV.

RESULTS: Compared to the LFD group, HFD feeding decreased blood flow to the brain as indicated by reduced carotid diameter, aortic velocity time integral (VTI), and carotid flow rate. Concurrently, HFD-fed mice also displayed strong trend for a decrease in VEGF protein content ($p = 0.0565$) in the cortex. Despite the reduction in blood flow, HFD-feeding did not alter mitochondrial content, nor maximal ADP, complex I- and complex II-supported mitochondrial respiration. Supplementation with +NIT+RSV prevented HFD-mediated decreases in carotid diameter, VTI and carotid flow rate in conjunction with an increase in VEGF protein content in the cortex. While combined treatment did not alter markers of mitochondrial content, despite the preservation of blood flow, +NIT+RSV supplementation decreased maximal complex I- and complex II-supported mitochondrial respiration.

CONCLUSION: While combined +NIT+RSV treatment prevented HFD-mediated decreases in blood flow to the brain, this occurred alongside reduced maximal mitochondrial respiration. Taken together, future research is required to integrate the effects of increased blow flow and reduced OXPHOS to understand in vivo biology, and to determine the effect on redox biology.

GREATER POST-EXERCISE HYPOTENSION IN HEALTHY UNTRAINED MEN AFTER EXERCISING IN THE HEAT

HORIUCHI, M.1, OLIVER, S.J.2

1. NATIONAL INSTITUTE OF FITNESS AND SPORTS IN KANOYA: KANOYA TAIIKU DAIGAKU, JAPAN; 2. BANGOR UNIVERSITY, BANGOR, WALES, UK

INTRODUCTION: Mean arterial pressure (MAP) is lowered for approximately 2 h after physical exercise; a phenomenon called post-exercise hypotension (PEH). Whether exercising in the heat increases PEH compared to exercise in temperate conditions is unclear [1,2]. This study compared changes in MAP in healthy young untrained men after an acute bout of exercise in a temperate and hot environment. We hypothesized that exercise in a hot environment would elicit greater PEH than in a temperate environment.

METHODS: Twelve participants completed two experimental conditions, 40-min leg-cycling exercise at the intensity of 60% of maximal oxygen uptake in 23°C (CON) and 35°C (HOT). After exercise, they rested in the supine position for 60 min at 23°C. Blood pressure, skin blood flow at chest (CVC), and cardiac baroreflex sensitivity (cBRS) were assessed pre-exercise and after 10, 20, 30, 40, 50, 60 min of exercise.

RESULTS: Post-exercise hypotension was greater after exercising in a hot than temperate environment as indicated by a lower mean arterial pressure (MAP) at 60 min recovery (CON 83 ± 5 mmHg, HOT 78 ± 5 mmHg, Mean difference [95% confidence interval], Δ−5 [−8, −3] mmHg). Throughout the 60 min recovery CVC was higher and cBRS was lower after

exercising in a hot compared to temperate environment (P < 0.001). Sweat loss was greater on HOT than CON (P < 0.001). After exercising in the heat changes in MAP were associated with changes in sweat loss (r > 0.66, P = 0.02) and CVC (r > 0.64, P = 0.03). In contrast, no relationships were observed between changes in cBRS and MAP (P > 0.05).

CONCLUSION: A single bout of exercise in a hot environment elicited greater hypotension during recovery than in a temperate environment Greater PEH in HOT of the present study was consistent with a previous study completed in an inactive untrained population [1]; however, it contrasts the findings of another study completed in an endurance trained population [2]. Collectively, these studies suggest after exercising in the heat inactive and untrained people suffer greater PEH than endurance trained people. As PEH is related to risk of syncope this suggests inactive and untrained people may be at increased risk of syncope and falls after exercising in hot conditions. Our correlative data (R square) identify that the relationship between changes in CVC and MAP explains 40% of the variance for PEH in HOT. In addition, the changes in CVC during recovery from baseline were related to the changes in MAP in the hot environment. These findings suggest that the changes in MAP during recovery, preceded by a single bout of exercise in a hot environment, were more passive to changes in cutaneous circulation and may help explain the increased risk for post-exercise syncope in hot environments.

EFFECT OF HOT WATER IMMERSION ON TRAINING ADAPTATION FOLLOWING A 10-WEEK RESISTANCE TRAINING PROGRAMME

WILSON, L.1, BELL, P.2, VAN SOMEREN, K.3, GONDEK, M.1, HILLS, F.1, COCKBURN, E.1, JACKMAN, J.1

MIDDLESEX UNIVERSITY, NORTHUMBRIA UNIVERSITY, ATLANTIC TECHNOLOGICAL UNIVERSITY,

INTRODUCTION: Hot water immersion (HWI) is a strategy that has been shown to influence acute physiological responses following resistance exercise. However, the impact of regular HWI following resistance exercise on adaptation following a period of training is yet to be determined. This study investigated the effect of regular post-exercise HWI on markers of training adaptation following a resistance training programme.

METHODS: Sixteen trained males performed resistance training twice per week for 10 weeks, with either 10 min of HWI or passive recovery (PAS) after each session. Anthropometric variables of body mass, body fat percentage, as well as lower limb fat mass and fat free mass were measured pre- and post-resistance training programme using dual energy x-ray absorptiometry. Performance measures of one-repetition max (1RM), six-repetition max (6RM), maximal voluntary isometric contraction (MVIC) and isometric squat peak force were assessed before and after the training intervention.

RESULTS: As a result of the training programme, there was a significant increase in lean tissue in the lower limbs ($F(1, 14) = 9.082$, $P = 0.009$), although there was no difference between groups. Post-training, there were significant increases in maximal strength, although there were no differences between groups (($F(1, 14) = 20.513$, $P = <0.001$) and ($F(1, 14) = 50.871$, $P = <0.001$) for 1RM and 6RM respectively).

CONCLUSION: These data suggest that HWI does not appear to enhance maximal strength following a 10-week resistance training programme. However, further research is warranted to determine whether HWI can manipulate acute physiological responses, which over time may accumulate to contribute to small enhancements in strength in response to a training programme.

THE EFFECT OF PRE-EXERCISE HYPERHYDRATION ON EXERCISE PERFORMANCE, PHYSIOLOGICAL OUTCOMES AND GASTROINTESTINAL SYMPTOMS: A SYSTEMATIC REVIEW

JARDINE, W.T.1, AISBETT, B.1, KELLY, M.K.1, BURKE, L.M.2, ROSS, M.L.2, CONDO, D.1, PÉRIARD, J.D.3, CARR, A.J.1

1 DEAKIN UNIVERSITY, CENTRE FOR SPORT RESEARCH; 2 AUSTRALIAN CATHOLIC UNIVERSITY, MARY MACKILLOP INSTITUTE FOR HEALTH RESEARCH; 3 UNIVERSITY OF CANBERRA, RESEARCH INSTITUTE FOR SPORT AND EXERCISE

INTRODUCTION: Fluid loss during prolonged exercise in hot conditions poses thermoregulatory and cardiovascular challenges that can impair performance. Pre-exercise hyperhydration, defined as an increase in total body water above normal levels, can be achieved using osmotic aids (e.g., glycerol, sodium). This strategy may prevent or delay the adverse effects of dehydration and attenuate the impact of heat stress on exercise performance. The aim of this systematic review was to determine the effect of pre-exercise hyperhydration strategies on performance in temperate and hot conditions, key physiological responses (i.e., heart rate, core temperature and changes in plasma volume) and gastrointestinal symptoms.

METHODS: Inclusion criteria comprised: English language, full-text articles published up to and including October 2022 that compared the intervention to a baseline or placebo condition. Exclusion criteria comprised: studies that involved concurrent interventions or an initial dehydration period and rehydration period prior to exercise. A quality assessment was conducted by two authors using the American Dietetic Association Quality Criteria Checklist.

RESULTS: Thirty-eight studies involving 375 participants (n = 339 males) were included in this review (n = 22 assessed exercise performance or capacity). Two studies reported an improvement in time-trial performance (range 5-11%), three studies reported an improvement in total work completed (kJ) (range 4-5%), and five studies reported an increase in exercise capacity (range 12.5-28%). During constant work rate exercise, eight studies reported a reduced mean heart rate

(range 3-9 beats·min-1), and nine studies reported a reduced mean core temperature (range 0.1-0.8°C). Eleven studies reported an increase in plasma volume (range 3.5-9.8%). At least one gastrointestinal symptom was reported in 26 studies, with severity depending on the hyperhydration strategy (i.e., treatment, dose, ingestion rate).

CONCLUSION: Pre-exercise hyperhydration may improve exercise capacity in trained athletes at a given work rate in association with a reduced heart rate and core temperature, likely stemming from an acute increase in plasma volume. Limitations within this research area include a lack of valid and reliable tools used to monitor gastrointestinal symptoms and lack of adequate blinding techniques to reduce the possibility of a placebo effect. The inclusion of female participants and the effect of the menstrual cycle on fluid retention and pre-exercise hyperhydration remains a key area of interest for future research.

EFFECT OF CRYOSTIMULATION AFTER EXERCISE IN A HOT ENVIRONMENT ON THE CARDIOVASCULAR SYSTEM AND BODY TEMPERATURE

KANATANI, K., NAKAGAWA, Y., KAWABATA, T.

KANSAI UNIVERSITY

INTRODUCTION: Exercising in a hot environment causes hyperthermia, which reduces exercise performance (Gonzàlez-Alonso et al. 1999). Especially during standing exercise, the increase in skin blood flow due to elevated body temperature causes blood pooling in the lower limb and cutaneous vasculature (Rowell 1986). Cryostimulation of the whole body and lower limb after exercise reduces core temperature and eliminates blood pooling through peripheral vasoconstriction (Yamazaki et al. 2002), thereby restoring cardiovascular and thermoregulatory function. In this study, cryostimulation of the whole body and lower limb and sole after exercise in a hot environment was to examine the effect of cardiovascular and thermoregulatory function.

METHODS: Six trained subjects (age: 24 ± 2 years, height: 175.5 ± 4 cm, weight: 71.3 ± 5.8 kg) completed a submaximal (70% Vo_2max) constant load exercise test for 30 minutes in a hot environment (Ta 35°C, RH 60%). After exercise, the subjects were exposed to a whole-body (WBC) and lower limb to cryobath at -120°C and sole was cooling ice pack at -50°C for 2 minutes. Measurements were taken for esophageal temperature (Tes), skin temperature, heart rate (HR), cardio output (CO), stork volume (SV), forearm blood flow (FBF), muscle temperature.

RESULTS: There was a significant decrease in Tes(rest:38.50±0.48°C vs WBC:37.99±0.43°C, lower limb:38.18±0.50°C, sole:38.32±0.40°C P>0.05), HR(rest:130±14bpm vs WBC:117±15bpm, lower limb:118±17bpm, sole:121±15bpm P>0.05), muscle temperature(rest:38.72±0.72°C vs WBC:37.93±0.43°C, lower limb:38.10±0.60°C, sole:38.54±0.57°C P>0.05) and FBF(rest:13.07±3.19ml/min/100g vs WBC:8.92±1.23ml/min/100g, lower limb:9.88±4.16°C, sole:10.22±3.08°C P>0.05) and a significant increase in SV(rest:71±9ml vs WBC:82±7ml, lower limb:81±9°C, sole:75±8°C P>0.05) after cryostimulation compared to rest. Skin temperature decreased significantly in WBC and lower limb.

CONCLUSION: Cryostimulation for 2 minutes after exercise significantly decreased Tes and significantly increased SV in lower limb and sole. It is suggested that the cutaneous vasoconstriction caused by cryositimulation increased venous return and increased SV. Whole body cryostimulation showed a large decrease in temperature. But the same cooling effect as in the lower limb and WBC was obtained for all points except the mean skin temperature in sole, which has a smaller cooling area. The temperature was higher than that of the whole body and lower limb, but this result may have been due to through arteriovenous anastomoses in the sole. It was shown that there was no difference in cardiovascular function, although there was a large difference in temperature only due to the difference in the cryostimulation area.

INTERMITTENT RUNNING IN THE HEAT ON SYNTHETIC GRASS INCREASES MARKERS OF HEAT STRESS COMPARED TO NATURAL GRASS

SINGH, G., BENNETT, J.K., MCGUIGAN, H., STEVENS, J.C.

SOUTHERN CROSS UNIVERSITY

INTRODUCTION: The surface temperature of synthetic grass sports surfaces becomes considerably hotter than natural grass when exposed to high levels of sunlight. Some data has also demonstrated that synthetic grass surfaces can increase the ambient and radiant temperature above the surface. However, it is unknown if a synthetic surface can increase human heat stress during exercise compared to natural grass. Therefore, this study aimed to determine if synthetic grass surfaces impose a thermal load that elicits physiological or perceptual changes in athletes during intermittent running, compared to natural grass.

METHODS: Thirteen recreational team-sport athletes performed a baseline 30-15 fitness test, and then, with a randomised and cross-over design, two separate 50-minute standardised intermittent running trials on a synthetic and natural grass surface, separated by one week, on hot days. Environmental parameters, core and skin temperature, heart rate, sweat rate, and perceptual ratings were measured.

RESULTS: There were no significant differences in wet-bulb-globe temperatures between the two trials (synthetic: 27.41 ± 0.12°C; natural: 26.65 ± 0.49°C; p >0.05). The change in mean core body temperature from baseline to the end of the

trials was not significantly different between surface types (synthetic: 1.31 ± 0.34°C; natural: 1.42 ± 0.54°C; p >0.05). Compared to baseline, there was a significant increase in mid-calf skin temperature for synthetic (7.12 ± 2.92°C) compared to natural (0.48 ± 0.90°C; p <0.001) and shoulder skin temperature for synthetic: (2.48 ± 2.16 °C) compared to natural (0.64 ± 1.26°C; p <0.001), at the end of the trial. The mean perception of thermal sensation across the protocol was significantly higher on synthetic (2.8 ± 0.4) compared to natural (2.4 ± 0.5; p = 0.013). Sweat rate was also higher on synthetic (1.53 ± 0.43 L/hr) compared to natural (1.23 ± 0 .31 L/hr; p = 0.017). There were no significant differences in mean heart rate, rate of perceived exertion, thermal comfort or chest skin temperature across the trials (p >0.05).

CONCLUSION: The findings demonstrate that running on a synthetic grass surface compared to natural grass on a hot day increases a range of markers of heat stress, including skin temperatures, sweat rate, and perceived thermal sensation. However, there was no difference in core body temperature. Sport's governing bodies, facility managers, and any individual organising or prescribing exercise or sport on a synthetic surface on hot days should consider this additional heat stress. More data is required to determine the implications for different sports in different environmental conditions and on different synthetic surfaces.

ICE INGESTION MAINTAINS COGNITIVE PERFORMANCE ON A REPEATED SPRINT PERFORMANCE IN THE HEAT

MAZALAN, N.

THE UNIVERSITY OF NATIONAL MALAYSIA

INTRODUCTION: Environmental factors have a major influence on exercise performance. Notably, excessive exercise in the heat often results in increased physiological demands and reduced ability to deal with cognitive loads. This has been attributed to the elevation of core body temperature (Tc), which can subsequently impair exercise and cognitive performance. The elevation of Tc is a result of a disturbance in thermoregulation processes during exercise in the heat, which reduces the ability of the body to return to homeostasis. Hence, the body is unable to regulate its Tc within a normal range (36.5 – 37.5°C). Consequently, when Tc reaches 39°C, which is known

as a critical Tc threshold, it represents one of the key limiting factors to exercise tolerance in the heat, leading to reduced force output, cardiovascular strain, premature termination of exercise, and increased risk of heat illness. Of relevance, when Tc increases during exercise, particularly when performed in the heat, the temperature of arterial blood flow to the brain also increases, placing a thermal load on the brain, which in turn can result in central fatigue. Furthermore, an increase in Tc during exercise in the heat results in a concomitant reduction in cerebral blood flow to the brain due to the need for the body to direct blood flow to the

periphery for cooling purposes, with blood flow to the brain further compromised if dehydration, as a result of sweating, occurs.

METHODS: Nine males, non-acclimatised to heat (mean age: 28.2±2.7 y; height: 175.7±9.7 cm; body-mass: 76.9±10.6 kg) completed a 30 min bout of repeated sprint (36 sprint × 4 s) on a cycle ergometer. Crushed ice ingestion (7g·kg-1, -0.4°C, ICE) or no cooling (CON) interventions were completed at rest, 30 min prior to exercise in the heat chamber (35°C, 70% relative humidity). Working memory was assessed via Serial Seven Test (S7) and the Automated Operation Span Task (OSPAN) before cooling/no cooling, prior and after exercise. Core body temperature (Tc), forehead temperature (Th) and thermal sensation (TS) were assessed during the protocol.

RESULTS: Precooling significantly decreased Th (-0.59°C, p<0.001) and Tc (-0.67°C, p=0.005) in ICE compared to baseline but increased in CON (Th: +0.54°C, p<0.001, Tc: +0.17°C; p=0.01). Further, S7 and OSPAN scores significantly declined over time in CON compared to baseline, p<0.05. Although S7 and OSPAN were not different in ICE (p=0.94, p=0.84, respectively) compared to CON, ICE has been shown to preserve working memory by maintaining S7 between baseline (20±2.6) and min 27 (20±3.7,p>0.05) and OSPAN between baseline (65±5.4) and min 30 (66.8±4.2 p>0.05) compared to CON. In addition, thermal sensation was lower at baseline in ICE compared to CON (p<0.05).

CONCLUSION: Crushed ice ingestion significantly reduced Th and Tc and subsequently facilitated maintenance of cognitive performance responses during intermittent repeated sprint in the heat.

INTERVAL TRAINING AS A MEANS OF MAINTAINING A HIGH LEVEL OF PERFORMANCE OF ATHLETES IN CONDITIONS OF HIGH AMBIENT TEMPERATURE.

VASILEV, A.D., KALININ, E.M., KOSMINA, I.P.

FEDERAL SCIENCE CENTER OF PHYSICAL CULTURE AND SPORT

INTRODUCTION: This study aimed to investigate the effects of hyperthermia on physiological parameters of a high-level athletes at rest and during exercise of varying intensity. The study was conducted in a laboratory setting and results were tested under real conditions of increased environmental temperature at training camps in Brazil. Physiological parameters were measured at rest, at the aerobic threshold, anaerobic threshold, maximal power output and during submaximal exercises. The results of this study have important implications for athletes competing in the upcoming Olympics in 2024 and 2028, as the ambient temperature during the competition will be high [1,2,3].

METHODS: 86 highly qualified team sports athletes were tested to determine VO2max and maximum alactic power. Testing was performed on Ergoline 200 and Monark 894E bicycle ergometers using a Cortex Metamax 3B gas analyzer. To simulate the conditions of hyperthermia, the subjects entered the sauna (t=90-95°C, humidity <10%) until the temperature of the core of the body increased to 38-38.5°C. The temperature was measured in the ear with the "TermoScan" device

(p<0.1°C). After that, the subjects performed a load on a bicycle ergometer at room conditions (tk = 25.3 °C) with a load of varying intensity. The results obtained were tested on 15 athletes of the countrys national rugby-7 team in Brazil at an ambient temperature of 33-35 °C during training and competitive exercises. Athletes were measured core body temperature, the concentration of lactic acid in capillary blood, the subjective state of the athlete was assessed, the intensity of the exercise was recorded using Catapults GPS performance tracking system monitors, measuring heart rate (HR) and heart rate variability (HRV).

RESULTS: When performing a load at the level of the aerobic threshold and below, the core temperature of the athletes body decreases. Performing a load at the level of the anaerobic threshold (AT) leads to a faster achievement of the maximum temperature of the body core (40-40.5 °C) and, as a result, reduces the duration of the load with the AT power by 40-50% and an increase in heart rate at the AT level by 30±4 bpm. With an increase in body temperature, the maximum duration of the exercise with submaximal power decreases by 15% (p<0.001), while the indicators of maximum strength and power increase by 7% (p<0.001).

CONCLUSION: The temperature of the core of the body after heating to 39 - 40 °C can be significantly reduced when performing work with a power below the aerobic threshold. Performing a rest interval with power at the level of anaerobic threshold and above leads to the accumulation of heat in the body of athletes. Therefore, the interval method of training with the performance of speed and speed-strength exercises and active rest intervals, with power below the aerobic threshold, will allow organizing effective training sessions in a hot climate, while maintaining the high performance.

EFFECTIVENESS OF MIXED METHOD PRECOOLING ON PERFORMANCE IN NATURALLY HEAT ACCLIMATISED TEAM-SPORT ATHLETES

BRADE, C., CHONG, E., VAUGHAN, M., DUCKER, K.

CURTIN UNIVERSITY

INTRODUCTION: Heat alleviation techniques, acclimatisation/acclimation and pre-cooling are often used to combat the negative effects heat and humidity have on exercise performance. Unsubstantiated claims suggest that pre-cooling may not add additional benefit to those already acclimatised/acclimated due to the reduced efficacy of precooling when the thermal stress experienced by an individual is low. This study aimed to determine if those who present as being naturally acclimatised to hot and humid environmental conditions benefit from precooling under differing thermal conditions.

METHODS: Ten male, team-sport athletes completed six experimental trials under three thermal conditions; (1) warm and humid (33˚C, 70% relative humidity [RH], 41˚C apparent temperature [AT]); (2) hot and dry (38˚C, 30% RH; 43˚C AT); (3) hot and humid (38˚C, 70% RH; 50˚C AT). All participants resided in Singapore and were naturally acclimatised to hot and humid thermal conditions. Each trial was completed twice in the three thermal conditions, once with 30 min of mixed-method (7 g·kg-1 BM of shaved ice plus ice jacket) pre-cooling (PC) and once without (CON). Following the PC or CON period, participants completed a repeat sprint exercise protocol on a cycle ergometer. The protocol consisted of 2 x 30 min halves, consisting of 30 x 4 s maximal sprints every minute interspersed with 56 s of exercise at varying intensities (25, 50, 75 and 100 Watts [W]). An additional six sprints were performed every 5 min, starting at 2.5 min. Separating the two halves was a 10 min break where during the PC trials, participants ingested 2.3 g·kg-1 BM of shaved ice and wore the cooling jacket whilst during the CON the equivalent in plain water was ingested. Water was consumed at the 15 min mark of each half (100 mL) and an additional 100 mL of a sports drink was consumed during half-time.

RESULTS: Overall mean power, and first and second half mean power were not different between the PC and CON trials within each of the same thermal conditions. Between the PC and CON trials within the same thermal conditions, core temperature was not different except at the start of the first half where participants started cooler in the PC trial (36.0 ± 0.7°C) compared to CON (36.9 ± 0.2°C) in the 50˚C AT condition (p<0.05). No differences were apparent between trials (PC vs CON) within each of the same thermal conditions for HR, RPE, thermal sensation or thermal comfort.

CONCLUSION: These results suggest that those who are naturally acclimatised to hot and humid environmental conditions did not benefit from precooling in either a warm dry, hot dry, or hot humid environment, when performing repeat-sprint exercise. This contributes to the evidence that precooling in male team-sport athletes who are naturally acclimatised to hot, humid conditions may not enhance repeat-sprint performance.

HEART RATE AS AN EARLY INDICATOR OF PREDICTED CORE TEMPERATURES DURING EXERTION IN THE HEAT

DALTON, C.

UNIVERSITY OF CAPE TOWN

INTRODUCTION: It is well documented that exercise in hot environments leads to higher core temperatures and associated decreased performances than cooler settings. (1) Heat illnesses constitute an array of conditions from exercise-associated collapse, heat intolerance to the most severe presentation of exertional heat stroke, of which one of the main clinical features include a core temperature greater than 40 degrees Celsius (˚C).(2) Identifying potentially susceptible individuals is of clinical value in certain settings. While finishing core temperature is often utilized as an outcome measure in heat tolerance tests, determining clinically relevant, easier to measure physiological factors, e.g. heart rate, could allow for improved monitoring during heat-stress related settings.

METHODS: Eight men and seven women regular runners performed four self-paced 10km treadmill time trials, one in cool (15˚C; 50% relative humidity(RH))and three in hot (32˚C; RH 50%) conditions in an environmental chamber, one week apart. Due to the complexity of thermoregulatory homeostasis, multiple physiological variables were recorded at regular inter-

vals, however, only finishing core temperature (Tc-fin), finishing time (Tmin-fin) and HR recorded at 10 and 20 minutes and finish were analysed and correlated in this analysis.

RESULTS: Significantly higher Tc-fin and HR were recorded in the hot trials compared to the cold trial ($p < 0.05$). No relationships were found in the cold trial measures between Tc-fin and HR. In the hot trials, relationships were found between Tc-fin and finishing % maximum HR in the male group only ($r=0.74$, $p< 0.05$). At both 10 and 20 minutes, relationships were found between Tc-fin and %maximum HR at these time points; ($r=0.82$, $p<0.05$);($r=0.83$, $p<0.05$) respectively, but again the male group only. In contrast, no relationship between finishing % max HR and Tmin-fin for the male group, but weaker correlations present in females ($r=0.68$, $p<0.05$).

CONCLUSION: While HR at 10 minutes of 40-60 minutes of running exercise can suggest which individuals are likely to finish with higher core temperatures and thus potentially at higher risk of heat-related conditions, this appears to only be of value for males, whereas females had higher HR associated with slower times. This is presumably related to previously documented differences in thermoregulation and performance between males and females of the general population such as sweat rates, pacing strategies and body surface to mass ratio differences. (3) Therefore in settings like the mining or military sector or individuals with underlying heat intolerance, where core temperature measurement may be challenging, heart rate monitoring with definition of norms for each population may be useful tool for identifying high risk individuals or guiding vulnerable individuals on how to manage themselves during certain physical activities in thermally challenging environments. 1. EFFECT OF KNEE ANGLE AND SUBMAXIMAL VOLUNTARY CONTRACTION INTENSITY ON VASTUS MEDIALIS AND VASTUS LATERALIS RIGIDITY

BOUVIER, J., OGIER, A.C., MARTIN, C., FOURÉ, A.

UCBL , UNIL .

INTRODUCTION: Ultrasound shear wave elastography (SWE) provides a local and accurate assessment of muscle rigidity (i.e., an estimation of the Young's modulus calculated from shear wave velocity (Bercoff et al. 2004)) leading to a closer estimation of individual muscle tension (Hug et al. 2015). Few studies have reported an influence of joint angle on muscle rigidity during submaximal voluntary elbow, hip and plantar flexions (Zimmer et al. 2023, Lin et al. 2022, Kato et al. 2021). The aim of the present study was to investigate the effect of knee joint angle on the local mechanical properties of the vastus medialis (VM) and the vastus lateralis (VL) during isometric submaximal voluntary contractions from SWE mapping.

METHODS: Young's modulii of the VM and the VL were assessed using SWE at rest and during submaximal voluntary contractions for two knee angles in twelve subjects. The VM and the VL Young's modulii at rest and during constant isometric submaximal voluntary contractions (i.e., 25%, 50% and 75% of maximal voluntary contraction [MVC]) were evaluated for two knee angles (50° and 100° | knee fully extended = 0°) in twelve participants. Surface electromyographic (sEMG) signals for the VM and the VM were also recorded during the experiments. A paired Student's t-test was performed to assess the effect of knee angle on MVC torque. A three-way ANOVA (knee angle × muscle × contraction intensity) was used for sEMG and SWE parameters. Post-hoc analysis was conducted using Tukey HSD test when appropriate.

RESULTS: No significant difference was found in the VM Young's modulus among all torque levels and knee angles ($P > 0.05$). In contrast, VL Young's modulus was significantly higher at 25% MVC for a knee angle of 100° than for the other torque levels at the same knee angle and was greater at 25% MVC for a knee angle of 100° than for 50° ($P < 0.001$).

CONCLUSION: The SWE explorations reveal the local mechanical state of the muscle during isometric submaximal voluntary contractions. The relative contribution of the VL during isometric voluntary contraction appears dependent on the initial muscle length and the relative knee extension torque level as previously reported (Zimmer et al. 2023), in contrast to the VM. The influence of inhomogeneous intramuscular architecture changes and muscle tension during submaximal contractions needs to be further examined.

CHARACTERISTICS OF ACUTE CARTILAGE DEFORMATION AFTER MECHANICAL LOADING IN PATIENTS WITH EARLY-MILD KNEE OSTEOARTHRITIS

OKADA, S., TANIGUCHI, M., YAGI, M., MOTOMURA, Y., OKADA, S., NAKAZATO, K., FUKUMOTO, Y., KOBAYASHI, M., KANEMITSU, K., ICHIHASHI, N.

KYOTO UNIVERSITY

INTRODUCTION: Early cartilage degeneration in patients with knee osteoarthritis (KOA) is characterized by qualitative rather than quantitative change. As an indicator of cartilage quality, acute cartilage deformation after cyclic mechanical loading has attracted attention. Greater acute deformation, for example, is observed in young participants with arthroscopic cartilage damage following anterior cruciate ligament injury [1]. However, it is unknown whether acute cartilage deformation is associated with early cartilage degeneration in patients with KOA. This study aims to determine whether acute cartilage deformation differs between patients with KOA and healthy controls using an ultrasound imaging device.

METHODS: We recruited 56 women aged≥50 years with Kellgren-Lawrence grade (KLG)≤2 (age, 70.6±7.4y; height, 153.7±5.2cm; weight, 51.9±8.2kg). The knee symptom was assessed using the symptom section of the Knee Society Score (KSS). The scores range from 25 to 0, and lower scores indicate more severe knee pain and stiffness. We defined a score of 23 or more as asymptomatic. Based on KLG and KSS, participants were grouped into two groups: the control group (KLG≤1, asymptomatic, n=27) and the early-mild KOA group (KLG 1 and symptomatic, KLG 2, n=29). Medial femoral cartilage was assessed using an ultrasound imaging device. Longitudinal (corresponds to the tibiofemoral joint) and transverse (corresponds to the patellofemoral joint) B-mode images of the femoral cartilage were acquired three times before and after treadmill walking (15 minutes, 3.3 km/h), and measured cartilage thickness at each time point. On the ground, all participants measured the external knee moment impulse during the stance phase of gait at the same speed as treadmill walking using a motion capture system and force plates. Acute cartilage deformation was analyzed 2×2 (groups×time) repeated measures analysis of covariance with adjusted age, external knee moment impulse, steps during treadmill walking, and cartilage thickness at baseline. The statistical significance level was set at 5%.

RESULTS: A significant interaction was found on the longitudinal image, and cartilage thickness in the early-mild KOA group after walking was thinner than that in the control group (mean±standard error, control; 1.56±0.00→1.50±0.00mm, KOA; 1.56±0.00→1.44±0.01mm, p=0.002). On the transverse image, there was a significant main effect of time, but not an interaction(control; 1.58±0.00→1.53±0.02mm, KOA;1.58±0.00→1.52±0.02mm, p=0.802).

CONCLUSION: The femoral cartilage of the medial tibiofemoral joint deformed more in patients with early-mild KOA than in healthy controls. Our finding suggested that greater acute deformation was a feature of early cartilage degeneration in patients with early-mild KOA.

CLARIFICATION OF SOFT TISSUES ASSOCIATED TO KNEE EXTENSION LIMITATION IN PATIENTS WITH KNEE OSTEOARTHRITIS

OKADA, S., YAGI, M., TANIGUCHI, M., MOTOMURA, Y., OKADA, S., KOBAYASHI, M., KANEMITSU, K., ICHIHASHI, N.

KYOTO UNIVERSITY

INTRODUCTION: Patients with knee osteoarthritis (KOA) often exhibit knee extension limitation, which exacerbates knee symptoms and functional impairments. Although various tissues of the posterior knee would be associated with knee extension limitation, it remains to be determined which tissue is involved. It is probable that the tissue associated with knee extension limitation is stiffer. Ultrasound shear wave elastography (uSWE) could non-invasively quantify soft tissue stiffness in vivo. We aimed to clarify the relationship between knee extension limitation and tissue stiffness in patients with KOA using uSWE.

METHODS: Seventy-one women older than 50 years with a medial KOA grade ≥ 2 according to the Kellgren-Lawrence (KL) grading system participated in this study. The side with more severe radiographic KOA was selected for data acquisition. If the patient had equal radiographic KOA severity of knees, the more painful side was selected. After the evaluation of the maximum knee extension angle, shear wave velocity (SWV) of the following tissues was measured using uSWE: medial posterior capsule (PC), lateral PC, medial collateral ligament, popliteus muscle, biceps femoris short head, distal biceps femoris short head, medial gastrocnemius (GM), proximal medial GM, lateral GM, and proximal lateral GM. During the SWV measurement, patients lay in prone at 15° knee flexion, where each tissue was slightly stretched, and had their lower leg fixed in a neutral position using a self-made device. During measuring GM, the ankle joint was also fixed at 0° dorsiflexion in addition to the measurement position mentioned above. Three images of each tissue were measured, and the averaged SWV was used for further analysis. High SWV means that tissue is stiff. To clarify the associations of each tissue with knee extension limitation, we performed a single linear regression analysis with maximum knee extension angle as a dependent variable and SWV of each tissue as an independent variable. The level of statistical significance was set at 5%.

RESULTS: A total of 66 participants were included in this study (age: 72.9 ± 7.1 years, KL grade 2, n = 24; 3, n = 18; 4, n = 24; the maximum knee extension angle: -3.5 ± 4.6°). The maximum knee extension angle was significantly negatively associated with SWV of medial PC (R2 = 0.094, p = 0.012), indicating that patients with stiffer medial PC had more limited knee extension. On the other hand, the maximum knee extension angle was positively associated with the SWV of the proximal medial GM (R2 = 0.12, p = 0.004), indicating that patients with a softer proximal medial gastrocnemius had more limited knee extension. There were no associations between the other tissues and the maximum knee extension angle.

CONCLUSION: Given the assumption that stiffer tissue is associated with a more limited joint angle, our results suggest that the stiffness of the medial PC is associated with knee extension limitation in patients with KOA.

TISSUE COMPRESSION STIFFNESS OF LOWER LIMB MUSCLE GROUPS USING A LOW-COST DEVICE AND ITS RELATION TO OXYGEN COST WHILE RUNNING

PATERNOSTER, F.K.1, TILP, M.2, MEHMENTI, L.1, MAHNIC, N.1, SEIBERL, W.3, KONRAD, A.2

1> TECHNICAL UNIVERSITY OF MUNICH 2> UNIVERSITY OF GRAZ 3> UNIVERSITÄT DER BUNDESWEHR MÜNCHEN

INTRODUCTION: Running economy is one of the main factors influencing endurance running and can be quantified as energy utilization at a given submaximal speed. Current research showed that a stiffer Achilles tendon [1] as well as triceps surae muscle [2] might be beneficial in terms of oxygen cost while running. Contrary, other studies showed that a more compliant quadriceps tendon [1] and muscle [2] might be in favor for running economy. Therefore, the aim of this study was to relate the tendon and muscle stiffness of the quadriceps and triceps surae muscle groups with respect to oxygen cost in a single running session to obtain an overall picture. For this purpose, a low-cost device (MyotonPro, Myoton Ltd., Estonia) was used for assessing resting tissue compression stiffness.

METHODS: 17 male trained runners/triathletes (age:29.6±6.0 yrs; weight:74.4±6.7 kg, height:181.8±3.7 cm) with a mean VO2max of 55.9±6.8 ml/kg/min and an average running distance of 44.1±12.8 km per week took part in the study. After a familiarization session (day 1), participants did an incremental test to determine VO2max (day 2). Prior to the running test, resting tissue compression stiffness of the patellar and Achilles tendon as well as the gastrocnemii and superficial quadriceps muscles was measured. On day 3, the athletes did a submaximal run for 15min at a velocity corresponding 70% of VO2max. The oxygen cost was estimated by averaging the steady-state V02 of the last 5 minutes during the 15min run.

RESULTS: The average speed of the 15min run was 11.3±1.2 km/h. Correlation analysis revealed a significant relationship between resting Achilles tendon stiffness to oxygen cost with a large effect size (rp=-0.52;CI(95%):-0.81 to -0.33;p=0.03). No further correlation was found for the other tested parameters (p>0.09).

CONCLUSION: Our analysis showed that recreational athletes with a stiffer resting Achilles tendon had a lower oxygen cost during running, whereas resting patellar tendon, quadriceps muscle and triceps surae muscle compression stiffness was not related to oxygen consumption during submaximal running. According to our findings, but also in accordance with previous studies [4], strategies to increase Achilles tendon stiffness could be part of daily training routines of endurance athletes, to decrease their oxygen cost during running. Our first results using a low-cost device to relate resting compression stiffness to running economy are well in line with previous research using classic tissue stiffness assessments. Further research is needed to see if such devices can be used in daily testing routines to track changes in resting stiffness and to obtain if these changes are related to a lower oxygen cost while running.

STATIC STRETCHING OF THE PECTORALIS MAJOR MUSCLE FOR 7 WEEKS INCREASES MUSCLE FUNCTION BUT HAS NO EFFECTS ON MUSCLE STIFFNESS

REINER, M., GABRIEL, A., SOMMER, D., BERNSTEINER, D., TILP, M., KONRAD, A.

UNIVERSITY OF GRAZ

INTRODUCTION: The glenohumeral joint is the most flexible joint in the human body (Halder et al. 2000) and surrounded muscles and other connective tissues play a major role in joint positioning, function and performance (Kim et al. 2018). The aim of this study was to investigate the effects of a 7-weeks static stretching (SS) program of the pectoralis major (PMa) muscle on shoulder extension ROM and maximum voluntary isometric contraction (MVIC) peak torque of the PMa in two different elbow and shoulder joint positions (45°±5° or 90°±5° and 8°±8.6° or 31°±7.5°, respectively). The muscle stiffness of the PMa (pars clavicularis) was measured in the same positions as the force assessments pre and post the intervention.

METHODS: 38 physically active, healthy volunteers (23 males, 15 females) visited the laboratory for a familiarization, a pre- and a post-intervention session. The participants were randomly assigned to either the PMa-SS (7-weeks intervention, 3 times per week, 3 exercises with 5 min each) or the control group (CG). At the pre and post appointments the parameters PMa muscle stiffness, shoulder extension ROM and MVIC peak torque (similarly to an unilateral bench press movement - elbow angle at 45°±5° and 90°±5°) were measured at 45° shoulder abduction on a custom-made testing item. After checking for normal distribution, a repeated measures linear model and if permitted paired t-tests were done. For non-parametric data, a Wilcoxon test and if permitted a Mann-Whitney-U- test were done.

RESULTS: The baseline values (per parameter) were the same between the groups. Following the PMa-SS, shoulder extension ROM increased significantly by 6% (t(17)=-3.92, p<0.01), without a change in the CG (-1%;t(18)=0.48, p=0.64) (ANOVA time effect: F(35)=7.21, p =0.01; interaction effect: F(35)=10.97, p<0.01). Moreover, a significant increase was present in MVIC peak torque values at 45°±5° elbow joint angle in the PMa-SS (+11%, t(16)=-3.12, p<0.01), without a change in the CG (-1%, t(19)=0.14, p=0.89) (ANOVA time effect: F(35)=5.93, p=0.02; interaction effect: F(35)=6.81, p=0.01). No changes were

detected in MVIC peak torque with 90°±5° elbow joint angle (PMa-SS=+5%; CG=-5%) (ANOVA time effect: F(35)=0.79, p=0.38; interaction effect: F(35)=2.77, p=0.11). Furthermore, there were no changes detected in shear modulus in any group in 45° ± 5° (PMa-SS: Z(15)=-1.05, p=0.29, CG: Z(16)=-0.54, p=0.59) and 90° ± 5° elbow joint angle (PMa-SS: Z(15)=-0.91, p=0.36; CG: Z(16)=-0.63, p=0.53).

CONCLUSION: PMa muscle stretching increased shoulder extension ROM and additionally, our study showed an improved maximum force production at longer muscle length (45°±5° elbow joint angle), indicating possible changes in the force-length-relation of the sarcomere. It can be assumed that either pain tolerance and/or changes in stiffness of other structures than the muscles are responsible for the changes in ROM.

EFFECTS OF A SOFT BACK EXOSKELETON ON LUMBAR LOADING DURING A MANUAL HANDLING TASK: A PILOT SIMULATION STUDY.

FAVENNEC, A.1, FRÈRE, J.2, MOISSENET, F.3, MORNIEUX, G.1

UNIVERSITÉ DE LORRAINE, NANCY, FRANCE; 2 UNIVERSITÉ GRENOBLE ALPES, GRENOBLE, FRANCE; 3 GENEVA UNIVERSITY HOSPITALS AND UNIVERSITY OF GENEVA, GENEVA, SWITZERLAND

INTRODUCTION: Back exoskeletons are wearable structures that provide an assistive torque to one or multiple joints and can prevent low back disorders during manual handling tasks (1). A previous study already reported a reduced low back muscle activity using the CORFOR® exoskeleton during stoop liftings (2), but the influence of this exoskeleton on lumbar loading hasn't been investigated yet. The aim of this study was thus to assess the effects of wearing such a soft back exoskeleton on lumbar compression force and flexion moment.

METHODS: Eight male participants (178.6 ± 2.6 cm, 72.9 ± 7.1 kg, 21.4 ± 2 years) performed 10 repetitions of a lifting task in the sagittal plane using the stoop technique (8 kg; 15 cycles / min). Participants were familiarized to the exoskeleton and to the task before starting the experiment. They carried out the task with (EXO) and without (FREE) wearing a CORFOR® soft back exoskeleton. This exoskeleton is made of a pair of elastic bands attached to shoulders and knees, stretched by hip flexion. The 3D trajectory of a full body marker set was recorded using an optoelectronic camera system (Arqus A12, Qualisys, Sweden) sampled at 200 Hz synchronized to 3D ground reaction forces and moments measured using force plates (BMS600900, AMTI, USA) sampled at 1000 Hz. These data were then imported in OpenSim 4.2 to estimate compression force and flexion moment at L5/S1 intervertebral joint. The OpenSim Lifting Full-Body model (3) was scaled to each participant anthropometric characteristics and completed by adding the exoskeleton. Exoskeleton elastic bands were modeled as springs. Related slack length and stiffness were measured at the end of each experiment and participant-specific spring path was obtained during EXO task using 16 markers taped on the exoskeleton. Lumbar compression force and flexion moment were estimated through an inverse dynamics-based static optimization procedure. Student's t-tests were finally performed to assess the effects of the exoskeleton by comparing EXO and FREE.

RESULTS: Statistical analyses showed that L5/S1 compression forces were significantly lower ($p = 0.02$, $d = 1$) in EXO (38.8 ± 3.3 N/Kg) than in FREE (41 ± 2.4 N/Kg). Flexion moments were also significantly lower ($p \leq 0.001$, $d = 2.8$) in EXO (1.8 ± 0.12 Nm/Kg) than in FREE (2.1 ± 0.08 Nm/Kg).

CONCLUSION: This study suggests that wearing the CORFOR® exoskeleton may reduce lumbar loading and thus contribute to prevent low back disorders. These results are consistent with the reduction of back neuromuscular activity observed while using this exoskeleton (2). Future experiments should focus on the effect of such an exoskeleton during other handling tasks (e.g. squat, asymmetric lifting). Simulating the effect of different stiffnesses and paths of the spring on lumbar loading may also help to optimize the exoskeleton design.

POST-ACTIVATION-PERFORMANCE ENHANCEMENT: POSSIBLE CONTRIBUTING FACTORS

FISCHER, J.

UNIVERSITY OF GRAZ

INTRODUCTION: This study aimed to narrow down the possible mechanisms of Post-Activation-Performance Enhancement (PAPE) and especially if they are exclusively found in the muscle. It was therefore investigated whether the PAPE mechanism is influenced by spinal and supraspinal factors, if Post-Activation-Potentiation (PAP) influences PAPE, especially during the first minutes after the conditioning contraction (CC) and whether PAPE influences the muscle's EMG activity and frequency.

METHODS: Thirteen strength-trained participants (26.5 ± 3.16 years) took part in at least one of three interventions (PAP, PAPE-Electrical (PAPEE), and PAPE-Voluntary (PAPEV)). The task was to perform isometric leg extensions on an isokinetic device. The CC was either voluntarily or electrically stimulated. At baseline and after two seconds, four minutes, eight minutes, and twelve minutes of the CC, a maximum voluntary isometric contraction (MVIC) was performed for the PAPE

trials, to see if the peak torque, rate of force development (RFD), and the EMG amplitude and frequency of the quadriceps showed any significant changes.

RESULTS: Peak torque ($p < 0.001$) and RFD ($p = 0.005$) increased significantly during the PAP protocol immediately two seconds after the CC and decreased to near baseline values for the following time points. Peak torque and RFD showed no significant differences during PAPEE and PAPEV trials. Surface electromyography (EMG) measurements revealed significant differences concerning the amplitude of the EMG signal only for the PAPEE trial. EMG amplitude was significantly higher immediately two seconds after the conditioning contraction compared to the baseline measurement for all measured muscles. Concerning the frequency of the EMG signal, there was a significant difference in the M. rectus femoris and the M. vastus lateralis for the PAPEE trial. The mean frequency of those muscles was significantly lower immediately two seconds after the conditioning contraction compared to baseline measurement. For PAPEV, the mean frequency of the M. rectus femoris increased significantly ($p=0.007$) after four minutes compared to baseline.

CONCLUSION: Due to the lack of a visible PAPE effect, the question of whether PAPE depends on spinal or supraspinal mechanisms cannot be answered. The assumption that the PAP-mechanism influences PAPE cannot be confirmed for the same reason. However, it seems that PAPE, especially with an involuntary conditioning contraction, influences the EMG amplitude and frequency of the tested muscles.

THE EFFECTIVENESS OF A CAR-INTEGRATED MONITORING & INNOVATIVE COACHING SYSTEM ON LOWER BACK MUSCLE STIFFNESS, AND PERCEIVED DISCOMFORT AND FATIGUE DURING PROLONGED DRIVING

JULIEN, M., BESBES, N., MARCHIORIE, C., DE ALMEIDA, D., FABRE, J.B., BAUDU, S., GARCIA-VICENCIO, S.

HUMANFAB

INTRODUCTION: The prolonged fixed or poor position while driving may lead to high levels of low back soft tissue compression, early muscle fatigue and an important extent of discomfort resulting in low back pain. The development of posture monitoring systems based on different sensitive methods and posture recognition algorithms has dedicated large effort in the automotive industry and could be an interesting strategy to improve comfort, safety and health while driving.

The aim of this study was to evaluate the effects of a specific combination of massages delivered by the car-seat (backrest and cushion) and in-car exercises proposed by an embedded monitoring system, both inducing a passive and active mobilization of the driver, on perceived fatigue and discomfort, muscle function and stiffness of the low back fascia and muscle structures during and after a 4-hour driving session.

METHODS: 5/15 healthy car drivers (study in progress) have realized two counterbalanced 4-hours driving sessions separated by one week. During the "active" session drivers experienced a car-integrated coaching and monitoring system including a countermeasure (i.e., a massage or an exercise or a well-positioning advice) every 20 minutes while driving through a digital interface or the massage system embedded in the car-seat. The "passive" session consisted of 4 hours driving task without any countermeasure. Immediately after each countermeasure (or every 20 minutes), the body-segment comfort was assessed. Before, after two and four hours driving the low back fascia and muscle stiffness were evaluated quantitatively using shear-wave elastography. Moreover, functional capacities including back chain flexibility, reaction time, and upper limb muscle force and perceived fatigue were evaluated.

RESULTS: Preliminary results showed that subjective responses (fatigue and discomfort) were attenuated (by -14 and -27% after the entire task) when drivers experienced a car-integrated coaching and monitoring system compared to a traditional driving condition. While muscle quality (based on a low back stiffness) was increased after traditional driving by 10%, it was reduced (-10%) using the car-integrated coaching and monitoring system. Functional capacities (back chain flexibility, reaction time, and upper limb muscle force) were not different after driving between conditions.

CONCLUSION: Studies have shown that the constant low back mechanical constrain represented by higher stiffness or intra vertebral compression is strongly related to chronic back pain developed over months or years of driving. To monitor bad postures while driving and to deliver different types of countermeasures based on passive and active motion such as stretching exercises, backrest and cushion massages and well-positioning could be a good strategy to reduce discomfort, fatigue through a more compliant muscle (better choc or vibration dissipation) which would reduce pain experienced while driving.

RELATIONSHIP BETWEEN ANGULAR DISPLACEMENT OF SHOULDER JOINT AND FORCE ACTING ON THE POLE IN THE POLE VAULT

KAGEYUKI, T.1, KIGOSHI, K.2, YOKOZAWA, T.1

1 JAPAN INSTITUTE OF SPORTS SCIENCES, TOKYO, JAPAN; 2 UNIVERSITY OF TSUKUBA, IBARAKI, JAPAN

INTRODUCTION: The bending of the pole is the one of the main factors determining the maximum height of the vaulters centre of gravity in the pole vault. The bending of the pole is caused by the conversion of the mechanical energy of the vaulter, in particular the translational energy, into the elastic energy of the pole (1)(2). Although it has been suggested that the action of the shoulder joint muscles was important in exerting force on the pole (3), the vaulters motion in relation to the force acting on the lower tip of the pole, the box reaction force, has not been elucidated. Therefore, the aim of this

study was to investigate the relationship between the angular displacement of the shoulder joint and the box reaction force.

METHODS: 14 Japanese male pole vaulters (season record = 5.22±0.19m) performed trials with run-up steps and poles identical to those used in competition. Three-dimensional body coordinates were obtained using a motion capture system (250 Hz) and the box reaction force was measured using a force platform (1000 Hz). The global coordinate system was defined as the Y axis in the direction of the progress of the run-up, the Z axis in the vertical upward direction, and the X axis as the cross product of the Y and Z axes. Several events were defined; pole plant (PP), take-off (TO), maximum vaulter's angular momentum (MAM) and maximum pole bending (MPB) (2). MAM was the instant when the vaulters swing motion was represented and was defined as the instant when the vaulters angular momentum peaked (2). The shoulder joint angle was defined as the angle between the long axis of the upper trunk and the long axis of the upper arm around the traverse axis of the upper trunk (flexion +/ extension -). The impulse of the box reaction force between each event was calculated using a fourth-order Runge-Kutta method. Pearsons correlation coefficient was used to analyse the relationships between the variables.

RESULTS: The results were summarised as follows:

1) The impulse of the Y-component of the box reaction force (Fy) from PP to MPB was negatively correlated with the elastic energy in the pole at MPB ($r=-0.57$, $p<0.05$).

2) The angular displacements of both shoulder joints from MAM to MPB were negatively correlated with the impulse of Fy from PP to MPB (upper: $r=-0.54$, $p<0.05$; lower: $r=-0.62$, $p<0.05$).

3) The average angular velocity of the shoulder joint on the lower grip side from MAM to MPB was negatively correlated with the impulse of Fy from PP to MPB ($r=-0.56$, $p<0.05$).

CONCLUSION: These results suggest that the phase from MAM to MPB is the important in causing the pole to bend. In addition, considering the muscle force-velocity relationship, there seems to be a specific vaulting technique and shoulder strength that leads to an increase in the box reaction force. The results of this study would have practical implications for pole vault training.

CHANGES IN GASTROCNEMIUS MUSCLE ARCHITECTURE FOLLOWING STRETCHING TRAINING: A SYSTEMATIC REVIEW WITH META-ANALYSIS

PANIDI, I.1, DONTI, O.1, KONRAD, A.2, TERZIS, G.1, GASPARI, V.1, DONTI, A.1, BOGDANIS, G.C.1

1NATIONAL AND KAPODISTRIAN UNIVERSITY OF ATHENS, GREECE; 2UNIVERSITY OF GRAZ, AUSTRIA

INTRODUCTION: Gastrocnemius muscle architecture (fascicle length and angle, and muscle thickness) is an important determinant of muscle function in athletes, clinical and aging populations. There is evidence to suggest that stretching training may alter muscle morphology (1, 2), however, the effect of static stretching training on gastrocnemii muscles remains unclear. This systematic review with meta-analysis aimed to examine the effect of static stretching training on gastrocnemius architecture in healthy participants.

METHODS: We searched PubMed Central, Web of Science, Scopus, and SPORTDiscus with a structured algorithm, and randomized controlled trials and controlled trials were included. Risk of bias was assessed using Cochrane RoB2 and ROBINS-I tools. Subgroup analyses and random-effects meta-regressions were also performed using stretching volume and intensity as covariates. Quality of evidence was determined by GRADE analysis.

RESULTS: From the 2946 records retrieved, 15 studies were included in the systematic review and meta-analysis (n = 375 participants). Risk of bias was low in 82.1% of all criteria. Confidence in cumulative evidence was high. Stretching training induced small increases in fascicle length at rest (SMD = 0.21; 95% CI = 0.03 to 0.40; p = 0.024) and during stretching (SMD = 0.48; 95% CI = 0.17 to 0.79; p = 0.002). No increases were observed in fascicle angle (p = 0.61), and trivial increases were found in muscle thickness (SMD = 0.17; 95% CI = 0.00 to 0.35; p = 0.046). Subgroup analyses showed that fascicle length increased when high stretching volumes and intensities were applied ($p < 0.001$), while no changes were found for low stretching volumes ($p > 0.15$; subgroup difference, $p < 0.014$). Also, high stretching volumes and intensities resulted in increased muscle thickness ($p < 0.04$). Meta-regression analyses showed that fascicle length was positively associated with stretching volume and intensity (p = 0.003 and p = 0.03, respectively).

CONCLUSION: Gastrocnemius muscle remodels its geometry in response to stretching training. High but not low stretching volumes and intensities induce longitudinal fascicle growth. Notably, long duration and high intensity stretching interventions increase muscle thickness. This strategy of remodeling may alter muscle contractile properties and thus, muscle mechanical function (3).

INDOOR ENDURANCE EXERCISE PROVOKES HIGHER AEROSOL PARTICLE EMISSION AND POSES A HIGHER RISK OF INFECTION THAN RESISTANCE EXERCISE

SCHÖNFELDER, M.1, SCHUMM, B.2, HEIBER, M.1,2, GRÄTZ, F.1, STABILE, L.3, BUONANNO, G.3,4, HAIN, R.2, KÄHLER, C.J.2, WACKERHAGE, H.1

1 TECHNICAL UNIVERSITY OF MUNICH, GER; 2 UNIVERSITÄT DER BUNDESWEHR MÜNCHEN, NEUBIBERG, GER; 3 UNIVERSITY OF CASSINO AND SOUTHERN LAZIO, CASSINO, IT; 4 QUEENSLAND UNIVERSITY OF TECHNOLOGY, AUS

INTRODUCTION: Pathogens such as severe acute respiratory syndrome coronavirus type 2 (SARS-CoV-2), influenza, and rhinoviruses are transmitted by airborne aerosol respiratory particles that are exhaled by infectious subjects. We have previously reported that the emission of aerosol particles increases on average 132-fold from rest to maximal endurance exercise [1]. The aims of this study are to first measure aerosol particle emission during an isokinetic resistance exercise at 80% of the maximal voluntary contraction until exhaustion, second to compare aerosol particle emission during a typical spinning class session versus a three-set resistance training session. Finally, we then used this data to calculate the risk of infection during endurance and resistance exercise sessions with different mitigation strategies.

METHODS: We recruited 24 healthy participants (age: 21 to 37 years): eight of them for the endurance training session, eight for a resistance training, and eight for an isokinetic resistance training. In each training setting, we included four women and four men. The BMI of the participants ranged between 20.7 kg/m2 and 37 kg/m2 in the resistance exercise groups due to high muscle mass. In the endurance exercise group, the BMI ranged from 20.7 kg/m2 to 26.5 kg/m2. To measure ventilation and particle emission we coupled a spiroergometry device (Metalyzer; Cortex Medical™) with a particle counter (Palas Promo 3000 with Welas 2300 sensor, Palas GmbH) in a closed system. All measurements were performed in a clean air tent with reduced aerosol particle concentration (<150 particles/L compared to >30,000 particles/L in the ambient air). The airspace in the tent was flooded with cleaned air (H14 filter quality), and subjects directly inhale filtered air.

RESULTS: During a set of isokinetic resistance exercise, aerosol particle emission increased 10-fold from 5,400 ± 1,200 particles/min at rest to 59,000 ± 69,900 particles/min during a set of resistance exercise. We found that aerosol particle emission per minute is on average 4.9-times lower during a resistance training session than during a spinning class. Using this data, we determined that the simulated infection risk increase during an endurance exercise session was sixfold higher than during a resistance exercise session when assuming one infected participant in the class.

CONCLUSION: Collectively, this data helps to select mitigation measures for indoor resistance and endurance exercise classes at times where the risk of aerosol-transmitted infectious disease with severe outcomes is high. Even though exercise seems to impose a higher risk of getting infected, exercise holds many health benefits and should not simply be avoided. Thus, during periods with many consequential infections, the first focus should be to, for example, limit the number of people in endurance exercise classes, and increase the air exchange rate of the facility.

EFFECTS OF A COMMUNITY INTERVENTION PROGRAM BASED ON CONDUCTED PHYSICAL EXERCISE AND SUPPORT NETWORKS ON THE QUALITY OF LIFE AND THE FEELING OF COMMUNITY IN ADULT WOMEN

JIMÉNEZ DÍAZ-BENITO, V., ZAFRA DÍAZ, S., ESPADA MATEOS, M.

FACULTY OF HEALTH, DEPARTMENT OF PHYSICAL ACTIVITY AND SPORT SCIENCE, CAMILO JOSÉ CELA UNIVERSITY; FACULTY OF HEALTH SCIENCES, REY JUAN CARLOS UNIVERSITY

Introduction

The factors that condition the differences in the practice of physical activity prevent an increase in sports practice in Europe. Most recent studies are based on the theory of community participation (Long & Perkins, 2003; Vidal, 2001), however, from the point of view of the content of the interventions of physical exercise that enable the action of planning and managing community participation, everything seems to indicate that to date the content of the most effective exercise program that predicts the greatest benefits on QoL and the sense of belonging in the community is unknown in adult women. Therefore, the objective of this pre-experimental study was to make an exploratory contribution to find out if a conducted physical exercise program can influence quality of life (QoL) and the feeling of community (FoC) in adult women in an urban center, seek networks of collaboration between women and contribute to the social determinants of health in the urban nucleus.

Methods

A pre-experimental pre- and post-test study was designed, carried out by a multidisciplinary team made up of physical and social educators. A multicomponent program was designed consisting of supervised aerobic and functional physical exercise, activities aimed at self-knowledge of the body through movement, group bike rides and mutual support to promote autonomous, safe, and sustainable mobility. The program has a duration of 16 weeks. The QoL was measured

using the SF-36 v.2 instrument. (Ware Jr & Sherbourne, 1992). The FoC was measured through the community feeling scale (Vidal, 2001). The Wilcoxon technique was used for pre- and post-test comparisons. As an index of the effect size, eta squared was calculated for the Wilcoxon tests ($\eta 2 = Z2 / N$, where N is the number of observations). The values 0.01, 0.06, and 0.14 were used to interpret the effect size as small, medium, and large, respectively (Cohen, 1988). The significance level was set at 0.05.

Results

A better social function ($p = 0.007$; $\eta 2 = 0.38$) and the total mental health component of the QoL ($p = 0.007$; $\eta 2 = 0.38$) in the post-test of the QoL were localized. No significant improvement observed in FoC ($p > 0.05$).

Discussion

Numerous interventions have been proposed in different communities to favor the improvement of the social determinants of health (Bauer et al., 2014). However, our results were not in line with previous research, in which case they did find effects on their programs (Choi & Mutrie, 2020). An explanation could be found in the duration of the program. The most successful programs, in addition to having had a more continuous follow-up over time, require strong financing and support measures to be carried out, often due to a lack of available facilities and resources (Cereijo et al., 2019). The conducted physical exercise program could establish improvements in the QoL of adult women with barriers to the practice of physical activity and increase the exploration of other environm

PHYSICAL ACTIVITY, DAYTIME ACTIVITY AND SLEEP DURING A SPA STAY

CASTELLI, L.1, GALASSO, L.1, CIORCIARI, A.1, MULÈ, A.1, FORNASINI, F.2, MONTARULI, A.1,3, ROVEDA, E.1,3, ESPOSITO, F.1,3

1 UNIVERSITY OF MILAN; 2 GB HOTELS ABANO; 3 IRCCS ISTITUTO ORTOPEDICO GALEAZZI

INTRODUCTION: Recently, the Spa stay, including facilities (e.g., swimming pools and gyms), and treatments, have been described as incrementing physical activity (PA), sleep quality, and, more generally, the quality of life [1, 2]. To date, no studies have investigated these aspects in sub-healthy subjects visiting Italian Spa; thus, the current study aims to shed light on leisure-time PA and sleep habits during a one-week stay at the Spa.

METHODS: Eighty-eight participants (M=30, 30%; 64.1±10.9yrs) staying one week at GB-Hotels (Abano Terme, Italy) and undergoing thermal treatments filled in the Godin-Shepard Leisure-Time Physical Activity Questionnaire (GSL-TPAQ) and the Mini Sleep Questionnaire (MSQ) at the beginning and the end of the spa stay. Actigraph Motion Watch 8 (CamNtech) monitored the daytime activity, whereas the daily PA was recorded through a diary. Comparisons were adjusted for age, BMI, and sex. The current study was funded by FORST.

RESULTS: During the Spa stay, the percentage of active subjects raised from 52% to 67% with a significant increase in the GSL-TPAQ score (before: 27.6±22.7 LSI; during: 40.3±30.1 LSI; $p<0.001$), indicating an increase of PA during the thermal stay. The percentage of participants with no sleep problems incremented from 32% to 48% during the Spa stay, with a significant decrease in the mean MSQ score (before: 30.3±10.3a.u.; during: 25.3±9.5 a.u.; $p=0.001$), indicative of better sleep quality. The questionnaires compiled at the end of the Spa stay showed that active and sufficiently active participants tend to report better MSQ values than inactive subjects and that those with no sleep problems practised more PA than participants with moderate and severe sleep problems (even though without significance). Regarding the actigraphic data, moderate daytime activity reached 30% of the monitored time, followed by low (17%) and vigorous (1%) daytime activities. From the daily diaries, the most reported physical activities were: walking, swimming, gym use, and thermal-water gymnastics, with 500.3±402.7 minutes of PA in a week.

CONCLUSION: A week of Spa stay and thermal treatments seemed to be effective in incrementing the PA and sleep quality. Participants reported reaching the recommended 300 minutes of physical activity in a week. Leisure-time PA could be favoured by the resorts' facilities, free time, and better predisposition of the participants to being active during the Spa stay. Sleep could improve thanks to the relaxing atmosphere, the effect of the hot water on body temperature and mud applications on cortisol's circadian rhythm regulation.

LONG-TERM EFFECTIVENESS OF EXERCISE, COGNITIVE BEHAVIORAL THERAPY, AND PHARMACOTHERAPY ON IMPROVING SLEEP IN ADULTS WITH CHRONIC INSOMNIA: A SYSTEMATIC REVIEW AND NETWORK META-ANALYSIS

YU, D.J., RECCHIA, F., BERNAL, J.D.K., YU, A.P., FONG, D.Y., LI, S.X., DCLINPSY, R., CHAN, N.Y., HU, X., SIU, P.M.

THE CHINESE UNIVERSITY OF HONG KONG

INTRODUCTION: Despite the well-established treatment effectiveness of exercise, cognitive behavioral therapy for insomnia (CBT-I), and pharmacotherapy on improving sleep, there have been no studies to compare their long-term effectiveness, which is of clinical importance for sustainable management of chronic insomnia. This study aimed to compare the long-term effectiveness (≥ 6 months post-intervention follow-up) of exercise, CBT-I, and pharmacotherapy on improving sleep in adults with chronic insomnia.

METHODS: Data Sources: MEDLINE, PsycInfo, Embase, and SPORTDiscus were searched between January 1990 and January 2022.

Study Selection: We included randomized controlled trials investigating the long-term effectiveness of the three interventions on improving sleep in adults with chronic insomnia. The post-intervention follow-up (duration between the post-intervention measurement and the last follow-up measurement) of the trial had to be ≥ 6 months to be eligible.

Data Extraction: Study characteristics, quality, and data were assessed independently by two researchers. The primary outcome was the long-term effectiveness of the three interventions on improving sleep, which reflected the sleep-promoting effects of the interventions during the post-intervention follow-up period (time duration between the post-intervention measurement and the last follow-up measurement). The secondary outcome was the treatment effectiveness of the three interventions on improving sleep, which reflected the sleep-promoting effects of the interventions during the intervention period (time duration between the baseline measurement and the post-intervention measurement). A random-effects network meta-analysis was carried out using a frequentist approach.

RESULTS: Thirteen randomized controlled trials involving 1350 participants were included in the analysis. After an average post-intervention follow-up period of 10.3 months (95% confidence interval, 6.7 to 13.9), both exercise (standardized mean difference, -0.29; 95% confidence interval, -0.57 to -0.01) and CBT-I (-0.48; -0.68 to -0.28) showed superior long-term effectiveness on improving sleep compared with the control interventions. Temazepam was the only included pharmacotherapy and it demonstrated superior treatment effectiveness (-0.80; -1.25 to -0.36) but not long-term effectiveness (0.19; -0.32 to 0.69) on improving sleep compared with the control interventions.

CONCLUSION: The findings of our study support the use of both exercise and CBT-I for long-term management of chronic insomnia in adults, while temazepam may only be used for short-term insomnia treatment. The generalizability of the study findings was limited as temazepam was the only included pharmacotherapy.

EXERCISE AS TREATMENT FOR DRUG USE DISORDERS: A META-ANALYSIS

DENG, X., ZHENG, S., WANG, Z., LIU, Y., JIANG, J., LIANG, C., HUANG, Z., ZENG, X., NI, G.

BEIJING SPORT UNIVERSITY ; JIANGXI NORMAL UNIVERSITY ; JIANGSU NORMAL UNIVERSITY

INTRODUCTION: Drug addiction, which involves impulsive and compulsive factors and represents a dramatic dysregulation of motivational circuits, is a chronic relapsing disorder. It doesnt just lead to serious health consequences, even death, for the drug users themselves and serious damage to their families, but also affects social stability. In recent years, a number of reviews have been published on the effects of exercise on substance use disorders, including alcohol/tobacco use disorders. However, the effects of exercise interventions on drug dependence have not been assessed separately. While these descriptive reviews clearly advance the field, to our knowledge no meta-analysis has pooled data to consider the benefits of multiple trials and health outcomes. A review of randomised controlled trials is needed to determine whether these associations are causal. This meta-analysis aimed to provide an overview of the effectiveness of exercise interventions for drug dependence. This review enabled scientific societies to formulate exercise recommendations in their clinical guidelines by examining the effects of exercise interventions on drug-dependent individuals.

METHODS: We searched the following electronic databases for relevant literature Web of Science, PubMed, Embase, Ebsco, Cochrane Library. We also searched the online trials registry, ClinicalTrials.gov, to identify unpublished trials. There were no language restrictions, and we did not search for unpublished literature in English-language databases. The search period ended on 21 October 2022. As heterogeneity between studies was expected, we performed a random-effects meta-analysis using Review manager 5.3 software.

RESULTS: Seventeen studies were included in the analysis. The results showed that exercise was effective in reducing cravings [I2 = 0%, P = 0.84; SMD = -0.52, 95% CI (-0.74, -0.30), Z = 4.59, P＜0.00001] .Exercise also significantly reduced anxiety [I2 = 0%, P = 0.45; SMD = -0.43, 95% CI (-0.60, -0.26), Z = 5.02, P＜0.00001], depression[I2 = 14%, P = 0.31; SMD = -0.36, 95% CI (-0.53, -0.19), Z = 4.17, P＜0.0001]and improved quality of life[I2 = 68%, P ＜0.00001; SMD = 0.46, 95% CI (0.30, 0.61), Z = 5.72, P＜0.00001]. It had no significant effect on the physical fitness score [I2 = 85%, P < 0.00001, SMD = -0.02, 95% CI (-0.23, 0.19), Z = 0.16, P = 0.87] of drug-dependent individuals. Using the different physical fitness indices as grouping criteria, exercise was found to have a significant effect on improving pulse, vital capacity, body flexion, one leg stand with eye closed in drug-dependent individuals.

CONCLUSION: Exercise had a significant effect on drug-dependent people. For the main outcome (craving), we found that the current level of evidence for exercise intervention in drug-dependent people is high. For secondary outcomes, we found that exercise was beneficial for improving emotional state and quality of life in drug-dependent patients. More robust studies are needed to validate these findings, including long-term follow-up of a range of health outcomes.

DOES ESPORTS PARTICIPATION BRING ABOUT AN UNHEALTHIER LIFE?

TANG, D., SUM, R.K.W.

THE CHINESE UNIVERSITY OF HONG KONG

INTRODUCTION: This study is designed as a cross-sectional study to explore whether there are significant differences in health between eSports players and non-eSports players among young adults and aims to show the general health status of the eSports population compared with non-eSports players. This study collected detailed information on their eSports game participation (e. g. genres) to strictly distinguish eSports players from general video gamers.

METHODS: A total of 1549 responses were selected for the final data analysis (incomplete responses were excluded). They are identified as eSports players, general video gamers and non-eSports participants. The data on the health status of different categories of participants were also collected by means of an online questionnaire designed by the team. The whole questionnaire is divided into four sections: personal information (gender, age, education, etc.), gaming behavior (type of games, frequency of game, gaming habits), sports behavior (type, frequency, etc.), and health status (sleep duration, physical and mental health problems). Health problems were selected based on previous relevant studies where they were considered to be related to eSports or video gaming: physical health (hearing, vision, or musculoskeletal problems (e. g. neck, wrist, back pain or strain) and malnutrition), and mental health problems (anxiety, insomnia, depression).

RESULTS: It was found that participation in traditional sports was significantly higher among eSports participants (66%) than non-eSports participants (49.2%) ($p<0.001$). No significant difference in sleep duration, visual problems, hearing problems, neck, wrist, neck, upper or lower back pain or strain, or malnutrition was found between these two groups. The proportion of participants who reported having a mental issue (anxiety, depression, loneliness or insomnia)) is significantly higher among non-eSports participants (38.5%) than eSports players (30.3%) ($p<0.01$).

It was also found that participation in traditional sports is significantly more common among eSports players (66%) than among general video gamers (43%) ($p<0.001$). Significant differences were found in issues of visual impairment, myopia or dry eyes ($p<0.05$) and mental issues ($p<0.03$) between the two groups. 61.8% of video gamers reported having a visual impairment, myopia, or dry eye while 55.3% of eSports players reported it and a higher proportion of general video gamers reported having a mental issue than eSports participants ($p<0.05$).

CONCLUSION: eSports players did not reflect worse outcomes in terms of sports participation, and physical and mental health issues. Instead, we see higher levels of motivation in sport participation among eSports players. We also found that players who focused on their posture and proper rest during gameplay were less likely to suffer from muscle pain and strain, prompting us to think about exploring healthier ways to participate in eSports in the future.

COMBINED COGNITIVE AND PHYSICAL TRAINING FOR IMPROVED COGNITIVE AND PHYSICAL PERFORMANCE: PRELIMINARY FINDINGS FROM A RANDOMISED CONTROLLED TRIAL WITH YOUNG HEALTHY ADULTS.

SCOTT, A., MCDICKEN, K., MARTIN, K., NORTHEY, J., LAMPIT, A., FLOOD, A., FOGARTY, A., TEMBY, P., RATTRAY, B.

UNIVERSITY OF CANBERRA

INTRODUCTION: Combining cognitive and physical exercise is gaining attention as a training modality by offering greater adaptations to both physical and cognitive performance. Research supports the benefits of concurrent training for improving cognition in older adults [1] but it is unclear if this applies to younger people [2]. This study sought to investigate the effectiveness of combined training for improving cognitive and physical performance in young healthy adults.

METHODS: At submission, 52 of the intended 93 participants (29 female, 27±6 years, baseline maximal oxygen uptake 34.9±9.4 mL/min/kg) were recruited for a 12-week, investigator blinded RCT. Participants were allocated to either physical training only (PAonly), concurrent cognitive and physical training (PACog) or separate cognitive and physical training (PA&Cog). Physical training involved stationary cycling at 70-80 % of maximum heartrate achieved during baseline fitness assessments. Cognitive training was administered using an adaptive, multidomain, computer program. Pre, mid, and post-intervention assessments included a maximal cardiorespiratory fitness (VO2peak) test, followed by a cognitive battery completed at rest. Pre- and post- intervention, participants also completed a dual task assessment (moderate intensity walking on inclined treadmill whilst wearing weighted vest and completing cognitive tests of inhibitory control and memory), followed immediately by a repeat of the cognitive battery.

RESULTS: Improvements during the fitness assessment showed no difference across groups in VO2peak (PACog: b = -2.4 mL/kg/min, 95%CI -8.8 to 3.9, PA&Cog: b = -0.5 mL/kg/min, 95%CI -6.6 to 5.6) or time to exhaustion (PACog: b = -36.6s, 95%CI -149.6 to 76.4, PA&Cog: b = 18.9s, 95%CI -89.0 to 126.8). Mean reaction time on a sustained attention task at rest improved mid-intervention (PACog: b = -28.9 ms, 95%CI - 54.9 to -3.3, PA&Cog: b = -36.1 ms, 95%CI -60.7 to -11.6) and post-intervention (PACog: b = -21.3 ms, 95%CI -47.0 to -4.4, PA&Cog: b = -29.8 ms, 95%CI -54.3 to -5.3). There was a significant group*time interaction for working memory performance (p = .018) suggesting PACog's maximal recall capacity reduced more than PA (b = - 0.4, 95%CI -1.0 to 0.2) while there was a greater improvement observed in PA&Cog (b = 0.4, 95%CI -0.2 to 1.0), however these estimates were non-significant.

CONCLUSION: Cardiorespiratory fitness improved in all groups, however, sustained attention and working memory – two key cognitive constructs for high performance [3] – improved to a greater extent in both groups receiving the cognitive training, with PA&Cog superior for maximal recall following the dual-task assessment. These findings suggest combined training may be a time efficient modality for improving cognitive performance with similar improvements in fitness to physical training only.

CHANGES IN TRAINING LOAD ACROSS A 12-WEEK CONCURRENT COGNITIVE AND PHYSICAL TRAINING INTERVENTION IN YOUNG, HEALTHY ADULTS (PRELIMINARY FINDINGS)

MCDICKEN, K., SCOTT, A., MARTIN, K., NORTHEY, J., LAMPIT, A., FLOOD, A., FOGARTY, A., TEMBY, P., RATTRAY, B.
UNIVERSITY OF CANBERRA

INTRODUCTION: Concurrent cognitive and physical training may offer an efficient training modality to provide both physical and cognitive benefits (Nahleen et al., 2021). The logistics and acceptability of delivering such training, however, is unclear and potentially complex. In particular, it is unclear how participants will respond to changes in training load and whether an effective progressive overload can be achieved for both cognitive and physical benefit.

METHODS: At time of submission, 42 healthy individuals (22 female, 27±6 years) had completed a 12-week training intervention. Participants were randomly allocated to either a control group (n=16), a concurrent training group (n=13), or a separate training group (n=13). All groups completed two 50-min bouts of stationary cycling at 65% heart rate peak per week. While cycling, the concurrent group conducted cognitive training on an adaptive, multi-domain platform. The separate group completed two cognitive training sessions seated at rest per week, in addition to cycling only. Measures of physical load (average power, average speed, and rating of perceived exertion (RPE)) were taken in weeks 3, 7, and 10. Cognitive assessments were completed within the cognitive training platform in weeks 1, 6, and 12 to examine whether the cognitive tasks (and associated load) were sufficient to provide cognitive benefits.

RESULTS: There were no significant group*time interactions for average power, average speed, or RPE. There was a significant time effect for mean power (B = 6.3 W, 95% CI: 1.1 to 11.6). There were no significant group effects for the cognitive training tasks; however, there were significant time effects for tasks involving reaction time (B = -196.8 ms, 95% CI: -256.1 to -139.0; B = -148.0 ms, 95% CI: -230.8 to -64.4) and working memory (B = 0.2 numbers, 95% CI: 0.1 to 0.4).

CONCLUSION: Mean power increased for all groups over the course of the intervention, which suggests that participants are experiencing progressive overload while cycling. Improvements observed across time in all groups on adaptive cognitive training tasks suggests an effective progressive overload can be achieved. Since there were no significant differences in physical and cognitive training load measures between the concurrent group and the separate group, concurrent training might be just as effective, and more efficient, as separate physical and cognitive training.

FEASIBILITY, TOLERABILITY, AND PRELIMINARY EFFECTIVENESS OF A CONCURRENT COGNITIVE AND PHYSICAL TRAINING INTERVENTION IN YOUNG HEALTHY ADULTS

MARTIN, K., SCOTT, A., MCDICKEN, K., NORTHEY, J., LAMPIT, A., FOGARTY, A., TEMBY, P., RATTRAY, B.
UNIVERSITY OF CANBERRA

INTRODUCTION: Concurrent cognitive and physical training has proved an effective and efficient method for improving cognitive [1], physical [2], and dual task performance [2]. However, much of this research lacks the application of basic training principles such as individualisation and progressive overload, and consideration of the participant experience. This study employed an individualised, adaptive concurrent training intervention in young healthy adults. We discuss preliminary effectiveness, feasibility, and tolerability.

METHODS: At submission, 52 of 93 participants (23 male, 27±6 yrs, baseline maximal oxygen uptake 35.0±9.3 mL/min/kg) had been recruited for a 12-week investigator blinded RCT. Participants were randomised to either physical training only (2 x 60 min stationary cycling sessions per week), concurrent cognitive and physical training (2 x cycling sessions whilst simultaneously completing cognitive training) or separate cognitive and physical training (2 x cycling sessions and 2 x cognitive training sessions at rest). Physical training was prescribed using heartrate during baseline fitness assessment. Cognitive training was administered using an adaptive multidomain computer program. Pre, mid, and post-intervention assessments included a maximal cardiorespiratory fitness test, a cognitive battery, and a cognitive and physical dual task. Throughout the intervention physical load was recorded alongside subjective workload and enjoyment as measures of tolerability. Feasibility outcomes included recruitment, dropout, and attendance. All participants randomised with baseline assessments were included in intention-to-treat analysis using linear mixed effects models.

RESULTS: Of the participants recruited, 50 were allocated to an intervention. Eight participants withdrew prior to completion (physical: 2 of 17, concurrent: 1 of 15, separate: 5 of 18), with no reports of adverse effects. Across groups, attendance was 94±6%. Maximal oxygen uptake increased across the intervention with no difference between groups, as was also observed for mean power of the physical training. Compared to physical only, mean reaction time on a sustained attention task was faster at mid (concurrent: b=-28.9 ms, 95% CI - 54.9 to -3.28, separate: b=-36.1 ms, 95% CI -60.7 to -11.6) and post assessment for concurrent and separate training (concurrent: b=-21.3 ms, 95% CI -47.0 to -4.4, separate: b=-29.8 ms, 95% CI -54.3 to -5.3). Response inhibition and memory at rest, and memory during the dual task improved over time with no group x time interaction. Subjective workload and enjoyment did not vary significantly across the intervention or between groups.

CONCLUSION: Our preliminary findings support concurrent and separate cognitive and physical training as effective and acceptable methods for improving cognitive, physical, and dual task performance in young healthy adults. For the reduced time impost, we recommend concurrent training as the preferred modality.

ASSOCIATION OF BDNF RS6265 POLYMORPHISM WITH LITHUANIAN ELITE ATHLETES' STATUS

GINEVICIENE, V., ANIKEVICIUTE, G., SIVACIOVA, M.O.

VILNIUS UNIVERSITY

INTRODUCTION: Regular physical activities lead to an increase in brain-derived neurotrophic factor (BDNF) and other myokines concentration level in the blood serum, which determines the general physical and psychological health of a person. BDNF (encoded by the BDNF gene) is present in the blood both at rest and during exercise training, and is derived from several tissue sources (such as skeletal muscle, brain, vascular endothelial cells, peripheral neurons, blood mononuclear cells, platelets etc.) known to produce and release neurotrophic factors into circulation in response to exercise. The single nucleotide polymorphism (SNP, rs6265, C>T, Val66Met) in the BDNF gene affect the intracellular distribution, packaging and release of BDNF protein, and can affect neuronal adaptation and response to exercise, as well as the ability to activate the appropriate muscles and generate more power. However, the influence of this SNP on the characteristics of elite athletes remains not clear. The purpose of this study was to investigate the relationship of the BDNF rs6265 genetic variant with elite Lithuanian athlete status.

METHODS: In the present study, BDNF rs6265 (C>T) polymorphism was investigated in 230 Lithuanian elite athletes representing three functional sports groups [endurance, N=59; sprint-power, N=87, and team sports, N=84], as well as in 230 control samples (non-athletes) from the Lithuanian population. Genotyping was performed using TaqMan Real-time polymerase chain reaction assay.

RESULTS: The results of the case-control analysis showed that the frequencies of BDNF genotypes were significantly different in the general group of athletes (CC/CT/TT: 58.1/33.5/0.0%, p = 0.01) and in sprint-power group (CC/CT/TT: 63.2/36.8/0.0%, p=0.03) compared to the control group (CC/CT/TT: 74.3/23.9/1.7%). The findings indicated that the heterozygous CT genotype is more prevalent in sprint-power athletes (36.8%) compared with endurance athletes (28.8%) and controls (23.9%). The logistic regression analysis suggests that the odds ratio (OR) of CT genotype (vs CC+TT) and being an elite athlete was 1.6 (95%CI: 1.06–2.41; p=0.02). OR of sprint-power athletes harboring the CT genotype was 1.85 (95%CI: 1.09–3.15; p=0.02). Our results suggest that BDNF CT heterozygous athletes have a higher sprint-power ability than homozygous.

CONCLUSION: Our findings provide support the hypothesis that the BDNF rs6265 polymorphism is associated with elite athletic status. The BDNF CT heterozygotes had a significantly higher prevalence among elite Lithuanian athletes (especially sprint-power oriented athletes) than in the control group. Possible explanations for heterozygote advantage of BDNF rs6265 variant for elite athletes are BDNF expression in brain and skeletal muscle (especially in the fast-twitch muscle fibers) during exercise training. Replication studies are needed to support our data and to fully understand the relationship between BDNF gene and physical performance of athletes.

EXERCISE-SPECIFIC EFFECTS ON THE MOTOR PERFORMANCE, GLYCAEMIA REGULATION AND MUSCLE HISTOLOGY OF A MOUSE MODEL OF LIMB-GIRDLE MUSCULAR DYSTROPHY R1 (CALPAINOPATHY)

MIGNOT, T., KAMMOUN, M., ERBLANG, M., MALGOYRE, A., THOMAS-JUNIUS, C., BIONDI, O.

LABORATOIRE DE BIOLOGIE DE L'EXERCICE POUR LA PERFORMANCE ET LA SANTÉ , UMR, UNIVERSITÉ D'EVRY, IRBA, UNIVERSITÉ DE PARIS SACLAY, 91025 EVRY-COURCOURONNES, FRANCE.

INTRODUCTION: Calpainopathy is one of the most common Limb-girdle Muscular dystrophies (LGMD R1) caused by the homozygous deletion of Calpain-3 gene and characterized by a symmetric and progressive weakness of the proximal muscles1. The absence of calcium-dependent-cysteine protease CAPN3 induced intracellular calcium dysregulation and sarcomere disorganization that generate sensitivity to exercise damages and avoid proper adaptation to aerobic training2. Thus, we questioned whether a non-lesional exercise performed in high-intensity could alleviate the disease progression in vivo in comparison to an eccentric exercise on a mouse model of calpainopathy.

METHODS: From 2 to 4 months of age, C57BL/6J CAPN3 KO mice were subjected to a 5 days-per-week 30 minutes training protocol performed either in an eccentric running condition (inclined treadmill -20°) at 16 m.min-1 or in a high intensity swimming condition (4 L.min-1), and were compared to untrained control and CAPN3 KO mice. Spontaneous activity (open field), muscles strength (grip strength), resistance to fatigue at low (grip test) or high (incremental test) intensity and glucose homeostasis were assessed once a month. The dystrophic process (HE staining) and muscular typology adaptations (immunofluorescence against-MyHC isoforms) were evaluated on antigravity muscles (psoas, deltoid, gluteus, soleus).

RESULTS: We noted a decrease of around 27.8% of the time of suspension and around 21.4 % in maximal aerobic performance in CAPN3 KO mice compared to controls throughout the studied ages, without any defect in spontaneous activity or muscle strength. Moreover, we observed a 9,3% increase in the area under the curve of the glucose tolerance test at 4 months of age. After exercises, we noted that only concentric swimming training increased the resistance to fatigue at low and high intensity (around 33.7% and 45.4%, respectively) compared to untrained CAPN3KO mice at 3 and 4 months of age. However, the swimming protocol failed in correcting glycaemic homeostasis while eccentric protocol restored the

area under the curve to control values at 4 months of age. At the muscle phenotype level, only eccentric protocol worsened the dystrophic processes in a muscle-specific manner in CAPN3KO mice at 4 months of age. Those muscular adaptations were accompanied by exercise- and muscle-specific adaptations of muscular typology.

CONCLUSION: Our study suggests that the muscular metabolic alteration of a calpainopathy model mouse could be positively or negatively modulated by adapted exercises. This opens new avenues in personalizing clinical care for this dystrophy.

EFFECTS OF RESISTANCE TRAINING AS A BEHAVIOURAL PREVENTIVE MEASURE ON MUSCULOSKELETAL COMPLAINTS, MAXIMUM STRENGTH AND ERGONOMIC RISK IN DENTISTS AND DENTAL ASSISTANTS

HOLZGREVE, F.

GOETHE UNIVERSITY

INTRODUCTION: For dental professionals, musculoskeletal disorders (MSD) are common health hazards. Resistance training programmes are promising approaches in the quest to decrease the pain intensity. Therefore, the aim of the current study was to investigate the effect of a trunk-oriented 10-week resistance training, especially designed for dental professionals, on the pain intensity, the maximum voluntary isometric contraction (MVIC) and the body posture during dental treatments.

METHODS: In total, 17 participants (3m / 14f) volunteered to take part in this study. Of these, 6 (0m / 6f) participants worked as dental assistants and 11 (3m / 8f) as dentists in Germany. The intervention programme consisted of 11 resistance training exercises where the participants trained for 10 weeks, 2 times a week, for one hour. Outcome values collected were the pain intensity (visual analogue scale (VAS) combined with a modified version of the Nordic Questionnaire), the MVIC and the rapid upper limb assessment (RULA) score (based on data from inertial motion units) during a standardised dental treatment protocol. In order to quantify the effects of the intervention on each outcome measure, the paired t-test and Wilcoxon signed-rank test were performed depending on the distribution. The significance level was set at $\alpha = 5\%$.

RESULTS: A significant reduction in pain intensity was found for each queried body region: the neck ($p < 0.001$), upper back ($p = 0.004$), lower back ($p < 0.001$) and the right ($p = 0.005$) and left ($p = 0.02$) shoulders. The MVIC improved significantly in all outcome measures: the flexion ($p = 0.001$), extension ($p = 0.004$), lateral flexion right ($p < 0.001$) and left ($p < 0.001$) and the rotation right ($p = 0.01$) and left ($p = 0.011$). The intervention had only marginal effects on the ergonomic risk, derived from a kinematic analysis; the neck showed a significant improvement ($p = 0.02$), however, the left upper arm revealed a significant worsening ($p = 0.018$). Correlation analyses revealed no relevant significances between the pain intensity and the MVIC and RULA scores.

CONCLUSION: A ten-week resistance training programme in dentists and dental assistants had significant effects on pain intensity reduction and on the MVIC of the musculature of the trunk and is, therefore, suitable as a behavioural preventive measure against MSD in dentistry. Since improvements in trunk force seem to have rather small effects on the body posture during dental treatments, the ergonomic risk is apparently determined predominantly by the arrangement of the dental treatment concept.

GASTROCNEMIUS VISCOELASTIC PROPERTIES, STRENGTH, FUNCTIONAL PERFORMANCE, AND PAIN FOLLOWING ECCENTRIC EXERCISE-INDUCED SORENESS: COMPARISON OF THE EFFECTS OF VIBRATION FOAM ROLLING AND FOAM ROLLING

GONEN, I., UYSAL, O., ATAY, O.A., HARPUT, G.

HACETTEPE UNIVERSITY

INTRODUCTION: The aim of this study was to investigate and compare the effect of vibrating and non-vibrating foam roller application on viscoelastic properties of the gastrocnemius muscle, plantar flexion strength, functional performance and pain after EIMS in healthy physically active individuals.

METHODS: Thirty healthy physically active individuals (15 Male, 15 Female, Age: 23.80±0.94 years, body mass index: 22.23±2.19 kg/m2) were included in the study. Participants' legs were randomly divided into two groups: vibration foam rolling (VFR) and foam rolling (FR). The participants performed a standardized eccentric calf muscle exercise on an inclined plane while wearing a weighted vest (approximately 25% of body weight). The tests were performed before and after the exercise protocol, 48 hours after the exercise protocol and immediately after foam rolling. Foam roller applications were done 48 hours after the exercise protocol. Visual analog scale was used to assess pain during resting, gastrocnemius stretching, isometric contraction and heel-rise. Muscle viscoelastic properties such as tonus, elasticity and stiffness were measured by using myotonometry. Plantar flexion isometric strength was measured by hand-held dynamometer. Weight bearing lunge test (WBLT) for ankle dorsiflexion range of motion and Y Balance test (YBT) with anterior, posteromedial and posterolateral reach directions were used for assessing functional performance. 2-way repeated measures of ANOVA (time by group) was used for statistical analysis.

RESULTS: There were no significant "time by group" interactions for pain in resting ($F(3,87)=1.73$, $p=0.17$), isometric contraction ($F(3,87)=1.73$, $p=0.17$), stretching ($F(3,87)=1.31$, $p=0.27$) and heel rise ($F(3,87)=0.23$, $p=0.87$). Pain gradually increased

after the exercise and decreased after foam roller applications (p<0.001). There were no significant time by group interactions for lateral and medial gastrocnemius tonus, elasticity and stiffness and plantar flexion strength (p>0.05). Gastrocnemius tonus and stiffness decreased and plantar flexion strength increased after foam rolling (p<0.001). Time by group interaction was significant for WBLT (F(3,87)=11.66, p<0.001). VFR increased ankle dorsiflexion ROM more than NVFR (p=0.01). Time by roller interaction was also significant for YBT_anterior (F(3,87)=3.72, p=0.01) and YBT_posteromedial (F(3,87)=2.62, p=0.04) directions. VFR increased YBT scores more than NVFR after exercise protocol (p=0.01).

CONCLUSION: Both foam rolling improved perceived pain, gastrocnemius tonus and stiffness, ankle dorsiflexion ROM, gastrocnemius strength and dynamic balance after eccentric exercise induced soreness. However, vibration foam roller is more effective than non-vibrated foam roller to improve ankle dorsiflexion ROM, plantar flexor strength and dynamic balance after eccentric exercise induced soreness. Thus, for functional recovery, vibration foam rollers can be selected after exercise induced fatigue and/or soreness.

BENEFICIAL EFFECTS OF POST-INJURY ICING ON SKELETAL MUSCLE REGENERATION IN A NEW INJURY MODEL WITH NECROSIS LIMITED TO A SMALL FRACTION OF MYOFIBERS IN RATS

KAWASHIMA, M.1, NAGATA, I.2, MIYAZAKI, A.2, MIYOSHI, M.2, SAKURAYA, T.2,3, SONOMURA, T.3, OYANAGI, E.1, YANO, H.1, ARAKAWA, T.2

1. KAWASAKI UNIVERSITY OF MEDICAL WELFARE, 2. KOBE UNIVERSITY GRADUATE SCHOOL OF HEALTH SCIENCE, 3. ASAHI UNIVERSITY SCHOOL OF DENTISTRY

INTRODUCTION: Accumulating evidence from animal experiments has demonstrated that post-injury icing impairs the natural regenerative process of skeletal muscles. However, previous experimental models yielded massive necrotic myofibers, which contrasts with muscle damage upon human sports activities in which typically a small percentage (<10%) of myofibers necrotize. During muscle regeneration, macrophages accumulate in the damaged site and exhibit a pro-reparative profile, whereas they have cytotoxic potential on muscle cells dependent on inducible nitric oxide synthase (iNOS) expression. In this study, we established an animal injury model with necrosis limited to a small myofiber fraction and investigated the effect of icing on muscle regeneration with a focus on macrophage-related events.

METHODS: Eight-week-old male Wistar rats were divided into the non-icing and icing groups. Muscle injury was induced by crushing the extensor digitorum longus muscle for 30 s with forceps which a weight was attached as reported previously (1), but the attached weight was changed to 250 g (500 g in the previous study), causing necrosis in 4.0% ± 0.5% of myofibers as the initial damage. Animals in the icing group were given a session of ice pack application (three sets of 30 min each with 90-min intervals) beginning immediately and at 24 h and 48 h after injury. Injured muscles were harvested on post-injury days 1, 2, 3, 5, 7, and 14 (n = 5, respectively). The muscle cross sections were subjected to hematoxylin and eosin staining for morphological observation of the regenerative process and to immunofluorescence for detecting and quantifying the iNOS-expressing macrophages and activated satellite cells. The targeted protein expression was determined by western blot. Data comparison was conducted using the Student's t-test or two-way analysis of variance to determine statistical significance.

RESULTS: Icing after muscle injury resulted in an enlarged size of regenerating myofibers compared with those in untreated animals on days 7 and 14. During the regenerative process, icing reduced the iNOS-expressing macrophage invasion, suppressed the iNOS protein expression in the damaged muscle, and limited the expansion of injured area. Additionally, an early accumulation of activated satellite cells within the damaged/regenerating area was noted in the icing group. The protein expression level of MyoD and myogenin (myogenic regulatory factors) was not affected by icing.

CONCLUSION: Icing after skeletal muscle injury with necrosis in a small myofiber fraction could facilitate muscle regeneration. This phenomenon was associated with the attenuated iNOS-expressing macrophage invasion, limited muscle damage expansion, and accelerated accumulation of myogenic cells during icing-treated regenerative process. Our findings first unveil the benefits of post-injury icing for muscle regeneration provided that myofiber necrosis is not substantial following injury.

THE EFFECT OF FUNCTIONAL EXERCISES PERFORMED ON SLIDING PLATFORM ON THIGH MUSCLE ACTIVATION AND HIP AND KNEE FLEXION ANGLES

DEMIR, C.

HACETTEPE UNIVERSITY

INTRODUCTION: "Sliding" exercises are very popular in work-out programs. They are thought to be very effective for improving core stability and muscle strengthening1,2. Slideboards are commonly used in the exercise programs but the information about how they affect muscle activities during exercises are limited. The aim of this study was to investigate the quadriceps and hamstring muscle activation levels and hip and knee flexion angles during functional exercises on a sliding platform and to compare them with normal ground.

METHODS: Thirty healthy individuals (age: 23.83±2.84 years, body mass index: 21.75±1.72 kg/m2) were included in the study. Single leg squat and lunge exercises were performed with forward, lateral and back reaching, and muscle activation levels of vastus medialis (VM), vastus lateralis (VL), biceps femoris (BF), semitendinosus (ST) were measured by surface electromyography. The exercises were performed randomly on the normal ground and on the slideboard. Exercises were performed at slow pace (60 beats/min). The phases of the exercises were analyzed with a video camera. Hip and knee

flexion angles/ratios were evaluated with 2D motion analysis. Repeated measures analysis of variance was used to analyze platform X exercise interaction, and paired samples t-test was used to determine the differences between hip and knee flexion angles.

RESULTS: In all exercises, VM and VL activation levels were greater during reaching and returning phases of the exercises on slideboard compared to normal ground ($p<0.05$). However, ST and BF activity were greater only during the returning phase of the forward lunge ($p<0.001$) and the returning phase of the back squat ($p=0.002$, $p=0.009$, resp.). Knee flexion angles were greater when forward lunge, back lunge, and lateral squat exercises were performed on the slideboard (respectively, $p<0.001$, $p=0.032$, $p=0.05$). Hip-to-knee flexion ratios were closer to 1 when the forward lunge ($p<0.001$), back lunge ($p=0.004$) and forward squat ($p=0.001$) exercises were performed on a slideboard.

CONCLUSION: Single leg squats and lunges provide more quadriceps-hamstring muscle activation when performed on a sliding platform. Therefore, sliding platforms can be used in exercise training of the knee muscles. Forward and back lunge and lateral squat exercises can be helpful for improving the balance between hip and knee flexion angles.

BENEFITS OF INSPIRATORY MUSCLE TRAINING IN IMPROVING THE PROGNOSIS OF HEART FAILURE PATIENTS WITH LEFT VENTRICULAR EJECTION FRACTION BELOW 50% - PILOT STUDY

ROZEK-PIECHURA, K., KALKA, D., OKRZYMOWSKA, P.

WROCLAW UNIVERSITY OF HEALTH AND SPORT SCINCES

INTRODUCTION: The aim of the study was to evaluate the effect of attached 4-week inspiratory muscle training to standard phase II cardiac rehabilitation in post-myocardial infarction patients diagnosed with heart failure with a left ventricular ejection fraction below 50% on the respiratory muscle strength, exercise tolerance and physical capacity of these patients.

METHODS: Twenty-four post-myocardial infarction patients with established class II and III heart failure (EF< 50%) were enrolled in the study. Patients were randomized according to the distribution table into two groups by a cardiologist. Experimental group I - patients performing inspiratory muscle training up to 60% MIP (IMT group), control group II (sham-IMT group) - patients performing simulated training at a load level <1cm H2O.

The following tests were performed in each patient: somatic characteristics, assessment of maximum inspiratory pressure (MIP) and expiratory pressure (MEP), spiroergometric test on a treadmill according to the Bruce modified protocol.

The tests were performed 2 times: before the start of inspiratory muscle training and after 4 weeks. Jaegers Vyntus apparatus and the MicroRPM was used in examination.

The following were used to evaluate the effects of IMT training: test time [min]; VO2 peak oxygen consumption level, BP, HR and MET. A Threshold IMT breathing trainer was used for training. Training intensity was determined individually based on MIP. The initial training load was 30% of MIP. Then it gradually increased to a level of 60% of MIP. Training took place 7 times a week.

The control group performed sham inspiratory muscle training with a training load < 1 cm H2O - a placebo procedure. Stage II cardiac rehabilitation was performed in both groups according to standards (interval endurance training).

RESULTS: After the application of rehabilitation along with IMT training, a highly significant increase in MIP inspiratory muscle strength and MEP expiratory muscle strength was observed in group I. There was also a highly significant increase in patients peak oxygen consumption and MET energy expenditure. In Group II, significant changes at p less than 0.05 in Peak VO2 and MET were recorded after rehabilitation. Comparative analysis between groups showed the achievement of significantly higher inspiratory muscle strength, peak VO2 and MET values in Group I patients after 4 weeks of therapy.

CONCLUSION: 1.The use of inspiratory muscle training additionally in standard phase II cardiac rehabilitation in post-myocardial infarction patients with heart failure with a left ventricular ejection fraction below 50% highly significantly increased the values of physical performance parameters in the study subjects compared to those with standard rehabilitation.

2 The use of inspiratory muscle training in the second stage of cardiac rehabilitation of post-myocardial infarction patients with established heart failure with a left ventricular ejection fraction below 50% increases its effectiveness.

DISCRIMINATION OF THE KINEMATICS FEATURES OF GAIT WITH THE POTENTIAL RISK OF TRIPPING BASED ON A MACHINE-LEARNING APPROACH

SATOSHI, O., RINTARO, K., HIKARU, Y., HIDEYUKI, T.

TOKYO UNIVERSITY OF AGRICULTURE AND TECHNOLOGY

INTRODUCTION: Tripping is a common cause of falls in older persons. Wearable-sensor systems that monitor walking in real-time are expected to be effective tools for detecting tripping; however, gait characteristics with an associated increased risk of trips remain unclear. Against this background, the present study determined foot kinematics with potential

risk of trips during level ground walking by applying a supervised machine-learning method to data acquired from a single inertial measurement unit (IMU).

METHODS: In 20 trials, 10 older adults and 4 young adults walked a distance of 10 m at their preferred walking speed. Translational accelerations along the three-dimensional (3D) axes of the foot and angular velocities around the 3D axes were measured by an IMU attached to their right shoe. A MoCap system was used to determine the minimum toe clearance (MTC) and event timings of toe-off, heel-strike, and MTC. Coefficients of variation of MTC (cvMTC) were calculated from all participants' strides. The group mean and SD of cvMTC were used to define those participants with potential tripping risk as well as those without risk, in which individual cvMTCs were larger than the mean+0.5SD and smaller than the mean-0.5SD, respectively. Supervised classification learnings were carried out using a Support Vector Machine (SVM) algorithm for time-series data of the IMU measurements during the swing phase between toe-off and MTC for each stride as predictor variables.

RESULTS: Leave-one-subject-out (LOSO) cross-validation tests showed that a linear regression model with translational acceleration along the anterior-posterior axis of the foot, as well as angular velocity around the lateral axis of the foot as a predictor, was most suitable for discriminating between the groups. The average discrimination accuracy of the LOSO tests was 70.0%. The trained linear regression model had larger beta coefficients at approximately 20–30% of the early swing phase between toe-off and MTC. This suggests that the difference in dorsiflexion at the ankle joint immediately after toe-off is a determinant of cvMTC magnitude.

CONCLUSION: Previous research hypothesized that the kinematic features of gait with potential risk of tripping would be included in individuals with smaller MTC and larger variations of MTC (Barrett et al. 2010, Gait & Posture). This motivated us to construct a discrimination model with cvMTC as a response variable. In conclusion, the present study has provided additional evidence demonstrating that a larger cvMTC may be a criterion for tripping risk during walking. Our findings are likely useful for the development of a system that predicts the occurrence of tripping in advance based on IMU measurements.

RELATION BETWEEN VISUAL EXPLORATION AND KINEMATIC SYNERGY CONTROLLING SWING FOOT WHILE CROSSING AN OBSTACLE

YAMAGATA, M., NAGAI, R., MORIHIRO, K., NONAKA, T.

KANSAI MEDICAL UNIVERSITY

INTRODUCTION: To step over obstacles of varying heights, two distinct ongoing streams of activities—visual exploration of the environment and gait adjustment— were required to occur concurrently without interfering with each other. Yet, it remains unclear whether and how the manner of embodied behavior of visual exploration is related to the synergistic control of foot trajectory to negotiate with the irregular terrain. Thus, we aimed to explore how the synergistic control of the vertical trajectory of the swing foot (i.e., obstacle clearance) crossing an obstacle is related to the manner of visual exploration of the environment during the approach.

METHODS: Twenty healthy young adults walked 15 times at their comfortable speed along a 7-m walkway with an obstacle of 8-cm height (depth: 1 cm, width: 60 cm), which was placed halfway down the walkway. An eye-tracker headgear was used to record the eye movements of each participant, and the visual exploration was evaluated as the amount of time spent fixating on the vicinity of the obstacle on the floor during the period from two to four steps prior to crossing the obstacle. Kinematic data during obstacle crossing were collected using a Motion Shadow inertial measurement unit (IMU)-based full-body motion capture system, and time normalized from right toe-off to right initial contact while crossing the obstacle. The strengths of kinematic synergy to control obstacle clearance were estimated using the uncontrolled manifold approach, and we partitioned the participants into higher and lower synergy groups (H-Synergy and L-Synergy) based on a median split of the kinematic synergy. To explore the relation between visual exploration and kinematic synergy, the total gaze duration was compared between H- and L-Synergy.

RESULTS: The time fixating on the vicinity of the obstacle in participants in L-Synergy was significantly longer than those in H-Synergy. Additionally, those in L-Synergy exhibited a greater amount of head flexion movement and larger variability of foot clearance compared to those in H-Synergy.

CONCLUSION: Kinematic synergy to control foot trajectory is essential for safe locomotion. The current study found that the participants who exhibited relatively weak synergy moved their heads more to fixate on the obstacle on the floor during the period critical to controlling the foot placement, implying that there are some kinds of trade-off between the strength of kinematic synergy to control the swing foot trajectory and the gaze behavior of look down at the obstacle. Adjustments of this complex relationship between exploratory activities (e.g. looking movement) and performative activities (e.g. adjustment of ground clearance) would be crucial to adapt to walking in a complex environment.

COGNITIVE-MOTOR INTERFERENCE DURING DUAL-TASK WALKING

WUNDERLICH, A., WOLLESEN, B.

TECHNISCHE UNIVERSITÄT BERLIN

INTRODUCTION: In everyday life walking happens most of the time under dual-task (DT) conditions. Whether it is walking and talking on the phone or reading an advertisement at different signs along the street. Processing auditory or visual information as a secondary task is expected to interfere differently with the resources needed for the motor task. While young healthy adults can cope with the demands of dual-tasking well, other groups like older adults or hearing-impaired

people are more vulnerable and the risk of falling increases. However, it is important to investigate Cognitive-Motor-Interference (CMI) in the young population to understand better the interaction of performance, gait and brain activity measures. The Mobile Brain/Body Imaging approach (MoBI) allows for the parallel analysis of brain activity and body movement during unrestricted movement.

METHODS: Aiming for a sample size of 96 (48 healthy and 48 mildly hearing impaired) community-dwelling older adults (50–70 years) and 48 younger adults (20–30 years), the data of a first subset of thirty young participants has been collected so far. While the ongoing study has a multifactorial mixed-measure design comparing three groups, we present here only the analysis of the within-subject factors task complexity (sitting vs. walking) and cognitive task modality (visual vs. auditory) for the young participants. Stimuli of the auditory and visual discrimination task varied according to presentation side (left vs. right), and presentation-response compatibility (ipsilateral vs. contralateral). Gait parameters were captured with the OptoGait system and EEG activity was recorded using 64 active electrodes (LiveAmp, BrainProducts).

RESULTS: Cognitive-motor-interference (CMI) was analyzed by dependent variables of task performance (accuracy and response time) and gait parameters (Gait speed, step length, double support phase) as well as stimulus evoked brain potentials during single and dual task. Performance results showed that on average 80% (ST: 81%, DT: 79%) of the visual stimuli and 90%(ST: 88%, DT 92%) of the auditory stimuli were correctly discriminated. The rate of correct responses from all given responses was 88% and 95%, respectively, showing that dual task costs were represented similarly in misses and incorrect responses.

CONCLUSION: Cognitive-motor interference varied between task modalities. The stimulus-related brain activity shows the respective signatures known for the stimulus processing of the chosen modalities during sitting and walking. The gait parameters of the young population did not reveal the impact of dual-tasking, while the performance in the cognitive task demonstrated dual-task costs by misses and incorrect responses. These performance decrements can be associated with different cognitive-motor processes, i.e., stimulus input, resource allocation, and movement execution. The results allow first conclusions about task-specificity and general mechanisms of CMI (single task vs. dual-task overground walking).

EFFECTS OF LEG LENGTH DISCREPANCY ON SPATIOTEMPORAL AND DYNAMIC GAIT PARAMETERS DURING TREADMILL WALKING

MANDALIDIS, D., KORONTZI, M.

NATIONAL AND KAPODISTRIAN UNIVERSITY OF ATHENS

INTRODUCTION: Leg length discrepancy (LLD) is a common skeletal asymmetry usually manifested by joint misalignments of the lower extremities and lumbopelvic region as well as muscle imbalances. The uneven distribution of loads caused during standing and functional activities such as walking and running may contribute to clinical syndromes and osteoarthritis. Although many individuals experience some degree of LLD, the amount of difference between the legs that is considered clinically significant remains controversial. The purpose of the study was to investigate the effects of artificially induced LLD on gait symmetry during treadmill walking.

METHODS: Spatiotemporal (e.g., step length and time, cadence, stance and swing time) and dynamic parameters (e.g. force exerted during stance phase) of gait were recorded in 11 male and 15 female physically active uninjured college students, who required to walk for 150 sec at 5 km/h on an instrumented treadmill without (0 cm) and with artificially induced LLD of 1, 2 and 3 cm. LLD was artificially induced by means of a special pair of shoes, which was applied externally to the shoes each person normally worn for walking, with the sole of one shoe being 1, 2, or 3 cm thicker than the sole of the contralateral shoe. A two (long and short leg) by four (0, 1, 2 and 3 cm of LLD) way ANOVA was used to investigate possible effects of LLD on gait for all parameters measured.

RESULTS: Our findings revealed that step length increased, and step time decreased by up to 3% as LLD increased ($p<0.001$) when a step was performed from the long (stance) leg to the short (swing) leg during walking. The duration of stance phase was increased and swing phase was decreased by up to 3.1% and 2.7%, respectively in these steps as LLD increased ($p<0.001$). The opposite occurred when a step was performed from the short leg to the long leg. Step length decreased and step time increased by 1.1% and 4.9%, respectively while the duration of stance phase decreased, and the swing phase increased by up to 1.7% and 5.3% respectively ($p<0.001$). Cadence was not affected by LLD. The maximum force (MaxF) applied by the midfoot of both long and short limbs increased by up to 26.8% and 10.9%, respectively as the LLD increased ($p<0.001$). The MaxF applied by the heel of the long leg was not affected but the MaxF applied by the heel of the short leg increased by up to 9.0% as LLD increased ($p<0.001$). The MaxF exerted by the forefoot of the longer limb significantly decreased by up to 7.8%, and the MaxF exerted by the forefoot of the short limb increased by up to 2.7% ($p<0.001$)

CONCLUSION: The asymmetry presented by the spatiotemporal parameters of gait in conjunction with the increased midfoot force applied during the stance phase of walking can justify to a certain extend the negative effects of LLD on body function, potentially leading to pain and increased risk injury, especially of the foot (Gurney et al 2000).

THE PROTECTIVE FIRE BOOTS ACUTELY ALTER THE GAIT PATTERN OF FIREFIGHTERS.

MARCEL-MILLET, P.1,2,3, GROSPRÊTRE, S.3

1: INSTITUT DE RECHERCHE BIOMÉDICALE DES ARMÉES; 2: LABORATOIRE DE BIOLOGIE DE LEXERCICE POUR LA PERFORMANCE ET LA SANTÉ; 3: LABORATOIRE CULTURE, SPORT, SANTÉ, SOCIÉTÉ

INTRODUCTION: Firefighting scenes are dangerous and chaotic with many hazards for firefighters to protect against. Thus, firefighters wear personal protective equipment including fire heavy boots. If these protective boots ensure the safety of firefighters during emergencies, they are generally worn all day at the fire station, even when firefighters are not confronted with dangers. However, the weight, size and stiffness of the boots could affect gait (Chiou et al. 2012; Park et al. 2019). Therefore, we assessed in firefighters the spatiotemporal parameters of walking with fire boots and compared it to usual sports shoes.

METHODS: Twenty-nine firefighters (25 males and 4 females, age: 37.1 ± 9.4 years, heigh: 175.7 ± 8.2 cm, weight: 76.3 ± 16.0 kg) were instructed to walk 100 m in a straight line at comfortable pace, with either sports shoes or fire boots, in a randomized order. The spatiotemporal parameters of walking were recorded and analyzed using connected insoles (Podosmart, Nancy, France). The recorded parameters were: the walking speed, the cadence, the cycle length (the length between two successive stances of the heel of the same foot), the ground contact time (the time during which the foot is in contact with the ground), the pronation/supination angles (the inclination in the transverse plane of the foot at four moments: heel and toe ground contact and heel and toe take-off), the step progression angle (the path and the orientation of the foot in the air) and the minimum toe heigh (the minimum height between the toes and the ground during foot oscillation).

RESULTS: Walking speed was similar between the two conditions, but fire boots increased stride length ($p < 0.001$), ground contact time ($p < 0.05$), and decreased cadence ($p < 0.001$). These changes were accompanied by an alteration in the angle toe's ground contact ($p < 0.001$), in the minimum toe heigh ($p < 0.001$), and in the step progression angle ($p < 0.01$).

CONCLUSION: The results of the present study revealed that fire boots alter the acute spatiotemporal parameters of firefighter walking compared to sports shoes. These results should encourage firefighters to change their practices and not systematically wear their fire boots when it is not necessary, such as in the fire station. Furthermore, future research should investigate the chronic impact of fire boots.

THE JOINT ANGLE-TORQUE RELATION OF THE TOE FLEXORS IN UPRIGHT STANDING

KOYAMA, K., YAMAUCHI, J.

TOIN UNIVERSITY OF YOKOHAMA

INTRODUCTION: The force-generating mechanism at the metatarsophalangeal(MTP) joints is one of important features to understanding the unique function of human bipedal locomotion. The intrinsic and extrinsic muscles and tendon complexes around the metatarsophalangeal joints help to support the foot arch and generate the plantar flexion torque at the MTP joint during walking (McKeon et al., 2015). As one of the unique function of the foot, changing the form of the foot arch in the standing increases the maximum force of the toe flexor muscles (Yamauchi and Koyama, 2019). Although the plantar flexion torque-angle relationships at the MTP joint was measured at the joint angle between 0-45 degrees in the sitting position (Goldmann and Bruggemann, 2012), there has been no study into how the MTP joint angle contribute to the plantar flexion torque when the MTP joint angle is changed with a wide range of joint motion between 0-90 degrees in the standing and whether these values are related to the toe flexor strength. The purpose of this study was to investigate the relation between the MTP joint angle and the maximum isometric torque of the toe flexor muscles in standing position and the relation between this plantar flexor torque at different MTP joint angles and the maximum toe flexor strength.

METHODS: The maximum isometric plantar flexion torque at the MTP joint and toe flexor strength were measured in the left and right feet of 55 healthy young individuals. The plantar flexion torque was measured at 10 different metatarsophalangeal joint angles between 0-90 degrees in the standing position using a specifically custom designed dynamometer . The maximal isometric toe flexor strength in the standing position was measured using a toe flexor dynamometer. For both measurements, subjects exerted maximum force for 3 seconds and the maximum value among three measurements for each foot was used for further analysis. Additionally, these values were further normalized by body mass.

RESULTS: The plantar flexion torque at the MTP joint exhibited a peak when the MTP joint angle was at dorsiflexed 20-50 degrees, and these values were correlated with the maximum toe flexor strength.

CONCLUSION: The result of this study suggests that there is an optimal position for maximum force generation at the MTP joint and thus limiting the movement of the MTP joint from this optimal position could impair force production of the toe flexor muscles and physical performance in bipedal locomotion.

CHANGES IN MEDIAL LONGITUDINAL ARCH AND PLANTAR LOAD DURING WALKING AT DIFFERENT SPEEDS

KIUCHI, A., HIRANO, T., FURUTA, N., YOON, H., FUNATO, K.

KOKUSHIKAN UNIVERSITY

INTRODUCTION: As one of the important foot functions, medial longitudinal arch (MLA) plays spring-like action for braking and accelerating especially in walking and running. During the stance phase, MLA changes in response to load, absorbing shock at foot contact and generating propulsive force during push-off phase [1]. Walking at different speeds make changes in the spatio-temporal variables and the plantar load. Walking at a faster speed increases the stiffness of the MLA by activating the plantar intrinsic muscles, which contributes to increased push-off against the ground during walking [2]. However, it has not been clear how much load is applied to deform the MLA during stance phase. Purpose of this study was to clarify the changes in the MLA and plantar load distribution during the stance phase of walking at different speeds.

METHODS: Eight healthy male subjects participated in this study (Age 20.8±3.4 years; Height 174.2±4.7 cm; Mass 69.9±5.6 kg). Plantar pressure measurement plate (Novel GmbH®, 100Hz), motion capture system (Oxford, 100Hz) and force plate (Kistler, 1KHz) were synchronized. Using this system, subjects performed 3 walking trial at 0.8 (Slow), 1.2 (Normal), 1.7 (Fast) m/s. Plantar load distribution was divided into five sub-area based on anatomical measurement points [3]. MLA angle was calculated as the angle between the distal first metatarsal, navicular tuberosity and calcaneus. In addition, the plantar load data were used to divide the stance phase into three phases: (1) from initial foot contact till medial and lateral forefoot ground contact (forefoot contact phase : FCP), (2) from medial and lateral forefoot ground contact till heel off (foot flat phase : FFP), (3) from heel off till last foot contact (forefoot push-off phase : FPOP).

RESULTS: In comparison with Slow, Fast showed a significant increase in MLA angle, medial and lateral rearfoot plantar loads from FCP to FFP. On the other hand in FPOP, there was no difference in the amount of change in MLA angle among different speed conditions despite the greater load applied to the medial forefoot. In comparison with Slow, Fast showed no difference in the amount of change in MLA angle, despite the greater load applied to the medial forefoot at FPOP. When more forceful push-off, it has reported that the abductor hallucis is more activated and produces a greater plantar flexion moment [2]. Therefore, it was suggested that activity of the plantar intrinsic muscles increased foot stiffness, remaining the constant MLA angle at push-off.

CONCLUSION: Increasing the plantar loads in medial foot as well as stiffening the MLA might be important roles during push-off phase in walking at fast speed.

A LONGITUDINAL STUDY OF THREE-DIMENSIONAL PELVIC BEHAVIOR IN MAXIMAL SPRINT RUNNING.

OTA, K., MAEMURA, H., TANIGAWA, S.

UNIVERSITY OF TSUKUBA

INTRODUCTION: Sprinting speed is determined by step frequency and step length, and there is an inverse relationship between step frequency and step length. It is important to increase step frequency while maintaining the large step length for achieving high sprinting speed. Improvement in the recovery of leg motion during sprinting results in an improvement in step frequency, and this motion is associated with the pelvis rotating to the free leg side (Sado et al., 2017). Sado et al. (2017) found that the pelvis rotates to the free leg side, which is associated with the greater free leg side lumbosacral joint torsional torque, assisting in the recovery of leg motion of the stance leg. Thus, it seems reasonable that the free leg side lumbosacral joint torsional torque during sprinting may have an important function in terms of achieving high sprinting speed. However, these findings were investigated cross-sectional in terms of the relationship between variables and differences in competition levels, and no longitudinal study has been reported to investigate changes in the factors influencing step frequency and step length with increasing sprinting speed. Therefore, the purpose of this study was conducted to investigate the longitudinal change in the kinematics and kinetics of the pelvis using data with the increasing sprinting speed.

METHODS: Nine male sprinters performed a 60 m sprint from a crouching start at maximal effort, which was conducted at twice in a 1-year period, and the data from the 2 tests were analyzed. Each participant was attached with 47 retroreflective markers to their trunk and limbs for motion capture. A 26-camera motion capture system at 250 Hz was used to record the three-dimensional coordinates of the position of each reflective marker. The ground reaction force at 1000 Hz was recorded using a force platform, and the values were synchronized with the motion data. After normality was confirmed, Student's paired t-test was applied to compare the statistical significance at $p < 0.05$.

RESULTS: During the test 2, the sprinting speed and step frequency were significantly higher compared to the test 1. The kinetics pattern of pelvic rotation indicated that the lumbosacral joint torsional torque toward the stance leg side was greater until the middle of the stance phase and that the lumbosacral joint torsion torque toward the free leg side was greater. The integrated contributory component of the lumbosacral joint torsion angular impulse during the total and stance phase were significantly greater in the test 2 than in the test 1.

CONCLUSION: It is important for achieving high sprinting speed to exert free leg side lumbosacral joint torsional torque from the middle of the stance phase to toe-off, resulting in the faster recovery leg motion and increasing step frequency.

MECHANICAL PROPERTIES OF LOWER EXTREMITY MUSCLE CHANGED AFTER FATIGUE AND RECOVERY USING VIBRATIONAL INSTRUMENT IN ADULTS

CHENG, K.

NATIONAL CHENG KUNG UNIVERSITY

INTRODUCTION: Jogging is a getting popular aerobic exercise in the general population around the world. Lower extremity muscle strains and stiffness as well as knee pain are commonly observed sports injuries in the runners. Applying proper and sufficient muscle relaxation techniques to facilitate muscle recovery and maintain soft and flexible muscle properties after training are believed to have effects on preventing sports injuries. Many relaxion instruments are available in the market such as foam rollers and vibrational guns. However, to date only one study showed increased ankle dorsiflexion after 5 minutes application of vibrational gun on calf muscles in young males. The effects of using vibrational gun as the recovery intervention on mechanical property of the lower extremity muscle are still very limited. Therefore, this study aimed to investigate how the mechanical properties of quadriceps would be changed after fatigue and after recovery intervention using the vibrational gun in young adults.

METHODS: A total of 16 young adults who never receive regular running training and without any health concern participated in this study. All participants first received a pre-designed fatigue protocol to induce aerobic fatigue using power biking and followed by muscle fatigue using repeated jumping, hopping and stepping tasks. The recovery intervention was then delivered using the Hypervolt vibrational gun (Hyperice, California, United States) with 53 Hz on the middle and caudal one-third locations of the right rectus femoris (RF) for 2.5 minutes each location. Mechanical properties of right RF including tension, stiffness, elasticity, relaxation time and creep were assessed using the MyotonPro (Myoton AS, Tallinn, Estonia) immediately before, after designed fatigued protocol, and after relaxation intervention. Repeated ANOVAs were used for analyzing the differences of muscle mechanical properties among three time points. Post hoc with Bonferroni correction was done if indicated.

RESULTS: Both the tension and stiffness of the RF significantly increased after fatigue and decreased after recovery intervention. In contrast, the relaxation time and creep significantly decreased after fatigue and increased after intervention. However, all muscle proprieties did not return to the pre-fatigue level after recovery. The elasticity of the RF did not change in this study.

CONCLUSION: The current findings demonstrated that after a period of training or occurrence of a fatigue, the muscle became stiffer, with higher inner pressure, and more difficult to relax or deform. Applying vibrational gun on the targeted muscle as the recovery intervention was able to improve the mechanical properties and may have potential effects on preventing injuries.

KINEMATICS OF PELVIS DURING MAXIMAL SPRINT RUNNING: GENDER DIFFERENCES IN ITS RELATION TO RUNNING VELOCITY

MATSUBAYASHI, T., KAMEDA, M., KAGEYUKI, T., ZUSHI, A.

JAPAN INSTITUTE OF SPORTS SCIENCES

INTRODUCTION: Many studies have investigated the lower limb kinematics of maximal sprint running. However, few have focused on the pelvis; the root of the lower limb. As it plays a substantial role in lower limb movement, it is important to investigate the kinematics of pelvis during maximal sprint running and its influence on maximal running velocity. The aim of this study was to examine the relationship between pelvic kinematics and running velocity during maximal sprint running and its gender differences.

METHODS: Japanese track and field athletes (52 males and 52 females, including sprinters, hurdlers, long jumpers, decathletes and heptathletes) participated in this study. Their maximal sprint running was captured using a 250-Hz optical motion capture system. Kinematic parameters of the pelvis during the stance phase, e.g., 3-dimensional angles at toe-on and toe-off, angular displacements, and peak angular velocities, were obtained from two consecutive left and right steps of each athlete. Multiple regression analyses were performed separately for males and females, with each kinematic parameter as a dependent variable and running velocity, leg length, and step frequency as explanatory variables. Leg length and step frequency were included to standardize the influence of body dimensions and spatiotemporal characteristics of running. The relationships were determined based on the statistical significance (α=0.05) of the standardized partial regression coefficients (β).

RESULTS: All athletes showed a similar pattern of pelvic movement during maximal sprint running: the pelvis tilted anteriorly; tilted ipsilaterally to the stance side; and rotated slightly ipsilaterally, then counter-rotated contralaterally during the stance phase. In males, the kinematic parameters relevant to anterior tilt were only related to the running velocity (β = 0.373, 0.248, -0.295, -0.252, for the anterior tilt angle at toe-on, that at toe-off, anterior angular displacement, and peak anterior angular velocity, respectively). In females, however, the kinematic parameters relevant to late stance rotation

were only related to the running velocity (β = 0.288, 0.255, 0.353, for the maximum ipsilateral rotation angle, contralateral counter-rotation angular displacement, and peak contralateral counter-rotation angular velocity, respectively).

CONCLUSION: The current results suggest that pelvic kinematics have a substantial influence on maximal running velocity, and the underlying mechanisms may differ between males and females. A more anteriorly tilted and stabilized pelvic motion may contribute to running velocity in males, whereas a larger and faster rotational motion may contribute in females. Gender differences in shape of the pelvis, i.e., more vertical in males and wider in females, lead to a difference in its moment of inertia around each axis, which may result in the different pelvic movement requirements for higher maximal running velocity between males and females.

CP-PN14 Interval Training

ASSESSMENT OF HIGH-INTENSITY TRAINING LOAD AND EXERCISE-INDUCED LIPID PEROXIDATION IN PROFESSIONAL FOOTBALL PLAYERS

HOLLAND, C.R.1,2, FURBER, M.W.2, KASS, L.S.2, BOTTOMS, L.2

1UNIVERSITY OF WESTMINSTER; 2UNIVERSITY OF HERTFORDSHIRE

INTRODUCTION: It is documented that intense periods of football can induce lipid peroxidation, the negative effects of which can lead to compromised performance. However, few studies have explored the potential association between exercise-induced lipid peroxidation and training load intensity. Therefore, the aim of the study was to quantify a biomarker of lipid peroxidation relative to objective indicators of high-intensity training load in a cohort of professional football players throughout different phases of a competitive in-season.

METHODS: Ten professional football players (age: 23 ± 2 yrs; body mass: 83.5 ± 6.2 kg; stature: 181.3 ± 5.3 cm; VO2max: 57.2 ± 6.7 mL·kg·min^{-1}) participated in the study. Training load was assessed at three time points throughout a competitive in-season (T1: early in-season [1st microcycle]; T2: mid-season [16th microcycle]; T3: end of in-season [32nd microcycle]) using Global Positioning System (GPS) and heart rate (HR) based methods to quantify high-intensity external training load (HETL) and high-intensity internal training load (HITL). Urine samples were collected at each time point and analysed for urinary malondialdehyde (MDA) as a biomarker of lipid peroxidation; data normalised to creatinine. Results presented as M ± SD.

RESULTS: High-intensity training load varied significantly throughout the competitive in-season and was significantly higher at T2 compared to T1 (HETL: 18.56 ± 7.30 m.min-1 vs. 6.71 ± 2.62 m.min-1, an increase of 11.84 m.min-1, 95% CI [4.33, 19.36], p = .004; HITL: 60 ± 34 %Time spent > 80% HRmax vs. 23 ± 14 %Time spent > 80% HRmax, an increase of 37 %Time > 80% HRmax, 95% CI [13, 60], p = .004; T2 vs. T1, respectively). Urinary MDA concentrations decreased significantly throughout the competitive in-season, x2(2) = 6.889; p = .032, (T1: 0.76 ± 0.90 µM.mmol-1 vs. T3: 0.18 ± 0.12 µM.mmol-1, Z = -2.192, r = .52, p = .028). No significant correlations were observed between indicators of high-intensity training load and MDA.

CONCLUSION: Participation in chronic football training appears to promote an adaptive response as lipid peroxidation was attenuated over the competitive in-season, irrespective of high-intensity training load. Monitoring urinary MDA may be a useful tool to provide sports scientists with an insight into adaptive or maladaptive responses throughout a competitive season in football.

KINETICS OF PERFORMANCE FATIGABILITY DURING A SINGLE SESSION OF 8X4-MIN HIGH-INTENSITY INTERVAL TRAINING

TRIPP, T.R., CASWELL, A., ABOODARDA, S.J., MACINNIS, M.J.

UNIVERSITY OF CALGARY

INTRODUCTION: Performance fatigability—a decline in an objective measure of performance over a discrete period—reflects complex processes in the nervous and skeletal muscle systems in response to exercise. Studies have quantified performance fatigability during sprint interval exercise; however, to our knowledge, no studies have examined the kinetics of fatigability during a session of longer intervals, representative of high-intensity interval training (HIIT). The purpose of this study was to examine performance fatigability during a cycling HIIT session. We hypothesized that (i) successive intervals would cause smaller declines in maximal voluntary contraction (MVC) force and central and peripheral indices of fatigability, compared to the previous interval; and (ii) the session would cause greater peripheral fatigue than central fatigue.

METHODS: Healthy participants (n=8 males, n=7 females, age = 26±5 yrs., VO2max = 47±6 ml/kg/min) performed cycling trials to task failure to determine critical power (CP) followed by a HIIT trial consisting of 8x4-min intervals at 105% CP interspersed with 3 min at 15% CP. Neuromuscular function (NMF) tests, which consisted of femoral nerve electrical stimuli delivered during and after an MVC, were performed prior to and immediately after the 1st, 4th, and 8th intervals. From these tests, we measured overall fatigability (MVC), voluntary activation (VA), and low-frequency fatigue (LFF). Data were analyzed using one-way, repeated measures ANOVAs. Statistical significance was set at $p<0.05$, and effect sizes (ES) were estimated using Cohen's d for repeated measures.

RESULTS: After 8 intervals, MVC decreased by 26±11% (708±174 N vs. 528±154 N, p<0.01). The first interval (ES: -0.6, p<0.01) had a larger effect than intervals 2-4 (ES: -0.2, p=0.40) and intervals 5-8 (ES: -0.3, p=0.09). A 32±18% decline was observed for LFF after 8 intervals (0.98±0.18 vs. 0.65 ± 0.13, p<0.01), with most of the decline attributable to the first interval (ES: -0.7, p=0.22) and intervals 2-4 (ES: -1.0, p<0.01) as opposed to intervals 5-8 (ES: -0.1, p=0.99). We found a significant effect of time for VA, despite small changes after 8 intervals (87±5% vs 85±8%, p=0.04). VA showed larger effects of the final four intervals (ES: -0.3, p=0.69) compared to the first interval (ES: 0.2, p=0.97) or intervals 2-4 (ES: 0.1, p=0.99).

CONCLUSION: Over the course of an eight-interval exercise session, there was a notable decline in MVC, which was primarily attributable to substantial impairment in muscle contractile function (peripheral fatigue), with limited central fatigue. A large proportion of the total decline in MVC (~60%) was present after just one interval, and ~70% of this impairment was present after four intervals. These findings suggest that the common "4x4" high-intensity interval training protocol elicits muscle metabolic stress with diminishing returns for subsequent completed intervals.

TH17 CELLS PROTECT THE LEAKY GUT FROM HIGH-INTENSITY EXERCISE-INDUCED DAMAGE IN MICE

SONG, Y.1, PARK, H.1, LEE, S.1, LEE, M.2, KANG, H.1

1 KYUNG HEE UNIVERSITY 2 BIO-CENTER, GYEONGGIDO BUSINESS & SCIENCE ACCELERATOR

INTRODUCTION: Moderate exercise has a beneficial effect on the immune system, but high-intensity exercise is known to reduce the number of lymphocytes in the blood during recovery, leading to the "open window" that is vulnerable to infection. A seminal study found that T cells are redistributed to peripheral tissues including the intestine following an even bout of high-intensity exercise (1). During high-intensity exercise, an intestine is temporarily damaged and leaky, allowing gut bacteria to enter the intestine (2). In defense of gut bacteria, T helper 17(Th17) cells play an important role in enhancing the tight junction between intestinal epithelial cells by inducing interleukin-17 (IL-17) and IL-22 (3, 4). This study aims to identify Th17 cells in the Peyer's patches (PPs) of the small intestine for immune surveillance following high-intensity exercise.

METHODS: Twenty male Balb/c 8 weeks of age mice were divided into normal group (N) and exercise group (EX). The EX mice were subjected to swimming until exhaustion, and blood and PPs were collected 1 h after the forced swimming test. For in vivo evaluation of gut permeability, serum levels of lipopolysaccharide (LPS) and FITC-conjugated dextran were analyzed. Specific subsets of immune cells were analyzed by fluorescent-labeled antibody staining of blood and PP cells using flow cytometry. Gene expression was analyzed by realtime-PCR. Data were analyzed by Student's t-test and expressed as mean ± SD.

RESULTS: The average time spent for swimming was 28±4 min. In the EX group, the levels of serum FITC-dextran (N: 1520.18±219.17, EX: 1907.79±234.66ng/ml, p=0.005) and LPS (N: 1.029 ± 0.096, EX: 1.148 ± 0.099 EU/ml, p = 0.011) increased respectively. In analysis of blood cells, the percentages of T cells (p=0.02), CD4(+) T cells (p=0.01), CD8(+) T cells (p=0.015), and B cells (p=0.001) decreased in the EX group, as previously reported in PP, the percentage of dendritic cells (DC) (CD11c+) (p=0.039), macrophages (F4/80+) (p=0.002), and Th17 cells (CD3+CD4+IL-17+) (p=0.021) increased in the EX group, indicating the redistribution of immune cells to the gut. In the PP of the EX group, the expression of CD80, a DC activation marker, increased in the EX group (p=0.041). Also, the expression of CD69, a T cell activation marker, increased in the EX group (p=0.036). Further, the upregulation of IL-23 and IL-22, which induce the expression of Th17-type cytokines, was observed in the EX group (p=0.001 for IL-23 and p=0.021 for IL-22).

CONCLUSION: This study demonstrated that high-intensity exercise stimulates various immune cells to migrate to the PP. The increased number of Th17 cells indicates that they may protect the leaky gut from exercise-induced damage.

THE INFLUENCE OF DOMAIN-SPECIFIC EXERCISE INTENSITY PRESCRIPTION ON CHANGES IN GUT MICROBIOTA COMPOSITION IN HEALTHY HUMANS

SALES, K.M., INGLIS, E.C., CHO, N.A., LOWRY, D.E., NOYE TUPLIN, E.W., MURIAS, J.M., REIMER, R.A.

UNIVERSITY OF CALGARY

INTRODUCTION: The gut microbiota comprises all microbes inhabiting the intestines and has been implicated in a variety of health and disease states [1]. Cardiovascular exercise training has been shown to positively influence the gut microbiota by enriching bacterial diversity and increasing the abundance of health-associated bacteria and their metabolites, including butyrate [2]. The majority of research to date has focused on low- or moderate-intensity continuous exercise interventions, thus the influence of higher intensities of continuous (i.e., heavy domain) or intermittent (severe or extreme domains) exercise training on the gut microbiota remains unknown. The purpose of this study was to evaluate the influence of domain-specific exercise training on the gut microbiota.

METHODS: Sixty-seven (n=67) healthy young adults were randomized to 6 groups (5 exercise interventions, 1 control (CON)). Exercise interventions consisted of three groups performing continuous cycling in the 1) moderate (MOD)- (n=11), 2) lower heavy (HVY1)- (n=10), and 3) upper heavy-intensity (HVY2) domain (n=13) and two interval cycling groups including 4) high- intensity interval training (HIIT) in the severe-intensity domain (n=11) and 5) sprint interval training (SIT) in the extreme-

intensity domain (n=13). Exercise intervention groups, except SIT were work matched. Participants performed 3 training sessions per week for 6 weeks. Stool samples were collected immediately prior to and following the 6-week period for gut microbiota analysis via 16S rRNA sequencing.

RESULTS: Bacterial alpha diversity was unchanged by the exercise intervention in all groups except SIT, which showed a significant decrease in alpha diversity (inverse Simpson) post intervention. Bacterial relative abundance at the genus level was unchanged in CON and MOD, however, significant ($p<0.05$) changes were observed post intervention in HVY1, HVY2, HIIT, and SIT. In the continuous exercise groups, the abundance of Faecalibacterium, a beneficial butyrate producer, was reduced post-intervention in HVY1 and HVY2, while HVY2 also increased butyrate producing Anaerostipes. In the interval exercise groups, Agathobacter - another butyrate producer - was decreased and increased in HIIT and SIT, respectively, while SIT also showed a non-significant ($p=0.062$) increase in Faecalibacterium post intervention.

CONCLUSION: These results suggest that 6 weeks of cardiovascular exercise training influences gut microbiota alpha diversity and relative abundance in healthy humans, but there may be a minimum exercise intensity required to stimulate changes. Additionally, intermittent exercise in the extreme intensity domain may be the most optimal for increasing the abundance of beneficial bacteria.

REPEATED SPRINT TRAINING IN HYPOXIA INDUCES SUPERIOR GLYCOLYTIC ADAPTATIONS THAN IN NORMOXIA THROUGH S100 PROTEIN SIGNALING

LANFRANCHI, C., WILLIS, S., LARAMÉE, L., KAYSER, B., ZANOU, N., MILLET, G.P., PLACE, N.

UNIVERSITÉ DE LAUSANNE

INTRODUCTION: Athletes increasingly engage in repeated sprint training that consists of repeated short all-out effort (<10 s) interspersed by short recoveries (<60 s). When performed in hypoxia (repeated sprints in hypoxia, RSH), it may lead to greater training effect than in normoxia (RSN). The literature on the molecular response to RSH remains moot about the effects on muscle oxidative vs glycolytic activity. To clarify it, we studied the effects of RSH on these molecular pathways, in comparison to RSN.

METHODS: Two groups of healthy young men (randomized) performed three training sessions/week for three weeks. Each training session consisted in six series of six sprints (6 s effort / 24 s rest) in either normoxia (RSN, n = 7) or normobaric hypoxia (FiO_2 = ~13%, RSH, n = 9). Before and after the training period, vastus lateralis muscle biopsies, a repeated sprint ability (RSA) test and a Wingate test were performed. Metabolic muscle adaptations were studied with proteomics and western blotting.

RESULTS: RSN and RSH similarly improved power output ($p<0.05$) during the RSA test (RSN: +7.2±7.7% vs. RSH: +7.9±6.6%) and the Wingate test (RSN: +1.3±3.6% vs. RSH: +4.4±5.0%). Proteomics revealed a decrease in several processes involved in oxidative phosphorylation, confirmed by Western Blot with a reduction ($p<0.05$) in complexes I (-21%) and V (-18%) protein levels in response to both RSN and RSH. RSN and RSH increased ($p<0.05$) protein levels of the hypoxia inducible factor 1α (HIF-1α, +106%) and vascular endothelial growth factor A (VEGFa, +80%). Protein levels of the glycolytic enzyme hexokinase II increased (+80%, $p<0.05$) after both training types. Only RSH induced increased glucose transporter 4 (GLUT4, +31%, $p<0.05$) protein level, suggesting specific glycolytic adaptations in response to hypoxia, supported by proteomics data. This specific adaptation may be triggered through the signaling of S100 protein family as we observed an increased S100A13 protein level (+730%, $p<0.05$) as well as several other S100 proteins in proteomics.

CONCLUSION: To conclude, RSH did not result in greater performance improvement than RSN. However, it further improved the glycolytic phenotype compared to RSN, possibly through specific S100 proteins signaling. Thus, we suggest that the reported superiority of RSH to RSN in the literature may result from superior glycolytic adaptations.

EXERCISE MITIGATES REDUCTIONS IN GLUCOSE TOLERANCE, SKELETAL MUSCLE MITOCHONDRIAL FUNCTION AND PROTEIN SYNTHESIS, BUT NOT COGNITIVE FUNCTION, INDUCED BY SLEEP RESTRICTION.

SANER, N.J., LEE, M.J.C., KUANG, J., PITCHFORD, N.W., ROACH, G.D., ESSER, K.A., SCHRODER, E.A., HUO, Z., STOKES, T., PHILLIPS, S.M., BARTLETT, J.D.

INSTITUTE FOR HEALTH AND SPORT, VICTORIA UNIVERSITY

INTRODUCTION: Inadequate sleep is increasingly common and has been associated with reductions in glucose tolerance. While the factors underpinning this require further investigation, reduced mitochondrial function has been suggested as a candidate mechanism. Moreover, inadequate sleep is known to reduce mood state and decrease vigilance. Given that exercise can improve glucose tolerance and mitochondrial function and improve mood, we hypothesised that exercise may mitigate the detrimental effects associated with a period of sleep restriction.

METHODS: 24 healthy young males participated in an eight-night, laboratory-controlled sleep study. Participants were allocated into one of the three experimental groups: a Normal Sleep (NS) group (8 h time in bed (TIB) per night, for five nights), a Sleep Restriction (SR) group (4 h TIB per night, for five nights), and a Sleep Restriction and Exercise group (SR+EX) (4 h TIB per night, for five nights and three high-intensity interval exercise (HIIE) sessions). Glucose tolerance, skeletal mus-

cle protein synthesis (via deuterium oxide administration), mitochondrial respiratory function, transcriptomic responses, and measures of mood and vigilance were assessed pre- and post-intervention.

RESULTS: We report that the SR group had reduced glucose tolerance post-intervention (mean change ± SD, P value, SR glucose AUC: 149 ± 115 A.U., P = 0.002), which was also associated with reductions in mitochondrial respiratory function (SR: -15.9 ± 12.4 pmol O2.s-1.mg-1, P = 0.001), and a lower rate of sarcoplasmic protein synthesis (SarcPS, FSR%/day SR: 1.11 ± 0.25%, P < 0.001). These effects were not observed when incorporating three sessions of HIIE during this period (SR+EX: glucose AUC: 67 ± 57, P = 0.239, mitochondrial respiratory function: 0.6 ± 11.8 pmol O2.s-1.mg-1, P = 0.997, and SarcPS (FSR%/day): 1.77 ± 0.22%, P = 0.971). However, there were no differences in POMS total mood disturbance score or PVT-assessed reaction time (P < 0.05) between the SR and SR+EX groups.

CONCLUSION: We report that performing three sessions of HIIE throughout a period of sleep restriction can prevent the reductions in glucose tolerance, mitochondrial function, and skeletal muscle protein synthesis observed with sleep restriction alone. However, the reductions in mood state and vigilance with sleep restriction were not ameliorated by performing HIIE. Therefore, exercise may be a viable candidate to mitigate the detrimental metabolic consequences associated with sleep loss, although it's benefit for improving mood and alertness in this context requires further research.

RELATIONSHIPS BETWEEN CHANGES IN PERFORMANCE RELATED-MEASURES FOLLOWING HIGH-INTENSITY INTERVAL TRAINING IN ELITE ATHLETES DERIVED VIA META-REGRESSION ANALYSES

HALLER, N.1,2, STÖGGL, T.3, STREPP, T.1, KILZER, F.1, SCHMUTTERMAIR, A.1, BLUMKAITIS, J.1, HOPKINS, W.G.4, WIESINGER, H.P.1

1 UNIVERSITY OF SALZBURG, AUSTRIA; 2 UNIVERSITY OF MAINZ, GERMANY; 3 RED BULL ATHLETE PERFORMANCE CENTER, SALZBURG, AUSTRIA; 4 INTERNET SOCIETY FOR SPORT SCIENCE, AUCKLAND, NEW ZEALAND

INTRODUCTION: Elite athletes use high-intensity interval training (HIT) to enhance competition performance. Meta-analyses have shown that HIT is effective for improving various performance-related measures in various settings (Wiesinger et al. 2023). However, visualization of relationships between HIT-induced change scores in performance-related measures may provide a more nuanced and practical interpretation by revealing trends and patterns that were not apparent in the separate meta-analyses. Here, we have explored these relationships.

METHODS: The change scores were the study-estimates for the performance-related measures (sprint speed/power, repeated-sprint ability, time-trial speed/power, peak speed/power, threshold speed/power, VO2max, work economy) for the HIT and control groups in the previous study (Wiesinger et al. 2023). The linear relationships between change scores of pairs of measures were quantified with a meta-analytic mixed model. The fixed effects were the linear-numeric predictor variable and the intercept. The mean value of the dependent variable was estimated with the same mixed model omitting the predictor variable, and the corresponding mean value of the predictor was estimated from the slope (the coefficient of the predictor) and the intercept of the first model. A random effect provided an estimate of heterogeneity as the standard error of the estimate, which represented differences in the effect of HIT between settings that were not explained by the predictor.

RESULTS: The scatterplots revealed positive linear relationships between appropriate pairwise combinations of time-trial speed/power, peak speed/power, VO2max, and aerobic/anaerobic threshold. The mean changes in the subset of study estimates in each plot were similar, but the variation in each dependent variable left unexplained by the predictor (the standard error of the estimate) was 2.0 to 2.6%. Mean change in work economy showed a slightly negative relationship with time-trial speed/power and a stronger negative relationship with VO2max. Repeated-sprint ability had a weak positive relationship with sprint speed/power.

CONCLUSION: The wide variation in change in mean time-trial performance between settings for a given change in peak speed/power, VO2max, or threshold speed/power implies that these three test measures would not accurately reflect the effects of HIT on performance in endurance competitions. Therefore, time-trials should be implemented whenever possible to accurately assess the effect of HIT. The three test measures, along with work economy, might nevertheless identify strengths and weaknesses to customize further implementation of HIT or other training interventions of the individual athletes in a given setting. Sprints and repeated-sprinted ability are both important performance-related measures for team-sport athletes, and their poor relationship implies that both should be measured to assess the effect of HIT.

EFFECTS OF EXERCISE IN HYPOXIA BUT REST IN NORMOXIA DURING SPRINT INTERVAL TRAINING ON ACUTE PHYSIOLOGICAL RESPONSES AND PERFORMANCE

TAKEI, N., KAKEHATA, G., INABA, T., MORITA, Y., SANO, H., HATTA, H.

THE UNIVERSITY OF TOKYO

INTRODUCTION: Exercise under hypoxia can induce arterial and tissue deoxygenation due to low oxygen availability. This arterial and tissue hypoxia can induce physiological adaptations through an oxygen-sensing signaling pathway. However, adding hypoxia to exercise can negatively impact training stimulus due to reducing absolute training intensity and/or volume. In this study, we tested our hypothesis that exercise in hypoxia but rest in normoxia during sprint interval training can induce larger arterial hypoxia during exercise with maintained absolute training intensity and volume compared to normoxic exercise.

METHODS: Seven male athletics sprinters volunteered to participate in this study. This study was conducted in a single-blinded, cross-over manner. All participants performed 4 × 30-sec all-out cycling sprints with 4.5-min rest in normobaric

hypoxia (12.7%O2, H), or normoxia (N), or exercise in normobaric hypoxia (12.7%O2) but rest in normoxia (HN) in a randomized order. Total work, arterial oxygen saturation, and blood lactate concentration were measured as performance and physiological variables.

RESULTS: Compared to N, total work was significantly decreased in H ($p<0.05$) but maintained in HN. Main effect of time ($p<0.001$), condition ($p<0.001$) and interaction ($p<0.001$) were observed for arterial oxygen saturation. Arterial oxygen saturation of HN significantly decreased only during exercise to the same level as H (SpO2: 85.4±2.6 vs 85.3±4.9%) but not different during rest compared to N (SpO2: 97.1±1.0 vs 97.6±1.4%). Blood lactate concentration significantly increased across repetition ($p<0.001$) but was not different between conditions.

CONCLUSION: In this study, compared to normoxic condition, exercise in hypoxia but rest in normoxia during sprint interval training induced large arterial hypoxia only during exercise with similar absolute training intensity and volume. Therefore, the hypoxic training protocol in this study could be a new potential training method to induce a large physiological training stimulus with the same mechanical training stimulus.

EFFECTS OF HIGH-INTENSITY INTERVAL TRAINING WITH BLOOD FLOW RESTRICTION ON CYCLING EFFICIENCY AND OXYGEN UPTAKE

DESANLIS, J., GERNIGON, M., COLIN, A., COTTIN, F., GORDON, D.

UNIVERSITÉ PARIS-SACLAY; INSTITUT FRANCO-EUROPÉEN DE CHIROPRAXIE; ANGLIA RUSKIN UNIVERSITY

INTRODUCTION: Blood Flow Restriction (BFR) is known to increase both muscular strength and hypertrophy but has also shown improvements in maximal aerobic power (VO2max) when using low-intensity training [1]. However, the effects of low-volume high-intensity interval training (HIIT) combined with BFR (HIIT+BFR) are unclear and need further investigation. In addition, the effects of occlusion pressure during training on central cardiovascular and peripherical metabolic adaptations are poorly documented. Thus, this study aimed to investigate the effects of HIIT+BFR on VO2max and the effects of different occlusion pressures on central cardiovascular adaptations.

METHODS: 25 participants (11 females, 14 males; 19 ± 7 years; 175 ± 8 cm; 66.8 ± 7.9 kg; 17.3 ± 8.2 % of body fat; 9 ± 5 h of physical activity per week) were trained three times a week for four weeks with BFR at different levels of occlusion (G1 = 20 mmHg (SHAM); G2 = 40% Limb Occlusion Pressure (LOP); G3 = 60% LOP). Training consisted of 4 to 7 bouts of 90 seconds HIIT+BFR performed at 90% of VO2max on a cycle ergometer, interspersed with 2 min recovery bouts, where cuffs were deflated. Pre-and post-cardiorespiratory fitness was assessed. Groups and sessions were compared using mixed ANOVA

RESULTS: Training did not affect VO2max, but significantly improved maximum power attained at volitional exhaustion for all groups, with no difference between groups (269 ± 45 vs. 300 ± 51 watts, $p<0.05$). Training enhanced power at both Gas Exchange Threshold (GET) (175 ± 48 vs. 212 ± 48 watts, $p<0.05$) and Respiratory Compensation Point (RCP) (227 ± 43 vs. 265 ± 51 watts, $p<0.05$), for all groups but with no difference between groups.

CONCLUSION: 4 weeks of HIIT combined with BFR is not enough to improve the participants' VO2max. However, the increase in maximum wattage attained without any increase in VO2max shows a training-induced improvement of cycling efficiency, suggesting peripherical metabolic or/and neuromuscular adaptations [2]. With this training modality, the stress stimulus induced by blood flow restriction during exercise was insufficient to induce significantly higher central cardiovascular adaptations, but induced peripherical adaptations even with low peripherical resistance, implying that higher pressures are not needed.

META-ANALYSES OF THE EFFECT OF HIGH-INTENSITY INTERVAL TRAINING ON PERFORMANCE-RELATED MEASURES IN ELITE ATHLETES

WIESINGER, H.P., HOPKINS, W.G., HALLER, N., BLUMKAITIS, J., STREPP, T., KILZER, F., SCHMUTTERMAIR, A., STÖGGL, T.

UNIVERSITY OF SALZBURG

INTRODUCTION: High-intensity interval training (HIT) enhances sprint and endurance performance, but its effect on elite athletes, who are already highly trained, could be limited by a ceiling effect. We have therefore meta-analysed the effects of HIT on such athletes.

METHODS: We followed the PRISMA guidelines. Studies were performed on endurance (mean VO2max: males ≥60 ml·min−1·kg−1, females ≥55 ml·min−1·kg−1) or other elite athletes. HIT consisted of ≥5 sessions and ≥1 session/wk at intensities ≥90% of HRmax or VO2max for intervals of ≤4 min or with all-out intervals of ≤90 s. Percent changes with HIT vs usual control training were derived via log-transformation from random-effects meta-regression with adjustment for one or more fixed-effect modifiers (sex, type of athlete, type of test, type of HIT, phase of training, training duration, whether HIT replaced some usual training, and relevant pre-test mean values). Separate analyses were performed for the following performance-related measures: sprint speed/power, repeated-sprint ability (RSA), time-trial speed/power, peak speed/power, threshold speed/power, VO2max, and work economy. Heterogeneity, representing unexplained real

differences between settings, was estimated from random effects for study- and sample-estimate identity. Level of evidence for effect magnitudes was evaluated via effect uncertainty and a smallest important change of 1%.

RESULTS: All performance-related measures except economy showed at least good evidence for enhancement in some subgroups and some settings, with effects ranging from 2.1% for 5-s sprints in male other athletes to 12.6% for threshold speed/power in female endurance athletes. Moderating effects of sex and type of athlete were inconclusive. Very good evidence was found for greater effects of HIT vs control on longer sprint and time trial. There was at least good evidence for reduced effects of more anaerobic types of HIT on VO2max and threshold speed/power, but its effects on other measures were inconclusive. Effects of other modifiers on the other measures, where they could be estimated, were also inconclusive. Heterogeneity of the effects of HIT ranged from small to moderate (SDs 1.1 to 2.3%) but was generally unclear.

CONCLUSION: On average, HIT works for endurance and other elite athletes across various performance demands, including short sprints, repeated sprints, and time trials, which relate closely to competition performance. The positive effects of HIT would hold for most sports, even if our already conservative estimate of the smallest important of 1% was doubled. However, when heterogeneity is taken into account, HIT could be ineffective for some measures in some settings. Additional research is required to address the uncertainty in the effects of HIT with female non-endurance athletes on some measures, the effect of HIT on economy, and the modifying effects of the duration of training, the phase of training, and type of HIT with most measures.

AUSCULTATORY, PALPATORY, PHOTOPLETHYSMOGRAPHIC AND ELECTROCARDIOGRAPHIC HEART RATE RECORDING DIFFERENCES DURING REST AND SUPMAXIMAL AEROBIC AND RESISTANCE EXERCISE

PANAYIOTOU, G., LADAS, A., BELLALI, T., FEIDANTSIS, K., PAPADOPOULOU, S.K., METHENITIS, S.

EUROPEAN UNIVERSITY OF CYPRUS

INTRODUCTION: Heart rate monitoring is important for determining acute and chronic exercise responses and adaptations during rest and exercise and can be used as a training stress measure for exercise participants. The present study aimed to compare different methodologies for heart rate measurement in three specific conditions: resting state, after submaximal aerobic exercise and after strength training.

METHODS: Thirty-seven female and male sports science students, aged 23.2+3 years, participated in the study. During their visit to the laboratory, their Heart Rate (HR) was assessed at rest in a supine position and after being previously rested for 5 minutes. The assessment was performed simultaneously by the following methods: auscultation, palpation, photoplethysmograph (PPG -hand finger pulse oximetry and wristwatch) and electrocardiographic activity (chest heart rate belt). The same recordings were followed after a three-minute sub-maximal running on a treadmill at zero inclination and 8km/hr speed. Finally, the same methodology was used to record HR after performing three deep leg squat sets of twelve reps, with an intensity at 70% of maximal strength (1 RM determined 15 min earlier using the multiple repetition method) and a 1 min break between sets. Data were analyzed using IBM SPSS Statistics v26 software. Data are described by measures of central tendency and variance (X̄±SD), and one-way ANOVA was applied to compare means. The level of significance (p) was set at 0.05.

RESULTS: The comparison of means revealed no statistically significant differences ($p>0.05$) between the different recording methods in each condition. However, it is noteworthy that the maximum differences between the methods of the individual conditions increased with increasing exercise intensity and particularly as the dynamic physiological demands increased. In particular, the greatest difference (6.7%) in resting HR was observed between the auscultatory 70.7±8.6 bpm and the electrocardiographic method (chest band): 75.1±11.8 bpm; after submaximal endurance exercise the difference increased to 9% and was recorded between the PPG method (wristwatch): 130.3±29.1 bpm and the palpatory method: 118.62±26.41 bpm. Following the strength training, the difference between the different methods became even greater (10.7%) and was recorded between the electrocardiographic method (chest band): 134.58±22.65 bpm and the PPG method (wristwatch): 120.15±23.28 bpm.

CONCLUSION: It is concluded that the methods of HR recording do not exhibit significant differences between them under different measurement conditions. However, a tendency for the differences to become more pronounced as the intensity and, therefore, the hemodynamic demands of the effort increase is apparent. The electrocardiographic method shows higher HR recordings compared to the other methods.

ACUTE EFFECTS OF DIFFERENT ANAEROBIC WORKLOADS ON PARAMETERS OF ARTERIAL STIFFNESS

LUBIAK, S., RIDDELL, S., WAGNER, H., MAY, J., DUNGEY, J., ANTUNES, V.A., TIRALLA, G., TAMULEVICIUS, N.

UNIVERSITY OF TAMPA

INTRODUCTION: High intensity interval training has been shown to improve cardiovascular health (1,2) and arterial stiffness (AS) (3,4). Additionally, AS after single and repeated Wingate bout(s) have been studied (5,6). However, there is limited evidence on the relationship between different anaerobic workloads and its impact on AS. The purpose of this study is to investigate the differences between low load (LL) and high load (HL) Wingate bouts and its effects on different AS parameters.

METHODS: Thirty participants (age: 21.5±2.24 years; females:males: 23:7) were randomly assigned to either the LL (7.5% of body weight; n=16) or HL (10% of body weight; n=14) group. Participants completed a baseline AS assessment, consisting of pulse wave analysis (PWA) and pulse wave velocity (PWV) using the SphygmoCor XCEL device. PWA measured augmentation index (AIx) which pertains to peripheral AS while PWV pertains to central AS. Next, participants completed a customized Wingate protocol consisting of a five-minute warm up followed by three bouts of ten second sprints with two minutes of rest between the first two bouts. After the third bout, participants immediately completed a second analysis of AS. PWA was conducted at the three-, eight-, and thirteen-minute mark while PWV was conducted at the five-, ten-, and fifteen-minute mark. Repeated measures ANOVA were used to examine the relationship between load across the respective time intervals for AIx and PWV.

RESULTS: A main effect (p=0.003) was found for AIx. There was a significant decrease between pre AIx and AIx at 13 minutes (p=0.005). Trends indicated lower AIx values in the HL group compared to the LL group across time, but not significant (LL AIx 3 min: 9.5%, HL AIx 3 min: 4.21%; LL AIx 8 min: 8.89%, HL AIx 8 min: 6.57%; LL AIx 13 min: 5.81%, HL AIx 13 min: 2.21%). PWV main effect was borderline significant (p=0.056). No group by time interactions were observed (AIx by load: p=0.400; PWV by load: p=0.886).

CONCLUSION: Similar AS responses occurred regardless of the load for repeated anaerobic bouts. AIx values decreased over time and were lower in the HL group compared to LL group. Further research is needed to understand the long-term effects of repeated anaerobic bouts using HL and its potential to decrease peripheral AS.

ASSOCIATIONS BETWEEN ARTERIAL STIFFNESS AND VISCERAL ADIPOSE TISSUE IN PHYSICALLY ACTIVE YOUNG-ADULTS

ANTUNES, V.A., LUBIAK, S., RIDDELL, S., WAGNER, H., MAY, J., MORRIS, J., TAMULEVICIUS, N.

THE UNIVERSITY OF TAMPA

INTRODUCTION: Arterial stiffness (AS) and high body fat (BF) are known to play a role in cardiovascular and metabolic events (1,2). Studies show higher correlations between visceral fat (VF) and cardiovascular risk compared to subcutaneous fat (SF) (1,2). However, the relationship between VF% and AS is limited and previous studies have focused on obese and/or older age subjects (1,3,4). The purpose of this study is to investigate the association between AS and VF% in physically active young adults.

METHODS: Thirty subjects (age: 21.5±2.24 y.o.; females: 23, males: 7) were asked to refrain from food, water, alcohol, nicotine, and caffeine 12 hours before measurements. Dual-energy X-ray absorptiometry was performed prior to AS measurements. AS was measured using the SphygmoCor XCEL device and is composed of pulse wave velocity (PWV) and pulse wave analysis (PWA). PWV measures central AS and PWA measures blood pressure (BP) which is used for PWV. BP was taken after five minutes of rest in the supine position and was conducted twice to get the average BP. Pearson correlations were used to analyze PWV and VF% while Spearman rank correlations were used to analyze PWV against SF, BF%, and waist circumference (WC).

RESULTS: Pearson correlation shows a moderate association between PWV and VF% (r=0.469, p=0.008). Spearman rank correlations showed low associations for PWV and SF (r=0.202, p=0.285), PWV and BF% (r=0.084, p=0.660), and a moderate association between PWV and WC (r=0.571, p<0.001).

CONCLUSION: PWV is moderately correlated with VF% and WC in young adults while SF and BF% were not associated with PWV. Potentially, these findings could be used as a prescreening tool for young adults prior to starting exercise. Further research is needed to better understand the correlation between AS and VF and its role in cardiovascular risk prevention in physically active young adults.

INTRODUCTION: Reduced arterial function is an independent risk factor for cardiovascular disease, and regular exercise improves arterial function. In recent years, increasing attention has been paid to electrical muscle stimulation (EMS) as an alternative modality to voluntary exercise. Acute EMS to lower limbs induces passive muscle activity by stimulating motor unit activities, which increases local arterial blood flow and decreases arterial stiffness. This suggests that EMS may serve as a new exercise modality for cardiovascular disease prevention. Therefore, we investigated whether an 8-week EMS training program improved arterial function.

METHODS: We recruited 38 normotensive (<140/90 mmHg) healthy males without obesity. The participants were randomly assigned to the EMS training group (n = 20, age: 21.9 ± 1.7 years) or the control group (n = 18, age: 21.6 ± 1.9 years). The EMS training group performed EMS training on the lower limbs three times a week for 8 weeks. The EMS system (Myoelectoric Medicine EMS) was designed to simulate the motor unit activities during voluntary muscle contraction, where the stimulation frequency was gradually increased from 12 to 60 Hz. Maximal isometric knee extension torque (MVC), brachial-ankle pulse wave velocity (baPWV; an index of systemic arterial stiffness), and flow-mediated dilation (FMD; an index of endothelial function) of the brachial artery were measured before and after the intervention, and the changes were compared by two-way analysis of variance.

RESULTS: We observed a significant interaction in the MVC ($p < 0.01$). The MVC increased significantly in the EMS group (pre: 171.9 ± 42.8 Nm vs. post: 200.7 ± 46.5 Nm; $p < 0.01$) but not in the control group (pre: 164.5 ± 27.6 Nm vs. post: 167.1 ± 32.0 Nm; $p = 0.94$). There was also a significant interaction in the baPWV ($p = 0.04$). The baPWV decreased significantly in the EMS group (pre: 1118.8 ± 118.7 cm/s vs. post: 1062.3 ± 125.1 cm/s; $p = 0.01$) but not in the control group (pre: 1060.9 ± 146.4 cm/s vs. post: 1068.9 ± 164.1 cm/s; $p = 0.72$). Although there was a significant interaction in the FMD ($p = 0.03$), changes in the FMD were not statistically significant in either group (EMS group: pre: 5.8% ± 1.9% vs. post: 6.6% ± 2.8%; $p = 0.08$ and control group: pre: 6.2% ± 2.0% vs. post: 5.6% ± 2.2%, $p = 0.18$).

CONCLUSION: EMS confers beneficial effects on arterial function, as indicated by a decreased baPWV (4.8%) and increased FMD (19.8%). These results suggest that EMS training may improve arterial function.

EFFECTS OF HIGH-INTENSITY INTERVAL EXERCISE IN WATER ON RENAL ARTERIAL BLOOD FLOW.

ONO, K., NAKAYAMA, Y., OKAGAWA, J., YAMAU, R., ISHIKAWA, A., ONODERA, S.

KOBE UNIVERSITY

INTRODUCTION: Whereas renal arterial blood flow decreases with increased exercise intensity on land, the ability to increase the resting baseline in an underwater environment may allow for increased exercise intensity while decreasing renal stress. This study aimed to determine the effects of high-intensity interval exercise (HIIE) in water on renal arterial haemodynamics by comparing moderate-intensity continuous exercise (MICE) and land-based exercise.

METHODS: The study included nine healthy young adult males (aged 22.9 ± 1.3 years). The exercise was performed on a recumbent ergometer under two conditions: the H condition, in which 10 sets of 20 s submaximal exercise were performed with a 1 min interval for a total of 13 min 20 s; and the M condition, in which 13 min 20 s of the moderate continuous exercise was performed (room temperature: 26.9 ± 2.4°C). There were two environmental conditions: in water (water level: xiphoid process, water temperature: 31.3 ± 1.4°C) (W condition) and on land (L condition). Each of these conditions was combined into four distinct conditions (WH, LH, WM, and LM). As primary endpoints, right renal artery haemodynamics (time-averaged blood flow velocity: Vm) were measured before, immediately after, and 30 min after exercise. Secondary endpoints included oxygen uptake (VO2), heart rate (HR), cardiac parasympathetic nervous system activity (LnHF), and urine volume. The significance level was set at less than 5%.

RESULTS: VO2 and HR during exercise did not differ significantly between environmental conditions within the exercise intensity conditions, suggesting that exercise could be performed at the same intensity irrespective of the environment. Vm showed significant differences between phases, and the post hoc analysis showed a significant increase at rest on the ergometer compared to at rest on land. Vm significant ly decreased immediately after exercise compared to resting on the ergometer, with no distinctions between the four conditions. LnHF showed a significant interaction and was lower immediately after exercise than rest on land in the LH condition. There was no significant change in the other three conditions. In the WH condition, LnHF tended to increase, although not significantly, after entering the water, a trend that was not significantly different from the LM condition The WM condition demonstrated a significant increase in urine volume post-exercise relative to pre-exercise.

CONCLUSION: HIIE on a recumbent ergometer did not significantly affect renal artery haemodynamics under different environmental conditions. On the contrary, the underwater condition increased urine volume and induced post-exercise

LnHF activation, which showed an insignificant difference in trend compared to the LM condition. These findings indicate that HIIE in water can be performed at a renal load, and cardiac autonomic nervous system activity is not significantly different from MICE on land.

CAROTID CHEMOREFLEX TONICALLY CONTRIBUTES TO SKIN BLOOD FLOW REGULATION DURING EXERCISE IN MALES AND FEMALES

PAULA-RIBEIRO, M.1,2, WUIJTSWINKEL, M.V.2, DE ANGELIS, K.1, LOW, D.A.2

<1>FEDERAL UNIVERSITY OF SAO PAULO, BRAZIL; <2> LIVERPOOL JOHN MOORES UNIVERSITY, UNITED KINGDOM.

INTRODUCTION: Skin blood flow (SBF) regulation is controlled by different reflex pathways to maintain thermoregulatory homeostasis during exercise. The carotid chemoreflex inhibition (via hyperoxia inhalation) at rest attenuates the cutaneous vasoconstrictor response to voluntary apnea, suggesting that SBF is partially controlled by the carotid chemoreflex (1). Importantly, humoral and neural signals related to exercise stimulate the carotid chemoreflex, modulating cardiovascular responses (e.g., HR, arterial blood flow) to exercise. However, it remains unclear if the tonic contribution of the carotid chemoreflex during exercise extends to the cutaneous circulation. Finally, the extent to which there might be sex differences in any potential carotid chemoreflex-mediated SBF regulation remains incompletely understood.

METHODS: Twelve healthy-young participants (6 females) performed steady-state moderate intensity exercise on a cycle ergometer (50% VO2peak). Once SBF stabilization was achieved (approx. 10 min of cycling), subjects inhaled, in random order: normoxia (21% O2, control) or hyperoxia (100% O2, carotid chemoreflex inhibition) for 2 min. Gas inhalations were separated by 10min (while exercise continued). Throughout the protocol, SBF was assessed using Laser-doppler flowmetry on the left ventral forearm and local skin temperature clamped at 33oC. Beat-by-beat mean arterial pressure (MAP) was obtained by photoplethysmography. Cutaneous vascular conductance (CVC) was calculated as SBF/MAP and expressed as a percentage of maximal cutaneous vasodilation (CVCmax) assessed via local skin heating following the exercise protocol. Additionally, core (Tcore) and skin (Tskin) temperatures were recorded. Two-way ANOVA was used to examine main effects and interactions of gases and sex. Significance was set at $P<0.05$. Data are presented as mean ± SE, as well as delta (Δ) between means.

RESULTS: Baseline data (i.e, prior gas inhalation) were similar between normoxia and hyperoxia for MAP (Δ = 0.8±1.8 mmHg; Pgas = 0.87), SBF (Δ: 6 ± 8 a.u; Pgas = 0.45) and CVC% (Δ: 1±2%; Pgas = 0.52), independent of sex. During gas inhalations, Tcore, Tskin and MAP showed similar values, independent of sex or gas. Compared to normoxia, hyperoxia increased SBF (167±16 vs 150 ± 15 a.u; Δ: 18±5 a.u; Pgas<0.01) and CVC% (53±7 vs 46±5%; Δ: 7 ± 2 %; Pgas < 0.01). SBF was lower in females vs males (Δ: -69±24 a.u; Psex = 0.02) and CVC% tended to be lower in females vs males (Δ: -21±11 %; Psex = 0.08), independent of the gas. There was no gas*sex interaction for SBF nor CVC%.

CONCLUSION: Carotid chemoreflex inhibition promoted cutaneous vasodilation, suggesting that the carotid chemoreflex contributes tonically to the control of the cutaneous circulation during exercise. Finally, the carotid chemoreflex contribution to SBF regulation occurs similarly in males and females.

THE INFLUENCE OF MATURATION AND SEX ON INTRA-CRANIAL BLOOD FLOW VELOCITIES DURING EXERCISE IN CHILDREN

DOUGLAS, A., TALBOT, J., PERKINS, D., DAWKINS, T., OLIVER, J., LLOYD, R., AINSLIE, P., MCMANUS, A., PUGH, C., LORD, R., STEMBRIDGE, M.

CARDIFF METROPOLITAN UNIVERSITY

INTRODUCTION: Cerebral blood velocity increases in response to moderate exercise in humans, but the magnitude of change is smaller in children compared to adults and post-pubertal adolescents. Whether biological sex differences exist in the anterior or posterior CBv response to exercise with across pubertal development remains to be determined.

METHODS: We assessed middle cerebral artery (MCAv) and posterior cerebral artery (PCAv) blood flow velocity via transcranial Doppler, alongside end-tidal carbon dioxide (PETCO2) and minute ventilation (VE). 39 pre-pubertal (18 male) and 48 post-pubertal (23 male) children completed an exercise test to exhaustion, with cerebrovascular and cardiorespiratory measures compared at baseline and ventilatory threshold.

RESULTS: At baseline, MCAv was greater in both sexes pre-puberty (pre- pubertal males; 71.8 ± 8.4 vs. post males; 61.6 ± 7.3cm.s-1 and pre- pubertal females; 78.2 ± 10.9cm.s-1 vs post- pubertal females; 67.8 ± 10.2cm.s-1). Main effect of maturation, biological sex, and exercise intensity were determined using a three-way repeated measures ANOVA. A two-way ANOVA was used to compared relative change from baseline to ventilatory threshold. Significant main effects and interaction effects were assessed using post-hoc analysis, with alpha set at 0.05 for all statistical analysis. Females demonstrated a higher MCAv ($P<0.001$) than their pubertal-matched male counterparts (pre- pubertal females; 78.2 ± 10.9cm.s-1 vs. pre- puberal males; 71.8 ± 8.4cm.s-1, and post- pubertal females; 67.8 ± 10.2cm.s-1 vs. post- pubertal males; 61.6 ± 7.3cm.s-1). PCAv was greater in pre- vs post-pubertal females (51.4 ± 8.9cm.s-1 vs. 45.1 ± 10.6cm.s-1), but there was no effect of sex in the posterior circulation. At ventilatory threshold, despite a greater PETCO2 ($P<0.001$) in post- vs. pre-pubertal children (post- pubertal 40.9 ± 3.6mmHg vs. pre- pubertal 36.4 ± 3.6mmHg), MCAv was greater in pre-pubertal (82.24 ± 11.95cm.s-1 compared to post-pubertal 77.18 ± 13.57 cm.s-1 ($P<0.001$).

CONCLUSION: Our findings suggest biological sex alters in the anterior cerebral circulation at rest is present in both pre- and post-pubertal groups, but in response to moderate exercise a sex difference was only present in our post-pubertal groups. Therefore, the CBv response to exercise is modified in both a sex- and maturation-specific manner.

PRESERVED ENDOTHELIAL FUNCTION IN RESPONSE TO ACUTE RESISTANCE EXERCISE IN STRENGTH-TRAINED MEN IS INDEPENDENT OF CATECHOLAMINE AND ENDOTHELIN-1 RELEASES

MORISHIMA, T., KASAI, N.

CHUKYO UNIVERSITY, AICHI SHUKUTOKU UNIVERSITY

INTRODUCTION: Acute resistance exercise impairs endothelial function in the sedentary individuals but not in the strength-trained individuals. However, the underlying mechanism(s) by which the vascular protection in the strength-trained individuals is still unclear. Herein, we compared catecholamine and endothelin-1 releases in response to acute resistance exercise between sedentary and strength-trained individuals.

METHODS: The untrained group comprised 12 male individuals with no regular training (age, 19.5 ± 1.1 years; height, 173.3 ± 5.3 cm; weight, 59.2 ± 5.1 kg; body mass index, 19.7 ± 1.4 kg/m2), and the strength-trained group comprised 12 male individuals (age, 19.6 ± 1.3 years; height, 171.3 ± 5.1 cm; weight, 71.5 ± 8.1 kg; body mass index, 23.9 ± 2.7 kg/m2). The strength-trained group participants had a 2-yr experience in resistance training at least. One repetition maximum (1RM) for chest press, lat pulldown and leg extension were initially determined in all participants using weight stack machine. At second visit, subjects performed a session of resistance exercise (chest press, lat pulldown and leg extension), which consisted of three sets of 10 repetitions at 75 % of 1RM (nine sets in total). During resistance exercise, heart rate and blood pressure were measured. Before and 10, 30 and 60 min after the resistance exercise, brachial artery flow mediated dilation (FMD), blood pressure, heart rate and blood collection were undertaken.

RESULTS: The 1RM for chest press, lat pulldown and leg extension were significantly higher in the strength-trained group (104.5 ± 23.1 kg, 75.9 ± 5.6 kg and 1425.0 ± 27.1 kg) than in the untrained group (68.9 ± 15.1 kg, 58.0 ± 10.8 kg and 114.7 ± 27.1 kg) ($P < 0.05$). There is no significant difference in baseline brachial artery FMD between the groups (7.8 ± 2.3 % in the untrained group vs. 6.0 ± 2.9 % in the strength-trained group) ($P > 0.05$). After the resistance exercise, brachial artery FMD was significantly reduced in the untrained group ($P < 0.05$) but it was prevented in the endurance-trained group. At 10, 30 and 60 min after the resistance exercise, there were significant differences in brachial artery ΔFMD from baseline between groups ($P < 0.05$). Blood pressure, plasma epinephrine, norepinephrine and serum endothelin-1 concentrations were significantly and similarly increased during and after the resistance exercise in both groups.

CONCLUSION: Consistent with previous studies, acute resistance exercise reduced FMD in the sedentary individuals but not in the strength-trained individuals. However, there were no differences in plasma catecholamine and serum endothelin-1 response between groups. In fact, blood pressure similarly elevated in response to acute resistance exercise in both groups. In conclusion, preserved endothelial function in response to acute resistance exercise in strength-trained men is independent of vasoconstriction factors.

THE ROLE OF FERROPTOSIS IN THE EFFECTS OF EXERCISE ON OBESITY-INDUCED CARDIAC FIBROSIS

CHEN, T.

TZU CHI UNIVERSITY

INTRODUCTION: Ferroptosis is a recently recognized type of cell death characterized by an iron-dependent and lipid peroxidation-mediated nonapoptotic cell death. Whether ferroptosis plays a role in exercise against obesity-induced cardiac fibrosis is still unknown. We, therefore, investigated the role of ferroptosis in that exercise affects cardiac fibrosis in obesity using an animal model mimicking high-fat diet-induced obesity.

METHODS: Eight-week-old male C57BL/6 mice were adopted in this study. Mice were randomly assigned to a normal diet combined with the sedentary (NDCON) or exercise (NDEXE) group and a high-fat diet combined with CON (HFDCON) or EXE (HFDEXE) group. These groups were randomly assigned to subgroups receiving either vehicle (Veh) or the glutathione peroxidase 4 inhibitor RSL3 (RSL3) for 14 consecutive days. At weeks 9-10, the NDEXE and HFDEXE mice were habituated to treadmill exercise at a speed of 5-10 m/min for 5 consecutive days. In the 11-20 weeks, the animals ran at a 70% maximal running speed on the treadmill, gradually increasing running time, beginning with 30 min/day and ending with 60 min/day.

RESULTS: Compared to the NDCON subgroup, the body weight was significantly increased in HFD subgroups from weeks 5-20, respectively ($p < 0.05$). Compared to the HFDCON subgroups, the body weight was significantly decreased in HFDEXE subgroups from weeks 15-20, respectively ($p < .05$). Maximum running speed was significantly higher in the NDEXE and HFDEXE subgroups after exercise training than in the pretest, respectively ($p < .05$). Compared to the NDCON subgroups, the myocardial fibrosis indexes of the HFDCON subgroups were significantly increased ($p < .05$), and the fibrosis indexes of the HFDEXE subgroups after exercise training were significantly lower than that in the HFDCON subgroups ($p < .05$). Compared with the Veh subgroup, the fibrosis indexes of the NDCON, NDEXE, HFDCON and HFDEXE groups were significantly higher than that of RSL3 subgroup, respectively ($p < .05$). Compared with the HFDCON+RSL3 subgroup, the fibrosis index of the exercise group was significantly decreased in the HFDEXE+RSL3 subgroup ($p < .05$). The results of histochemical staining of myocardial section showed that RSL3 may increase the concentration of myocardial iron ions in NDCON and HFDCON subgroups, and exercise training may also reduce the accumulation of myocardial iron ions caused by RSL3.

CONCLUSION: Our findings showed that a high-fat diet could increase myocardial fibrosis. Exercise training can reduce the effect of high-fat diet-induced myocardial fibrosis. In ferroptosis, inhibiting GPX4 can increase myocardial fibrosis and the concentration of myocardial iron ions. These results suggested that ferroptosis might play a role in high-fat diet-induced myocardial fibrosis. Exercise could reduce myocardial ferroptosis resulting in reducing myocardial fibrosis.

COMPARISON OF VASCULAR STRUCTURE AND FUNCTION BETWEEN HABITUAL OMNIVORES, VEGETARIANS AND VEGANS: AN OMNIPLANT PILOT STUDY

PAGE, J.1, STEBBINGS, G.K.2, MURPHY, C.H.3, KILDUFF, L.P.1, WALDRON, M.1, HEFFERNAN, S.M.1

1- SWANSEA UNIVERSITY, UK; 2- MANCHESTER METROPOLITAN UNIVERSITY, UK; 3- UNIVERSITY COLLEGE DUBLIN, IRELAND

INTRODUCTION: Studies assessing prognostic markers of cardiovascular disease demonstrate improved vascular function, assessed via flow-mediated dilation (FMD), and lower carotid artery intima media thickness (cIMT) in vegetarians compared with omnivores [1,2]. However, more recent studies have failed to replicate these findings in vegetarian and vegan populations [3, 4, 5]. Currently, it is unclear whether these discrepancies are the result of differences in study design/methodological approach or can be explained by potential changes in eating patterns over time. The aim of this study was to compare vascular structure and function between healthy, habitual vegans, vegetarians and omnivores.

METHODS: One hundred and fifteen participants aged between 18-79 years old were recruited between September 2020-February 2023 (omnivore, OMN=55, vegetarian, VEGT=15, vegan, VEG=45; men=59, women=56), in a cross-sectional observational design having followed their dietary pattern for > two years (VEGT=10.7yrs, VEG=7.2yrs). Dietary patterns were initially self-reported, confirmed using a food frequency questionnaire and a three-day weighed food diary. Food diaries were analysed using an online dietary analysis software (Nutritics, Ireland). Assessment of brachial artery FMD and cIMT were conducted using B-mode ultrasonography and analysed using automated edge-detection software. A cuff positioned around the forearm was manually inflated to 220 mmHg for 5-min following a 1-min measurement of baseline diameter (BD). Data were analysed using analysis of covariance (SPSS, version 28), controlling for physical activity (quantified via the Baecke questionnaire), sex and age.

RESULTS: VEG (43±12yrs) were older than OMN (31±14yrs) and VEGT (33±16yrs) and OMN (79.1±16.2kg) had higher body mass than VEG (70.0±12.8kg) ($P<0.05$). Mean daily cholesterol intake was lower in VEG (5.4±7.7mg/d) compared with OMN (273.5±179.0mg/d) and VEGT (167.8±157.4mg/d) and total fibre intake was higher in VEG (37.0±14.2g/d) compared with OMN (22.6±7.8g/d). There were no differences between diet groups for mean BD-adjusted FMD (2.75±1.35%; 2.68±1.48%; 3.02±2.71%), mean BD (3.70±0.68mm; 3.54±0.69mm; 3.25±0.49mm) or mean cIMT values (0.49±0.10mm; 0.53±0.12mm; 0.50±0.14mm) between OMN, VEG and VEGT, respectively.

CONCLUSION: There were no differences in brachial artery BD, FMD or cIMT between habitual OMN, VEG and VEGT in this study. Interestingly, there were differences for certain nutrient intakes reported to affect vascular structure and function, such as cholesterol and fibre. It is possible that changes in eating patterns over time, to include more processed/unhealthy foods [6], have suppressed the benefits to vascular health in VEG and VEGT reported in earlier studies.

THE EFFECT OF OVERSPEED TRAINING ON LINEAR KINEMATICS IN TWO FEMALE ATHLETES – A PILOT STUDY

FOSTER, T., INGLIMA, S.C., LUBIAK, S., GOTLA, T., RIDDELL, S., THOMPSON, B., MAY, J., WALTERS, J.

UNIVERSITY OF TAMPA

INTRODUCTION: Linear kinematics, such as stride rate (SR) and stride length (SL), have been shown to be important for an individual's sprint [1]. Research has investigated modalities to improve sprint performance, such as assisted (overspeed) sprint training [2]. However, there is a paucity of evidence investigating the effects of overspeed treadmill training (OTT) on the aforementioned variables. The purpose of this pilot study is to evaluate the effect of OTT on linear kinematics in two female athletes.

METHODS: Two college-aged female athletes (control: 22 y/o, 62.3 kg, 154.9 cm; intervention: 23 y/o, 67.3 kg, 165 cm) completed OTT. Within the seven-week protocol, week one consisted of a familiarization session with the treadmill device (h/p/cosmos locomotion system). Week two was comprised of pre-measurements on the track (TRA) and treadmill (TRE) which were separated by at least 48 hours. During the TRA and TRE testing sessions, subjects were equipped with motion capture devices from the ultium portable biomechanics lab (Noraxon, USA) to acquire kinematic data. Measurements included step time right (STR), step time left (STL), SL, step length right (SLR), step length left (SLL), SR, and stride time (ST). The average velocity during TRA sessions was captured using a radar gun (Stalker ATS II). All TRE sessions used a pressurized harness system that allowed subjects to sprint at 80% of their body weight. During the protocol, the control trained at the average velocity from their best 40m time trial (100%), while the OTT participant trained slightly above the average velocity

of their best time trial (105%). For each subject, the velocity remained constant throughout the protocol. Weeks three and four consisted of three sprints at their respective speeds; week five consisted of four sprints and week six consisted of five sprints. Post-testing during week seven consisted of the same measurements on the TRA and TRE acquired during week two pre-testing. Descriptives were completed using Excel.

RESULTS: For the control subject, STR increased by 13.06%, STL decreased by 14.93%, SL decreased by 25.88%, SLR decreased by 27.92%, SLL decreased by 24.53%, SR decreased by 0.37%, and ST increased by 0.45%. For the OTT subject, STR decreased by 15.29%, STL increased by 18.65%, SL decreased by 2.41%, SLR decreased by 2.50%, SLL decreased by 2.08%, SR decreased by 1.31%, and ST increased by 1.35%.

CONCLUSION: STR and STL showed differences over four weeks of OTT. Interestingly, in both participants, the step time of one side increased while the other side decreased. These opposing findings suggest the athletes developed a dominance throughout the training protocol. A dominance could have occurred due to training at a higher velocity than attainable without assistance. Further research is needed to examine if the current findings translate to a larger sample size, a longer training program, and different athletes.

CORRELATION BETWEEN RUNNING SAGITTAL KINEMATICS AND SPATIOTEMPORAL GAIT CHARACTERISTICS AND RUNNING ECONOMY

LI, F., SHI, Y., CHEN, S.

SHANGHAI UNIVERSITY OF SPORT

INTRODUCTION: Biomechanical characteristics play a critical role in distance running performance; however, their relationship with running economy (RE) remains unclear. The purpose of this study was to investigate the relationship between RE and sagittal plane kinematics of the lower extremity hip, knee, and ankle joints, ground contact/flight time, duty factor, and stride frequency/stride length in recreational runners.

METHODS: Thirty male recreational runners (age: 21±1years, VO2max: 54.61±5.42ml/kg/min) underwent two separate tests. In the first session, the subjects body composition index and RE at running speeds of 10 and 12 km/h were measured; In the second session, sagittal plane kinematic indicators of the hip, knee, and ankle joints, and spatiotemporal gait indicators such as ground contact/flight time, and stride frequency/stride length were collected at speeds of 10 and 12 km/h.

RESULTS: Pearson's correlation coefficients analysis found that RE at 12km/h was moderately correlated with ankle dorsiflexion angle at foot strike (r=0.423, p=0.020), hip and knee flexion angle at toe-off (r=0.374, p=0.042; r=0.405, p=0.026) and peak hip flexion (r=0.381, p=0.038) during the support phase. The peak ankle dorsiflexion (r=0.397, p=0.030; r=0.383, p=0.037) during the support phase was moderately correlated with RE at 10 and 12 km/h. In the flight phase, the peak knee flexion (r=0.457, p=0.011) and knee extension range of motion (r=0.439, p=0.015) were moderately correlated with RE at 10 km/h. RE at 12km/h was moderately correlated with peak hip, knee, and ankle flexion (dorsiflexion) (r=0.367, p=0.046; r=0.416, p=0.022; r=0.389, p=0.034) during the flight phase. In terms of spatiotemporal gait characteristics, RE at 10 km/h was moderately correlated with the corresponding ground contact time (r=-0.405, p=0.027), flight time (r=0.405, p=0.027) and duty factor (r=-0.451, p=0.012).

CONCLUSION: Smaller ankle dorsiflexion angles at foot strike, smaller hip, and knee flexion angles at toe-off, lower peak hip and ankle flexion (dorsiflexion) during the support phase, reduced peak hip, knee, and ankle flexion (dorsiflexion) during the flight phase and smaller knee extension range of motion during the flight phase are beneficial to improving RE in recreational runners. Regarding spatiotemporal gait characteristics, longer ground contact times at low speeds and increasing the duty factor are probably effective strategies for recreational runners to improve RE.

EXAMINATION OF THE RUNNING PATTERN BELOW AND ABOVE THE VENTILATORY ANAEROBIC THRESHOLD

RODRÍGUEZ-BARBERO, S.1, RODRIGO-CARRANZA, V.1, SALINERO, J.J.1, GONZÁLEZ-RAVÉ, J.M.1, GALÁN-RIOJA, M.A.2, GONZÁLEZ-MOHÍNO, F.1

1. UNIVERSITY OF CASTILLA-LA MANCHA, SPORT TRAINING LAB, TOLEDO, SPAIN; 2. FACULTY OF HEALTH SCIENCES, UNIVERSIDAD INTERNACIONAL DE LA RIOJA (UNIR), LOGROÑO, SPAIN

INTRODUCTION: Endurance running performance is influenced by factors related to muscle recruitment and force production (Roche-Seruendo et al., 2018). Runners unconsciously adopt their self-optimizing running pattern (Moore, 2016), but little is known about how the increase in running speed and muscle fatigue compromise running patterns. This study aimed to analyze the effects of running above and below the second ventilatory threshold (VT2) speed on spatiotemporal variables.

METHODS: Twelve male runners (five recreational and seven trained) participated in the study. All subjects completed a graded exercise test (GXT) (HP Cosmos Pulsar, Germany). The test started at 10 km·h-1, and speed was increased 1 km·h-1 every minute until volitional exhaustion. Running kinematics data (contact time [CT], flight time [FT], stride frequency [SF], stride length [SL] and vertical oscillation [VO]) were collected throughout the GXT through a wearable device (Stryd® device [Stryd Power Meter, USA]). Each test was analyzed individually, and the VT2 speed was established (15.00 ± 1.22 and 18.29 ± 1.80 km·h-1 for the recreational and trained group, respectively). Lastly, we analyzed the percentages of change in running kinematics occurring 1 and 2 km·h-1 below and above their VT2 speed within and between groups.

RESULTS: The main effect for speed was significant in all the kinematics variables ($p < 0.05$) except for VO ($p=0.10$). Speed × group interaction was significant in VO ($p=0.03$) showing a greater decline in trained runners, while in recreational runners did not change it ($p>0.05$). CT ($p=0.29$) and SF ($p=0.68$) presented similar trends in trained and recreational runners. Although FT and SL did not reach statistical significance in speed × group interaction ($p=0.06$ in both cases), there were significant differences between groups in the percentage at 2 km·h-1 below and at 1 km·h-1 above their VT2 speed in FT, and at all speeds in SL.

CONCLUSION: Running kinematics changed (reduction in vertical force production and increase in horizontal force production which induces a lower displacement of the center of mass) from 2 km·h-1 below to 2 km·h-1 above VT2 speed in trained and recreational runners, although percentage changes with respect to the values at VT2 speed were different according to training status.

HOW DOES MAXIMAL STRENGTH SPRINT AND JUMP PERFORMANCE EFFECT RESISTED SPRINT KINEMATIC VARIABLES?

OSTERWALD, K., KELLY, D., Ó CATHAIN, C.

TECHNOLOGICAL UNIVERSITY OF THE SHANNON; MIDLANDS MIDWEST

INTRODUCTION: Sprint performance (SP) is an essential skill to target within many sports [1]. Resisted sprint training is believed to increase strength specific to sprinting [2]. It is well-known that an athlete's acute kinematics change with increasing resistance [3]. However, to our knowledge, there remains a lack of clarity on how maximal strength and jump performance influences resisted sprint (RS) kinematics. Therefore, this study aimed to examine the correlation between back squat (BS) and hip thrust (HT) maximum strength (1RM) and jump measures with SP and change in kinematics (Ch).

METHODS: 20 sprint and 23 team sport athletes were tested over three days. After one familiarization session 1RMs, vertical jumps (CMJ and DJ) and resisted sprints with a resistance of 0, 10, 20, 30%Vdec were conducted on day 2 and 3. Timing gates were set up at 5-meter intervals to measure sprint time over 40m and average velocity. Kinematics (knee, hip, trunk, ankle angle) were measured at touch-down and toe-off using high-speed cameras. Then the percentage change of the angles between loads was calculated. Jumps were completed on force platforms. Jump height (JH) was calculated using the impulse-momentum method and the RSI was taken as the maximal height the athlete reached during the DJ divided by the ground contact time [4]. Pearson's correlation coefficient (r) was used to investigate the relationship between levels of strength, jump, SP and kinematic variables at each resistance.

RESULTS: Significant negative correlations were found between 1RMs and Ch (hip, knee and trunk angle) for the different loading conditions. Furthermore, correlations were displayed between acceleration SP and Ch (for trunk, knee, ankle angle) and between resisted (RSP) and unresisted SP (USP). Significant correlations were observed between 1RM and 40m RSP (BS: r= -0.47 to -0.61; HT: r= -0.67 to -0.72). Moreover, 1RM and USP presented significant correlations (BS: r= 0.44-0.47; HT: r= 0.71-0.72). Lastly, significant correlations were observed between CT at 30% Vdec and 1RM (HT) during maxV phase. (r= -0.504, p=0.014).

CONCLUSION: Faster RS times were associated with Ch, indicating that faster athletes see less change at the knee under load. Stronger athletes displayed less change in knee and hip kinematics, more similar to URS kinematics. The higher HT strength seemed to allow to create force through hip and knee. Faster and stronger athletes were also faster under load. Maybe the knee and hip were driving velocity under loaded conditions. Moreover, the stronger athletes (HT) demonstrated shorter CTs under load during the maxV phase, suggesting that the hip may be a greater contributor to the force produced. It could be concluded that maximum strength and SP measures explain some of the responses of athletes during RS, suggesting that stronger and faster athletes might be able to handle a higher overload without displaying changes in kinematics.

LOWER-LIMB MOMENT OF INERTIA IN THE ANATOMICAL POSITION DOES NOT EXPLAIN THE INTER-INDIVIDUAL VARIATION IN O2 COST IN TRAINED ENDURANCE RUNNERS

EDAGAWA, T.1, FUJIMORI, T.1, AKUTSU, K.1, HASHIMOTO, S.1, FUJI, N.2, OKAMOTO, Y.3, NAKAJIMA, T.3, SADO, N.2

1-3 UNIVERSITY OF TSUKUBA

INTRODUCTION: Morphological characteristics theoretically influence O2 cost. A manoeuvrable lower limb (i.e., a low lower-limb moment of inertia around the hip: ILowerLimb) can reduce the energy (WLowerLimb) required for the leg swing, thereby reducing O2 cost. In 10.8 km/h running, the O2 cost in the swing phase was shown to contribute to 20% of its total [1]. Meanwhile, running kinematics vary between individuals [2]. As the moment of inertia is mechanically proportional to the square of the radius of gyration, ILowerLimb can be controlled by lower-limb kinematics during running. Thus, ILowerLimb in the anatomical position (i.e., with fully extended knee) might not explain the inter-individual variance in O2 cost. We tested the hypothesis that adequate control of leg swing can reduce O2 cost regardless of ILowerLimb in the anatomical position.

METHODS: We analysed fat- and water-weighted MRI of the lower limbs in 12 endurance runners (19 ± 1 years, 170.7 ± 5.8 cm, 56.25 ± 3.91 kg). We calculated inertial properties by identifying the tissue (fat, lean or bone) of each voxel with the literature value of each tissue density [3]. Ten out of the 12 runners completed three bouts of 4-min treadmill runs at speeds of 14, 16, and 18 km/h each separated by 2-min recovery period. We measured the expired gases and volume and the lower limb kinematics during each run stage. WLowerLimb were calculated by combining the kinematic and MRI-based inertial data. O2 cost was assessed by oxygen uptake (VO2) measured during the last 1 min of each run stage. Pearson's correlation coefficients were calculated between ILowerLimb, WLowerLimb and VO2.

RESULTS: WLowerLimb was positivelly correlated with VO2 regardless of run speeds (r = 0.71–0.85 p ≤ 0.01). However, ILowerLimb (1.84 ± 0.26 kg.m2) in the anatomical position did not explain the inter-individual variance of WLowerLimb (14 km/h: 1.64 ± 0.18, 16 km/h: 2.03 ± 0.28, and 2.52 ± 0.39 J/kg; |r| = 0.08-0.36, p = 0.33-0.80) and of VO2 (14 km/h: 46.54 ± 3.41, 16 km/h: 55.04 ± 4.27, and 61.59 ± 4.72 ml/kg/min; |r| = 0.08-0.33, p = 0.29-0.82) at all speeds.

CONCLUSION: The adequate lower-limb kinematics during running can reduce ILowerLimb, and thereby the required WLowerLimb for swing execution. Thus, we speculate that even if ILowerLimb is large in the anatomical position, WLowerLimb can be reduced by adequate control of leg swing. WLowerLimb explained the individual variance in O2 cost, whereas ILowerLimb, that theoretically influences WLowerLimb did not explain the variance in WLowerLimb and VO2. We suggest that kinematic factors rather than morphological characteristics play a key role for reducing O2 cost.

COMPARISON OF GROUND REACTION FORCES CHARACTERISTICS BETWEEN TWO 180-DEGREE CHANGE OF DIRECTION TECHNIQUES IN FEMALE CRICKETERS

LAUCHA, T.1, SRISUWAN, N.2, JAMKRAJANG, P.1, MAWHINNEY, C.1, LIMROONGREUNGRAT, W.1

1. MAHIDOL UNIVERSITY, 2.THAILAND NATIONAL SPORTS UNIVERSITY SAMUT SAKHON CAMPUS

INTRODUCTION: Change of direction (COD) is one of the important factors for cricket performance. Batter requires running and turning 180 degrees between the wickets to score points. Half-half (HH) or side-lunge turning is a common technique performed by many cricketers (1). Presently, some cricketers perform a 180-degree turn by slightly jumping at the turn and landing in the sprinting position (2) to maximize sprinting speed, which is so-called sprinting technique (SP). The aim of this study was to compare ground reaction forces (GRF) characteristics including ground contact time via penultimate (PEN) and final (FINAL) foot contact between two 180-degree COD techniques.

METHODS: Nine Thai national female cricketers performed 2 different 180-degree turn techniques while holding a standard bat on force platforms. Three trials of each COD were collected and analyzed. GRF parameters including ground contact time (GCT), normalized peak and average GRFs and impulse (IMP) were compared between two techniques. Two successive decelerated foot contacts, penultimate (PEN) and final foot contact (FINAL) during deceleration phase were analyzed. Additionally, GRF foot contact ratios between FINAL and PEN (FINAL/PEN) were investigated in both vertical (vRatio) and horizaontal (hRatio) directions. Normality of data was examined by the Shapiro-Wilk test. Dependent t-test was employed for normality data.

RESULTS: Peak and average GRFs of HH were significantly greater than SP on both vertical and horizontal directions in PEN. HH showed significantly longer contact time than SP (GCT p =.002) in PEN but no significant differences of contact time were found in FINAL. It was also found that HH had significantly higher IMPs in both directions as compared to SP. For FINAL/PEN ratio, significant differences were also found in vRatio (p=.001) and hRatio (p=.047).

CONCLUSION: During deceleration phase of 180-degree COD, only PEN revealed significant differences of GRF parameters between the two techniques (3). When compared between the two techniques, HH provided greater GRFs, longer GCT and greater horizontal impulse which could be beneficial for athletes to be better prepared for the acceleration phase (4). However, future study is warrant for examining GRFs parameters between the two techniques during the acceleration phase.

RELIABILITY OF JOINT ANGLE CALCULATION IN RUNNING MOVEMENTS USING AN INERTIAL MEASUREMENT UNIT

HAMADA, K.1, OKAZAKI, S.2, NAKAGAWA, K.3

1 GUNMA UNIVERSITY HOSPITAL, 2 FUJIOKA GENERAL HOSPITAL, 3 TAKASAKI UNIVERSITY OF HEALTH AND WELFARE

INTRODUCTION: The purpose of this study was to clarify the standard error of measurement (SEM) and minimum detectable change (MDC) of joint angle data in running measured by the inertial measurement unit (IMU), as well as to provide information to help more accurately interpret subject differences and preintervention and postintervention comparisons in field assessments.

METHODS: The subjects were nine healthy males (28.0 ± 1.3 years old). To investigate the accuracy of joint angle data measurement in the right upper limb, pelvis, and right lower limb, myoMOTION (Noraxson) was applied to a total of 14 locations on the whole body, excluding the hands. During the calibration, the subjects were instructed to face forward and align both upper limbs with the trunk so that the joint angle reference points would not shift, and the feet were grounded parallel to the ground and the distance between the big toes was standardized at 10 cm. To assess the reliability of same-day measurement data, running measurements were taken twice daily on a treadmill (BIODEX, PRO WWT-600) at 10.0

km/h for 30 s. One running measurement was also taken on a different day to assess consistency of the data collected on different days. The acceleration data from the IMU in the foot were used to determine the right heel contact point, which is where the running cycle begins. The analysis included normalized joint angle data averaged over 10 running cycles from 10 s after the start of each running measurement. The SEM and MDC of each joint angle data were calculated using the following equations between measurements taken on the same day or different days: SEM = SDiff [standard deviation of difference in measurements] ÷ √2, MDC = SEM × 1.96 × √2. Further, to estimate the type of error affecting the calculated SEM and MDC, the Bland–Altman plot was used. This study was conducted with the approval of the Ethical Review Committee of Takasaki University of Health and Welfare.

RESULTS: The SEM and MDC between two measurements on the same day were 0.34–1.76 and 0.95–4.88 at all joints, respectively. For SEM and MDC between data measured on different days, all joints fell within the ranges 0.52–2.57 and 1.45–7.13. The SEM and MDC for ankle joint angle data were less accurate than those for other joint data. Further, fixed systematic error contamination was observed in the Bland–Altman plot for ankle dorsiflexion/plantar flexion angle data with a large measurement error.

CONCLUSION: It was found that for joint angles excluding the ankle joint angle data, changes of 1°–3° or more between measurements on the same day and 2°–5° or more between measurements on different days could be detected. Although the dispersion of ankle joint angle data is unknown, it is thought that the foot IMU sensor is susceptible to geomagnetism due to its proximity to the ground, which may result in errors in joint angles in a fixed direction.

EFFECTIVENESS OF THE CARBON FIBER PLATE TRAIL SHOES ON ENERGY COST AND LOWER LIMBS IMPACT DURING A SIMULATED TRAIL RUNNING SESSION

GARCIA-VICENCIO, S., BERTHE, P., JULIEN, M., LAVERTY, G., HERLIHY, J., FABRE, J.B.

HUMANFAB

INTRODUCTION: Besides the optimization of running performance by improvements of the cardiorespiratory capacity, the study of the repeated mechanical stress on the lower limb, at each step, during running in-field have reached great interest in sport sciences and in footwear development the last decades. Minimization of mechanical stress has been considered as major factor determining i) performance in trail running, ii) acute and chronic delayed neuromuscular alterations (e.g., fatigue and damage) and iii) trail-associated injuries.

This study aimed to investigate the effectiveness of an embedded decoupled carbon fiber plate (CFP) in a trail shoe associated to an increased rocker on running biomechanics (i.e., oxygen consumption and mechanical stress "impact" on the lower limbs) during a simulated 3 km-short distance trail running session in trained men and women in comparison to the trail market leader (without carbon fiber plate).

METHODS: Thirty-seven healthy well-trained trail runners' (age: 40 ± 8 years old; height: 170 ± 8 cm; body weight: 63 ± 10 kg) were involved in the present study. They were divided in two groups: MEN (n = 18) and WOMEN (n = 19). Two experimental sessions separated by at least 24 hours were made. During the first session, participants performed an incremental maximal aerobic speed test and a familiarization session with the trail course and pacing. Then, participants realized a 4 h session where they ran a 4 x 3 km trail lap divided as follows: 1 km at level, 1 km uphill and 1 km downhill at 60% of the speed at VO2max. During the field session, four shoes were compared (2 including a CFP) in a random order (3 km trail lap per shoe). Moreover, oxygen consumption, heart rate, rate of perceived exertion, running speed, spatio-temporal parameters of running and, tibial impact loading were analyzed.

RESULTS: The main results of this study showed that the running economy was significantly improved for both MEN and WOMEN when using CFP trail shoes (-3.1 ± 4.2 %) compared to the market leader at both level and uphill ($p<0.05$). Moreover, these differences were significantly higher in MEN (-3.6 ± 4.7 %) than WOMEN (-2.6 ± 3.7 %, $p<0.001$). Moreover, a reduced amplitude of the tibial vertical acceleration (-12.5 ± 18.5 %, $p<0.001$) was observed for CFP trail shoes compared to the market leader with lower values for MEN (-16.5 ± 23.0 %) than WOMEN (-9.0 ± 13.2 %) resulting in a reduced mechanical stress during running.

CONCLUSION: While, studies have suggested that the carbon fiber plate alone plays a limited role in the energy savings, the combination and interaction of the foam (cushioning), geometry (rocker), and plate plays a fundamental role in the attenuation of the impact transmitted from the ground to the lower limb reducing therefore the metabolic cost of running. It could be an interesting strategy to preserve muscle performance during trail running and to prevent lower limbs trail-associated injuries.

MUSCLE EMG ACTIVITY DISTRIBUTION BETWEEN THE HAMSTRING HEADS DURING HIGH-SPEED RUNNING IN HIGH ELITE ATHLETE WITH A HISTORY OF HAMSTRING STRAIN INJURY

GIROUX, C., HEGYI, A., MACCHI, R., HOLLVILLE, E., CAUMEIL, B., EDOUARD, P., COUTURIER, A., NORDEZ, A., LACOURPAILLE, L., RABITA, G., GUILHEM, G.

NATIONAL INSTITUTE OF SPORT

INTRODUCTION: Hamstring muscle strain injury (HSI) is the most prevalent injury in running-based elite level sports. After initial HSI, alterations in muscle activity may occur and influence the risk of reinjury. Bilateral differences in distribution of hamstring muscle activity dur-ing submaximal voluntary contraction have been observed in previously injured ath-letes

despite the completion of rehabilitation and the absence of symptoms (1,2). During sprint running, the alteration of muscle activity in previous HSI compared to the uninjured limb is unclear (3,4). This study aimed to compare the hamstring activity distribution between the two lower-limbs in a maximal sprint after a previous unilat-eral HSI.

METHODS: Ten elite athletes (age: 26.5±2.7years, height: 171.6±6.6cm, weight: 68.5±6.7kg) participating in Olympic, World and European events in athletics, rugby sevens and bobsleigh were included in this study. They reported unilateral HSI in average 3.3 ±1.6 years before testing. They performed two 40-m maximal sprints during which surface electromyographic electrodes (EMG) were used to estimate muscle activation of the biceps femoris long (BFlh) and short (BFsh) heads, the semitendinosus (ST) and the semimembranosus (SM). Sprint EMG was normalized to the EMG activity during MVIC. Mean EMG activity during the stance and swing phases were calculated for each muscle. The ratio of EMG activity between the hamstring muscles was calculated as the mean activity of the considered muscle divided by the sum of the activities of all muscle heads of the same limb. A linear mixed model by permutation was performed to compare the ratio of EMG activity between the uninjured (NI) and HSI limb.

RESULTS: No significant difference was observed between limbs for both the swing and stance phases for mean EMG activity and EMG activity ratio. The mean (±SD) EMG activity ratios during the swing phase for HSI side and NI side were 23.7±5.6% and 24.4±3.7% for BFlh, 28.0±6.9% and 27.6±7.2% for BFsh, 24.5±3.2% and 27.8±8.5% for SM, and 23.7±7.9% and 20.2±7.6% for ST, respectively. During the stance phase for HSI and NI side, ratios were 26.2±5.6% and 27.6±5.6% for BFlh, 29.7±7.5% and 29.5±10.6% for BFsh, 18.7±6.0% and 20.5±7.5% for SM, and 25.4±6.1% and 22.4±6.6% for ST, respectively.

CONCLUSION: The present study demonstrated that the mean and the distribution of EMG activity were not different during sprinting between injured and non-injured lower limbs. The tailored rehabilitation and training contents adopted by elite athletes may limit the alteration of muscle EMG activity. Further studies considering force-length and force-velocity properties, which influence muscle EMG activity in dynamic contractions, are required to strongly conclude on the muscle activity distribution within injured limb.

RELATIONSHIP BETWEEN ATHLETIC PERFORMANCE AND VISCO-ELASTICITY OF THE PLANTAR FLEXOR MUSCLES REVEALED BY THE VIBRATION METHOD IN LONG-DISTANCE RUNNERS

ODA, T., UENO, T., SAITO, S., TANJI, F., YAMADA, H.

HYOGO UNIVERSITY OF EDUCATION

INTRODUCTION: During the contact phase of running, the visco-elastic properties of the muscle-tendon complex (MTC) play a crucial role in functional muscle-tendon interaction and the recycling of elastic energy (1). In human experiments using B mode ultrasound, long distance runners have lower tendon stiffness (2) and higher muscle stiffness (3) in the plantar flexor muscles, which are associated with faster 5000 m times. However, viscosity, which has been the focus of attention in running shoes development in recent years, and viscoelasticity due to the exertion of multi-step forces have not been measured. The purpose of this study was to measure these values using the vibration method and to examine the relationship between these values and athletic performance.

METHODS: Twenty male athletes in long-distance of track and field participated. Athletic performance was calculated by converting the best 5000m season record (15 minutes 16.35 ± 50.45 seconds) in 2020 and 2021 into the IAAF Score (768.30 ± 147.75). We used the vibration method similar to (4). This method involved hitting a weight placed on the knee with a hammer, vibrating the triceps surae muscle, and inducing a damped oscillation. By combining the equation of motion of the mass-spring model and the waveform of the force, we calculated the elastic coefficient of MTC, and the viscosity coefficient from the vibration frequency and the amplitude reduction. We estimated each coefficient by regression for every 100N up to 800N. Then, the elasticity of MTC was separated into muscle and tendon components, based on the assumption that they are arranged in series.

RESULTS: IAAF Score and the elastic coefficient of the muscle-tendon complex were significantly positively correlated under various force conditions (e.g. 800N: $r=0.72$, $p<0.01$). The coefficient of determination increased as the Achilles tendon tension rose (e.g. 100N: $r^2 = 0.22$, 800N: $r^2 = 0.52$). The separation of elasticity in muscle and tendon revealed a significant positive correlation ($r=0.47$, $p<0.05$) between IAAF Score and the muscle elastic coefficient, but not between IAAF Score and the tendon elastic modulus. IAAF Score and the viscosity coefficient were not significantly correlated.

CONCLUSION: IAAF Score and the elastic coefficient of both muscle-tendon complex and muscle were significantly positively correlated. Higher muscle-tendon elasticity allows more elastic energy to be stored with smaller displacements during the stretch shortening cycle motion that occurs during ground contact. High elasticity also shortens the ground contact time (5). These effects are thought to enable energy-efficient movements with less vertical movement of the center of gravity and increased pitch.

EVENT-RELATED BRAIN POTENTIALS IN RESPONSE TO LOWER LIMB PROPRIOCEPTIVE STIMULI IN YOUNG ADULTS WITH A PROBABLE DEVELOPMENT COORDINATION DISORDER

TSENG, Y.T.1,2, CHEN, Y.T.1, LIN, Y.H.1
NATIONAL TSING HUA UNIVERSITY

INTRODUCTION: Proprioceptive deficits have been shown to underly motor problems in individuals with a probable developmental coordination disorder (pDCD). Behavioral studies have employed response times of passive limb movement to evaluate proprioceptive function in individuals with pDCD. However, the motor impairments inherent to individuals with pDCD may interfere with the accuracy of proprioceptive outcome measures. To address this issue, this study aims to investigate neuropsychological and neurophysiological performances using event-related potentials (ERP) on proprioceptive-motor processing in young adults with pDCD.

METHODS: Twenty-four young adults were recruited in this study, including twelve young adults with pDCD (M ± SD: 20.5 ± 1.08) and 12 age- and sex-matched controls (M ± SD: 20.75 ± 1.05) determined by the Bruininks□Oseretsky Test of Motor Proficiency 2nd Edition (BOT-2). Participants placed their dominant foot on a passive ankle motion apparatus that plantarflexed the ankle under velocities of 22°/s for a total of 75 trials in each proprioceptive condition. With the vision occluded, participants had to press the trigger bottom held by the dominant hand when they sensed the passive motion of the ankle (voluntary response, VR), or purely receive the movement without voluntary response (non-voluntary response, NVR). Behavioral performances [i.e., mean movement detection time (MDT), the standard deviation of the movement detection time (SDMDT)] and ERP indices (i.e., N1, P3 amplitude, and latency) related to ankle kinesthetic stimuli were obtained to determine the proprioceptive-motor function.

RESULTS: The results showed that young adults with pDCD exhibited longer MDT ($p < .001$) and SDMDT ($p = .002$) when compared to their controls. Electrophysiological indices showed that young adults with pDCD exhibited smaller N1 ($p = 0.024$, partial$\eta 2 = 0.21$) and P3 amplitude ($p = 0.025$, partial$\eta 2 = 0.21$) during VR and NVR conditions. Notably, correlation analysis revealed a significant negative relationship between MDT and N1 ($r = - 0.64$, $p < .001$) and P3 amplitude ($r = - 0.63$, $p < .001$) in the VR condition in young adults with and without pDCD.

CONCLUSION: This study sheds light on the central brain mechanisms underlying proprioceptive-motor deficits in young adults with pDCD. The combined analysis of behavioral and ERP data suggests that longer MDT and larger SDMDT in young adults with pDCD are associated with weaker proprioceptive afferent inflow (decreased N1 amplitude) to the frontal and parietal cortices. Such degraded proprioceptive signals are followed by reduced P3 amplitude, suggesting that young adults with pDCD allocate fewer neural resources to modulate motor processes with regard to proprioceptive stimuli.

ASSOCIATION BETWEEN DIFFERENT DOMAINS OF LOWER LIMB PROPRIOCEPTION AND DYNAMIC BALANCE PERFORMANCE IN CHILDREN WITH A DEVELOPMENTAL COORDINATION DISORDER

LIN, Y.H., CHEN, Y.W.1, HUNG, T.C.1, HSU, H.2,3, TSENG, Y.T.1,3
NATIONAL TSING HUA UNIVERSITY, HSINCHU

INTRODUCTION: Developmental coordination disorder is a condition marked by difficulties acquiring motor skills and performing coordinated movements. It has been shown that proprioception underlies motor abnormalities in children with DCD. However, it is still unclear how different domains of proprioception are affected and linked to motor dysfunctions in children with DCD. The purpose of this study was 1) to examine ankle proprioceptive function (i.e., ankle position sense and motion sense) in children with and without DCD, and 2) to investigate the relationship between different domains of ankle proprioception and dynamic balance performance in children with and without DCD.

METHODS: Forty children aged between 9-12 years, including 20 children with DCD and 20 age- and gender-matched typically developing children participated. Children in the DCD group had total motor scores below the 16th percentile assessed by Movement Assessment Battery second edition (MABC-2). Children underwent two proprioceptive tasks – a passive motion detection task and a position sense matching task. Mean and standard deviation of motion detection time (MDT and SDMDT) to passive ankle motion as well as position sense error (PE) and error variability (SDPE) were obtained to evaluate ankle motion and position sense performances. The dynamic balance performances were tested by Lower Quarter Y Balancing Test (YBT-LQ) and the component scores for the dominant and non-dominant foot were calculated.

RESULTS: In comparison to TD children, children with DCD showed significantly longer MDT ($p < .001$) and larger SDMDT ($p < .001$) when detecting the passive ankle motion. Furthermore, the PE and SDPE was significantly larger in the DCD group

than that of TD ($p < .001$). Correlation analysis revealed a significant negative relationship between MDT and YBT composite score in both dominant foot ($r = - 0.42$, $p < .01$) and non-dominant foot ($r = - 0.43$, $p < .01$) in children with and without DCD.

CONCLUSION: This study suggests that two submodalities of lower limb proprioception – motion sense and position sense – are both impaired in children with DCD. Poorer ankle motion sense sensitivity is correlated with poorer dynamic balance performance in children, which hints that decreased motion sense sensitivity might contribute to lower limb motor abnormalities in children with DCD.

CONTINUOUS RELATIVE PHASES OF WALKING WITH AN ADVANCED ARTICULATED PASSIVE ANKLE-FOOT PROSTHESIS TO PROMOTE PHYSICAL ACTIVITY

CORLÙY, H., LATHOUWERS, E., BAEYENS, J.P., TASSIGNON, B., ROELANDS, B., GOMEZ, F., CHERELLE, P., MEEUSEN, R., VANDERBORGHT, B., DE PAUW, K.

VRIJE UNIVERSITEIT BRUSSEL

INTRODUCTION: A new passive ankle-foot prosthesis was developed to improve the physical activity of people with unilateral transtibial amputations (TTA) and transfemoral amputations (TFA). The aim is to evaluate the walking patterns of the Talaris Demonstrator (TD) through continuous relative phases (CRPs).

METHODS: A total of 16 individuals aged 25 - 75 years were recruited for this explorative case-control study. Four TTA (one woman; mean ± SD age, 48.0 ± 15.9 yr; height, 176.0 ± 10.4 cm; weight, 85.8 ± 23.8 kg) and three TFA (one woman; mean ± SD age, 59.3 ± 2.5 yr; height, 177.3 ± 11.0 cm; weight, 95.0 ± 17.3 kg) individuals' current prosthesis were compared with the TD, and to nine able-bodied individuals (two women; mean ± SD age, 29.4 ± 5.7 yr; height, 183.2 ± 5.9 cm; weight, 82.3 ± 6.9 kg). Kinematics were captured during 6 minutes of treadmill walking in consecutive blocks of 2 minutes at slow, self-selected and fast speeds, and lower extremity CRPs were calculated. Gait cycles were defined based on the peak hip flexion angles. Statistical non-parametric mapping was applied, and statistical significance was set at 0.05.

RESULTS: The CRPs did not differ between the individuals' current prosthesis and the TD in people with TTA. Because of the limited sample size, no statistical tests could be conducted among individuals with a TFA. When comparing people with a TFA to able-bodied individuals, the CRP hip-knee was significantly larger in participants with a TFA at 0-5% ($p=0.009$) and 75-100% ($p=0.009$) of the gait cycle. In addition, results of the CRP knee-ankle in individuals with a TTA were smaller at 15-20% of the gait cycle during the fast ($p = 0.014$) and self-selected ($p = 0.014$) walking speeds compared to able-bodied individuals.

CONCLUSION: This study provides walking patterns in people with lower-limb amputation and reveals a possibly beneficial effect on physical activity improvement of the TD over the individuals' current prostheses. Our findings are consistent with prior studies using biomechanical kinematics in lower limb amputees. Further adequate sampled research is needed to investigate long-term adaptations in passive prostheses using CRPs.

THE REHABILITATION OF NEUROLOGICALLY IMPAIRED AND SPINAL CORD INJURED: EXOSKELETON (RISE) TRIAL

DUDDY, D.1, DOHERTY, R.1, CONNOLLY, J.1, LOUGHREY, J.2, CONDELL, J.3, HASSAN, D.4, FAULKNER, M.1

1ATLANTIC TECHNOLOGICAL UNIVERSITY DONEGAL, LETTERKENNY CAMPUS. 2 THE NO BARRIERS FOUNDATION, LETTERKENNY. 3 ULSTER UNIVERSITY MAGEE. 4. ULSTER UNIVERSITY JORDANSTOWN

INTRODUCTION: Neurological impairments (NI) of the central and peripheral nervous systems affect the brain, spinal cord, nerves, and muscles. The majority of individuals with NI rely on a wheelchair as their primary transportation, which may lead to a physically inactive lifestyle. Therefore, individuals with NI may be more susceptible to physical deconditioning and its comorbidities, therefore, appropriate rehabilitation techniques are paramount.

Powered exoskeletons have recently emerged as rehabilitation tools aiming to regenerate the physical capabilities of neurologically impaired individuals (Hong et al., 2013), however, research involving the devices remains limited. Existing research highlighted how powered exoskeletons can elevate cardiorespiratory and biomechanical response and can enable able-bodied participants to reach a moderate-intensity level of exercise (Duddy et al., 2022). Further research examining the effects of exoskeleton-based rehabilitation over time may be required to reach a more definitive conclusion. This trial aimed to investigate the effects of a 12-week exoskeleton-based physical activity (PA) and home-based strength training intervention on various physiological, biomechanical, emotional, quality-of-life (QoL), and mobility parameters.

METHODS: The impact of a 12-week exoskeleton rehabilitation program of neurologically impaired participants (N=6) was assessed using the six-minute walk test (6MWT), cardiorespiratory measurements using the Ganshorn PowerCube®, Shimmer 3 measurements of lower extremity movement, muscle activation and galvanic skin response, QoL and functional mobility. Participants received sufficient exoskeleton familiarisation upon recruitment.

RESULTS: Significant improvements in systolic blood pressure and gait performance ($P \leq 0.05$) were observed, while maintaining a similar cardiorespiratory stimulus. The 6MWT also significantly elevated all cardiorespiratory parameters, and gastrocnemius and rectus femoris electromyogram activity compared to the pre-walk standstill. Significant improvements in left knee acceleration from baseline to post-intervention, right hip acceleration from baseline to mid and post-intervention and left knee angular velocity from baseline to mid-intervention were also highlighted.

CONCLUSION: Participants improved gait function eliciting increased lower limb movement, muscle activity and PA levels.

THE ACUTE EFFECT OF SELF-INDUCED UNCLASSIFIED THERAPEUTIC TREMORS ON CARDIAC AUTONOMIC RESPONSES AND INTERICTAL STATE ANXIETY SYMPTOMS IN INDIVIDUALS WITH EPILEPSY

BOTHA, A.

STELLENBOSCH UNIVERSITY

INTRODUCTION: Individuals with epilepsy (IwE) are diagnosed with comorbidities up to eight times more than the general population, of which anxiety disorders are one of the most frequently reported. Interictal anxiety is unique to IwE and includes anticipatory anxiety of epileptic seizures, seizure phobia, epileptic social phobia, and epileptic panic disorder, which leads to avoidance behaviour compromising quality of life. Further, health and wellness practitioners (HWP) are reported to feel inadequately resourced in treating anxiety in epilepsy. There is growing evidence that complementary and alternative medicine (CAM) may reduce anxiety in IwE by inducing parasympathetic activation, and thus increase heart rate variability (HRV) and reduce state anx

METHODS: A RedCap survey was distributed to HWP (n = 52; age: 41.15 ± 13.59 years) to gain insights into their perceptions of and attitudes towards CAM, in particular TRE®. The experimental study was a cross-over randomized study design in IwE (n = 11; age: 23.18 ± 2.36 years) with a confirmed diagnosis, but seizure free for at least three months. Descriptive information was collected pre-intervention. Cardiac autonomic responses ((HRV, heart rate (HR) and blood pressure (BP)) were measured at 5, 10 and 15 minutes pre- and post-intervention (i.e. TRE® session and control), via (H10, Polar Electro Oy®, Finland). Perceived interictal state anxiety symptoms were measured (STAI-S) pre-and post-intervention. The potential comfort of the TRE® session was also measured using a subjective VAS comfort rating scale.

RESULTS: Survey results reported that 94% of HWP believed CAM therapies to be useful in treating anxiety in IwE and the most preferred CAM therapies included Breathing Methods (96%), Physical Activity (90%) and Yoga (81%). Furthermore, 48% of HWPs were familiar with SUTT, 52% knew of TRE® and 17% were qualified, TRE® practitioners. The intervention's eleven participants presented with moderate perceived stress (16.55 ± 7.79 A.U) and anxiety (8.55 ± 4.50 A.U) levels as well as a moderate descriptive allostatic load index. State anxiety symptoms improved ($p = 0.04$) as well as comfort levels ($p = 0.04$) after a single TRE® session. No treatment effect was observed in the CAR between the control and treatment group thus, Systolic BP ($p = 0.60$); Diastolic BP ($p = 0.54$); HR ($p = 0.88$); nLF ($p = 0.41$); nHF ($p = 0.84$); nLF/nHF ($p = 0.80$); Mean R-R ($p = 0.96$); RMSSD ($p = 0.87$) and SDNN ($p = 0.68$).

CONCLUSION: Generally, HWPs agree that CAM therapies are effective in treating anxiety in IwE. Most are hesitant, however, to use TRE® as a treatment option, suggesting that additional substantiation is needed. In this intervention, a single TRE® session did not influence the CAR acutely, requiring longer-term investigation. Interictal state anxiety symptoms were significantly reduced, and comfort levels increased, without adverse events. Therefore, promoting TRE® as a possible immediate state anxiety intervention for individuals with controlled epilepsy.

TIME FOR CHANGE: TOWARDS AN ACTIVE LIFESTYLE FOR PEOPLE WITH INTELLECTUAL DISABILITIES

OPPEWAL, A.1, PELLE, T.2, WANINGE, A.3

1. ERASMUS MC, UNIVERSITY MEDICAL CENTER ROTTERDAM, THE NETHERLANDS; 2. RADBOUDUMC, NIJMEGEN, THE NETHERLANDS; 3. HANZE UNIVERSITY OF APPLIED SCIENCES GRONINGEN, GRONINGEN, THE NETHERLANDS

INTRODUCTION: People with intellectual disabilities often have an inactive and sedentary lifestyle and low physical fitness levels, which puts them at an unnecessary risk for health problems. Even though the importance of an active lifestyle is well established and generally known, it remains difficult to improve the physical activity levels of people with intellectual disabilities and this group is not always prioritized and included in intervention and strategy development. We will present the socioeconomic value of sports and physical activity for people with intellectual disabilities and what the specific challenges are for this population to become sufficiently physically active.

METHODS: Based on literature and economic rapports, the socioeconomic value of sports and physical activity for people with intellectual disabilities has been assessed. The expenses for sports and physical activity in the Netherlands were compared to the monetary returns that adhering to the physical activity guidelines has by reducing the risk of negative outcomes in three domains: health, social aspects and employment. This socioeconomic value was compared to that previously found in the general population (1). Previous studies and sessions with both clients and stakeholders identified challenges for being sufficiently physically active for this population.

RESULTS: The socioeconomic value of sports and physical activity for adults with intellectual disabilities between 25-54 years was estimated at €50-90.000 compared to €35-75.000 for this age group in the general population, and at €20-40.000 for adults with intellectual disabilities aged 55 years and older compared to €12.5-25.000 for this age group in the general population. Challenges for people with intellectual disabilities to be sufficiently active were identified at the indi-

vidual (e.g. cognitive and physical capabilities, co-existing health conditions), interpersonal (e.g. lack of social support, lack of knowledge of caregivers, time constraints) and environmental level (e.g. limited opportunities, lack of financial and logistic support, lack of clear policy guidelines).

CONCLUSION: The relatively high socioeconomic value of sports and physical activity for adults with intellectual disabilities compared to the general population shows that it is time to prioritize investing in supporting this population towards an active lifestyle. This will result in high societal and health benefits. To take into account the challenges that are experienced by people with intellectual disabilities and stakeholders, it is important to take a socioecological approach and apply interventions and strategies at individual, interpersonal and environmental level.

DETERMINATION OF SECOND LACTATE THRESHOLD USING NEAR-INFRARED SPECTROSCOPY IN AN INDIVIDUAL WITH SPINAL CORD INJURY: A CASE STUDY

PRIEGO QUESADA, J., SANCHEZ-JIMENEZ, J.L., SENDRA-PÉREZ, C., CIBRIÁN ORTIZ DE ANDA, R., ENCARNACIÓN-MARTÍNEZ, A., APARICIO, I.

UNIVERSITAT DE VALENCIA

INTRODUCTION: Sports scientists and trainers are constantly studying new methods to determine thresholds in a non-invasive way in field situations. Near-infrared spectroscopy (NIRS) is a non-invasive and portable technology which provides information about muscle oxygen saturation (SmO2)[1]. Despite different mathematical methods were developed to determine systemic thresholds using lactate and gas exchange data, there is a lack of research about the best mathematical method to determine muscle oxygen threshold [2] in individuals with spinal cord injury. This case study aimed to explore the determination of muscle oxygen threshold in comparison with the second lactate threshold (LT2) in an individual with spinal cord injury.

METHODS: A highly trained male with complete spinal cord injury (age: 47 years; weekly training: 12h; level of injury: L1) visited the laboratory one time and completed an incremental test (start with 30W and increasing steps of 15W every three minutes) on an arm crank ergometer. SmO2 was measured continuously in the biceps and triceps brachialis (Moxy, Minneapolis, USA). Lactate samples were collected at rest and after each interval (Lactate Plus, Waltham, USA). LT2 and its associated SmO2 threshold (MOT) were calculated using the "lactater" package in RStudio. The methods that could not be applied to SmO2 data were discarded. Variation (Δ) of each variable was calculated as the difference between LT2 and MOT.

RESULTS: Similar values of power output were obtained between LT2 and MOT in biceps in five mathematical models (Dmax 80W vs 81W, ΔDmax = -1W; Log-Exp-ModDmax 92W vs. 93W, ΔLog-Exp-ModDmax = -1W; LTP2 90W vs. 91W, ΔLTP2 = -1W; Log-Poly-ModDmax 89W vs. 86W, ΔLog-Poly-ModDmax = 3W and ExpDmax 85W vs. 89W, ΔExpDmax = -4W). However, ModMax presented higher power output at the LT2 than MOT (92W vs 81W, ΔModDmax = 11W).

Similar results of power output were obtained between LT2 and MOT in triceps in three mathematical models (LTP2 90W vs. 91W, ΔLTP2 = -1W; ExpDmax 85W vs. 83W, ΔExpDmax = 2W and ModDmax 92W vs 97W, ΔModDmax = -5W). The remaining methods presented differences beyond 10W (Log-Exp-ModDmax 92W vs. 104W, ΔLog-Exp-ModDmax = -12W; Log-Poly-ModDmax 89W vs. 105W, ΔLog-Poly-ModDmax = -16W and Dmax 80W vs 97W, ΔDmax = -17W).

CONCLUSION: The lower differences obtained between a systemic variable, like the lactate, and local variables, such as SmO2, in biceps and tripes brachialis, suggest that LTP2 and ExpDmax may be the best mathematical models to determine thresholds in arm-crank exercise in individuals with spinal cord injury. However further research is necessary to affirm these mathematical models.

EFFECT OF AN EXERCISE PROGRAM ON CARDIOVASCULAR VARIABLES IN PEOPLE WITH MODERATE TO HIGH CARDIOVASCULAR RISK

MINHALMA, R.1,3, PINTO, M.1, NETO, T.1, BOTELHO, M.1,2, COSTA, H.1,2, ESPIRITO-SANTO, M.1, PAIS, S.1,2,3

1: ABC , 2: FMCB, UALG ; 3: ESEC, UALG

INTRODUCTION: A higher cardiorespiratory fitness is associated with a protective effect on overall mortality and the benefit on the attenuation of cardiovascular, hematologic, immunologic, and nervous system risk factors, being physical exercise known as non-pharmacological intervention for people with moderate to high cardiovascular risk (m-h CVR) (1). This pilot study aims to determine how physical exercise impacts cardiopulmonary variables in people with CVR.

METHODS: Sixteen m-h CVR patients, divided in exercise (N=8) and control group (N=8) volunteered to participate in a twelve-week exercise pilot study. Exercise program consisted in forty-five to sixty minutes sessions, twice a week for twelve weeks, and sessions were divided into aerobic and resistance training. Subjects performed two visits to the labora-

tory to scope cardiopulmonary exercise performance and limitations, and to establish first ventilatory threshold (LV1) to prescribe exercise intensity for the intervention, from an incremental Bruce protocol exercise stress test. In both visits, the cardiorespiratory variables of interest were the maximal oxygen consumption (V ̇O2max) and heart rate (HRmáx) and the oxygen consumption (V ̇O2LV1) and heart rate (HRLV1) at the first ventilatory threshold. The magnitude of between-subjects effects was assessed with a Mann–Whitney test. Significance level was set at p≤.05.

RESULTS: After exercise program the intervention group had a higher V ̇O2max (V ̇O2máxcontrol: 1.91±4.60 L.min-1; V ̇O2máxintervention: 2.07±3.85 L.min-1; p=0,046), a higher HRmáx (HRmáxcontrol: 140,3±12.8 bpm; HRmáxintervention: 150.8±25.7 bpm; p=0,046) and a higher V ̇O2LV1 (V ̇O2LV1control: 1.25±1.43 L.min-1; V ̇O2LV1intervention: 1.54±3.23 L.min-1; p=0,046), but no statistical differences in the HRLV1 (HRLV1control: 108.00±22.0 bpm; HRLV1intervention: 114.0±23.0 bpm; p=0,293).

CONCLUSION: The practice of physical exercise promotes improvement in the cardiorespiratory functional capacity in individuals with CVR, being important that this population benefits from public policies that improve their levels of physical activity.

EFFECTIVENESS OF TELEREHABILITATION VERSUS FACE-TO-FACE REHABILITATION IN SUBJECTS TREATED WITH SHOULDER ARTHROSCOPY: A SYSTEMATIC REVIEW AND META-ANALYSIS

YANG, H., HOU, X., RUAN, B.

BEIJING SPORT UNIVERSITY

INTRODUCTION: Shoulder arthroscopy has become the primary treatment modality for many shoulder disorders due to the unique advantages [1]. And rehabilitation after surgery is crucial. Compared with traditional in-person rehabilitation, telerehabilitation has advantages in the accessibility and convenience of access to physical therapy [2]. Previous study has shown the effectiveness of telerehabilitation in many musculoskeletal pain conditions [3]. Thus, telerehabilitation may have similar effects on shoulder function and patient-reported outcomes as traditional rehabilitation in subjects treated with shoulder arthroscopy. To confirm the hypothesis, we conducted this systematic review and meta-analysis.

METHODS: Six databases consisting of PubMed, Web of Science, CNKI, Cochrane Library, PEDro, and Embase before January 2023 were searched. Independent reviewers selected randomized controlled trials that compared the effects of telerehabilitation with face-to-face treatments in individuals with shoulder arthroscopy. Patient-reported outcomes (PROs), range of motion (ROM), motor function, and adverse events were reported. Effect size of PROs and motor function was synthesized using the standardized mean difference (SMD) with a 95% confidence interval (CI). Effect size of ROM was synthesized using the weight mean difference (WMD) with a 95% CI.

RESULTS: A total of 58 data points (covering 2611 individuals) from 7 studies were included in this meta-analysis. Our results showed that the difference between the effect of telerehabilitation and face-to-face rehabilitation on ROM (abduction: WMD = -2.02, 95% CI = -7.85 to 3.81, p = 0.50, I2 = 54%; flexion: WMD = 1.02, 95% CI = -1.11 to 3.15, p = 0.35, I2 = 22%; external rotation: WMD = -1.19, 95% CI = -4.16 to 1.77, p = 0.43, I2 = 0%) was not significant. Additionally, the difference between the effect of telerehabilitation and face-to-face rehabilitation on patient-reported outcomes (SMD = -0.12; 95% CI = -0.30 to 0.06; p = 0.020; I2 = 66%) and motor function (SMD = -0.19; 95% CI = -0.57 to 0.19; p = 0.34; I2 = 0%) was also not significant.

CONCLUSION: Both forms of rehabilitation have similar effects on improving patient-reported outcomes, ROM, motor function. Hence, telerehabilitation appears to be another option for patients after shoulder arthroscopy.

EFFECTS OF MENSTRUAL CYCLE ON CHEMOSENSITIVITY AND PREDICTION OF ACUTE MOUNTAIN SICKNESS

CITHERLET, T., RABERIN, A., MANFERDELLI, G., MILLET, G.P.

UNIVERSITY OF LAUSANNE

INTRODUCTION: The prevalence of acute mountain sickness (AMS) is estimated at 25-30% at an altitude of 3500 m and can cause serious discomfort (e.g., headache, gastrointestinal symptoms, fatigue, or dizziness). The severity of AMS is assessed by the Lake Louise Score. Several chemosensitivity tests (e.g., the hypoxic ventilatory response; HVR), including the pure nitrogen breathing test (N2T) (1) have been proposed to predict AMS. HVR is the ratio between the increase in minute ventilation (VE) and the decrease in pulse saturation (SpO2) during hypoxic exposure.

Moreover, sexual hormones such as Progesterone (P4) and Estradiol (E2) have a stimulatory effect on VE and HVR (2) and fluctuate over the menstrual cycle.

The aim of this study was to investigate chemosensitivity changes across the menstrual cycle which may alter the effectiveness of N2T to predict AMS.

METHODS: Thirteen eumenorrheic women (age= 31.7±7.8 yr) performed N2T, blood sampling, and a cycling exercise (5-min rest followed by 5-min cycling at 1.5 W/kg) in hypoxia (FiO2= 0.14) at three different phases of their menstrual cycle: early (Fol1) and late (Fol2) follicular, luteal (Lut3). They were then exposed to one night in hypobaric hypoxia (3375 m) with AMS assessment.

RESULTS: P4 and E2 fluctuated across the cycle (P4: 0.8±2.1, 1.0±1.8, 12.8±8.3 ng/ml; E2: 5.8±2.1, 44.0±81.0, 23.9±27.0 pg/ml for Fol1, Fol2 and Lut3, respectively), while HVR (0.34±0.12, 0.45±0.20, and 0.34±0.12 L.min-1.%-1) and VE (9.9±1.2, 9.6±1.6, and 10.1±1.6 L.min-1) did not differ between the three phases. SpO2 during exercise in hypoxia was higher (P= 0.04) at Fol2 (84.6±4.4%) compared to Fol1 (81.0± 3.7%) but not Lut3 (82.1± 4.0%).

After 6h at altitude, 31% of the participants developed AMS but no difference in HVR was noted between the subjects prone to AMS (AMS+) and others (AMS-). Interestingly, AMS+ had a lower SpO2 both at rest (87.5±2.6 vs 90.9±2.0%, P= 0.023) and exercise (78.5±3.0 vs 84.2±3.7%, P= 0.019) in hypoxia at Fol1, and a larger normoxia-to-hypoxia SpO2 decrease at rest (-6.2±2.7 vs -5.0±2.2%, P= 0.044) at Fol2.

CONCLUSION: Contradictory to previous studies (2,3) that reported an increased HVR during the luteal phase, we did not observe any differences between the menstrual cycle phases on HVR. AMS+ participants did not have a decreased HVR but showed larger hypoxia-induced desaturation during the follicular phase suggesting that AMS prediction is likely more effective during this phase.

INTRODUCTION: A biomechanical and epidemiological study by Hewett et al. (2005) showed that knee abduction moments and angles were significant predictors of future ACL injury risk and an increase valgus and valgus moments at the knee joint during the impact phase of jumping and landing tasks are key predictors of increased ACL injury potential in women (1). There is some controversy regarding whether jumps are a reliable test to measure these variables, thus, Krosshaug et al. (2016) established that vertical drop jump tests cannot predict anterior cruciate ligament injuries in elite handball and soccer players. The aim of this study is to evaluate the kinetic and kinematic variables of the knee during drop jumps in relation to the risk of injury, specifically the biomechanical variables related to the knee risk factors such as valgus, knee and ankle flexion and moment of force in the sagittal and frontal plane in the first landing after a deep drop jump in comparison between football players surgical operated and football players no operated.

METHODS: : Longitudinal descriptive observational study. Population: 11 female soccer players from the squad of a team belonging to the Feminine League (Spanish First Division of Womens Soccer) suffered an ACL and were compared to 11 female soccer players from a team belonging to the Feminine League (Spanish First Division of Womens Soccer) not operated. Methods: The evaluations of the jumps were performed using Go5D technology, reflective markers, BTS SMART DX cameras, dynamometric force platforms and a 30 cm box. Drop Jump starts with the participant climbing on a 30 cm box

and arms at the waist, then she will step forward one foot and land on both feet on the force platform. Then a monopodal deep jump test was performed and the athletes were asked to land on one foot only and jump as high as possible.

RESULTS: The results after the statistical analysis for each of the players in the jumping tests reveal the presence of significant differences between the injured and non-injured group in the monopodal jump with the dominant leg in the variables of ankle angle, knee flexion angle, knee valgus and ground reaction force. It was found that in the monopodal jump with the non-dominant leg there were statistically significant differences in knee valgus and GRF

CONCLUSION: The result follows the same line of studies that looked for the same differences previously where increased knee valgus and decreased ankle flexion turn out to be risk factors for ACL rupture, so that preventive work should consider these two variables to reduce the risk of injury. Although the present study agrees with the findings of other studies, it is necessary to measure the different variables to obtain greater reliability in the results, the type of longitudinal study limits the values obtained as the indicator of the limitations in only one moment in time, which makes it impossible to detect the adaptive changes that the players will present over time, therefore a prospective study would be necessary to follow up the players in their process of recovery, rehabilitation and return to play after undergoing ACL surgery.

DECISION MAKING INFLUENCES MOVEMENT VARIABILITY AND PERFORMANCE OF ELITE FEMALE FOOTBALL PLAYERS IN A BALL RESISTANCE TASK

TUYÀ VIÑAS, S., FERNÁNDEZ-VALDÉS VILLA, B., PÉREZ-CHIRINOS BUXADÉ, C., GONZÁLEZ, J., MORAS FELIU, G.

NATIONAL INSTITUTE OF PHYSICAL EDUCATION OF CATALONIA: INSTITUT NACIONAL DEDUCACIO FISICA DE CATALUNYA

INTRODUCTION: Nowadays, constraints are included in resistance training in order to develop strength within the context of sport and to maximise its effectiveness [1]. Considering that perceptual-cognitive abilities play a fundamental role in sport as they are directly related to individual and team success [2], decision making could be introduced in resistance training as a constraint to promote the development of the athletes abilities in a holistic way. Therefore, the aim of this study was to investigate the effects of the attacker and defender decision making on movement variability and performance during an elastic resisted forward-backward movement with ball in elite female football players.

METHODS: Twenty-three elite female football players (22.65 ± 5.16 years, 167.00 ± 6.37 cm, 59.75 ± 14.08 kg) performed the resistance task with ball as attackers and defenders without (NDM) and with decision making (DM). The movement variability was analysed by calculating the sample entropy of the acceleration, recorded at the lower back with an accelerometer. The accuracy of attacker's passes was measured as an indicator of task performance using a scoring scale.

RESULTS: The movement variability was higher in DM compared with NDM only in the defender. Furthermore, the attacker had a higher movement variability in both NDM and DM compared to defender. The attacker's passing accuracy was lower in DM than in NDM.

CONCLUSION: These findings suggest that adding a decision making to a football specific resistance task increased the defenders movement variability and compromised the attackers passing accuracy. Therefore, it is a useful strategy to reduce the control and movement regularity of the player who plays the role of defender and to increase the technical difficulty for the attacking role, which can favour the adaptive process of the players.

DOES MUSCLE STIFFNESS MEASURED WITH SHEAR WAVE ELASTOGRAPHY VARY ACROSS THE MENSTRUAL CYCLE?

BERNSTEIN, C., BEHRINGER, M.

GOETHE UNIVERSITY FRANKFURT

INTRODUCTION: Shear wave elastography (SWE) is a novel non-invasive imaging technique to evaluate muscle stiffness and elasticity. It provides a quantitative measurement of tissue stiffness by determining shear wave velocity displayed as a color-coded map. Research investigating skeletal muscle stiffness across the menstrual cycle is sparse, although it can be assumed that hormonal fluctuations may affect the elasticity of the muscle tissue.

METHODS: Muscle stiffness of m. rectus femoris was investigated and displayed as shear wave velocity (Vs) in the early follicular phase, at ovulation, and in the mid-luteal phase in six regularly menstruating women not taking oral contraceptives (age 24.8 ± 3.0 yrs; body mass 59.7 ± 5.8 kg; height 1.68 ± 0.04 m; cycle length 28.2 ± 1.2 d; BMI 21.1 ± 1.3). The onset of menses determined the early follicular phase, while a rise of luteinizing hormone in urine detected ovulation. The mid-luteal phase was set 7 to 10 days after ovulation. The stiffness of the m. rectus femoris was evaluated in a relaxed and contracted state, in which participants were verbally requested to contract the muscle to the maximum. Furthermore, the absolute stiffness between resting and contracted conditions was expressed as stiffness increase rate [(Vscontracted – Vsresting)/Vsresting].

RESULTS: SWE revealed a clinical-meaningful difference in shear wave velocity in the contracted state, which narrowly missed significance ($F(2,8) = 4.32$, $p = .053$, $\eta^2_{sub(p)} = 0.52$), with the highest values obtained at ovulation (3.55 ± 1.04 m/s) compared to the early follicular phase (2,60 ± 0.89 m/s) and the mid-luteal phase (3.04 ± 0.55). No significant differences were found in the relaxed state ($F(2,10) = 0.750$, $p = .50$, $\eta^2_{sub(p)} = .13$) or in the stiffness increase rate ($F(2,8) = 3.36$, $p = .09$, $\eta^2_{sub(p)} = .46$) between menstrual cycle phases.

CONCLUSION: Although the results missed significance due to the small sample size, the observed high effect size indicates a strong relationship between the menstrual cycle phases and stiffness. It may be suspected that fluctuating estrogen concentrations can affect skeletal muscle metabolism and, consequently, influence the quantity and quality of cross-bridges, displayed as altered muscle stiffness. However, future research should control the intensity of muscle contraction

evaluated during SWE. Furthermore, cycle phases and hormone concentrations need to be controlled according to the recommended methodology for cycle monitoring to elucidate if there are correlations between hormone concentrations and stiffness. In addition, future studies need to clarify whether the results gain significance with a larger sample size.

UNDERSTANDING EXPERIENCE, KNOWLEDGE AND PERCEIVED CHALLENGES RELATED TO BRA FIT FOR SPORTS PARTICIPATION: A SCOPING REVIEW

AITKENHEAD, R., HAWORTH, L., GRECIC, D., CHOHAN, A.

UNIVERSITY OF CENTRAL LANCASHIRE

INTRODUCTION: The breasts are reported as the fourth largest barrier to participation in physical activity (PA).

METHODS: This scoping review provides a comprehensive understanding of experiences, knowledge and challenges relating to bra fit and sports participation. The search strategy was adopted by the Preferred Reporting Items for Scoping Reviews (PRISMA-ScR) guidelines and multiple databases were searched. All research was in English and within the last 20 years. Exclusion criteria excluded reviews, male participants and the inability to locate or access full-text articles. The JBI critical appraisal tool assessed methodological quality.

RESULTS: Twenty-three studies were included. Key themes from the studies are breast motion during PA, sports bra design, perceived barriers to participation in PA and education/knowledge of breast support and bra fit. Increasing breast support reduces breast movement during PA yet breast motion and bra fit are still the most common breast concerns for females. This is likely influenced by poor breast knowledge, leading to poor breast support choices.

CONCLUSION: Future research should explore to what extent breast motion, knowledge and bra fit influences sport participation, and this research should include a more diverse range of adult ages, cup sizes, ethnicities and PA levels to provide a wider understanding.

PREVALENCE OF PROHIBITED SUBSTANCE USE AND METHODS BY FEMALE ATHLETES: EVIDENCE OF GENDER-RELATED DIFFERENCES

COLLOMP, K.

PÔLE STAPS, UFR ST

INTRODUCTION: To achieve optimal sports performances, women and men may show specific doping practices because of the physiological and psychological gender differences, but there are few data on this topic.

METHODS: Here, we report the apparent use of prohibited substances and methods by female athletes based on analyses of the doping tests collected by the French Anti-Doping Agency from 2013 to 2019. We compared the frequency of use and the ergogenic and side effects to those of their male counterparts.

RESULTS: The results revealed lower use of prohibited substances in female vs. male athletes, with significantly fewer anabolic agents, hormone and metabolic modulators, and cannabinoids. Gender specificity in utilization of substance classes was also shown.

CONCLUSION: Relatively lower use of hormone modulators and cannabinoids and higher use of beta-2 agonists, diuretics and glucocorticoids were found in the woman cohort compared with men cohort, combined with the different choice of substances, possibly because of the altered ergogenic and/or side effects. However, no impact due to gender regarding the sports disciplines was observed, with both women and men showing similar use of anabolic agents, mainly in the anaerobic sports, and EPO and corticoids, mainly in endurance or mixed sports.

ARCH-SPRING OR WINDLASS MECHANISM? THE STIFFNESS OF SPRINTERS' AND SWIMMERS' FEET: A PILOT STUDY

GOLDMANN, J.P., GROTHE, S., KERSTING, U.

GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: The human foot is thought to function like a flexible spring (Ker 1987) or a stiff lever (Hicks 1954). In both mechanisms, the stiffness of the plantar aponeurosis (PA) plays a central role in the deformation of the longitudinal arch (LA) under loading. If the PA is sufficiently stiff, metatarsophalangeal joint (MPJ) dorsiflexion should be closely coupled to LA deformation. We assume that, due to their daily impact load, sprinters have stiffer LA than swimmers. Therefore, more force might be needed for MPJ dorsiflexion, which should lead to greater deformation of the LA of sprinters compared to swimmers.

METHODS: Force-deformation of the MPJ during passive dorsiflexion was determined with a custom-built device in five male competitive sprinters (100 m PB 11.57 ± 0.46 s, training/week 10.8 ± 1.1 hrs) and eight male competitive swimmers (50 m freestyle PB 24.8 ± 1.18 s, training/week 12.5 ± 3.3 hrs). Deformation of the LA (change in navicular angle) was recorded with a motion analysis system (Vicon, Oxford). For statistics a Mann-Whitney-U-Test (SPSS Statistics 23, IBM) with a level of significance $\alpha < 0.05$ was used.

RESULTS: Forces for MPJ dorsiflexion were sig. ($p < 0.05$) higher in sprinters than in swimmers throughout the whole range of motion. At 40° MPJ dorsiflexion, the stiffness was 1.6 times higher in sprinters ($p < 0.05$). Energy absorption and return were 1.7 times elevated in sprinters compared to swimmers. Energy loss for the sprinters' feet was 28% and for the swimmers' feet 35%. The deformation of the LA increased by about 5° with increasing MPJ dorsiflexion, but showed no sig. differences ($p > 0.05$) between groups.

CONCLUSION: Our results showed that the forces for MPJ dorsiflexion noticeably deformed the LA (Carlson et al. 2000). The relationship between MPJ angle and LA deformation aligned well with the windlass mechanism and was observed for both groups. The higher force requirement to induce a similar LA deformation in sprinters might be explained by the difference in tissue material properties between the groups (Arampatzis et al. 2007). It is possible that the stiffer LA of the sprinters was a result of the higher impact load per training week. Their stiffer tissue was able to absorb and return more energy with a smaller hysteresis. Sprinters might benefit from their stiff arch-spanning structures that inhibit LA deformation and allow an efficient force transfer rapidly to the ground during running. As a stiff foot is a requirement for efficient ground contact, specific long-term training interventions may be developed and monitored using this device. Further, the interaction with muscular factors (strength and activation) may be included in the scope of study.

AN INITIAL EXPLORATION OF MUSCLE-TENDON UNIT PROPERTIES IN HIGHLY TRAINED FEMALE NETBALLERS AND RUNNERS

NEWBOULD, S., DINSDALE, A., WHITEHEAD, S., WALKER, J., NICHOLSON, G.

LEEDS BECKETT UNIVERSITY

INTRODUCTION: Muscle-tendon interaction during movement can be categorised into energy conservation or power amplification/attenuation strategies (1), and the mechanical and morphological properties of male athletes' tendons adapt to these loading demands (2). Although previous research observed no differences in tendon properties between female endurance runners and inactive controls (3, 4), little is known about these properties in females undergoing habitual power amplification-type loading, such as that experienced by team sport athletes. Therefore, this study investigated Achilles' tendon (AT) properties in trained female endurance runners and netballers.

METHODS: An observational investigation of 7 national level female netballers (16.2 ± 4.5 years netball training experience) and 7 female runners (8.3 ± 2.9 years training) was conducted. AT thickness was assessed at rest using B-mode ultrasound. The AT moment arm was calculated using the tendon excursion method. Participants performed graded isometric ankle plantar flexion contractions on a Cybex dynamometer until a voluntary maximum was reached, whilst dynamic ultrasound recorded displacement of the gastrocnemius medialis myotendinous junction. From each contraction plantar flexion moment, AT force, elongation, and strain were calculated. AT stiffness was defined as the slope of the AT force-elongation relationship (from 20-100% of maximum force). Mean differences (MD) with 95% confidence intervals (CI), Student's t-tests, and Hedge's g effect sizes (ES) were used to assess differences in AT properties between groups.

RESULTS: Netballers displayed a significantly greater maximal plantar flexion moment (MD 58.1 N.m-1, CI 35.5-80.7 N.m-1, ES 2.81, $p<0.001$), AT force (MD 822.4 N, CI 294.4-1350.5 N, ES 1.70, $p=0.008$), AT elongation (MD 5.70 mm, CI 0.40-11.07 mm, ES 1.17, $p=0.044$), and AT thickness (MD 0.69 mm, CI 0.08-1.30 mm, ES 1.24, $p=0.031$). No significant differences were found in maximal strain, stiffness, length, or moment arm.

CONCLUSION: The greater AT thickness of the netball group suggests that the power amplification-type loading demands inherent to netball training (i.e., jumping, landing) have a hypertrophic effect on the tendon. Additionally, the greater maximal plantar flexion moment, and hence AT force experienced by the netballers may also contribute to this hypertrophic stimulus. This adaptation may be protective in nature, as increased thickness (and presumably cross-sectional area) would reduce peak operating stress and enhance the safety factor of the tendon. Despite differences in AT thickness, no differences in strain or stiffness were found, corroborating earlier findings of uncoupled mechanical and morphological properties (2). These results provide evidence that the AT can adapt to high intensity loading in females.

ALTERED MUSCLE AND TENDON FUNCTION OF THE MEDIAL AND LATERAL GASTROCNEMII IN INDIVIDUALS WITH ACHILLES TENDINOPATHY DURING WALKING

PÉTER, A.1,2, HEGYI, A.1,2, STENROTH, L.3, GONÇALVES, B.4, NORDEZ, A.2

1HUNGARIAN UNIVERSITY OF SPORT SCIENCES; 2NANTES UNIVERSITÉ, MOVEMENT-INTERACTIONS-PERFORMANCE, FRANCE, 3UNIVERSITY OF EASTERN FINLAND, KUOPIO, FINLAND; 4UNIVERSITY OF VIENNA, AUSTRIA

INTRODUCTION: Achilles tendinopathy is a challenging-to-treat condition, which is common in runners (up to 52% prevalence) (1). Recent studies suggest that this condition is associated with altered neural function of the lateral gastrocnemius (LG) in submaximal isometric contractions (2). Whether this translates into suboptimal muscle-tendon interaction (i.e. decoupling) in functional tasks, such as walking, is unknown. Therefore, this study aimed to examine muscle-tendon interactions in the LG and medial gastrocnemius (MG) in walking in tendinopathy patients, as compared to healthy runners.

METHODS: In this ongoing study, four individuals with mid-portion Achilles tendinopathy and five healthy runners participated so far. They walked at self-selected speed on a treadmill while ultrasound images visualizing the muscle-tendon junctions of the MG and LG were recorded at 100 Hz after 6-min walking. 3-D motion analysis was used to estimate joint angles and in combination with the ultrasound data the length changes of the MG and LG tendons. Muscle-tendon junction displacement was tracked from the ultrasound images during the whole stride cycle to differentiate between muscle and tendon function for each of the MG and LG.

RESULTS: Maximal muscle-tendon junction displacement in healthy runners was 0.36±0.11 cm (ranged from 0.21 to 0.49) in MG, and 0.45±0.05 cm (ranged from 0.37 to 0.52) in LG. Individuals with tendinopathy showed larger displacement in both muscles, which was 0.41±0.04 cm (ranged from 0.37 to 0.45) in MG, and 0.59±0.19 cm (ranged from 0.46 to 0.87) in LG.

CONCLUSION: Although Achilles tendon function has mostly been examined through MG behaviour solely, muscle-tendon decoupling seems to be specific to each of the MG and LG. This was observed both in healthy runners and tendinopathy patients. In this study, displacements of MG and LG muscle-tendon junctions differed but the interpretation of the findings depends on joint kinematics which are yet to be analysed. Additionally, the difference between the two groups was more pronounced in LG than in MG. Further examining the mechanical behaviour of these muscles will help to further understand the sources and/or consequences of Achilles tendinopathy.

THREE-DIMENSIONAL DEVELOPMENTAL ASPECTS OF THE PECTORALIS MAJOR AND DELTOID MUSCLES IN SHOT PUTTERS.

HASHIMOTO, S.1, FUJIMORI, T.1, EDAGAWA, T.1, OHYAMA-BYUN, K.2, OKAMOTO, Y.3, NAKAJIMA, T.3, SADO, N.2

1-3 UNIVERSITY OF TSUKUBA

INTRODUCTION: In shot put, the mechanical output of the shoulder muscles is important. Among the shoulder muscles, the pectoralis major (PM) and deltoid (DELT) muscles are primarily responsible for horizontal shoulder adduction and anterior elevation of the upper extremity (1). Although the PM and DELT are not multifidus muscles, they are composed of multiple portion, each responsible for a specific action. Because of the multiple portion responsible for different actions, inhomogeneous development may occur in shot putters. However, to our knowledge, no study has investigated the size distribution of the PM and DELT in shot putters. We compared the intramuscular size distributions of PM and DELT in shot putters and controls. We hypothesized that PM and DELT are inhomogeneously developed in different portion.

METHODS: Transverse water-weighted magnetic resonance imaging (MRI) scans of the upper extremities (2 mm Interval) and trunk (5 mm Interval) were obtained from 11 male shot putters and 14 height-matched untrained males. Cross-sectional area (CSA), PM and DELT volumes of each slice were measured based on manual segmentation of the MRI. Welchs t-test was used for comparisons between groups. Welchs t-test was used for comparisons between groups. Cohens d was used for effect size for each t-test. CSA region curves were normalized to 101 data points (100% superoinferior muscle length). One-dimensional statistical parametric mapping (SPM1d) was used to test for significant differences between groups for CSA in continuous muscle regions.

RESULTS: The volumes of PM and DELT were significantly greater in shot putters than in controls ($p < 0.01$), with a larger effect size for PM ($d = 2.52$) than for DELT ($d = 1.42$). SPM1d showed significant differences at 0-88% for PM and 25-80% for DELT, with the peak t-values at 69% for PM and at 50% for DELT.

CONCLUSION: These results suggest that the PM and DELT develop differently and that some regions are more likely to develop with training than others. The mid-lower regions of the PM that showed specific development in this study are primarily responsible for horizontal shoulder adduction based on muscle structure, suggesting that development of this region may lead to improved shot-putting motion. The DELT is mainly developed in the middle part, suggesting that the muscle belly is homogeneously developed with respect to the vertical direction.In shot putters, the PM developed inhomogeneously, mainly in the middle and lower part of the muscle, whereas the DELT developed uniformly. These results suggest that PM and DELT develop in a site-specific manner due to their athletic characteristics.

RELATIONSHIP BETWEEN THE SHEAR MODULUS OF THE QUADRICEPS AND GASTROCNEMIUS MUSCLES AND THE HEIGHT OF THE DROP JUMP IN BASKETBALL ATHLETES

BRANDÃO, M.C.A., ALBUQUERQUE, M., OLIVEIRA, L.F.

FEDERAL UNIVERSITY OF RIO DE JANEIRO

INTRODUCTION: Basketball is a complex contact sport that involves multiple jumps, acceleration, deceleration and changes of movement direction. The mechanical properties of the musculotendinous tissue may be important for understanding the prevalent injuries and athletes performance. Elastography is a technique for assessing, in vivo, the shear modulus which is proportional to tissue stiffness, estimated from the propagation velocity of shear waves generated by high-intensity ultrasonic pulses focused at different tissue depths (1). Using another technique, Ando et al. (2) observed a relation between the stiffness of the medial gastrocnemius muscle and the Drop Jump height of non-athlete individuals, after a training period. There seem to be no studies describing this relationship in basketball athletes. This study aimed to correlate the shear modulus (μ) of the medial and lateral gastrocnemius, vastus medialis and the distal site of the vastus lateralis muscles with the height obtained in the Drop Jump jump test.

METHODS: Twelve male, competitive basketball players, for more than 5 years, in the sub20 category (18±0.92 years; 86.5±17.17 kg, 193±7 cm) with no history of lower limb injuries in the last 6 months, were submitted to the jump test protocol Drop Jump (DJ) (Ethic committee 5.776.787). Three trial of DJ tests were filmed and analyzed offline in the Kinovea® application. Three elastographic images of the vastus medialis (VM), vastus lateralis (VL), medial gastrocnemius (MG) and lateral gastrocnemius (LG) muscles of the non-dominant lower limb were acquired at rest, by an experienced examiner (Aixplorer® v.11 Supersonic Image, Aix-en-Provence, France, linear 40 mm, 10-2 MHz). The averages of the three jumps and three images for each muscle were considered for analysis.

RESULTS: The average height of the Drop Jump test was 41.23 ± 4.55 cm. The mean μ of the VL and VM muscles were 4,23 ± 1,32 kPa and 4.25 ± 0.58 kPa, respectively. The mean μ of the LG and MG muscles were 5.39 ± 1.26 kPa and 4.65 ± 1.06 kPa, respectively. Pearsons correlation showed a significant relationship between the DJ height and the μ of the VL (r= 0.64; p= 0.02) and the LG (r=0.75; p=0.004).

CONCLUSION: Our results with this group, very well trained for jumping, suggest that the muscle components with longer fibers showed a better adaptation to the jump demands. As specialized for contraction velocity (3), these muscles are heavily tensioned during jumps. The analysis of the shear modulus of these muscle groups can be an important factor for monitoring basketball players jump performance.

EXAMINATION OF THE ACTION OF THE ILIOCAPSULARIS – FOCUSING ON CHANGES IN SHEAR ELASTIC MODULUS DUE TO MUSCLE ELONGATION–

ITSUDA, H., YAGI, M., TATEUCHI, H., TOKORO, M., ICHIHASHI, N.

KYOTO UNIVERSITY

INTRODUCTION: The iliocapsularis muscle (IC) attaches to the anterior capsule of the hip joint. IC is assumed to stabilize the hip joint by tensioning the capsule through its muscle tension[1]. While the aforementioned anatomical characteristics have been revealed[1, 2], it is not clear how the IC works on the hip joint, and its actions have not yet been elucidated. Therefore, this study aimed to reveal the action of the IC using ultrasound shear wave elastography (SWE). The higher shear elastic modulus (G) means more muscle elongation, and the muscle is more elongated when the joint angle changes in the direction opposite to the moment arm. Given these, this study estimated the IC action, which is the direction of the IC's moment arm by studying the moment arm of the muscle from the increase in G during the passive stretching.

METHODS: The study included 15 healthy young females (age 22.5±1.3 years). G of the right IC was measured using SWE at the inferomedial aspect of the anterior inferior iliac spine. The following seven positions were used: rest (hip flexion 0°, abduction 0°, external rotation 0°), hip flexion 15°, hip extension 15°, hip abduction 15°, hip adduction 15°, hip external rotation 15°, hip internal rotation 15°. The subjects were instructed to relax completely, and their pelvis was fully fixed with a belt. G was measured three times for each position, and the average value was used for analysis. The Wilcoxon signed-rank test with Holm correction was used to compare the G between the rest and each position, as well as the G between hip flexion 15°–extension 15°, hip abduction 15° –adduction 15°, and hip external 15° –internal rotation 15°. The statistical significance level was set at 5%.

RESULTS: The interclass correlation (1,3) is above 0.91 for all positions, indicating high reproducibility of the measurement. The average G (unit: kPa) of each position is as follows; rest : 12.6, hip flexion 15°: 7.7, hip extension 15°: 19.6, hip abduction 15°: 10.9, hip adduction 15°: 10.2, hip external rotation 15°: 15.9, hip internal rotation 15°: 10.7. The G of the IC was significantly lower at hip flexion 15° compared to the rest ($p = 0.008$) and significantly higher at hip extension 15° ($p = 0.026$). Furthermore, the G was significantly higher at hip extension 15° compared to hip flexion 15° ($p = 0.006$). Although not significant, there was a trend toward higher G at external rotation 15° compared to internal rotation 15° ($p = 0.088$).

CONCLUSION: The results of this study show that the IC is significantly elongated in hip extension, which means the IC has a significant action of hip flexion. However, no clear trends were observed for the action of abduction or adduction and external or internal rotation of the hip joint.

FINITE ELEMENT ANALYSIS TO PREDICT THE EFFECTS OF ACHILLES TENDON GEOMETRY ON RUPTURE OR TENDINOPATHY

ENOMOTO, S.1, ODA, T.2

1: OKAYAMA UNIVERSITY, 2: HYOGO UNIVERSITY OF TEACHER EDUCATION

INTRODUCTION: The Achilles tendon (AT) is the largest and plays an important role in the human body's movement. AT is involved in human body movement such as walking, running, or sports activity and is exposed to high loads frequently and continuously. In elite runners, the cumulative incidence during their lifetime of AT rupture and tendinopathy is reported to be 5% and 52%, respectively (1). A previous study on AT rupture has reported that it takes 13.1 weeks to return to full sports activity (2). Achilles tendinopathy can also cause a prolonged absence from sports participation (3). Thus, it is important to identify risk factors for AT rupture and tendinopathy and to prevent them. This study aimed to investigate the effects of the AT geometry on a local strain that would relate to its rupture and tendinopathy using the finite element (FE) method.

METHODS: We calculated the following eight parameters from the 18 three-dimensional AT models obtained in our previous study (4): the thickness and width of the most distal site; the thickness and width of the minimum cross-sectional area (mCSA); the thickness and width of the most proximal site; and the length and position of the mCSA. We developed a standard three-dimensional AT model that has the aforementioned eight parameters. Furthermore, we developed the model by changing the parameter values every 1 standard deviation (SD) in the range of −2SD to +2SD. To simulate the loading applied to the AT during jumping, the models were only allowed to displace in the long axis direction, and a 4000 N (approximation of peak AT force during hopping: 3786 N, (5)) lengthening force was applied to the proximal surface. The distal surface was fully fixed. V-Biomech was used for FE analysis (6), and the maximum principal strain (MPS) was calculated. The mean and SD of MPS for 96% of the range except for the top and bottom 2% of the length of the model were determined every 3%. The highest mean MPS value in each model was used for analysis.

RESULTS: The MPS value was 0.071 (SD: 0.016) in the standard model at the 86–89% site (0% is the most distal, and 100% is the most proximal site of the AT). The highest MPS value was observed in the distal thickness −2SD model, and the 2–5% site had a 27.1% higher value than the standard model. The mCSA width −2SD model had the second-highest MPS value, and the 89–92% site had an 18.4% higher value than the standard model.

CONCLUSION: Our result suggests that ATs with a thin distal site and narrow mCSA have a higher risk of rupture or tendinopathy. Also, our results suggest that the location with the highest risk of rupture or tendinopathy may be different depending on the AT geometry.

MEASUREMENT OF MUSCLE-TENDON LENGTH USING 3D ULTRASOUND: VALIDATION OF OPENSIM MODEL AND DEVELOPMENT OF PERSONALIZED MODELS

GUENANTEN, H., RETAILLEAU, M., DOREL, S., SARCHER, A., COLLOUD, F., NORDEZ, A.

LABORATOIRE MOTRICITÉ, INTERACTION, PERFORMANCE

INTRODUCTION: Measuring the muscle-tendon unit (MTU) length is important to better understand their functional role. Models were developed to assess MTU length using joint angles and anthropometric data's (1). More sophisticated approaches, like OpenSim, involve the scaling of a generic skeleton using coordinates of body markers obtained using a 3D motion capture system (2). However, the validity of these approaches has not been demonstrated. This study aimed to investigate the validity of OpenSim for the measurements of MTU length of lower limb muscles in several postures using 3D freehand Ultrasound and to explore the development of 3D ultrasound personalized models.

METHODS: Fourteen participants performed 3D ultrasound scans for 6 biarticular MTU: Semimembranosus (SM), Semitendinosus (ST), Biceps femoris (BF), Rectus femoris (RF), Gastrocnemius medialis (GM) and lateralis (GL) in 5 postures per muscle. From these scans, MTU insertions and paths were used to calculate the MTU length (3D US). During the postures, motion capture acquisitions were also performed in order to scale a generic musculoskeletal model using OpenSim. MTU length was computed in OpenSim using 3 different models: OS: i.e. the generic scaled model, OS+INSER: OS with custom-

ized 3D US MTU insertions, OS+INSER+PATH: OS with customized 3D US MTU insertions and path obtained from one posture.

RESULTS: Linear mixed effect models showed the significant ($p<0.001$) differences in MTU length between OS model and 3D US for RF, GM, and GL (in average -10.9%, -7.4%, -6.3% respectively). Non-significant effects were reported for hamstrings, notably for ST (-1.5%, $p=0.71$) and BF (-1.9%, $p=0.54$), while the SM just crosses the alpha level (-3.4%, $p=0.049$). The OS+INSER model reduced the magnitude of bias by an average of 4% for RF, GM, GL but the difference was still significant ($p\leq0.001$). OS+INSER+PATH model showed the smallest biases in length measurements making them negligible and non-significant for all MTU (i.e. ≤ 2.2%; $p>0.05$).

CONCLUSION: The present study developed a 3D US pipeline to validate models developed to estimate MTU length. In our group of participants, the effect of personalization seems less important for hamstrings compared to RF, GM, and GL. A method is also proposed to personalize models using one 3D US scan. This could be valuable for musculoskeletal modeling and particularly for population that probably have specific MTU geometry (e.g., elite athletes, obese patients, patients with tendon transfer of bone deformations…).

REGIONAL DIFFERENCE IN MUSCLE ELONGATION TO COMPRESSION DURING STRETCHING.

MUKAI, H., YANASE, K., YAGI, M., SAEKI, J., UMEHARA, J., ITSUDA, H., ICHIHASHI, N.

KYOTO UNIVERSITY

INTRODUCTION: Manual compression of a muscle is often performed during stretching (Ylinen, 2008). However, no studies have investigated whether manual compression during stretching could elongate the muscle more than only stretching does. Additionally, the effects of compressed tissue (muscle or tendon) and intra-muscle difference (proximal and distal) on muscle elongation are unclear. This study aimed to investigate ⅰ) the change in the muscle shear modulus when compression of either the muscle or tendon was added to stretching, and ⅱ) the influence of the measurement point on the muscle shear modulus using shear wave elastography.

METHODS: Twenty healthy adults participated in this study. Two conditions, namely stretching with ⅰ) muscle belly compression and ⅱ) Achilles tendon compression, were performed for the gastrocnemius in random order. The shear modulus of the medial gastrocnemius muscle was measured during stretching and stretching with compressions. The measurement points were a point just proximal to the compression point for muscle belly compression (PROXIMAL) and a point distal to it (DISTAL). The shear moduli during stretching with compressions were compared with those during only stretching in each measurement point using a paired t-test.

RESULTS: For muscle belly compression, the shear modulus in stretching with compression was significantly higher than that in only stretching at PROXIMAL ($p < .01$), but significantly lower at DISTAL ($p = .01$). For Achilles tendon compression, there was no significant difference in the shear modulus between only stretching and stretching with compression for PROXIMAL and DISTAL ($p = .12, .92$).

CONCLUSION: As a result of stretching with muscle belly compression, the muscle was elongated more at PROXIMAL when compared with that during only stretching, whereas it was slackened at DISTAL. In gastrocnemius muscle that is pennate muscles, compression force from the body surface can be decomposed into a component perpendicular to the fiber which can elongate the muscle, and a component parallel to the fiber which can shorten the muscle. The former could be generated proximally to the compression point, while the latter in distally. On the other hand, stretching with tendon compression did not affect muscle elongation. Because the Achilles tendon is stiffer than the muscle (Zhou et al., 2019), when compression is applied to a muscle and tendon with the same pressure, the muscle could be compressed but the tendon could not. Therefore, in this study, the muscle was not elongated by the tendon compression because the applied pressure might not be sufficient.

CHARACTERISTICS OF MUSCLE STIFFNESS DURING ISOMETRIC CONTRACTION AND RELAXATION BY SHEAR WAVE ELASTOGRAPHY

OHTAKA, C.1, CHISHIRO, S.2, TAKAHARA, N.2, YAMAMOTO, K.2, FUJIWARA, M.3, SHIBASAKI, M.1

1,3 NARA WOMEN'S UNIVERSITY; 2 GRADUATE SCHOOL OF HUMANITIES AND SCIENCES, NARA WOMEN'S UNIVERSITY

INTRODUCTION: Well-coordinated control of both muscle contraction and relaxation are essential for various movements. Muscle conditions such as stiffness or contractile state during present force exertion may influence the subsequent force control. A previous study has characterized the stiffness of hamstring muscles during muscle contraction using ultrasound-based shear wave elastography (1). In the small muscle groups under small contraction levels, the relationship

between shear elastic modulus and torque have been determined by performing ramp contraction (up-going/down-going). However, the difference in the characteristics of muscle stiffness between muscle contraction and relaxation remain unclear. The aim of the study was to investigate the characteristics of muscle stiffness during isometric contraction and relaxation by shear wave elastography (SWE) and electromyography (EMG).

METHODS: Seventeen participants performed the force control tasks between 0-60% of maximal voluntary contraction (MVC) with isometric knee extension. They were asked to increase their force 10s each from 0% to 60% MVC in the contraction task and decrease from 60% to 0% MVC in relaxation task, with visual feedback. While conducting tasks, the produced force (torque), SWE (VL; vastus lateralis muscle), and EMG (RF; rectus femoris muscle, VM; vastus medialis muscle), were recorded. Then, SM (shear modulus) from SWE, and iEMG (integrated EMG) from EMG were analyzed. These variables were analyzed by two-way ANOVA with repeated measures using within-subjects of the task direction (contraction and relaxation) and the force level (0 to 60%MVC).

RESULTS: Force at each level was accurately performed in both task directions. iEMG of RF increased in proportion to the force levels in the contraction task, but began to decrease after 40%MVC in the relaxation task. As for between the task directions, 60%MVC was greater in the contraction task, but 10-40%MVC was greater in the relaxation task. Interestingly, the SM showed peak values at 30%MVC in both directions. At 20% and 30% MVC of the force levels, the SM was significantly greater in the relaxation task than in the contraction task ($p < 0.05$).

CONCLUSION: The SM during relaxation was greater than that during contraction in adjustment for the same force level. Similarly, EMG had greater activity while relaxing muscles compared with contracting muscles. Our results show the difficulty of performance due to muscle relaxation in relation to SWE and EMG.

IMPLEMENTATION OF TAILORED ERGONOMICS TRAINING FOR THE IMPROVEMENT OF NURSES MOVEMENT BEHAVIOR DURING THE REPOSITIONING OF RESIDENTS

OTTO, A.K., ARGUBI-WOLLESEN, A., WOLLESEN, B.

UNIVERSITY OF HAMBURG

INTRODUCTION: Everyday nursing care for the elderly is characterized, in particular by physical strain. Heavy physical work, frequent upper body bending and twisting during care activities, and repositioning residents in awkward body postures under time pressure can lead to musculoskeletal complaints such as back pain in nurses. Therefore, health promotion to reduce physical strain is of particular relevance (Kurowski et al., 2019). The present study investigates the effects of tailored ergonomics training (BASE program; Wollesen et al., 2016) on ergonomic movement behavior and trunk forward lean during the repositioning of residents.

METHODS: The randomized controlled trial was conducted in two nursing homes and included n= 15 in the intervention and n= 20 nurses in the control group. Trunk forward lean during repositioning was recorded using the validated Xsens MVN 2018, while a movement observation sheet recorded movement behavior. The analysis included ANOVA and statistical parametric mapping to assess time changes and differences between groups (SPSS 27, Matlab).

RESULTS: The analysis showed significant differences between the intervention and control group in foot position during turning ($F(1,33)= 5.912$, $p= 0.021$) and setting the person down ($F(1,33)= 5.617$, $p= 0.024$) in the repositioning process. However, there were no differences in trunk forward lean during repositioning between groups over time.

CONCLUSION: Tailored ergonomics training improved intervention group nurses' movement behavior. Nurses demonstrated a better standing position during repositioning, which is particularly relevant when dealing with heavy residents. In future research approaches, ergonomics training should be supplemented by further strategies for transferring the learned movement principles into everyday nursing care.

EFFECTS OF RESISTANCE EXERCISE WITH WEARING A KF94 MASK ON PERFORMANCE, VASCULAR, AND CARDIORESPIRATORY RESPONSES

LEE, D., JI, M., PARK, S., LEE, S.

INCHEON NATIONAL UNIVERSITY

INTRODUCTION: Wearing a face mask in public spaces including fitness training centers is recommended to reduce airborne transmission of the COVID-19 virus. Although physiological responses to wearing a mask during aerobic exercise have been reported, the effects of wearing a mask during resistance exercise on vascular and cardiorespiratory respons-

es remain largely unknown. This study aimed to investigate the effects of wearing a KF94 mask during resistance exercise on performance, vascular, and cardiorespiratory responses.

METHODS: Eighteen healthy and active young men voluntarily participated in this randomized crossover trial. All participants performed moderate resistance exercise (1RM 60%) sessions in two different conditions (without and with a wearing KF94 mask). Exercise volume (sets x repetitions x load [kg]), rating of perceived exertion (RPE), heart rate (HR), and respiratory parameters (minute ventilation [VE], oxygen consumption [VO2], carbon dioxide production [VCO2], and respiratory quotient [RQ]) were measured during exercise. In addition, lactate and arterial stiffness (augmentation index [AIx], carotid to femoral pulse wave velocity [cfPWV], and brachial to ankle PWV [baPWV]) were measured at pre-exercise and post-exercise.

RESULTS: VE, VO2, VCO2, and exercise volume were significantly lower in the KF94 mask condition than in the no mask condition during resistance exercise ($P < 0.001$, $P = 0.002$, $P < 0.001$, and $P < 0.001$, respectively). However, RPE was higher in the KF94 mask condition than in the no mask condition ($P = 0.001$). HR and RQ did not show significant differences between the conditions ($P = 0.843$ and $P = 0.486$, respectively). There was a significant time by group interaction for AIx, AIx75@, and cfPWV ($P < 0.001$, $P = 0.011$, and $P = 0.032$, respectively). Changes in AIx, AIx75@, and cfPWV after resistance exercise were significantly higher in the mask condition than in the no mask condition ($P = 0.001$, $P = 0.005$, and $P = 0.003$, respectively). However, there was no significant time by group interaction for baPWV and lactate ($P = 0.155$ and $P = 0.253$, respectively).

CONCLUSION: Our findings show that wearing a KF94 mask reduced exercise performance and increased RPE during resistance exercise. Furthermore, in the condition of wearing a face mask, respiratory volume decreased during exercise, whereas arterial stiffness increased after exercise. Therefore, people with respiratory or cardiovascular diseases need to be careful and consider wearing a face mask during resistance exercise.

EFFECTS OF REPEATED CRYOSTIMULATION EXPOSURES ON SLEEP AND WELLNESS IN HEALTHY SUBJECTS.

DUGUÉ, B., ARC-CHAGNAUD, C., PLA, R., BOUZIGON, R., BOSQUET, L., DUPUY, O.

UNIVERSITY OF POITIERS

INTRODUCTION: The importance of sleep for both mental and physical health has widely been demonstrated. Health-related sleep characteristics involve appropriate schedules, sufficient duration, and especially a good sleep quality. However, all these key factors for a restorative sleep are insufficiently complied. Even in a healthy young population with no severe sleep disorders, bad sleep quality is commonly observed and may affect mood, anxiety, and psychological well-being.

New strategies are therefore required to optimize sleep quality. In this context, whole-body cryostimulation (WBC) appears to be an interesting option, known to lead to numerous beneficial effects particularly on wellness feelings, through the activation of analgesic processes and autonomous nervous system. Acute cryostimulation sessions have already been investigated but the effects of repeated WBC exposure on healthy subjects, independently of training have not been assessed yet. The aim of this study was to evaluate the effects of daily WBC sessions during 5 consecutive days on wellness and sleep parameters in healthy young men and women.

METHODS: Twenty healthy subjects (9 females; 11 males) aged 23.1 ± 2.6 years old participated in this randomized protocol, with 5 consecutive days with or without WBC exposure. Sleep was analyzed over the 5 nights in each condition (CONT / CRYO). Skin temperatures were measured before and after each WBC session. Sleep quality and quantity were assessed via actimetry, cerebral activity and questionnary. Nocturnal heart rate variability (HRV) was also recorded and questionaries were given to assess wellness and mood.

RESULTS: Skin temperatures dropped after WBC exposure for all participants but with a greater amplitude in females. The inter-sex difference was significative and associated with body composition, as females exhibited higher body fat % compared to males. Repeated WBC exposures during 5 consecutive days had a beneficial impact on mood and anxiety. It also improved subjective sleep quality, especially in females. Repeated WBC modulated sleep architecture, increasing slow wave sleep duration during the nights, without impacting other sleep parameters, nor nocturnal HRV.

CONCLUSION: Repeated WBC in an effective strategy to improve slow wave sleep duration of healthy young subject. The reported psychological improvements may benefit women more than men.

EFFECT OF CO2 AND H2 GAS MIXTURE IN COLD-WATER IMMERSION ON THE SCAVENGING ACTIVITY OF REACTIVE OXYGEN SPECIES AND THE WINGATE PERFORMANCE IN HIGH-INTENSITY EXERCISE.

YOSHIMURA, M.1, SAWADA, Y.1, ICHIKAWA, H.1, NAKAMURA, M.2, FUKUOKA, Y.1

1 DOSHISHA UNIVERTSITY, KYOTO, JAPAN. 2 NISHI KYUSHU UNIVERSITY, SAGA, JAPAN.

INTRODUCTION: Cold water immersion (CWI) is commonly used by athletes as a post-training recovery technique. Our previous study showed that CWI with CO2 (C-CWI) could be an effective method to increase skin and muscle blood flow, decrease sublingual temperature (Tsub) and maintain aerobic work efficiency. Besides, high-intensity exercise in athletes results in the production of excess reactive oxygen species (ROS), thus athletes should maintain greater ROS scavenging activity in the body. We hypothesised that adding H2 to C-CWI could accelerate the removal of ROS after high-intensity exercise.

METHODS: Twenty trained male athletes (age 20.6±1.2 years) of a university athletic association team were randomised into four groups: control, CWI, C-CWI and CO2/H2 gas mixture CWI (CH-CWI). In the three CWI groups, all subjects were immersed in one of the three baths at 20 °C for 20 min immediately after the first high-intensity Wingate anaerobic test (WAnT). After the recovery intervention, the subjects performed the second WAnT. Tsub, blood lactate concentration ([La]b) and ROS (OH• and O2•–) were measured four times at basal rest (BL), end of first WAnT, recovery intervention and end of second WAnT. The ROS scavenging activities were evaluated by the electron spin resonance (ESR) spintrapping method. The mean power output of WAnT was also measured at first and second bout following each recovery intervention.

RESULTS: The Tsub values were significantly increased in CON after the recovery intervention compared to the first WAnT ($p<0.05$). The rate of Tsub increase in CH-CWI tended to be less than in the other three groups. [La]b disappearance was significantly accelerated in CH-CWI comparing the first WAnT and recovery interventions ($p<0.05$). At the second WAnT of the CWI and C-CWI, the OH• scavenging activity converted by using the GSH concentration tended to increase compared to the BL, otherwise it tended to decerase in control and CWI interventions. Similar trend in the O2•- scavenging activity converted using the superoxide dismutase concentration was found from BL to the second WAnT. A significant correlation between the rate of increase in mean power of WAnT and the rate of increase in the OH• scavenging activity in CH-CWI was revealed ($n=5$, $r = 0.89$, $p < 0.05$).

CONCLUSION: CH-CWI has the effetcitive of suppressing the increase in body temperature after high-intensity exercise and reducing blood lactate accumulation. CH-CWI may increase OH· and O2•- scavenging activity, and athletes having greater OH· scavenging activity may be able to generate higher mean power in high-intensity anaerobic exercise.

THE ORDER OF CONCURRENT EXERCISE AFFECTS THE DEGREE OF EXERCISE-INDUCED ACUTE COGNITIVE IMPROVEMENT

DORA, K., SUGA, T., SUGIMOTO, T., TOMOO, K., HASHIMOTO, T., TSUKAMOTO, H.

TOYO UNIVERSIT, RITSUMEIKAN UNIVERSITY

INTRODUCTION: Concurrent training, a combination of endurance exercise and resistance exercise in succession, simultaneously improve muscular strength and cardiovascular function (1), but exercise effects (e.g., muscle hypertrophy) are modified by the exercise order (i.e., aerobic exercise before or after resistance exercise) (2). In addition, aerobic exercise followed by resistance exercise (A-R) induces a large increase in the proliferator-activated receptor-γ coactivator-1α (PGC-1α) which regulates mitochondrial biogenesis than aerobic exercise alone (3). Concurrent training also improves cognitive function, and the degree of improvement is greater than aerobic training alone (4). However, it has not been clarified whether the order of concurrent exercise modifies exercise-induced improvement in acute cognitive function. Given the possibility that muscle PGC-1α is associated with acute neurotrophin increase (5), we hypothesized that the order of exercises in concurrent exercise modifies the degree of acute cognitive improvement. To test our hypothesis, we aimed to examine cognitive function after concurrent exercise with resistance exercise followed by aerobic exercise (R-A) and with A-R.

METHODS: Twelve healthy males (aged 21 ± 2 yrs; peak oxygen uptake [VO2 peak] = 47 ± 4 ml/kg/min; 1 repetition maximum [RM] = 120 ± 22 kg) performed trial for R-A and the trial for A-R in a within-subjects crossover posttest comparison design. Both trials consisted of a 20-min cycling exercise (60% VO2 peak; 148 ± 20 W) (6) and knee extension exercise of 6 sets of 10 repetitions (80% 1RM; 93 ± 16 kg) (7), which were separated by a 25-min rest interval. The reaction time and the response accuracy of color-word Stroop task as cognitive test was recorded 30-min after second exercise. The higher-order cognitive function (i.e., executive function [EF]) was estimated using the interference score calculated from reaction time. A paired t-test and the Wilcoxon signed-rank test were used to compare the response accuracy and EF at 30-min after second exercise between R-A and A-R trial.

RESULTS: There was no significant difference in response accuracy between both trials (R-A 91 ± 12 vs. A-R 91 ± 21 %, $P = 0.93$). EF (i.e., reaction time-based interference score) was better in the A-R trial than in the R-A trial (R-A 12.6 ± 6.0 vs. A-R 8.0 ± 5.1 %, $P = 0.02$).

CONCLUSION: This result shows that the degree of acute concurrent exercise-induced improvement in EF with A-R was better than with R-A. Because acute exercise-induced cognitive improvement may predict the long-term effects, habitual concurrent exercise with A-R may effectively improve EF and should be verified in the future.

COMBINING PASSIVE ISOKINETIC EXERCISE AND ELECTROMYOSTIMULATION EFFORTLESSLY IMPROVES MUSCLE STRENGTH

OGISO, K.

COLLEGE OF EDUCATION, PSYCHOLOGY AND HUMAN STUDIES, AOYAMA GAKUIN UNIVERSITY

INTRODUCTION: Regular exercise is considerably difficult for those who are in inadequate environments for voluntary exercise or who are not good at exercise. The combination of isokinetic, passive, and easy exercise with electromyostimulation (EMS) may be an effective exercise that 1) does not require effort or voluntary strength, 2) is not difficult, 3) has a low risk of injury, and 4) can be performed while doing other things. We hypothesized that a completely passive isokinetic cycle (PIC) exercise combined with EMS improves muscle strength without any effort, make daily activities less strenuous, and increase the likelihood of inducing vigorous voluntary movement.

METHODS: Participants were 19 sedentary female university students and were divided into 2 groups. The EMS anterior group comprised 9 participants who performed the PIC exercise while EMS was applied to the anterior thigh muscles. The EMS whole group comprised 10 participants who performed the PIC exercise while EMS was applied to the whole thigh muscles. Both groups performed the PIC exercise without EMS 3 times a week for 3 weeks (week 1-3) followed by a 1-week break and then performed the PIC exercise with EMS 3 times a week for 3 weeks (week 4-6). They fully relaxed their muscles while pedaling at 40 rpm for 10 min. An exponential waveform of EMS (frequency: 20 Hz, pulse width: 260 μs) was superimposed on each target muscle of both legs. The intensity was set at 100% of the baseline value (approx. 2.5 mA) in week 4, 110% in week 5, and 120% in week 6. The effects of training were evaluated by measuring the 30 second chair stand test (CS-30), maximum isometric knee extension (MIKE) and flexion (MIKF) torque, muscle soreness, and kinesthesia in daily life before the start of week 1, and 3 days after the end of week 3 and week 6. None of the participants found the PIC exercise with EMS difficult or hard.

RESULTS: The PIC exercise without EMS in weeks 1 - 3 did not increase the CS-30 scores and decreased the MIKE and MIKF torque in both groups. None of the participants reported muscle soreness and changes in their kinesthesia in daily life after week 3. The PIC exercise with EMS in weeks 5 - 7 significantly increased the CS-30 scores, MIKE and MIKF torque in both groups. The MIKF torque was more significantly altered in the EMS anterior group. Most of the participants in both groups reported that they felt more comfortable with daily exercise after week 6. Muscle soreness was significantly greater in the EMS anterior group than in the EMS whole group after training, but it was not severe.

CONCLUSION: The results suggest that superimposing EMS on the thigh muscles during the PIC exercise improves leg muscle strength easily and effortlessly, leading the participants to a kinesthesia that makes moving feel lighter. In particular, the EMS superimposition on the whole thigh muscles may be able to produce training effects similar to those of the anterior thigh muscles with less muscle soreness.

ECCENTRIC CYCLING EXERCISE TRAINING ENHANCES AEROBIC/MUSCULAR FITNESS AND BIOENERGETIC EFFICIENCY OF T LYMPHOCYTES IN SEDENTARY MALES

PENG, S.

CHANG GUNG UNIVERSITY

INTRODUCTION: Eccentric cycling exercise (ECE) features lower metabolic demand and higher improvement of muscle strength compared to traditional concentric cycling exercise (CCE). Mitochondria can regulate energy metabolism and adaptive immune quality in T lymphocytes. However, the effects of ECE on mitochondrial functions in T-lymphocytes have not yet been established. The study was to investigate the effects of ECE and CCE regimens on adaptive immune functions and mitochondrial bioenergetics of T lymphocytes in sedentary males.

METHODS: Eighteen healthy sedentary males were randomized and divided into ECE (n=9) and CCE (n=9) groups. These subjects progressively performed CCE or ECE from 60% to 80% maximal workload on a bicycle ergometer for 40 min/day, 5 days/week for 6 weeks. A graded exercise testing and an isokinetic strength test were conducted to evaluate cardiopulmonary fitness and muscle strength, respectively. Phenotypes and mitochondrial respiratory capacity in T lymphocyte were analyzed using flow cytometry and high-resolution respirometer, respectively. All statistical analyses were performed using two-way repeated measures ANOVA with Bonferroni post-hoc test.

RESULTS: After training for 6 weeks, there were significant increases in the VO2 values at anaerobic threshold (20.0 ± 1.6 vs. 25.6 ± 1.3 ml/min/kg, $p<0.001$) and maximal performance (31.8 ± 1.4 vs. 37.0 ± 1.6 ml/min/kg, $p<0.001$) in the CCE, compared to those in the ECE. Moreover, the ECE, rather than the CCE, regimen significantly improved maximal voluntary contraction in knee flexion (162.2 ± 7.4 vs. 184.3 ± 7.0 N-M, $p=0.021$) and extension (96.9 ± 5.4 vs. 111.9 ± 5.8 N-M, $p=0.010$). The ECE increased the percentage of effector memory T cell (CD45RO+62L-) in blood than the CCE (27.2 ± 1.8 vs. 40.5 ± 3.1 %, $p<0.05$). Additionally, the ECE produced a higher mitochondrial reserve respiration of intact T lymphocyte than the CCE (16.5 ± 1.8 vs. 24.1 ± 2.4 pmol/s/106 cells, $p=0.029$).

CONCLUSION: The ECE regimen effectively enhances aerobic/muscular fitness and simultaneously mobilizes more effector memory subsets into peripheral blood and improves mitochondrial reserve respiration in blood T lymphocyte. This study provides a suitable training strategy for improving either aerobic/muscular fitness or bioenergetic efficiency in T lymphocytes.

EXERKINES RESPONSE TO A SINGLE BOUT OF EXERCISE ACCORDING TO INTENSITY IN YOUNG MEN

JI, M.1, LEE, S.2,3

1DEPARTMENT OF HUMAN MOVEMENT SCIENCE, GRADUATE SCHOOL, 2DIVISION OF SPORT SCIENCE, COLLEGE OF ARTS & PHYSICAL EDUCATION, INCHEON NATIONAL UNIVERSITY.

INTRODUCTION: Exerkines are exercise-induced bioactive hormones that contribute to beneficial effects on cardiometabolic homeostasis and neurological health. Exercise intensity is a potentially important regulator of various exerkines secretion, but the optimal exercise intensity (moderate vs. high intensity, and submaximal continuous vs. supramaximal interval) that increases and sustains exerkines levels in humans have not yet been fully elucidated. Therefore, this study aimed to examine the levels of circulating exerkines according to the intensity of exercise using a cycle.

METHODS: Ten healthy and active young men (24.3 ± 0.5 years old) voluntarily participated in this study. All participants performed 4 different experimental sessions at 1 week intervals, and the order of exercise sessions was randomly determined using a counterbalanced Latin square design. The experimental sessions consisted of the following 4 parts: 1) a control session (CTRL; no exercise); 2) moderate-intensity continuous exercise (MICE, 55% of heart rate reserve [HRR]); 3) vigorous-intensity continuous exercise (VICE, 85% HRR); and 4) high-intensity interval exercise (HIIE, four 30 s bouts of "all-out" cycling efforts [Wingate test] interspersed with 4 min recovery). Whole blood samples were collected intravenously at 4 different time points (pre-exercise, immediately post-exercise, 30 min post-exercise, and 90 min post-exercise). Serum concentrations of FGF-21, FSTL-1, BDNF, and cathepsin B were measured using ELISA kits.

RESULTS: Serum FGF-21 concentration was significantly higher in the HIIE group than in the MICE group immediately post-exercise (P = 0.0306). In addition, the serum FGF-21 concentration was significantly higher in the VICE and HIIE groups than in the CTRL group at 30 min post-exercise (P = 0.0177 and P = 0.0369, respectively). Serum FSTL-1 concentration was significantly higher in the HIIE group than in the CTRL and MICE group immediately post-exercise (P = 0.0086 and P = 0.0157, respectively). Serum BDNF and cathepsin B concentrations were significantly higher in the HIIE group than in the MICE group immediately post-exercise (P = 0.0174 and P = 0.0385, respectively). Furthermore, serum cathepsin B concentration was significantly higher in the VICE group than in the MICE group immediately post-exercise (P = 0.0432).

CONCLUSION: This study showed that acute HIIE effectively increased serum FGF-21 and FSTL-1 compared to CTRL and MICE. Furthermore, BDNF and cathepsin B secretion responses were more effective in the HIIE than in the MICE group immediately post-exercise. Therefore, the secretion of exerkines, including FGF-21, FSTL-1, BDNF, and cathepsin B may be exercise intensity-dependent.

EFFECTS OF CAFFEINE SUPPLEMENTATION AND ZUMBA TRAINING ON FUNCTIONAL PERFORMANCES IN MIDDLE-AGED WOMEN

SAHLI, S.

UNIVERSITÉ DE SFAX INSTITUT SUPÉRIEUR DU SPORT ET DE LÉDUCATION PHYSIQUE DE SFAX

INTRODUCTION: As a consequence of aging and menopause, functional issues and disability are burdens for middle-aged women. Importantly. Zumba, as one of the most successful and popular dance-fitness programs especially for women, was proved to enhance functional capacity (i.e. cardiorespiratory fitness, walking speed, body composition, muscle strength and endurance, and dynamic balance) in women with or without clinical conditions (Arol, 2020; Barene et al., 2016; Donath et al., 2014; Kolayiş & Arol, 2020; Oktay, 2018). Despite all these Zumba training benefits, no data about Zumba effect on functional performance in middle-aged women was available. Additionally, caffeine is widely recommended as a useful strategy to enhance performance during daily living tasks in older adults (Cherniack, 2012). Combining physical activity and nutritional supplementation (as caffeine) has been proven to have additional effects on muscle mass and function as well as health-related quality of life (Rondanelli et al., 2016). While these beneficial effects of Zumba have been evidenced in different populations, to the best of our knowledge, there is still a paucity of data on this training modality in middle-aged women. This study aimed to explore the effect of daily caffeine supplementation (100mg/day) combined with a Zumba training program for 12-week on functional performances in middle-aged women.

METHODS: Seventy-nine healthy middle-aged women, aged between 50 to 60 years, were randomized into a caffeine-Zumba group (CZG), a Zumba group (ZG) and a control group (CG). Functional performances were assessed in two test sessions, before and after the intervention period, using 10m Walk test for walking speed, Timed Up and Go test for functional mobility, Functional Reach test for dynamic balance and 30-Second Chair Stand test for lower body strength.

RESULTS: Both Zumba and caffeine-Zumba training programs showed a significant functional performances improvement (mobility (CZG: $p<.0001$; ZG: $p<.05$); gait speed (CZG: $p<.0001$; ZG: .005); lower body strength (CZG: $p<.0001$; ZG: $p<.0001$) and dynamic balance (CZG: $p<.0001$; ZG: $p<.005$) with large effect size. However, CZG showed significantly ($p<.05$) better functional performances scores in terms of mobility, gait speed and lower body strength except for dynamic balance.

CONCLUSION: Supplementing caffeine (100mg/day) to a Zumba training program was effective in boosting Zumba benefits on functional performances in terms of mobility, gait speed and lower body strength in middle-aged women. Clinicians may, therefore, consider such a combination while designing intervention strategies for middle-aged women to improve their functional performances during performing daily physical activities, and therefore to achieve healthy aging.

EXERCISE-INDUCED MUSCLE DAMAGE AND RECOVERY IN YOUTHS; A META-ANALYTICAL COMPARISON

FERNANDES, J.F.T., HAYES, L.D., DINGLEY, A.F., TWIST, C., WILSON, L.J.

CARDIFF METROPOLITAN UNIVERSITY

INTRODUCTION: Exercise-induced muscle damage (EIMD) is a by-product of high volume, eccentrically biased or unaccustomed exercise. An understanding of how the peak magnitude of EIMD in youths compares to adults could help practitioners when scheduling high volume and eccentric exercise in youths. The aim of this meta-analysis was to provide a comparison of peak changes in indirect markers of EIMD in youth versus adults.

METHODS: Three data sources (Google Scholar, PubMed and Sport Discus) were searched from July 2022. Studies were eligible for inclusion if they 1) provided a youth versus adult comparison, 2) provided muscle strength, soreness or creatine kinase (CK) markers beyond ≥ 24 hours, 3) did not provide a recovery treatment or included a treatment free control group, 4) was performed in humans. An inverse-variance random-effects model for meta-analyses was employed because it allocates proportionate weight to comparisons based on the size of their individual standard errors whilst accounting for heterogeneity across studies. Effect sizes (ES) were represented by the standardised mean difference and presented alongside 95% confidence intervals.

RESULTS: Fourteen comparisons from 12 individual studies were included in the analysis; nine included a marker of muscle function, 11 included a marker of muscle soreness and nine measured CK. The main effects for strength (ES= 2.01, 95% CI range = 1.08 to 2.95, Z= 4.20, P <0.001), muscle soreness (ES = -1.52, 95% CI range = -2.15 to -0.90, Z= -4.76, P <0.001) and CK were (ES = -1.98, 95% CI range = -2.93 to -1.04, Z= -4.13, P <0.001) indicated greater peak changes in adults than youths.

CONCLUSION: The magnitude of EIMD as determined by changes in muscle strength, muscle soreness and CK is substantially less in youths compared to their adult counterparts. These findings provide insight and encouragement to practitioners who may be concerned about the potential impact of EIMD on youth athletes specifically.

CHANGES IN CARDIORESPIRATORY FITNESS FOLLOWING EXERCISE TRAINING PRESCRIBED RELATIVE TO PHYSIOLOGICAL THRESHOLDS AND TO TRADITIONAL INTENSITY ANCHORS: A META-ANALYSIS OF INDIVIDUAL PARTICIPANT DATA

MEYLER, S., SWINTON, P., BOTTOMS, L., HUNTER, B., WELLSTED, D., DALLECK, L., WILLIAMS, C., SARZYNSKI, M., MUNIZ-PUMARES, D.

UNIVERSITY OF HERTFORDSHIRE

INTRODUCTION: Exercise intensity is commonly prescribed relative to traditional (TRAD) intensity anchors such as maximum oxygen uptake (VO2max). Such approaches, however, elicit marked variation in exercise tolerance and physiological responses among individuals. This may explain a portion of the response variability observed in VO2max following training. Prescribing exercise intensity relative to physiological thresholds (THR) is shown to better normalise exercise intensity, creating a more homogenous exercise stimulus. Prescribing exercise intensity instead to physiological thresholds may thus elicit more homogenous changes in VO2max following a period of training.

METHODS: Electronic databases were searched for original articles using a predefined search strategy. Authors of studies meeting the inclusion criteria (N=206) were invited to share individual participant data (IPD). Data was received for 38 studies resulting in IPD for n=1422 participants. The dataset was divided into: controlled studies (N = 4), which contained volume-matched exercise groups (THR: n=46; TRAD: n=44) as well as non-exercise control groups (CON; n=49); and non-controlled studies (N=38), where data from any single THR and TRAD exercise group was included. A Bayesian approach with multi-level distributional models was used to separately analyse relative VO2max change scores from the two datasets where we: a) compared the difference in mean change scores between THR and TRAD exercise groups (plus CON group in the 2-ARM analyses), b) compared the proportion of individuals expected to increase CRF beyond a minimum clinically important difference (MCID: 3.5 ml/kg/min) following THR and TRAD (plus CON group in the 2-ARM analyses), c) tested the hypothesis that VO2max response variability is lower in THR compared to TRAD, and d) explored whether there was any evidence of inter-individual differences in trainability. Inferences were made using Bayes factors (BF).

RESULTS: In the controlled studies mean change scores were greater in THR compared to TRAD (4.1 vs 1.8 ml/kg/min, BF:>100). Individuals were 48% more likely to experience an increase in CRF > MCID in THR compared to TRAD. There was no difference in the standard deviation of change scores between THR and TRAD (1.5 vs 1.7 ml/kg/min, BF: 0.55), but greater variation in THR and TRAD combined compared to CON (1.9 vs 1.3 ml/kg/min, BF: 12.4). Similar results were obtained in the non-controlled studies with greater mean changes in THR compared to TRAD (4.6 vs 3.4 ml/kg/min, BF: 63.3) but no difference in standard deviation (2.9 vs 3.2 ml/kg/min, BF: 0.41).

CONCLUSION: Prescribing exercise intensity using THR approaches elicited superior mean changes in VO2max and increased the likelihood of experiencing increases in CRF exceeding the MCID compared to when TRAD approaches were used. There was no difference in variation between THR and TRAD exercise training, however, there was evidence of trainability whereby variation in THR and TRAD exceeded that of controls.

CHANGES IN THE MAXIMAL RATE OF HEART RATE INCREASE IN RESPONSE TO OVERLOAD TRAINING ARE LINEARLY RELATED TO SUBSEQUENT CHANGES IN EXERCISE PERFORMANCE

BURGESS, S., CHALMERS, S., DUNIENVILLE, N.M.A., BUCKLEY, J.

UNIVERSITY OF SOUTH AUSTRALIA

INTRODUCTION: The maximal rate of heart rate increase (rHRI) during the transition from rest to light exercise has shown to be linearly related to exercise performance across different training phases. As a result, it has been proposed that rHRI could be used to guide training, but for this to be the case changes in rHRI during training would need to be related to subsequent adaptations in exercise performance.

METHODS: Five-minute cycling time trial performance (5CTT) and rHRI were assessed in 112 male cyclists after six days of light-training (LT), 13 days of heavy-training (HT) and a 13-day recovery taper (T).

RESULTS: rHRI was linearly related to 5CTT within-individuals across LT, HT and T (B = 0.02, 95% CI 0.004 to 0.04, p=0.02). Percent change in rHRI from LT to HT (overload period) was linearly related to subsequent percent change in 5CTT performance by the end of T (B= 0.037, 95% CI 0.002 to 0.072, p=0.04). In 13 non-functionally overreached (NFOR) participants rHRI decreased from LT to HT compared with those who were functionally overreached (FOR) (NFOR = -3.96 ± 35.95%; FOR = 18.17 ± 32.59% p=0.04). A 9.2% reduction in rHRI was associated with an increased risk of NFOR (OR 1.02; 1.0009 – 1.05, p=0.04).

CONCLUSION: A faster rHRI after overload training was related to improvements in performance following a period of recovery and adaptation, while reductions in rHRI were associated with less improvement or an increased risk of NFOR. rHRI could be used to guide training to optimise performance.

THE RELATIONSHIP BETWEEN RUNNING ECONOMY AND RUNNING PERFORMANCE AND STRIDE PARAMETERS

OGAWA, K., HIROYAMA, T., NABEKURA, Y.

UNIVERSITY OF TSUKUBA

INTRODUCTION: Training aimed at enhancing running economy (RE) has been conducted in the field to improve running performance. Stride parameters such as stride frequency (SF) and stride length (SL) are components of RE. Recently, SL and SF have been assessed noninvasively and simply using wearable devices. If RE and running performance are related to stride parameter constants, they can be measured on a regular and continuous basis. This study aimed to determine the relationship between stride parameters, RE, and running performance at various velocities.

METHODS: This study was conducted with 36 runners, recording the results of the incremental running test and those of the JAAF-approved 5000 m race. Experiments were conducted during the summers of 2021 and 2022. For the 5000 m race, the highest record within two weeks before and after the incremental running test was used as the seasonal best time (SB). Nine runners were able to track all data for both years. The incremental test was divided into two parts with a five-minute rest: the first test consisted of three minutes of running divided by a two-minute rest, with each stage increasing by 1.2 km/h until the blood lactate concentration (bLa) exceeded four mmol. The first test was set to the personal best running pace of 10000 m in the fifth stage. The participants ran in five to six stages. The second test contained no rest period and was performed at an acceleration of 0.6 km/h per minute from the velocity at which bLa was observed to be four mmol. SF was measured using a stride sensor attached to a shoe strap. SL was calculated by dividing the treadmill velocity by the SF. The relative stride length was calculated by dividing the stride length by the height (SL/H). The velocity at which all the subjects ran with a bLa of less than four mmol was 16.8 km/h. A 16.8 km/h stride parameter and RE were used in the analysis.

RESULTS: SF, SL, and SL/H were correlated with RE and SB ($r = 0.40$, $r = -0.43$, and $r = -0.41$, $p < 0.05$, respectively). No changes in stride parameters could be identified in runners that could be tracked. No significant differences from the previous year were identified in RE and SB in the nine trackable runners. No significant relationship was identified between changes in SF and SL, and changes in RE and SB.

CONCLUSION: This result is contrary to that of Ruiter et al. (2014), who reported that a higher SF utilizes more elastic energy. Traditionally, runners do not wear high-cushion carbon fiber plate (CFP) shoes. Highly cushioned CFP shoes have been reported to improve RE while extending the SL (Hoogkamer et al., 2017). The runners in the present study wore high-cushion CFP shoes, and the relationship between SF, SL, and RE may differ from previous studies. In conclusion, athletes with a larger SL/H have superior RE, which may lead to higher performance in 5000 m running.

INFLUENCE OF STRIKE PATTERN ON RUNNING ECONOMY IN RUNNERS OF DIFFERENT ABILITIES

GÓMEZ GARCÍA-OCHOA, M., RODRIGO CARRANZA, V., RODRÍGUEZ-BARBERO, S., MUÑOZ DE LA CRUZ, V., GONZÁLEZ-MOHÍNO, F.

UNIVERSITY OF CASTILLA LA MANCHA

INTRODUCTION: Running economy (RE) is influenced by multiple factors, such as running biomechanics. Several studies had evidenced the beneficial effect of running biomechanics on RE. The results have shown benefits on low vertical oscillation, minus 3% self-selected step length, barefoot or lightweight shoes. Currently, there is still some controversy about the influence of strike pattern on RE. Therefore, the aim of this study was to analyse the influence of strike pattern and spatiotemporal variables on RE in two group of runners (trained and recreational runners).

METHODS: A total sample of 27 runners, divided into 2 groups based on performance levels (14 trained and 13 recreational runners) were individually evaluated in a single visit. Two consecutive 3-minute intervals were performed at different submaximal speeds depending on their performance level (13 and 17 km·h-1 for trained group; 9 and 13 km·h-1 for recreational group). Energy cost (EC) and oxygen consumption (VO2), as well as spatiotemporal variables (contact time, flight time, step length, step frequency, vertical oscillation) and strike pattern (fore-foot strike, mid-foot strike, heel strike) were measured using the Stryd® Power Meter device and Runmatic® mobile application. To prevent the influence of shoe characteristics on strike pattern, all runners used the same shoe model during the test.

RESULTS: As the most relevant result, no significant differences were found in RE according to the type of runner's strike pattern between the two performance groups. At the common speed in both groups (13 km·h-1), trained runners had lower RE than recreational runners (p=0.003); however, no significant differences were observed between strike patterns (p=0.577). Trained runners that used a forefoot pattern presented lower RE than trained runners using a rearfoot pattern (p=0.003). The RE assessed as VO2 showed no significant differences depending on the performance group, strike pattern, or the interaction performance * strike pattern.

CONCLUSION: It seems that strike pattern has lower influence on RE. Therefore, we would not recommend a specific strike pattern for RE improvement. In that case, coaches should not attempt to improve performance by modifying the spontaneous strike pattern of endurance runners. Despite not having found significant differences in RE, the strike pattern remains a fundamental component for measuring running performance maybe with a clinical or injury prevent purposes.

Based on these findings, trained runners seem more economical than recreational runners, with no clear influence of the strike pattern to explain these differences.

THE ACUTE EFFECT OF HIGH-INTENSITY TRACK RUNNING ON NON-LINEAR ANALYSIS OF HEART RATE VARIABILITY

VAN RASSEL, C.R., AJAYI, O.O., SALES, K.M., NAGAI, K., MACINNIS, M.J.

UNIVERSITY OF CALGARY

INTRODUCTION: Recently, a non-linear index of heart rate variability (HRV) - detrended fluctuation analysis alpha 1 (DFAa1) - has been investigated as a metric to delineate exercise intensity domains and to quantify physiological disturbances following prolonged exercise. For example, DFAa1 values of 0.75 and 0.5 coincided with the first and second ventilatory thresholds during incremental exercise, respectively [1], and an attenuation of DFAa1 was observed following completion of an ultramarathon [2]. It remains unknown whether DFAa1 responds similarly to short-duration, high-intensity exercise. The purpose of this investigation was to evaluate DFAa1 measures during severe intensity running and to determine the subsequent effect of intense exercise on DFAa1 measures during moderate intensity outdoor running.

METHODS: During three separate visits to a 400m outdoor athletic track, 10 trained runners (mean[SD]; 7M, 3F; 29[7] years; 59.0[4.2] ml/kg/min) performed maximal running time trials (TT) at distances between 1200-4400m. Prior to (PRE) and 5-min following (POST) each TT, runners performed 800m of track running at a running speed of 2.36 m/s. During all running trials, heartbeat RR-interval (RR) data were recorded (H10, Polar Electro Oy, Kempele, Finland). After preprocessing, DFAa1 values were calculated every 10 seconds throughout each trial using 2-min RR data series, using a window width of 4 >= n >= 16. The average calculated DFAa1 during each trial was used for analysis. A one-way repeated measures ANOVA was used to examine differences in DFAa1 measures across the three TT intensities. A two-way repeated measures ANOVA (time x intensity) was used to examine differences in DFAa1 measures between PRE and POST and across intensities.

RESULTS: Average running speeds during the 1200m, 2400m, 3600-4400m TTs were 4.8[0.4] m/s, 4.3[0.4] m/s, and 4.2[0.4] m/s, respectively. Average DFAa1 measures during the 1200m (0.56 [0.15]), 2400m (0.54 [0.13]) and 3600-4400m (0.54 [0.15]) TTs were not significantly different (p=0.528; n=9). No significant time x intensity interaction effect (p=0.084) or main effect of intensity (p=0.305) for DFAa1 measures was detected. However, a main effect of time for DFAa1 was detected, indicating that POST DFAa1 (0.69 [0.20]) measures were significantly lower than PRE DFAa1 (1.12 [0.22]) measures (p=0.001; n=10) at the same intensity.

CONCLUSION: Average DFAa1 measure during all three TTs were greater than 0.5, suggesting that DFAa1 measures below 0.5 - as previously suggested [1] - may not appropriately delineate the severe exercise intensity domain during high intensity running. However, an attenuation in DFAa1 measures following high intensity running suggests a disturbance in autonomic control of HRV that may indicate physiological perturbation induced by intense running exercise.

DECREMENTAL EXERCISE PROTOCOL AS A TRAINING STIMULUS: MORE OR LESS EFFICIENT THAN TRADITIONAL HIGH-INTENSITY INTERVAL TRAINING?

BELTRAMI, F., KÄLLIN, S., SPENGLER, C.M.

ETH ZURICH: EIDGENOSSISCHE TECHNISCHE HOCHSCHULE ZURICH

INTRODUCTION: A high-intensity interval sessions based on decremental exercise loads (DEC) has been shown to elicit higher levels of physiological perturbation in trained cyclists compared to a traditional, even-paced session (TRA). This

study tested whether a training period including either DEC or TRA would lead to differences in performance increments during a 40-km time-trial (TT40) in well-trained cyclists.

METHODS: On separate visits, twenty cyclists performed an incremental test to determine peak power output (PPO), the lactate threshold (determined using Dmax), maximal cardiac output (using thoracic bioimpedance) and maximal oxygen uptake (VO2max), plus a TT40 on an ergometer, which was preceded by a standardized warm-up used to determine gross efficiency. All testing was repeated to account for any familiarization effects (Baseline). Both groups performed 4-weeks of supervised high-intensity training in the laboratory (3 x per week). The sessions consisted of 4 x 4 min intervals at 80% of PPO with 3 min of active recovery in between. Power output was held constant for every bout within TRA (N = 10, 3 female) whereas power started 40 W higher and finished 40 W lower than average within each bout of DEC (N= 10, 2 female). Training loads during the 4-week period were adjusted based on physiological and perceptual responses during the preceding session and the warm-up of the day, which was kept constant throughout the training period. At least 48 h after the last training session, participants returned to the laboratory for post training assessments (POST). All comparisons were performed using 2-way ANOVA (factors time and group) with significance set at $P < 0.05$.

RESULTS: There was no difference in time spent above 90% heart rate max per supervised session between the groups (12.1 ± 3.9 vs. 11.3 ± 2.7 min for DEC and TRA respectively, P = 0.603). TT40 performance significantly improved from PRE to POST training (factor time, $P < 0.001$), with a 1.3% reduction in time in DEC (64.63 ± 4.75 vs. 63.79 ± 4.80 min) and a 2.9% in TRA (66.12 ± 5.36 vs. 64.17 ± 5.54 min). This difference was not significant between the groups (group * time interaction P = 0.122). PPO (factor time P= <0.001) as well as power at the lactate threshold (factor time P = 0.002) increased from PRE to POST training, again without differences between the two groups. Neither VO2max, peak cardiac output nor gross efficiency showed significant differences following the training program.

CONCLUSION: Both DEC and TRA interventions were effective in enhancing TT40 performance. Performance improvements seemed related to the ability to sustain a higher percentage of maximal VO2max during the time-trials, as seen from the higher power at the lactate threshold, rather gains in efficiency or aerobic capacity. Contrary to our hypothesis, high-intensity interval training based on decremental loads did not lead to further gains in performance compared to a traditional, even-paced approach.

RESTRICTED NASAL-ONLY BREATHING STIMULATES VENTILATORY EFFICIENCY DURING LOW INTENSITY TRAINING BUT DOES NOT AVOID TRAINING INTENSITY FLUCTUATION

RAPPELT, L., HELD, S., WIEDENMANN, T., DEUTSCH, J.P., WICKER, P., DONATH, L.

GERMAN SPORT UNIVERSITY COLOGNE: DEUTSCHE SPORTHOCHSCHULE KOLN,

INTRODUCTION: Low-intensity endurance training is frequently performed at gradually higher training intensities than intended, resulting in a shift towards threshold training. By restricting oral breathing and only allowing for nasal breathing this shift might be reduced and ventilatory efficiency may be trained.

METHODS: N = 19 physically healthy adults (3 females, age: 26.5 ± 5.1 years; height: 1.77 ± 0.08 m; body mass: 77.3 ± 11.4 kg; VO2peak: 53.4 ± 6.6 ml·kg−1·min−1) performed two 60 min sessions of self-paced low-intensity cycling with breathing restriction (nasal-only breathing; induced by a strip of tape applied over the mouth) and without restrictions (oro-nasal breathing) in a randomized order. During these sessions, heart rate, respiratory gas exchange data and power output data were recorded continuously. Furthermore, capillary blood lactate was obtained every ten minutes (T10-T60).

RESULTS: No significant condition x time-effects were found for power ($F(1.5, 22.7) = 1.42$, $p[GG] = 0.26$, $\eta p2 = 0.09$) and cadence ($F(3.0, 44.7) = 2.27$, $p[GG] = 0.09$, $\eta p2 = 0.13$). For blood lactate concentrations, a significant and large condition x time-interaction effect was found ($F(3.2, 57.1) = 3.61$, $p[GG] = 0.02$, $\eta p2 = 0.17$) with lower values during the nasal-only compared to the oro-nasal breathing condition towards the end of the session (T50: 1.21 ± 0.52 vs. 1.48 ± 0.59 mmol·l-1, $p = 0.01$, SMD = 0.49 & T60: 1.21 ± 0.47 vs. 1.45 ± 0.52 mmol·l-1, $p = 0.02$, SMD = 0.48). VO2 showed significant and large main effects for both time ($F(1.7, 31.1) = 5.73$, $p[GG] = 0.01$, $\eta p2 = 0.24$) and condition ($F(1, 18) = 5.49$, $p = 0.03$, $\eta p2 = 0.23$), indicating higher values for the oro-nasal training session. In terms of gross efficiency, simple main effect analysis for time revealed large effect sizes ($F(1.9, 29.2) = 37.9$, $p < 0.001$, $\eta p2 = 0.72$). Although main effect analysis for condition did not show statistical significance ($F(1.0, 15.0) = 3.7$, $p = 0.075$, $\eta p2 = 0.20$), pairwise comparison between time points indicated small to moderate effects with higher values for the nasal-only condition ($0.24 \leq SMD \leq 0.31$). Nevertheless, heart rate based calculations of the time in training zones did not reveal significant effects (Zone 1: ($F(1, 18) = 0.03$, $p = 0.85$, $\eta p2 = 0.00$); Zone 2: ($F(1, 18) = 0.14$, $p = 0.71$, $\eta p2 = 0.01$); Zone 3: ($F(1, 18) = 0.19$, $p = 0.67$, $\eta p2 = 0.01$).

CONCLUSION: Although nasal-only breathing seems to stimulate ventilatory efficiency, it does not prevent participants from performing low-intensity training at higher intensities than intended. Longitudinal studies are warranted to evaluate longitudinal responses of changes in breathing patterns.

EFFECT OF HYPOBARIC "LIVE HIGH – TRAIN LOW" TRAINING ON BLOOD PARAMETERS IN ELITE TRACK CYCLISTS.

BLOKKER, T., KELLENBERGER, K., MÜLLER, B., ZENGER, N., WEHRLIN, J.P.

SWISS FEDERAL INSTITUTE OF SPORT MAGGLINGEN: EIDGENOSSISCHE HOCHSCHULE FUR SPORT

INTRODUCTION: By combining hematological adaptations to chronic hypoxia benefits, while avoiding the hypoxia-induced reduction of maximal training intensity, "Live High – Train Low" (LHTL) has popularly grown to be a common hypoxic training practice in elite endurance sport disciplines [1]. However, despite arguably being the "gold standard" of altitude training for sea-level competition, its validity and effect, particularly within elite athletes with a high natural hemo-

globin mass (Hb(mass)), remain debated [2]. Hence, the purpose of this case-study was to evaluate the effect of LHTL on blood parameters in elite track cyclists.

METHODS: Four Swiss male national team track cyclists (age: 24.9 ± 2.1 years; relative VO2max: 73.3 ± 3.8 ml/kg/min; relative Hb(mass): 14.7 ± 1.0 g/kg) underwent a typical 23-day hypobaric LHTL altitude training intervention, residing in hypobaric hypoxia (2309 m) and training between 440 m and 1850 m. Hematological parameters were assessed with duplicate measures before (PRE) and after (POST) the intervention with a modified version of the carbon monoxide rebreathing technique [3]. Blood oxygen saturation (SpO2), body weight, subjective sleep quality, and subjective training quality were recorded daily. Training, as well as nutrition and hydration were individualized, adapted and optimized according to these parameters. Athletes' ferritin levels were assessed two weeks pre-altitude, and were thenceforth supplemented with 138 mg elemental iron three times/week until the end of the intervention.

RESULTS: From PRE to POST, the total Hb(mass) increased by 8%, from 1097 ± 111 g to 1185 ± 143 g ($p = 0.01$). Similarly, the red blood cell volume increased by 6% from 3294 ± 295 ml to 3518 ± 397 ml ($p < 0.05$). Pre-altitude ferritin levels were 82.0 ± 9.1 µg/L. Mean SpO2 the first four and last four days were 93.6 ± 0.9% and 95.05 ± 1.29% ($p > 0.05$), respectively. The body weight remained stable from PRE to POST (74.5 ± 3.5 kg vs 73.9 ± 4.6 kg, $p > 0.05$).

CONCLUSION: A 23-day LHTL sojourn at 2309 m induced large improvements in hematological values in elite endurance athletes, despite already high natural Hb(mass) values. This underlines the importance of both individualizing all possible parameters as well as maximizing the altitude dosage (high altitude and sufficient time spent at altitude) in order to trigger erythropoietic adaptations.

AMATEUR FEMALE ATHLETES PERFORM THE RUNNING SPLIT OF A TRIATHLON RACE AT A HIGHER RELATIVE INTENSITY THAN THE MALE ATHLETES: A CROSS-SECTIONAL STUDY

FERNANDES, G.

FEDERAL UNIVERSITY OF SÃO PAULO

INTRODUCTION: In spite of the increase in female interest on endurance sports, such as triathlon [1], the majority of studies on this subject are restricted to male athletes [2]. Therefore, the aim of the study was to evaluate the differences between male and female triathletes considering the physiological variables that are commonly used predictors of endurance performance, such as: the ventilatory threshold (VT), respiratory compensation point (RCP), and the percentage of the maximal aerobic speed (MAS) that they can maintain in a triathlon race.

METHODS: Forty-one triathletes (22 men and 19 women) that had at least three years of experience in the triathlon practice and raced the same Olympic triathlon underwent a cardiorespiratory incremental maximal test using a treadmill (Inbrasport, ATL, Porto Alegre, Brazil). The VO2, VCO2, O2 end-tidal pressure (PET O2), CO2 end-tidal pressure (PET CO2) and minute ventilation (VE) were measured to assess their VT, RPC, and MAS, and compare them to the race speed.

RESULTS: The absolute (4.00±0.52 vs. 2.89±0.40 L/min, $p < 0.001$) and relative to body mass maximal oxygen uptake (VO2 max) (54.0±5.1 vs. 49.8±7.7 ml/kg/min, $p < 0.001$) and MAS (17±2 vs. 15±2 km/h, $p=0.001$) were significantly higher in male than in female athletes. Conversely, there were no sex differences according to the percentage of VO2 max reached at VT (74.4±4.9 vs. 76.1±5.4%, $p = 0.298$) and RCP (89.9±3.6 vs. 90.6±4.0%, $p = 0.560$). However, the speeds at VT (11.8±1.1 vs 10.7±1.5 km/h, $p = 0.021$) and RCP (14.3±1.2 vs 12.8±1.6 km/h, $p = 0.001$) were higher in male athletes. Also, the mean speed during the race also did not differ between men and women (12.1±1.7 km/h and 11.7±1.8 km/h, $p=0.506$, respectively). Finally, men performed the running split at a lower percentage of speed at RCP than women (84.0±8.7 vs. 91.2±7.0%, respectively, $p = 0.005$).

CONCLUSION: Despite showing no differences according to the VT and RCP in the percentage of VO2 max values, male and female athletes accomplished the running split in an Olympic triathlon distance at distinct relative intensities, as female athletes run at a higher relative intensity (a higher RCP percentage). These finding can be useful for coaches and athletes to design the strategy for a triathlon race that may be different for each sex.

100 000 STEPS DAILY FOR MORE THAN A YEAR: MORPHOLOGICAL AND FUNCTIONAL (DIS)ADAPTATIONS OVER AN EXTREME ULTRARUNNING CHALLENGE

VENCKUNAS, T., CHAILLOU, T., SATKUNSKIENE, D., MICKEVICIUS, M., SNIECKUS, A., ZUOZIENE, I., RUTKAUSKAS, S., KAMANDULIS, S.

LITHUANIAN SPORTS UNIVERSITY

INTRODUCTION: While sport enthusiasts such as ultra-endurance athletes strive for very high daily exercise energy expenditures, the side-effects of excessive training volume may eventually abolish the benefits e.g. by precluding the continuation of regular physical activity. The aim of the study was to follow the morpho-functional (dis)adaptations of a male runner in response to an extreme ultrarunning challenge.

METHODS: A highly experienced male ultra-distance runner (49 yrs) undertook a challenge of running around the globe (>30 000 km) and covering the longest ever distance on foot during a year. The challenge was preceded by regular running (~120 km/wk) and resistance training (up to 10 h/wk). Due to travelling restrictions, it was mainly performed in Lithuania (mostly on flat asphalt roads, temperatures ranging from –25 to +33 °C). Distances were recorded using a GPS watch and data were transferred on Strava. Various morphological and functional parameters were measured before, during and after the race.

RESULTS: Daily distances ranged from ~80 km during first weeks, to ~60 km in the middle, and to ~70 km towards the end of the challenge, totaling 30303 km in 444 days. During the first 12 months, the subject ran ~25 000 km. Body mass was reduced by 7 % (4 kg) within the first month and remained stable afterwards. % body fat estimated from skinfold thickness dropped from 13.5 % to 10 % at the end of the challenge. Compared to baseline, plasma creatine kinase activity (CK) soared to ~15-fold during the first few weeks and remained elevated by ~4-fold afterwards. Other blood markers (except ferritin) remained largely unchanged. Baseline ultrasound (US) examination revealed multiple but mostly mild lesions in the knees and ankles of both legs. Most of them remained morphologically stable, but some, especially those in the left leg, exacerbated in the middle and/or by the end of the challenge. After ~14 000 km (i.e., ~200 days), pain appeared in the lower left leg and a tibial stress fracture was confirmed by US and MRI. Although the subject maintained a roughly similar training load (i.e., distance and speed), the pain gradually decreased and no lesions were visible at the post-race examination. Post-race US-measured m. quadriceps thickness was reduced by 12 % in the left and by 6 % in the right leg, with ~20 % decrease in voluntary and electrically stimulated knee extension torques of both legs, and vertical jumping ability and muscle power were severely compromised. No changes in either absolute cardiac size and function (US, MRI) or size of the parenchymal organs (except for a slight liver enlargement at the end of the run) have been observed.

CONCLUSION: This case study proved that highly increased energy turnover with ~9 hours of daily running is feasible for periods extending beyond a year. Even though some lesions in the legs seem inevitable with such large daily running distances, these do not preclude the continuation of the activity in an athlete with high intrinsic motivation.

NEURAL ADJUSTMENTS DURING REPEATED BRAKING AND THROTTLE ACTIONS ON A MOTORCYCLE SETUP

MARINA, M.1, TORRADO, P.1, DUCHATEAU, J.2, BAUDRY, S.2

1 INSTITUT NACIONAL D'EDUCACIÓ FÍSICA DE CATALUNYA, UNIVERSITAT DE BARCELONA; 2 LABORATORY OF APPLIED BIOLOGY, RESEARCH UNIT IN APPLIED NEUROPHYSIOLOGY, UNIVERSITÉ LIBRE DE BRUXELLES

INTRODUCTION: Previous work indicates a progressive increase in muscle activity, as assessed by surface electromyography (EMG), during submaximal intermittent fatiguing protocols (IFP) (1, 2). However, the recording of surface EMG alone does not permit to assess the potential neural (spinal vs. supraspinal) mechanisms that limit the endurance time (TLim). In that context, the recording of both the Hoffmann (H) reflex and the maximal M-wave (Mmax) can provide relevant information on neural changes at spinal level during the time course of a fatiguing contraction (3, 4). Furthermore, as the neural adjustments observed during a fatiguing contraction are specific to the details of the task performed (5), it is necessary to assess the fatigue-related mechanisms as much as possible during ecological protocols. This study aimed to assess the acute neural adjustments during an IFP designed to replicate the fundamental actions and ergonomics encountered when riding a motorcycle.

METHODS: Twenty height participants repeated a sequence of six submaximal brakes-pulling (0.6 duty cycle) and two gas throttle actions, interspaced by one 3-s maximal brake-pulling (MVC), until failure. During the submaximal brakes-pulling actions performed at 30% of MVC, force fluctuations (FF), EMG root mean square (RMS30), and elicited Mmax and H reflex responses were measured in the flexor digitorum superficialis (FDS).

RESULTS: At the end of the IFP (1975 ± 813-s), the MVC force and the associated RMS (RMSMVC) of the FDS decreased ($P<0.001$) by 46% and 26%, respectively. During the IFP, the FF and RMS increased gradually (106% and 61% respectively) with respect to the pre-fatigue state ($P<0.029$ for both parameters). The Hmax amplitude increased by 49 % ($P<0.039$) without significant change of the Mmax first phase amplitude ($P>0.524$). Noteworthy, the relative increase in H-reflex amplitude (Hmax/Mmax) was positively correlated with changes in RMS values during the IFP ($r=0.68$; $P<0.001$).

CONCLUSION: The results suggest that an IFP mimicking brakes-pulling and gas throttle actions observed during race motorcycling induces a gradual decrease in MVC force production capacity and its associated RMS/MVC, possibly due to a derecruitment process (6). The increment of the Hmax/Mmax ratio suggests that the spinal reflex pathway and the motoneurone excitability were not a limiting factor of TLim. The fact that the FDS muscle activity (RMS30) reached at TLim was only 55% of the prefatigued MVC activity, in absence of noticeable peripheral propagation failure (Mmax), support the hypothesis of a fatigue- induced deficit in supraspinal activation.

DOES EXTRA FORCE OCCUR DURING WIDE-PULSE, HIGH-FREQUENCY NEUROMUSCULAR STIMULATION ON WRIST FLEXORS COMPARED WITH CONVENTIONAL STIMULATION ?

EON, P.

UNIVERSITY OF BOURGOGNE FRANCHE-COMTÉ

INTRODUCTION: In contrast to conventional (CONV) neuromuscular electrical stimulation (NMES), the wide-pulse, high-frequency (WPHF) NMES can generate a progressive increase in force when delivered at a low and constant stimulation intensity (1,2,3). This phenomenon called "extra force" (EF) has been mainly attributed to the recruitment of sensory axons in addition to the direct recruitment of motor axons (4). To this day, EF development has been mainly studied in lower limb muscles (1,2), while only one study conducted in patients with neurological impairments investigated EF in upper limb (5). Here, we aim to compare forces evoked by CONV and WPHF NMES of the flexor carpi radialis muscle (FCR).

METHODS: In this experiment, fourteen healthy participants (age: 28 ± 6 years) took part in one session consisting of two NMES protocols targeting the FCR: WPHF (100 Hz, 1ms) and CONV (20 Hz, 0.05 ms). Two electrodes were placed over the FCR belly. For each protocol, contractions were evoked at a stimulation intensity eliciting an initial force corresponding to 5%, 10% and 20% of maximal palmar flexion during 10 s. For each contraction, real force-time integral (i.e. FTI resulting from the NMES, FTIr) and theoretical FTI (i.e. calculated by multiplying FTIr measured during the first second of NMES by the duration of the evoked contraction, FTIth) were measured. A FTIr/FTIth > 1 indicated EF development (4).

RESULTS: The results revealed a condition (P = 0.006) and intensity (P = 0.001) effect on EF (WPHF, 5%: 0.87, 10%: 0.95, 20%: 1.00; CONV, 5%: 1.07, 10%: 1.1, 20%: 1.11). EF was significantly higher during CONV than WPHF, and EF was significantly lower during 5% compared to 10% and 20%.

CONCLUSION: These results showed that EF only occurred during CONV. In contrast, the FTIr/FTIth < 1 observed during WPHF suggests a progressive decrease in force in response to WPHF. In the same way, a decrease in force has already been reported during submaximal electromyostimulation at high frequency stimulation (6). Therefore, in contrast to what has been observed in lower limb, this absence of EF during WPHF suggests that muscle stimulation of FCR induced a reduction in the recruitment of motor units due to 1) fatigue of the activated motor units and/or 2) changes in axonal excitability threshold.

CORTICOSPINAL EXCITABILITY OF THE TRICEPS BRACHII FOLLOWING HIGH-VELOCITY CONCENTRIC CONTRACTIONS: EXTENDING OUR UNDERSTANDING OF PERFORMANCE FATIGABILITY

HA, P.L., PAISH, A.D., BENNETT, E.T., MCNEIL, C.J., DALTON, B.H.

UNIVERSITY OF BRITISH COLUMBIA

INTRODUCTION: Muscle fatigue is often induced and characterized by isometric contractions, with reductions in maximal torque accompanied by alterations in cortical and motoneuronal excitability. Despite the task-dependent nature of fatigue, little is known regarding fatigue-related alterations in excitability at the cortical and motoneuronal levels as a result of repetitive, dynamic contractions. The purpose of this study was to explore the fatigue-related effects of high-velocity elbow extensions on cortical and motoneuronal excitability of the triceps brachii.

METHODS: Although data collection is ongoing, to date, five healthy participants (age:31+/-7 years; height:168.8+/-12.2cm; mass:67.2+/-8.5kg) performed a fatiguing task that included 2 sets of 60 isotonic-like elbow extensions against a resistance set to 30% of maximal voluntary isometric contraction (MVC) torque. Performance fatigability was characterized via a reduction in peak power during the dynamic task, as well as a change in MVC torque with voluntary activation (VA) from baseline to 30s following task termination. Neural excitability was assessed before and immediately following task termination via triceps brachii surface electromyography (EMG). Motor evoked potentials (MEPs) from transcranial magnetic stimulation, cervicomedullary motor evoked potentials (CMEPs) from transmastoid electrical stimulation, and maximal compound muscle action potentials (Mmax) from brachial plexus electrical stimulation were recorded during brief (~5s) isometric contractions at the level of integrated EMG produced at 15% of baseline MVC torque. At baseline, both MEP and

CMEP were elicited at ~20% Mmax peak-to-peak amplitude. To isolate changes in motoneuronal and cortical excitability, the CMEP and MEP were normalized to Mmax and CMEP absolute area, respectively.

RESULTS: Although VA (93.9+/-7.2% at baseline) was not reduced by the fatiguing protocol following task termination (p=0.96), MVC torque decreased by 29.0+/-13.6% (p<0.01) and peak power was reduced by 70.2+/-14.9% (p<0.01). Compared to baseline (amplitude: Mmax=18.2+/-3.9mV; CMEP=26.4+/-10.2%Mmax; MEP=19.1+/-6.1%CMEP), there were no detectable differences after task termination for Mmax (108.2+/-16.1%Change; p=0.19), CMEP (51.7+/-78.2%Change; p=0.10), and MEP (166.1+/-124.4%Change; p=0.34) areas.

CONCLUSION: Despite large fatigue-related decrements in elbow extension peak power, isometric strength was only reduced moderately, which was likely owing to factors predominantly within the muscle as VA remained high following task termination. Although the post-fatigue normalized CMEP and MEP values were 51% and 166% of their baseline values, respectively, these did not represent statistically significant changes, presumably owing to the small sample size collected to date. Thus, further, ongoing investigation is required to adequately assess the possibility of fatigue-related alterations in triceps brachii cortical and motoneuronal excitability following fast, dynamic elbow extensions.

COMPARISON OF SIMULATED AND ACTUAL TRAIL RUNNING RACES ON NEUROMUSCULAR FUNCTION IN TRAIL RUNNERS

PANTONG, S.1, TANAKA, H.2, SUKSOM, D.1,3

1 FACULTY OF SPORTS SCIENCE, CHULALONGKORN UNIVERSITY, 2 THE UNIVERSITY OF TEXAS AT AUSTIN, 3 EXERCISE PHYSIOLOGY IN SPECIAL POPULATION RESEARCH UNIT, CHULALONGKORN UNIVERSITY

INTRODUCTION: The effects of trail running on neuromuscular function and muscle fatigue are not fully understood primarily because the evaluation of such function in trail runners is challenging in field settings. The present study aimed to compare the impact of simulated and field trail running races on neuromuscular function in 26 trail runners (13 females and 42 ± 6 years) with an average of 4.1 ± 1.5 years of trail-running experience. The participants had a maximal oxygen consumption (VO2max) of 42.7 ± 8.1 ml/kg/min measured on a treadmill and knee extension/flexion torque of 144 ± 41/62 ±21 Nm measured on a Biodex machine.

METHODS: A simulated trail running test was conducted in a laboratory, consisting of 30 minutes of uphill running at 75% of heart rate reserve (HRR) and 30 minutes of downhill running at 40% HRR on a treadmill. Transcutaneous electrical stimulation was applied to the femoral nerve before and after the running. The short distance trail running test was run on mountain single tracks with technical rocky sections and a total distance of 18 km with a positive elevation of 1,080 m (located in Khao Chalak, Chon Buri in Thailand).

RESULTS: The results showed that after the treadmill running test, quadriceps maximal voluntary contraction (MVC) and rectus femoris M-wave decreased significantly (p<0.05), indicating total and peripheral fatigue. However, no significant changes were observed in central fatigue as assessed by maximal voluntary activation. After the short distance trail running test, the average time was 279 ± 45 minutes, and counter movement jump (CMJ) decreased significantly (p<0.05). The decreases in MVC observed in the laboratory were associated with the corresponding reductions in CMJ (r = 0.428, p = 0.029) obtained in the field setting, VO2max (r = 0.548, p = 0.004), and knee flexion torque (r = 0.534, p = 0.005).

CONCLUSION: In conclusion, the simulated trail running test produced total and peripheral fatigue but not central fatigue in trail runners. Additionally, maximal voluntary contraction measured after the simulated trail running was significantly associated with counter movement jump obtained after the actual trail running race. This is a first step in creating a useful experimental tool for simulating short trail running and investigating neuromuscular fatigue in this population.

POST-ACTIVATION POTENTIATION AND POTENTIATED MOTOR UNIT FIRING PATTERNS IN THE VASTUS LATERALIS AMONG BOYS AND MEN

MCKIEL, A., WOODS, S., GABRIEL, D., VANDENBOOM, R., FALK, B.

BROCK UNIVERSITY

INTRODUCTION: Post-activation potentiation (PAP) describes the enhancement of twitch torque following a conditioning contraction in skeletal muscle. In adults, PAP is greater in muscles with a higher percentage of type-II fibres1 and PAP-related augmented contractility is accompanied by a decrease in motor unit (MU) firing rates (MUFRs)2. Children may have lower PAP due to lower type-II muscle fibre composition3 and lower activation of their higher-threshold (type-II) MUs compared to adults4. The purpose of this study was to examine PAP and MU firing patterns of the potentiated knee extensors in boys and men.

METHODS: Twenty-three boys (10.5±1.3 years) and 20 men (23.1±3.3 years) completed familiarization and experimental sessions. Maximal isometric evoked-twitch torque (Digitimer stimulator model DS7AH) and MU firing patterns during

submaximal contractions (20% and 70%MVC) were recorded before and after a conditioning contraction (5s MVC). PAP was calculated as the percent-increase in evoked-twitch torque after the conditioning contraction. MU firing patterns were extracted from the vastus lateralis using Trigno Galileo surface electrodes (Delsys Inc) and decomposition algorithms (NeuroMap, Delsys Inc). MU action potential amplitudes (MUAPamp) and MUFRs were calculated for each MU found during the submaximal torque traces. For each participant and trial, exponential MUFR vs. MUAPamp relationships were calculated. The y-intercepts and rates of decay for these relationships were extracted to estimate changes in firing rates with potentiation. Age-related differences in PAP data were analyzed using independent t-tests and MU data were analyzed using 2-way mixed-model ANOVAs.

RESULTS: PAP was higher in men (98.3±37.1%) than in boys (68.8±18.3%) (p=0.002). There was a significant decrease in the rate of decay of the MUFR vs. MUAPamp relationships in both the 20%MVC (p=0.009) and 70%MVC (p=0.001) contractions in the potentiated relative to the unpotentiated state, reflecting a decrease in MUFRs with increasing MUAPamp following potentiation. This decrease was greater among boys during 70%MVC contractions (p=0.017).

CONCLUSION: It is concluded that despite greater PAP in men, similar or even smaller MUAPamp-dependent reductions in MU firing rates occur during low and high-intensity contractions, respectively, in men compared with boys. These differences may be related to children's lower fatiguability5 and potentially lower functional type-II muscle fibre pool4.

SOLEUS RESPONSES TO TRANSCUTANEOUS SPINAL CORD STIMULATION SHOW SIMILAR CHANGES THAN H-REFLEX IN RESPONSE TO TENDON VIBRATION

GRAVHOLT, A., PFENNINGER, C., GROSPRETRE, S., MARTIN, A., LAPOLE, T.

JEAN MONNET UNIVERSITY

INTRODUCTION: Recording of the H-reflex through percutaneous electrical stimulation is widely considered the go to method for investigating changes in spinal loop excitability following an intervention (Zehr 2002). Yet, it remains difficult to evoke H-reflexes in a large variety of muscles and it is further limited by the very localized effect, necessitating several setups to investigate more than one muscle within the same experiment. Recently, the use of transcutaneous spinal cord stimulation (TSCS), a method in which one stimulates the lumbar part of the spinal cord to elicit muscle responses throughout the lower limbs, has been proposed as a viable alternative to prevent these limitations (Saito, Masugi et al. 2019). Although H-reflex and TSCS responses are thought to involve the same neural pathways, it remains to be verified if those two responses behave the same in response to a given intervention. In this study, we therefore aimed at comparing the effect of Achilles tendon vibration on soleus TSCS and H-reflex responses. It was hypothesized that the two modes of spinal cord excitability investigation would be similarly sensitive to the vibration-induced depression.

METHODS: Fifteen healthy participants enrolled in this study. Participants were tested at baseline (PRE), during Achilles tendon vibration (VIB) and after 20 min of vibration (POST). Right Soleus EMG responses to tibial nerve stimulation (H-reflex) and TSCS were recorded at each timepoint, their size being matched at PRE and expressed as a percentage of maximal M-wave. Care was taken that effective stimulation intensity was comparable across timepoints.

RESULTS: Both H-reflex and TSCS responses decreased in VIB (pooled mean decrease: -73%) and POST (pooled mean decrease: -32%) when compared to PRE-values ($p < 0.05$ both). Vibration-induced changes in responses amplitude correlated well throughout the study ($p < 0.05$, coefficient of correlation = 0.65)).

CONCLUSION: TSCS can detect similar changes to those detected by percutaneous electrical stimulation in the soleus muscle of healthy young people, suggesting that the two stimulation modalities share the same neural pathways.

EFFECTS OF TIME-OF-DAY ON MOTOR UNIT FIRING AND MUSCLE CONTRACTILE PROPERTIES IN HUMAN

IGAWA, K.1, HIRONO, T.1, OKUDAIRA, M.1, NISHIKAWA, T.1,2, TAKEDA, R.1, KUNUGI, S.3, UEDA, S.1,4, WATANABE, K.1

1. LABORATORY OF NEUROMUSCULAR BIOMECHANICS, CHUKYO UNIVERSITY 2. GRADUATE SCHOOL OF HEALTH AND SPORT SCIENCES, CHUKYO UNIVERSITY 3. AICHI INSTITUTE OF TECHNOLOGY 4. SUGIYAMA JOGAKUEN UNIVERSITY

INTRODUCTION: Many physiological responses, i.e., hormones secretion or body temperature, have a diurnal rhythm. Diurnal differences of exercise performance such as muscle strength were also well known. Muscle strength are determined by two main factors; the central nervous system and peripheral muscle components. Since both factors can be influenced by various physiological processes, it is necessary to evaluate the time differences of them separately. The knowledges of time-of-day differences would be effective to establish training strategies and to provide higher performance based on diurnal rhythms in neural and muscular components. This study aimed to demonstrate the time-of-day differences of neural excitability and muscle contractile properties in human.

METHODS: Ten healthy young men participated in the present study (age: 22.6±5.1years). At 10:00 (morning), 13:30 (noon), 17:00 (evening), and 20:30 (night), the knee extensor maximal isometric voluntary contraction (MVC) torque and high-

density surface electromyography (HDsEMG) of vastus lateralis, electrically evoked twitch torque, and skin and core (intra-aural) temperature were measured. HDsEMG was recorded during isometric ramp-up contraction to 50**%**MVC. Individual motor unit was detected and tracked among four different times, and firing rate (FR) at 35-45%MVC (median) and recruitment thresholds (RT) were calculated.

RESULTS: Ninety-one motor units were detected and tracked among four different times, totally. There were no significant differences in the maximal strength, RT, or body temperatures among the times. FR significantly changed among the times ($p<0.001$), and those at evening and night was significantly higher than those at morning and noon. Twitch torque significantly changed among the times ($p=0.036$), and those at noon, evening and night were significantly higher than that at the morning.

CONCLUSION: Since we found the time differences in FR and twitch torque, there are a diurnal rhythm in neural excitability and muscle contractile properties. The higher FR at evening and night may be explained by diurnal variations in excitability of the spinal cord and cerebral motor cortex, as well as in the secretion of melatonin and other substances . Whereas, the time differences in twitch torque may be influenced by diurnal variations in core temperature, muscle viscoelasticity, and calcium ion concentrations in sarcoplasmic reticulum . Diurnal rhythms in neural excitability and muscle contractile properties were not consistent, suggesting that different mechanisms may be contribute to each factor. According to these findings, we may be able to establish diurnal rhythm-based training or peaking/tapering strategies. In conclusion, the motor unit FR increased at the evening and night, and the evoked muscle strength by electrical stimulation increased in the noon, evening, and night, allowing us to observe the effect of time-of-day in neuromuscular function.

STIMULATION FREQUENCY: SHOULD WE GO BEYOND WHAT'S NATURAL?

PAISH, A.D., EVES, N.D., MCNEIL, C.J.

UNIVERSITY OF BRITISH COLUMBIA

INTRODUCTION: Despite the understanding that stimulation frequency influences the contractile responses of skeletal muscle, including fatigability, no study to date has assessed force loss across stimulation protocols when all parameters apart from frequency are identical. To limit discomfort, it is common practice for electrical stimulation (ES) frequencies to be two- or three-fold higher than the natural motor unit discharge rates (MUDRs) expected for a given level of force. However, there is evidence that force loss is exacerbated by high- compared to low-frequency ES, which means that unnaturally high frequencies may be ill-suited for protocols that involve repeated or prolonged muscle stimulation (e.g., fatigue, rehabilitation, and training-based studies). The aim of the current study was to compare quadriceps force loss with intermittent ES at frequencies of 10, 15, and 30Hz, which represent the mean MUDR at 25% maximal voluntary contraction (MVC) force (10Hz) and two higher frequencies that have been used in previous studies to evoke this level of force. We hypothesized that the magnitude of force loss will increase with stimulation frequency.

METHODS: Eight healthy, young adults (29±3yr, 173±13cm, 74±14kg; 3 females) completed three sessions of ES separated by at least 48h. To begin, participants performed brief MVCs with the interpolated twitch technique to assess voluntary activation (VA). The ES current was set to evoke a contraction of 25% MVC force, with single trains having 7, 10, and 19 pulses train for 10, 15, and 30Hz, respectively. The intermittent fatigue protocol was 3-min in duration, consisting of 144 contractions, with each contraction separated by 1.25s (0.6s stimulation and 0.65s rest). After the final train, recovery of evoked force was tracked over a 5-min period.

RESULTS: Baseline MVC force (54.9±19.3kg) and VA (95.9±1.9%) were not different across sessions ($p\geq0.231$). At the end of the 3-min protocol, force loss was greater for 30Hz (53.6±4.3%) than 15Hz (40.7±7.3%) or 10Hz (23.3±9.5%), and greater for 15 than 10Hz. After 5min of recovery, peak evoked force returned to baseline for 10Hz, but not 15 or 30Hz (96.6± 9.9, 82.2±9.7 and 75.2±7.8% baseline, respectively).

CONCLUSION: As hypothesized, force loss was exacerbated by increases in ES frequency. Indeed, even with a seemingly modest increase in frequency (10 vs. 15Hz), force loss was nearly doubled. Furthermore, evoked force generation remained impaired for at least 5min following the protocols involving ES frequencies higher than the mean MUDR at 25% MVC force (i.e., 15 and 30Hz). The exacerbated force loss at higher frequencies of stimulation likely reflects greater metabolic cost and myofibril impairment associated with additional E-C coupling cycles.

ECCENTRIC CYCLING AT DIFFERENT PEDALLING CADENCES LEADS TO SIMILAR NEUROMUSCULAR ALTERATIONS BUT DISTINCT PERCEIVED RESPONSES

MATER, A., BOLY, A., MARTIN, A., LEPERS, R.

UNIVERSITÉ DE BOURGOGNE

INTRODUCTION: While the effects of locomotor submaximal eccentric exercise performed on cycle ergometers have been explored since the 50s, characteristics still need to be fully considered. Current equipment allows specific parameters to be modulated, such as power output, mode (isoload or isotonic), or pedalling cadence. The effect of the latter on the neuromuscular alterations remains unknown. A previous study found a greater loss of strength after pedalling at 35 compared to 5 rpm during 5 min. However, as exercises were maximal, power output at the lower pedalling cadence was five times lower than at the higher one. Since the rehabilitation program chose submaximal intensities, longer exercises and higher pedalling cadences, the present study aimed to compare the effects of pedalling cadence of 30 and 60 rpm during 30 min eccentric cycling.

METHODS: Twenty-two participants completed three sessions three weeks apart: 1) a determination of maximal concentric aerobic power and a familiarisation of eccentric exercise cycling and neuromuscular function assessment; 2) and 3) eccentric cycling exercise consisting of 30 min at 60% MAP, at 30 or 60 rpm. Perceived effort (PE) was rated by the participants every 2 minutes. In addition, the knee extensors maximal voluntary contraction (MVC) torque, the torque evoked by double stimulations at 100 Hz and 10 Hz (Dt100; Dt10), and the voluntary activation level (VAL) were evaluated before and after each exercise.

RESULTS: PE was greater and increased more during cycling at 30 rpm than at 60 rpm ($P < 0.01$). MVC and evoked torques decrease (all $P < 0.05$) in both conditions without cadence effect. VAL did not change ($P > 0.082$) for any cadence. Dt10/Dt100 ratio declined ($P < 0.001$) in both conditions without cadence effect.

CONCLUSION: As it was previously found that cycling at 30 rpm caused greater perceived effort compared to cycling at 60 rpm (1), it also appears that 30 rpm led to greater perceived fatigability. However, MVC torque decreased similarly after pedalling at both cadences. The loss of voluntary torque was mainly caused by peripheral alteration, as evidenced by reduced evoked torque, while VAL remained constant. Moreover, we found a decrease in Dt10/Dt100 ratio usually associated with a failure in excitation-contraction coupling due to a reduction in Ca2+ release (2). Therefore, even if performance fatigability was similar in both conditions, as perception of effort could limit peoples engagement in regular physical activity, a rehabilitation program should be proposed at 60 rpm.

SEX-DIFFERENCES IN PERFORMANCE-RELATED VARIABLES DURING A MAXIMAL INTERMITTENT SQUAT TEST PERFORMED ON A FLYWHEEL DEVICE

SALSE-BATÁN, J., ALARCÓN, À., TORRADO, P., MARINA, M.

UNIVERSITAT DE BARCELONA

INTRODUCTION: Flywheel devices (FW) have gained relevance due to their benefits compared to traditional training (1), not only in domains as sports performance and injury rehabilitation, but also in clinical settings. Furthermore, this type of training can elicit larger levels of force and muscle activity in the eccentric phase compared to the concentric phase (2). Despite the increasing number of studies focused on women population in recent years (3), research oriented on sex-differences while using FW maximal testing protocols is still limited. This study aimed to investigate the sex-differences in performance-related variables measured throughout a maximal intermittent squat flywheel protocol (FWsq).

METHODS: Eighteen active young adults (11 women and 7 males) performed a maximal intermittent FWsq consisting of 10 sets of 10 repetitions with three minutes of recovery between sets. Three additional repetitions were performed at the beginning of each set to accelerate the disc and develop maximal momentum. The 10 effective repetitions of each set were averaged. Representative mean power (MP) and work (W) per set were obtained by averaging the values corresponding to the eccentric and concentric phases separately from the 10 repetitions. Both variables were also normalized to body mass (MPBm and WBm). A three-way ANOVA of repeated measures (factors: contraction phase, sets and sex) was used to study the time-course of change of the MP and W, and potential interactions among the two groups. Statistical level of significance was set at $p<0.05$.

RESULTS: In both sexes MP and MPBm decreased significantly throughout the 10 sets ($P=0.005$) and in the two phases ($P=0.018$; $P=0.016$). Significant sets by sex interactions were found in MP ($P=0.021$). W and WBm diminished significantly across the sets ($P=0.001$), with different patterns of fatigue between sexes, confirmed by a significant set by sex interaction ($P=0.005$) and set x phase x sex interaction ($P=0.016$; $P=0.042$).

CONCLUSION: It appears that changes in MPBm along the maximal intermittent FWsq do not differ between men and women. However, larger decrement in MP, W and WBm were observed in men than in women. These data suggest that, among other variables such as strength or speed, MP, W and WBm should be considered when using such devices to compare motor performance between men and women.

KINEMATICAL DIFFERENTS BETWEEN HEALTHY AND SHOULDER-INJURED SOFTBALL PLAYERS

ZINNO, R.1, DI PAOLO, S.1, MAXIME, H.2, MINARDI, A.1, BRAGONZONI, L.1

1.UNIVERSITY OF BOLOGNA, 2. EPF CACHAN SCHOOL OF ENGINEERING, CACHAN, FRANCE

INTRODUCTION: Softball is a sport that is growing in popularity. Injuries related to throw movement are increasing in softball players. The shoulder and elbow constitute the main sites of injuries in professional softball players. To design and prescribe a sport-specific strength and conditioning program targeted at reducing the risk of injury, boosting performance, and improving health and lifespan, it is essential to comprehend softball task mechanics. The aim of the study was to assess the kinematic differences in the upper limb and trunk between healthy and shoulder-injured softball field players.

METHODS: A cohort of 11 first-division softball players (mean age 25.9±8.1) were enrolled in the study. Among the participants, 5 experienced a shoulder injury with consequent surgery while 6 did not report previous shoulder injuries. The shoulder-injured and the healthy groups have been practicing softball for 15.8±7.5 and 18.8±9.3 years, respectively. After a proper warm-up for throwing, the players were asked to perform 3 trials. The players were assessed while performing a typical field motor task, from the moment when they pick up a ball on the ground to the complete throw. For the analysis, the motor task was divided into 2 phases: Pickup, which starts from ball grabbing to throw position; Pass, from hand far in the back to the complete throw. Wearable inertial sensors (Xsens MTw Awinda) were used to collect kinematical data on the shoulder, elbow, and trunk. The kinematical parameters analyzed were peaks joint angle and range of motion (ROM). The data extraction and analysis were made in Matlab. The unpaired T-test was used for comparing the difference between the groups and $p<0.05$ was considered statistically significant.

RESULTS: In the Pickup phase, the shoulder showed a higher internal-/external rotation ROM in healthy players than in injured ones ($p<0.001$). The same results were observed for the elbow flex-/extension ROM ($p<0.01$). Healthy players showed a higher peak of trunk flexion than the injured ones ($p<0.01$). Concerning the Pass phase, the ROM of shoulder internal/external rotation and flex-/extension of healthy players was wider than the injured ones ($p<0.001$). Healthy players showed a higher elbow flexion ($p=0.01$).

CONCLUSION: The shoulder-injured players showed less ROM than healthy ones during the assessed motor task. Kinematics differences were found in the shoulder, elbow, and trunk. Despite being all returned to play at the pre-injury level, the injured players could voluntarily or unconsciously perform the motor task in a more conservative way than the healthy players. The kinematical analysis through wearable sensors could be used to assess compensatory movements in softball and inform the return-to-sport process after shoulder injuries.

AN EMPIRICAL STUDY OF HOW TASK CONSTRAINTS CAN INFLUENCE THE INTERPRETATION OF FUNCTION

KIMURA, A.

JAPAN INSTITUTE OF SPORTS SCIENCES

INTRODUCTION: In darts or ball throwing, the release positions and velocities of the darts or ball (release parameters) may be systematically related [1,2]. The systematic relationship between release parameters reduces the variability of the ball or darts arrival position. However, it should be noted that such a systematic relationship between release parameters does not always increase the success rate of the motor tasks (e.g., hitting rate to the target during the darts or ball throwing). Without recognizing this point, we might incorrectly conclude that the systematic relationship always has the function of increasing the success rate of motor tasks. Here our study will experimentally illustrate that the systematic relationship between release parameters may not increase the hitting rate to the target during ball throwing. Given the results of this experiment, our study attempts to discuss the proper interpretation of function.

METHODS: Twelve right-handed college baseball players participated in the study. Each participant threw 30 baseballs at two different-sized targets (small and large targets) aiming at a target 10 m away from the participants, for a total of 60 balls. Furthermore, the participants threw alternately with an overhand and a sidearm throwing. Therefore, the participants threw 15 balls with overhead throwing and 15 balls with sidearm throwing to a large target out of the 30 balls and did the same to a small target. We identified the systematic relationship between release parameters to reduce the variability of the ball arrival position and to increase the hitting rate to the target by using the method of the previous study [3].

RESULTS: The height of the release position and vertical release velocity were systematically related to reducing the variability of the ball arrival position in the small target. In other words, these release parameters had the function of reducing the variability of the ball arrival position. Furthermore, these release parameters also had the function of increasing the hitting rate. For the large target, the height of the release position and vertical release velocity parameters had the function of reducing the variability of the ball arrival position. However, these release parameters did not have the function of increasing the hitting rate to the target. These findings showed that the function of the parameters may be altered depending on the target size, or task constraints in abstract terms.

CONCLUSION: Our study concluded that the proper interpretation of the function requires the consideration of the task constraints.

THE INFLUENCE OF THE FORCE-VELOCITY MECHANICAL PROPERTIES OF UPPER LIMB ON THROWING PERFORMANCE IN YOUNG EXPERIENCED HANDBALL PLAYERS

ZHANG, Q.S.1,2, EYMARD, N.2, HAUTIER, C.2

1 SCHOOL OF ATHLETIC PERFORMANCE, SHANGHAI UNIVERSITY OF SPORT, SHANGHAI, CHINA; 2 UNIV-LYON, UNIVERSITÉ CLAUDE BERNARD LYON 1, LIBM EA 7424, LYON

INTRODUCTION: Overarm throwing is considered one of the most critical actions in handball sports related to the gain of competition, which requires the players to throw as fast and accurately as possible to score a goal. It is well known that the overarm throw is a typical ballistics movement that requires the athlete to accelerate a given ball as much as possible to reach the highest throwing velocity in the shortest amount of time (1). Although previous studies have proposed fundamental methods for quantifying upper-limb explosive capacity, such as the ballistics bench press, the Force-Velocity (F-V) mechanical properties obtained during the ballistics bench press have not explored its association with the throwing performance. Thus, the present study aimed to investigate the F-V mechanical properties obtained during the ballistics bench press with a different type of throwing performance in handball players

METHODS: Twenty-seven French national second-division male handball players (age: 20.0 ± 3.2 years, height: 180.5 ± 6.3 cm, weight: 73.9 ± 7.9 kg) volunteered for the investigation. Force-Velocity (F-V) mechanical parameters (i.e., theoretical maximal force [F0], velocity [V0], power [Pmax]) of the upper limb were obtained during the single-arm ballistics bench-press for the dominant arm according to the validated method (2). The throwing performance was assessed by the maximal standing and 3-step running throwing velocity using a Stalker ® ATS II radar gun.

RESULTS: The simple linear correlation analysis found that the V0 was significantly correlated with standing throwing velocity ($r2 = 0.51$, $f2 = 1.04$, $p < 0.001$) and 3-step running throwing velocity ($r2 = 0.46$, $f2 = 0.85$, $p < 0.001$). Additionally, a significant correlation was found between the 3-step running throwing velocity and the Pmax ($r2 = 0.18$, $f2 = 0.22$). In contrast, no significant correlation was found between other mechanical properties and throwing performance.

CONCLUSION: The main results of the present study showed the importance of the upper limb F-V profile assessment in predicting throwing performance, especially the V0. In short, the handball players revealed higher V0 during the ballistics bench press, which could also perform the faster-throwing performance. This finding demonstrated that the mechanical parameters obtained from the ballistics bench press should be used to evaluate the upper-limb explosive capacity and allow the coach to design the particular training session to improve the explosive capacity of the upper limb to enhance the throwing performance.

AN ANALYSIS OF KINEMATIC DIFFERENCE BETWEEN SUCCESSFUL HURDLE STEP AND BAULK IN 3M SPRINGBOARD DIVING

PARK, J., KANG, J., KIM, J., PARK, S., YOON, S.

KOREA NATIONAL SPORT UNIVERSITY

INTRODUCTION: In springboard diving, which is one of the diving competitions, a certain approach called hurdle step must be performed. Although the baulk in which the stop of jumping due to incorrect performance of hurdle step by divers happens often, a clear kinematic difference between successful hurdle step performance and baulk has not yet been identified. The purpose of this study was, therefore, to identify the difference between successful hurdle step performance and baulk.

METHODS: Ten finalists for the 3m springboard at the National Sports Festival (age: 23.4±3.4 yrs.; weight: 64.9 ±5.6 kg; height: 170.1±5.8 cm; Career: 10.6±2.4 yrs) participated in this study. The motions to be analyzed were limited to those with a difficulty level of 3.0 or higher, and baulks motions were compared with hurdle step motions performed in trials with a skill score of 7.5 or higher. The hurdle step motions were recorded using six video cameras (sampling rate: 60Hz). To set the spatial coordinates, DLT camera calibration was performed around the springboard. 14 body joint points were digitized using the Kwon 3D XP (Visol, Korea) program. In this study 4 events were set for analysis (E1: hurdle step contact, E2: maximum springboard depression, E3: hurdle step take off, E4: highest jump point). A paired t-test was conducted to compare the kinematic differences between two groups and the statistical significance level was set at $\alpha=.05$.

RESULTS: The results showed that the difference in CoM velocity between two groups was statistically significant at E3: the backward velocity in the baulk (-0.01 ± 0.07 m/s) was faster compared to that in the successful hurdle step (0.12 ± 0.04 m/s). They also showed that the difference in the take off angle between two groups was statistically significant at E3: the take off angle in the baulk (-7.74±1.44°) was bigger compared to that in the successful hurdle step (-6.55±1.55°), showing the non-perpendicular jump angles.

CONCLUSION: Since the huddle jump performed immediately after the hurdle step is a forward jump, it is estimated that the take off angle greatly deviating from the perpendicular and the backward movement of the CoM have a negative effect on the successful performance of the technique. Therefore, the divers that recognized the backward movement of the CoM during the hurdle step are likely to commit baulk without connecting hurdle step to jump in the hurdle step.

KINEMATIC PROPERTIES OF JUDO ATHLETES WHEN PERFORMING THE THROWING TECHNIQUE UCHIMATA.

MATSUI, T.

TEIKYO UNIVERSITY OF SCIENCE

INTRODUCTION: Severe neck injury of attacker in judo (tori) often occurs in the situation where tori tries to throw the opponent (uke), caused by direct hitting of the head against mat (tatami) resulting in hyperflexion of the cervical vertebrae, especially in uchimata. However, there is no sophisticated instruction method to teach uchimata based on the detailed kinematical analysis. In addition, most previous studies exhibiting the kinematical feature of uchimata have focused on the movement of tori when the opponent makes no resistance. Thus, the purpose of the present preliminary study was to compare the kinematic features of tori under two conditions where uke intends to resist being thrown or not.

METHODS: Two female judo athletes（subject A and B）whose specialties are uchimata participated in the All Japan University Tournament were recruited as tori (left kumite). They conducted two different practices: yakusoku rensyu (uke is thrown by tori with no resistance) and jiyu rensyu (uke resists being thrown by tori, like a real match). In each judo practice, we collected 3D coordinate values of toris body analysis points from the captured video using FrameDias-6 for one trial to throw. The analysis interval was set from the time when tori took off her left foot to take the first step, until ukes back touched tatami after thrown by uchimata. The three phases of toris movement were categorized as follows: "kuzushi" until toris left foot touches the tatami, "tsukuri" until toris right foot touches the tatami, "kake" until ukes back hits against tatami. Forward trunk inclination angle in the sagittal plane was measured by connecting a perpendicular line from the superior tip of the greater trochanter to the tatami and a line from the superior tip of the greater trochanter to the top of the head. The angle formed by lines connecting the top of the humerus head, the epicondyle of the humerus and the scaphoid was defined as the elbow joint angle.

RESULTS: In both subject A and B, maximal forward trunk inclination angles were observed in kake phase regardless of whether uke resist to being thrown. In subject A, values of the forward trunk inclination angle were obviously greater with resistance (average±SD, 110.7±7.2 deg; maximum, 119.1 deg) than without resistance (average±SD, 78.1±22.0 deg; maximum, 110.2 deg). Additionally, subject B also showed a greater angle with resistance (average±SD, 131.3±12.7 deg; maximum, 148.6 deg) than without resistance (average±SD, 96.6±21.0 deg; maximum, 120.9 deg).

CONCLUSION: From these preliminary results observed in two judo experts, the forward trunk inclination angle of tori is apparently large when uke resists being thrown and the maximal angle might be derived in kake phase. In other words, if uke resists being thrown by uchimata, the possibility that tori falls into tatami from the top of the head causing to overflex the cervical spine increases as previous studies have expected.

FIXING THE FIRST BOUNCE IN TABLE TENNIS SERVE

KUO, C.Y., LIN, Y., LIN, T.C., GUO, C.W., CHU, H.H., HUANG, C.C., LIN, J.F., LAI, H.Y., CHEN, Y.H.

NATIONAL TAIWAN SPORT UNIVERSITY

INTRODUCTION: In table tennis, the serve length can be usually distinguished by its first bounce point. That is, a short serve first bounces close to the net, whereas a deep serve first bounces close to the endline. Recently, top players seem to reduce such differences by fixing the first bounce of serves. However, the current understanding is limited. Moreover, whether rotation of the serve has an impact on this strategy (fixing the first bounce) remained unknown. Therefore, the aim of this study was to investigate the bounce location of short and deep serves with different rotation types, with and without using this strategy.

METHODS: We recruited 2 male national representatives as participants. They were asked to perform short and deep serves, with 2 types of rotation (no rotation and backspin), with and without fixing the first bounce, each with 20 serves. The bounce location of each serve was recorded with a videocamera from the bird's eye view, and then input to Kinovea for tracking the bounce location in x-axis of the table. Two sets of three-way (2 ways of serve x 2 serve lengths x 2 serve rotations) repeated measures ANOVAs were performed to examine the serves of the two participants under different manipulated conditions separately. The significance level was set at alpha =.05.

RESULTS: For both players, there were significant serve length x strategy interaction effects [$F(1, 19) = 431.466$, $p < .001$; $F(1, 19) = 1.155$, $p = .296$, for player #1 and player #2, respectively]. These results revealed that both players could successfully fix or differentiate the first bounce locations between short and deep serves when they were asked. Moreover, there were significant three-way interaction effects [$F(1, 19) = 5.911$, $p = .025$; $F(1, 19) = 6.041$, $p = .024$, for player #1 and player #2, respectively]. Post hoc comparisons indicated that for player #1 when serving short in standard way, the first bounce location of serves without rotation was closer to the table compared to serves with backspin. On the contrary, when serving short by fixing the first bounce, the first bounce location of serves without rotation was closer to the net compared to serves with backspin. For player #2, the differences were found when serving short by fixing the first bounce. That is, the first bounce location of serves without rotation was closer to the table compared to serves with backspin.

CONCLUSION: Our results revealed that top players successfully fix the first bounce of serves between short and deep serves, and this might be difficult for the opponent players to anticipate their serve length by observing the first bounce.

The serve rotation seemed to have an impact on the first bounce location, but the differences between different rotation types were within 5 cm. Whether they are empirically important needs future study to further investigate.

EARLY DEVELOPMENT IN YOUTH SWIMMING? A CATEGORISATION OF MATURITY STATUS AND RELATIVE AGE EFFECTS

CRAMER, L., STAUB., I., BIEDER, A., VOGT, T.

KREISSPORTBUND DÜREN E.V. AND GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: In talent identification, recent investigations provide data contributing to research on the relative age effects (RAE) and its relation to biological maturity (Deprez et al., 2013; Müller et al., 2016). These studies have shown no significant differences in maturity-related characteristics (i.e., age of peak height velocity; APHV) between the four age quartiles (Q), regardless of gender. Therefore, relatively younger swimmers may be able to counteract their relative age disadvantage if they have the same biological maturity status as their somewhat older counterparts. Thus, an in-depth analysis was conducted to categorise the swimmers into early, normative, and late-developed athletes. Whether the sample tends to include early developers because the parameter APHV cannot provide insight into the biological maturity categorisation remains to be elucidated.

METHODS: 650 German state-level swimmers (age 11.00 ± 1.27 years; female n=377, APHV: 11.56 ± 0.46; male n=273, APHV: 13.31 ± 0.61) were categorised into three groups of biological maturity (late, normative vs early) based on APHV's mean (M) ± standard deviation (SD), regarding gender (normative: APHV = M ± SD; early: APHV < M – SD; late: APHV > M + SD). To analyse the difference between the expected standard normal distribution and the observed relative frequency distribution [%] of early, normative, and late-developed athletes for the male and female sample, Chi-square tests were computed ($p<.05$).

RESULTS: Female athletes were normative developers if they had an APHV between 11.10 and 12.02 years (male: APHV = 12.70-13.92), early developers if their APHV was less than 11.10 years (male: APHV < 12.70), and late developers with an APHV higher than 12.02 years (male: APHV > 13.92). Most athletes (70.31%) were normative developers, 14.92% were early developers, and 14.77% were late developers. The percentage distributions of the developmental categorisation did not differ significantly from the expected standard normal distribution in both gender (male: $p = .753$, female: $p = .193$).

CONCLUSION: The findings indicate that the sample of German youth swimmers only includes a small proportion of early developers on average. At the same time, there are conspicuously few late developers born in Q4. Therefore, it can be assumed that relatively younger swimmers can counteract their disadvantage only with an early or normative biological maturity status, which significantly impacts swimmers talent identification and development.

PHASE ANGLE IS A PREDICTOR OF PERFORMANCE IN SWIMMING

MATIAS, C.N.1, REIS, J.F.2,3,4, CAVACA, M.L.3,4, MENDES, F.4, CUNHA, P.1, MORGADO, J.P.1

1CIDEFES - UNIVERSIDADE LUSÓFONA, LISBOA, PORTUGAL; 2CIPER, FMH; 3PORTUGAL FOOTBALL SCHOOL, PORTUGUESE FOOTBALL FEDERATION, FPF, OEIRAS, PORTUGAL; 4FMH

INTRODUCTION: Preparation for major competitions in swimming involve monitorization of physical and physiological measures along the season, where overload periods are followed by a reduction of training load, or taper. Taper is designed to obtain peak performance in the main competitions. It is associated with increased muscular strength, power, fiber size, and glycogen storage, affecting intracellular water volume, and body composition.

Bioelectrical impedance analysis (BIA) is a non-invasive, cheap and practical field measurement that allows for evaluation of body composition and phase angle (PhA). PhA has been suggested as an indicator of nutritional status, cellular integrity, and muscle quality and as a predictor of the competitive level/sports performance of athletes. It is obtained through the raw data (resistance (R) and reactance (Xc)) representing cellular health, as R arises from water intra and extracellular compartment, while Xc appears from cell membranes lipidic structures.

Our two-aim study intended, to verify if PhA is a predictor of performance, more specifically of 100m swim time simulation, along a 3-month training macrocycle; and to attest the existence of correlations between PhA and body composition, strength, and performance variables, in young swimmers.

METHODS: 20 youth age group swimmers (11 females, 9 males; 13-15 yrs.) were evaluated in 4 moments (M) of a winter macrocycle: M1, 3rd wk of the season; M2, 8th wk, after a period of elevated volume and high aerobic capacity loads; M3, 13th wk after a progressive decrease of volume and increase of aerobic power and anaerobic loads; and M4, 14th wk, after the 1st wk of taper. Athletes were assessed for phase angle (PhA), whole-body composition [fat free mass (FFM, kg), fat mass (FM, kg)] and water compartments [(total body water (TBW, kg), extracellular (ECW, kg) and intracellular water

(ICW, kg)] using bioelectrical impedance raw data or BIA-based equations for athletes, previously developed from our group. Regarding performance athletes were evaluated for forearm maximal isometric strength using a portable dynamometer and performed an all-out 4x25m front crawl on a 30s cycle. Time at each 25m (T25, s) was recorded and 100m total time was calculated [T100 (s)].

RESULTS: A positive correlation of PhA with FFM, TBW, ECW, ICW, and handgrip was observed. Also, a negative correlation with FM and T100, average T25 and minimum T25 was found. PhA itself explained T100 between 26.8% (in M3) and 49.4% (M4).

CONCLUSION: Our results show that phase angle, being an indicator of cellular integrity and muscle quality, is a good predictor of performance (T100) in short distance races and is representative of the peaking throughout a macrocycle culminating with the swimmers' personal best performance. Also, should be acknowledged that swimmers with more FFM and less FM have better performance and higher PhA.

THE RELATIONSHIP BETWEEN LOAD-VELOCITY PROFILES AND SPATIOTEMPORAL PARAMETERS IN ELITE 100 M AND 200 M FREESTYLE SWIMMERS

RAINETEAU, Y.1,2, PETERSON SILVEIRA, R.1, BIDEAU, B.1, BIDEAU, N.1, PLA, R.1,2, NICOLAS, G.1

1 UNIVERSITÉ RENNES 2, RENNES, FRANCE; 2 FÉDÉRATION FRANÇAISE DE NATATION, CLICHY, FRANCE

INTRODUCTION: Power, strength and speed assessment is of great interest when monitoring swimming performance (1). In this perspective, semi-tethered swimming tests are commonly used to evaluate dynamic parameters based on load-velocity (L-V) profiles in conditions consistent with free swimming (2). Maximal predicted velocity (V0) and maximal predicted load (L0) assessed by a L-V profiling, has been reported respectively as strongly and moderately correlated with the mean velocity in the 50 m butterfly (3) as well as the 50 m freestyle (4). Nevertheless, it is unclear if L-V profiling is associated with performance in other distances. Therefore, the aim of this study was to test the correlation between load-velocity profiling and performance parameters in the 100 m and 200 m freestyle events.

METHODS: Seven male elite swimmers (100 m freestyle best time: 51.17 ± 1.04 s; 770 ± 49 FINA points) completed a freestyle load-velocity profiling using a resisted sprint protocol. Swimmers were asked to swim four all-out distances (25, 25, 20 and 15 m) against increasing loads (0.1, 2.0, 4.0 and 6.0 kg respectively). Average swimming speed was obtained from three cycles on the middle of the sprint (4). V0, L0 and the slope of L-V linear regression were computed from the testing session. Swimmers competed the 200 m & 100 m freestyle events in a 50 m pool within 3-4 days after the tests, at an international competition. Video analysis of both races were performed to compute average values of speed (Vmean), stroke length (SL) and stroke rate (SR). The normality of all variables was verified using a Shapiro-Wilk test and Pearson correlations were computed between race performance parameters and L-V results (α=5%).

RESULTS: Main results show that, on the 100 m, SR and V0 as well as SL and L0 have a low negative correlation (r= -0.13 and r= -0.46 respectively). On the other hand, on the 200m, SR and V0 as well as SL and L0 show large positive correlations (r= 0.69 and r= 0.53 respectively). Slope has also a large correlation with Vmean on the 100 m (r=0.59) but a trivial correlation with Vmean on the 200 m (r= 0.09). Other results indicate a nearly perfect correlation of SR in the 100m with L0 (r= 0.91) and Slope (r= 0.91).

CONCLUSION: It appears that the correlations between L-V profiling and performance parameters differ depending on the race distance, each one involving specific physiological and biomechanical constraints. Indeed, this conclusion could be related to active drag as the correlation between the slope of the L-V regression, which is described as an indicator of drag (5), and the average speed over 100 m is strong whereas negligible with the average speed over 200 m.

VALIDATING LABORATORY-BASED EXERCISE TESTING FOR SPORT-SPECIFIC PERFORMANCE IN RECREATIONAL SCUBA-DIVING

CETIN, D., JACOBI, E., HOFFMANN, U., VOGT, T., MÖLLER, F.

GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: Improvement of physical fitness increases safety for all underwater activities with higher reserves during unexpected and rescue scenarios (Bosco et al., 2014). Many diving-related accidents are caused by poor physical conditioning (Lynch & Bove, 2009). However, medical examinations mandatory in SCUBA diving include only laboratory-based bicycle exercise, neglecting sport-specific factors and physiological adaptations to water immersion (Astrand, 1984). Thus, the transfer to underwater performance is critically mitigated. Although in-water testing should be preferred (Steinberg et al., 2011), we hypothesized incremental bicycle exercise in the supine position to mimic submersion-induced blood-shift and closely match the physiological reactions of underwater exercise testing with SCUBA (Toska & Eriksen, 1994).

METHODS: 15 experienced SCUBA-divers (age: 28 ± 6.4) conducted incremental exercise-testing on two separate days: In the laboratory, exercise was conducted on a bicycle ergometer in the supine position, starting at 50W and increasing intensity by 25W every 3 minutes until exhaustion. Underwater, incremental fin-swimming exercise testing was conducted

(fin-swimming with SCUBA, 4m water depth), starting with 0.4m/s, velocity increased by 0.1m/s every 3 minutes. Measurements were performed continuously (heartrate (HR), minute ventilation (VE)) and following every exercise step (blood lactate concentration (lac), rate of perceived exertion (RPE)). Values of HR, VE, RPE, and lac were investigated with Wilcoxon pairwise comparisons for rest, max, and recovery values (1, 3, and 5 minutes after stop of exercise for lac; HR until 5 minutes after stop of exercise). Statistical significance was set to 0.05.

RESULTS: For maximum values, significant differences were observed for VE max ($p < 0.001$; effect size $r = 0.85$), RPE max ($p < 0.001$; $r = 0.91$), and lac ($p = 0.006$; $r = 0.7$). No significant differences were found for HR max ($p = 0.121$).

CONCLUSION: Findings show persisting differences between underwater exercise and lab exercise, even in the supine position. However, because HR does not differ significantly, it can be assumed that participants were equally stressed in both conditions. Data might enable an improved transfer from lab to underwater. Still, sport-specific factors like water immersion and movement technique have to be considered and further investigation on underwater performance assessment is required.

THE PERFORMANCE EFFECT OF AGE ON IRONMAN HAWAII MALE AND FEMALE AMATEUR TRIATHLETES

PUCCINELLI, P.1, SACCHELLI, A.N.2, SEFFRIN, A.1, KNECHTLE, B.3,4, WEISS, K.3,4, ANDRADE, M.S.1

1 DEPARTMENT OF PHYSIOLOGY, FEDERAL UNIVERSITY OF SÃO PAULO, BRAZIL 2 FEDERAL UNIVERSITY OF SANTA CATARINA, BRAZIL 3 MEDBASE ST. GALLEN AM VADIANPLATZ, ST. GALLEN, SWITZERLAND 4 INSTITUTE OF PRIMARY C

INTRODUCTION: The effect of age in endurance athletic performance is already well stablished. However, it is not known whether the effect of aging is similar in both sexes. Therefore, the aim of the present study was to examine the performance effect of age on Ironman Hawaii male and female amateur triathletes from 2003 to 2019.

METHODS: 30,354 amateur triathletes were selected using the OBSTRI website. For further analysis, a "TOP 5" division filter was applied, which resulted in a total of 1,851athletes being included in this study. Moreover, Kruskal-Wallis non-parametric test with independent variables and pairwise comparison was used to analyze the impact of age group and overall time. Differences found were investigated with the Posthoc Bonferroni test. The level of significance was set at 0.05. SPSS version 26.0 (SPSS, Inc., Chicago, IL, USA) was used for all statistical analyses.

RESULTS: Female age group 18-24 years seemed to present higher overall race times than in 25-29 age group as for their male counterparts. There were no significant performance differences ($p>0.05$) between age groups 25-29 and 40-44 years for both sexes. Moreover, in agreement with the pattern observed in male age groups, the female age groups between 25-29 years and 40-44 years showed a plateau in performance. In addition, female triathletes had this plateau broken at the same age as males, in the age group 45-49 years. As the athletes started to get older, a significant difference ($p>0,001$) in performance started to appear when compared to the previous decade (e.g., 45-49 vs. 35-39, 50-54 vs. 40-44, 55-59 vs. 45-49 and continued until 70-74 years).

CONCLUSION: The main finding of the present study was that the aging effect on performance is similar in male and female athletes. The best overall race times were found between the age groups 25-29 and 40-44 for both sexes. The expected performance decline because of aging was observed after 45 years for both sexes. The predicted starting age of the decline in performance was correct. The investigation showed that the youngest age group (18-24 years) presented a significant performance improvement when it got older. This reinforces the notion that experience gain and physical training are significant contributors to the final performance.

When comparing the decades of life for both male and female groups, the differences start to appear significantly, suggesting that race times gradually get slower with the advanced age. These findings align with the expected physiological and functional capacity of aged participants and the peak performance in endurance sports of older athletes for both sexes.

IMAGERY AND PERFORMANCE DURING JUMPS IN WOMEN'S ARTISTIC GYMNASTICS: PRELIMINARY FINDINGS

VEIT, J., VOGT, T.

GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: In artistic gymnastics, the athlete's performance depends not only on motor abilities and technical skills but also on psychological abilities [1]. In general, motor and visual imagery is widely accepted as a strategy to enhance performance, also in gymnastics [3]. Based on the effects of two different visual perspectives (i.e., external-visual, internal-visual) and kinesthetic imagery, the aim was to investigate gymnasts' preference of a specific imagery modality. We assume, more vivid imagery enhances gymnastic jump performance.

METHODS: Women's artistic gymnasts were tested for their vividness of movement imagery using the Vividness of Movement Imagery Questionnaire (VMIQ-2, [2]); participants aged 14 to 24 years (n=30; mean 20 ± 3 years) were subdivided

into three groups (n=10) with imagery preferences respectively: external-visual (VMIQ-2 = 1.30 ± 0.32), internal-visual (VMIQ-2 = 1.53 ± 0.40), or kinesthetic (VMIQ-2 = 1.76 ± 0.88). Participants performed 6 stretched jumps with 450° turn. Crucial gymnastic-specific performance criteria such as jump height (optojump) as well as body position and landing (kinovea) were videotaped and analysed.

RESULTS: Findings following ANOVA indicated no significant differences, neither in performances between groups (i.e., jump hight: p=0.920, body position 1: p=0.394, landing 1: p=0.719) nor for expertise (p=0.768) or age (p=0.721). There were no correlations between imagery vividness and performance (jump hight (r=-.099; p=.603; n=30), body position 1 (r=-.048; p=.802; n=30), landing 1 (r=-.127; p=.505; n=30)), the expertise (r=-.087; p=.647; n=30) or age (r=-.107; p=.575; n=30).

CONCLUSION: Possibly missing group differences connected to the movement quality in gymnastic jumps can be explained because one may not be able to transfer the VMIQ-2 from general movements to gymnastic-specific performances (i.e., jumps). With each participant being able to solidly perform the jump, the lack of preference for a particular imagery modality may be due to similar expertise [4]. Further, absent performance differences depend on imagery intensity, causing similar imagery vividness for all participants. Alternatively, modality and vividness of motor imagery is very individual. Suppose imagery is to be considered for training, e.g., for different forms of coaching instruction, the preferred imagery modality must first be tested individually, to be adequately used.

EFFECT OF CLASSICAL MUSIC ON BALANCE, EMOTIONAL STATE AND PERCEIVED EFFORT ON YOUNG PRECOMPETITIVE ARTISTIC GYMNAST AND TRAMPOLINE ATHLETES

DALLAS, G., STAVROPOULOU, E.F., TOLI, D.I., DALLAS, C.

KAPODISTRIAN UNIVERSITY OF ATHENS

INTRODUCTION: Artistic gymnastics (AG) and trampoline (TR) are two Olympic sports where balance is a basic factor of successful execution [1]. Listening to music can elicit emotions, help recall memories, reduce stress, and improve exercise performance [2]. The purpose of the study was to examine the effect of classical music on balance, emotional state and perceived effort on precompetitive young artistic gymnast and trampoline athletes after a six-week training program.

METHODS: Thirty-six athletes (20 AGs and 16 TRs) were separate randomly into two equal groups; music (Experimental group: EG) and no music (Control goroup: CG). Trampoline athletes performed all exercises on a trampoline whereas artistic gymnasts performed their exercises on floor. During the 6 weeks, the athletes completed the questionnaire before and after each training session; and before and after evaluation test as well. Balance ability was assessed with Balance Error Scoring System (static balance) and Y- Balance test (dynamic balance). Before and after intervention the questionnaire RPE-FS with perceived fatigue scale and emotion scale was completed. A 2 x 2 x 2 ANOVA method with repeated measures on the third factor was used. In cases where an interaction between factors was found, the main effect was examined with the Bonferonni correction. A dependent samples t-test analysis was also performed to determine group differences on the dependent variables of emotional state and perceived fatigue.

RESULTS: A statistically significant improvement in static and dynamic balance in athletes of both sports ($p < .05$) was revealed with the percentage of improvement of AGs being comparatively higher than that of TRs. Also, there were significant differences in individual measures of emotional state and perceived fatigue in the examined sample.

CONCLUSION: EG on AGs showed greater improvement in static balance compared to TRs, whereas EG on TRs revealed greater improvement in dynamic balance compared to AGs. It was speculated that the nature of sport affect in a different way athletes balance. Conclusively, classical music differentiates the rate of performance improvement in pre-competitive young athletes in these two sports.

A STUDY OF ARRANGEMENT OF SIDE DISHES IN BENTO BOXES FAVORED BY JAPANESE AESTHETIC ATHLETES

FUKUDOME, Y.

JAPAN WOMAN COLLEGE OF PHYSICAL EDUCATION GRADUATE SCHOOL

INTRODUCTION: Female aesthetic athletes experience a mental burden about their diets as a result of losing weight. The triad of female athletes (the interaction of three disorders: nutrition, menstruation, and bone decalcification) is complicated. In Japan, bento boxes typically contain rice and side dishes. However, no studies have examined whether the arrangement of side dishes in bento boxes can be adjusted. Therefore, this study aimed to use the technique of visual illusions to determine how the placement of side dishes in bento boxes can ensure peace of mind for aesthetic athletes.

METHODS: Participants comprised Japanese female college students from gymnastics, rhythmic gymnastics, cheerleading, and cheer dance clubs (N=92). They were divided into two groups: those whose weight had reduced (weight loss group, n=28) and those whose weight had increased, those who were maintaining their current weight, and those who were not concerned about their weight (other groups, n=64). A survey on their awareness of the total number of meals,

quantity of staple food items, number of side dishes, and presentation awareness was conducted using an anonymous questionnaire. In addition, we enquired about the preference of the two types of lunch boxes for three groups with the same type of food, amount, and area viewed from above but with different placements. The first, second, and third group consisted of a bento with rice on the left and on the right, a boxed lunch with triangular-shaped rice and inverted triangular-shaped rice, and rice that was placed inside and outside the bento box, respectively. Cross-tabulation of the data of the three groups and question items was performed using the chi-square test.

RESULTS: In the weight loss group, 86% of participants were not concerned about the amount of food they were eating ($p=0.001$). However, 75% had a lower intake of staple foods ($p<0.001$). Approximately 90% of the respondents were aware of eating several side dishes ($p=0.914$). Food arrangement awareness and preference were not significantly different between the two groups ($p=0.810$). Placement of the first group was preferred by around 50% on each side ($p=0.652$). In the placement of the second group, about 80% preferred the bento with triangular-shaped rice ($p=0.187$). In the third group, about 70% preferred bento boxes containing rice because the amount of rice seemed to be small ($p=0.216$).

CONCLUSION: Among aesthetic athletes, those who have lost weight are conscious of eating fewer staple foods. Therefore, the preferred arrangement of the lunchbox is one in which the quantity of rice appears to be less and the number of side dishes is large. It consists of a bento box with triangular-shaped rice placed inside the box. Thus, aesthetic athletes can eat without any mental burden by arranging food such that the amount of rice appears to be less than usual.

MUSCULAR ACTIVATION DURING THE DEMI-PLIÉ MOVEMENT IN ITS DIFFERENT ROLES IN CLASSICAL BALLET

QUADRADO, V., PASSOS, P., FERREIRA, H.

UNIVERSITY OF LISBON

INTRODUCTION: Human movement activities as dance require coordination at the muscular, interlimb and brain level. A basic coordinated movement in dance is the demi-plié, which can be defined as a smooth bending of the knees, while maintaining turnout at the hips and the heels on the floor. Demi-plié acts as a springboard for jumps, and it is critical for high performance turns. However, due to differences in task goals, performing a demi-plié itself and to jump or turn, might have implications in its coordination. There is little scientific description of the demi-plié at the kinematic and muscular activity level, which raises questions regarding changes in coordination varying with the demi-plié task goal. Therefore, in the present study, we analyze EMG to demonstrate differences in muscle activation in relation to different task goals of the demi-plié itself and linked to 4 other ballet movements: demi-plié for vertical jumps (sauté), demi-plié for turning outward (pirouette en dehor), demi-plié for heel rises (relevé), and demi-plié for lateral displacement of the body (sissonne fermée de côté). We hypothesize that different movements linked to demi-plié will show differences in muscle activation.

METHODS: Six classical ballet dancers with at least 8 years of experience, performed the demi-plié on the 5 experimental conditions aforementioned. Participants wore soft ballet shoes, and had no injuries for 6 months prior to the experiment date. EMG data was acquired using 2 BITalino devices via bluetooth, each with 4 channels, placed in the rectus femoris, hamstrings, tibialis anterior, and gastrocnemius medialis of both legs, with sample rate of 100Hz. SENIAM recommendations were applied. Participants performed 5 repetitions of each ballet movement, in random order, with 5 minutes interval between conditions. A metronome at 64bpm was used to set the pace of the demi-plié performance. EMG data was filtered and rectified using Matlab software with personalized designed routine.

RESULTS: The tibialis anterior is active only during the descending phase, and the rectus femoris increase in the end of the descending phase, followed by decreasing activity as the ascending phase begins, with increase activation of the gastrocnemius. Both phases appear to be actively controlled by the quadriceps femoris. Gastrocnemius plays an important role to link other movements in the ascending phase of the demi-plié, reaching its peak contraction as the subsequent movement begins.

CONCLUSION: The descending phase demands great turnout of the hips, alignment between knees and toes, relying on minimum pelvic tilt for stabilizing posture and balance. The ascending phase is often in preparation for subsequent movements, requiring biomechanics adjustments for next steps. Muscle activation varies in both phases, respecting agonist-antagonist muscle function. We confirmed our hypothesis that there are differences in muscle activation when the demi-plié is performed itself and when it is linked to other ballet movements.

THE ACCLIMATION PROCESS OF THE PORTUGUESE RACE-WALKING TEAM IN PREPARATION FOR THE TOKYO 2020 OLYMPIC GAMES

CUPIDO SANTOS, A.1,2,3, AFONSO, J.1,2,3, GASPAR, A.R.2, TEIXEIRA, A.M.1,3, DA SILVA, M.G.2

UNIVERSITY OF COIMBRA

INTRODUCTION: The Walk Race competition of the 2020 Tokyo Olympic Games, was held in Sapporo during summer, were it was foreseen a temperature of 34ºC with high humidity (>70%) for the race time, which means a thermal stress indicator (WBGT)> 31ºC which falls already in the dangerous category. With this type of warning, the acclimation process becomes essential in an athletes sports preparation, not only to improve his/her sport performance but also to preserve the athlete's physical integrity.

METHODS: Two Portuguese Walk Race Team athletes, one male and one female, participated in this study. Both underwent three periods of acclimation compose by six days spaced 15 and 20 days apart respectively. Tests were performed in a climate chamber (CC) (4.5 x 4.5 x 3 m3) located at the Industrial Aerodynamics Laboratory (LAI). The indoor environmental conditions within the CC were imposed through control of the supplied air and the inner wall temperatures and

the tests took place under calm conditions, with air velocities inside the CC lower than 1.9 m.s-1. A treadmill (HP Cosmos) was used where maximum oxygen consumption tests were performed on the first day of each acclimation period using a gas analyser (Metamax cortex), in order to define the work intensity of the following acclimation sessions (60% of VO2 max). Before and after each session, body mass and urine density and temperature were acessed. In addition, heart rate and lactate concentration (Dr. Lange, Germany) and fluid consumption, loss of plasma volume and percentage of loss of body mass throughout each session were controlled

RESULTS: For the same percentage of VO2 max an increase of 13.33% and 14.02% in velocity was recorded, followed by the increase in efficiency, that translated into a decrease in oxygen consumption of 1.5 ml/kg/min and 1 ml/kg/min for the female and male athletes respectively. During the tests mean blood lactate concentration was 1.44mmol/l and 1.36 mmol/l, mean core temperature was 37.6±0.2ºC and 38±0.1 ºC, urine density before exercise 1011.88±3.09 and 1006.7±2.64, after exercise 1010.85±2.62 and 1007.1±2.84, sudation increased 1433ml and 397ml, while % of body mass loss was higher 1.34% and lower 0.08% for female and male athletes respectively. Furthermore, plasma volume loss was lower on the last acclimation period, from 7.01±2.72 to 5.75±0.95 and from 7.42±2.64 to 0.02±2.18 % for female and male athletes respectively.

CONCLUSION: In the acclimation process we found an increase in velocity at 60%VO2max with the same core temperature, and therefore higher efficiency. It was also verified, higher liquid ingestion, decrease in oxygen consumption, decrease in plasma volume lost and decrease in urine density trough the all acclimation process was also found.

In conclusion the physiological adaptations from the acclimation process are key towards performing in these extreme environmental conditions while preventing heat stress related constraints.

CP-AP16 Resistance Training I

DO EXISTING METHODOLOGIES ALLOW EQUALIZATION OF RESISTANCE TRAINING PROTOCOLS?

DESGORCES, F.D.1,2, GREK, M.1,2, TESTA, M.1, RENFREE, A.3, TOUSSAINT, J.F.1,2

1- UNIVERSITÉ PARIS CITÉ; 2- IRMES (INSTITUTE FOR RESEARCH IN MEDICINE AND EPIDEMIOLOGY OF SPORT), INSEP, PARIS, FRANCE; 3- SCHOOL OF SPORT & EXERCISE SCIENCE, UNIVERSITY OF WORCESTER, WORCESTER, UK.

INTRODUCTION: To compare the effects of resistance training modalities, studies equalize their training protocols by prescribing sessions with similar total training volumes (i.e., by intensity×volume calculations) or sessions with a given number of sets performed until momentary muscular failure. The aim of the study was to analyze the relevance of such methods for protocols equalization. A similar individual endpoint was used throughout the study, the exercise maximums were measured in varied resistance training sessions.

METHODS: 12 trained participants performed five sessions at 50 or 85% of one-repetition maximum (1-RM). Sessions' endpoints were determined by the inability to complete a set of at least 50% of the maximal repetitions number. Two sessions were performed with sets until failure and two sessions with sets prescribing 50% of the maximal-repetitions-number, each with 120s of inter-set recovery. The last session was performed at 85% of 1-RM with the inter-set pause reduced to match the density (exercise volume/pause duration) of the 50% 1-RM session with 50% of the maximal repetitions number. Sessions were quantified by using intensity×volume methods (including methods based on ratings of perceived exertion), and methods based on session equalization were applied through use of number of sets/repetitions completed until fatigue.

RESULTS: Sessions resulted in different number of sets until failure and repetitions number ($p<0.05$). Few differences were found in sessions' perceived exertion suggesting that each represented a similar effort. Intensity×volume methods were moderately correlated and reported marked differences between sessions. Sessions' density matching reduces differences in sessions volumes.

CONCLUSION: Despite similar sessions' endpoint sessions volumes markedly changed from one session to another. Equalization from total volume does not consider the slope of the intensity-volume relationship nor the influence of density on that relationship. Protocols equalization based on sets until failure hypothesize that a similar effort is generated whereas significant differences appeared in the ability to accumulate sets. The intensity-volume relationship and exercise density should be considered for equalizing training protocols suggesting to account for individual maximal tolerable volume in the considered exercise.

EFFECT OF REDUCED BALLISTIC TRAINING FREQUENCY ON UPPER BODY MUSCLE POWER, AFTER 12 WEEKS OF SYSTEMATIC BALLISTIC TRAINING

MPAMPOULIS, T.1, METHENITIS, S.1, STASINAKI, A.1, ZARAS, N.2, BOGDANIS, G.1, PASCHALIS, V.1, TERZIS, G.1

1NATIONAL AND KAPODISTRIAN UNIVERSITY OF ATHENS, 2UNIVERSITY OF NICOSIA, CYPRUS

INTRODUCTION: Systematic ballistic resistance training results in substantial increases in muscle strength and power as well as major improvements in various health indices [1]. However, athletes and sports enthusiasts are frequently forced to reduce their training frequency or completely abstain for training for certain periods due to sports-related injuries or lack

of time. Yet, it remains uncertain whether reducing ballistic training frequency might result in preservation of the training adaptations achieved during the systematic training period. The purpose of this study was to investigate the effect of ballistic training once per week or once every two weeks, on muscle power, after a period of 12 weeks of systematic ballistic training performed twice per week.

METHODS: Sixteen young moderately trained women (height 180±2, body mass 80±5), unacquainted with resistance exercise, followed 12 weeks of ballistic bench press training: Smith machine, 2 sessions per week, 4 sets X 6 repetitions, 60% of maximal strength performed explosively (throwing the bar into the air). The training load was increased by 5% each week after the initial 2 weeks of training. Then participants were assigned into 2 groups: group A trained once per week, while group B trained once every two weeks, for another 12 weeks, with the training intensity and volume used at the last training session of the initial 12 weeks. Maximum strength (1-RM) in bench press and muscle power in ballistic elbow extensions from prone position [(ballistic push up (BPU)] were evaluated before (T1), at the end of the 12 weeks of systematic training (T2), after 6 weeks (T3) and after 12 weeks (T4) of reduced training frequency. Statistical analysis was performed with repeated measures ANOVA, with Tuckey post-hoc test, and the level of statistical significance was set at $p \leq 0.05$.

RESULTS: BPU power and 1-RM increased after systematic training (from T1 to T2: 44.3±6.3% and 27.6±3.2%, respectively, $p<0.05$). BPU power decreased similarly in both groups after the first 6 weeks of reduced training frequency (T2-T3, group A: 10.6±2.8%, $p<0.05$, group B: 7.7±2.4 %, $p<0.05$). However, BPU power did not change during the last 6 weeks of reduced training frequency ($p>0.05$). In contrast, 1-RM decreased after the end of the reduced training frequency period only in group B (T2-T4: 7.7±2.4%, $p<0.05$).

CONCLUSION: These results suggest that muscle power of the upper extremities is significantly decreased when ballistic training frequency is reduced to one session every week or one session every 14 days. However, continuation of training with the same intensity and volume may preserve a large part of the muscle power adaptations achieved after the initial training period, in young moderately trained women.

COMPARISON BETWEEN VOLUME LOAD PROGRESSION MODELS IN RESISTANCE TRAINING ON MUSCLE HYPERTROPHY: A RANDOMIZED CONTROLLED TRIAL

LIBARDI, C.A., CHAVES, T.S., SCARPELLI, M.C., BERGAMASCO, J.G.A., DA SILVA, D.G., MEDALHA JÚNIOR, R.A., DIAS, N.F., CARELLO FILHO, P.C., BITTENCOURT, D., ANGLERI, V.

FEDERAL UNIVERSITY OF SÃO CARLOS

INTRODUCTION: It has been suggested that the progression of volume load (VL = sets x repetitions x load [kg]) may influence muscle hypertrophy. However, little is known about the causal relationship between the progression of VL and muscle hypertrophy. In a secondary analysis of studies from our group [1], we demonstrated that the model of progression by load (LOADprog) presented a higher VL progression and muscle hypertrophy than the model of progression by repetitions (REPSprog). Additionally, a correlation was demonstrated between VL progression and muscle hypertrophy. However, the absence of randomization makes it impossible to assign causality to the effects of the VL progression on muscle hypertrophy, especially when associated with a low sample size. Thus, this study aimed to investigate whether LOADprog promotes a higher VL progression and muscle hypertrophy than REPSprog. Additionally, we investigated whether there is a correlation between VL progression and muscle hypertrophy.

METHODS: This prospective, randomized controlled, single-blind, intrasubject study was registered at the National Clinical Trials (RBR-57v9mrb). Twenty men (24±3 years, 73.0±13.5 kg, 176±6.5 cm) and nineteen women (23±4 years, 62.6±8.4 kg, 163±5.4 cm) completed the study. Each participants leg was randomly allocated into LOADprog (4 sets of 9-12 repetitions maximum) or REPSprog (4 sets until muscle failure at 80% 1RM). Both RT protocols were performed unilaterally on the leg extension, 2-3 times a week for 10 weeks (24 sessions). The cross-sectional area of the vastus lateralis muscle (CSA) was assessed before (Pre) and after (Post) the RT period. For the analysis of the VL progression, the averages of the 1st and 2nd sessions (T1) and the 23rd and 24th sessions (T2) were used.

RESULTS: Mixed model analysis indicated only one main time effect for CSA ($F[1, 76]=99.93$; $P<0.0001$). The post hoc analysis revealed that both protocols significantly increased CSA from Pre (LOADprog: 21.34±4.71 cm2, REPSprog: 21.68±4.62 cm2) to Post (LOADprog: 23.53±5.41 cm2, REPSprog: 23.49±5.19 cm2). The mixed model analysis also indicated only one main time effect for VL progression ($F[1, 76]=265.5$; $P<0.0001$). Both protocols significantly increased VL from T1 (LOADprog: 1554±519 kg, REPSprog: 1439±520 kg) to T2 (LOADprog: 2531±853 kg, REPSprog: 2600±1019 kg; $P<0.0001$). There was no significant correlation between the relative change in VL progression and the relative change in CSA ($R=-0.12$; $P=0.29$).

CONCLUSION: LOADprog does not promote a higher VL progression and muscle hypertrophy than REPSprog in untrained individuals. Additionally, VL progression is not associated with muscle hypertrophy. Taken together, these findings suggest that both models of VL progression can be used for this population. Future studies should replicate and expand these findings by analyzing other muscle groups and a more extended training period.

ACUTE IMPACT OF BLOOD FLOW RESTRICTION ON STRENGTH-ENDURANCE PERFORMANCE AND TRICEPS BRACHII MUSCLE STIFFNESS DURING THE BENCH PRESS EXERCISE IN PHYSICALLY ACTIVE WOMEN

LATOCHA, A., NOWAK, M., KRZYSZTOFIK, M.

AKADEMIA WYCHOWANIA FIZYCZNEGO IM. JERZEGO KUKUCZKI W KATOWICACH

INTRODUCTION: One of the training methods used during resistance exercise is blood flow restriction (BFR). This involves applying external pressure via a cuff to the most proximal area of the upper and/or lower limbs. The majority of studies investigating the impact of this method on strength-endurance performance were assessed on single-joint lower-body exercises using low training intensity, while only a few examined the effects of BFR on performance during high-intensity, multi-joint upper-body exercises. Therefore, the main goal of the present study was to evaluate the acute effects of blood flow restriction (BFR) at 80% of full arterial occlusion pressure on strength-endurance performance and stiffness of the lateral head of the triceps brachii muscle during the bench press exercise.

METHODS: The study included 12 physically active women (age: 22.5 ± 1.9 years; body mass: 64.1 ± 7.5 kg; bench press 1 repetition maximum (1RM): 46.7 ± 8.2 kg; resistance training experience: 2.4 ± 1.7 years). During the experimental sessions in a randomized crossover design, the subjects performed five sets of the bench press exercise at 70% 1RM until voluntary failure under two different conditions: without BFR (CON) and with BFR (BFR). The following variables were analyzed: the number of performed repetitions, time under tension, mean bar velocity, and stiffness of the lateral head of the triceps brachii muscle (via myotonometry).

RESULTS: The two-way repeated measures ANOVA didn't show a significant interaction and a main effect of condition for the number of performed repetitions (p=0.939; p=0.613), time under tension (p=0.805; p=0.097), and mean bar velocity (p=0,276; p=0.552). However, a significant main effect of the set to decrease the number of performed repetitions (p<0.01), time under tension (0<0.01), and mean bar velocity (p<0.01) across the workout was found. The three-way repeated measures ANOVA didn't show a significant interaction, main effect of condition, and set for triceps muscle stiffness (p=0.826; p=0.489; p=0.620; respectively).

CONCLUSION: This study shows that blood flow restriction has no acute effect on strength-endurance performance during the bench press exercise in physically active women. Despite no differences in performance between conditions in this study, BFR could potentially cause a significant increase in physiological, hormonal, and metabolic post-exercise responses, as indicated in previous studies.

SPATIOTEMPORAL DIFFERENCES ASSOCIATED WITH VERTICAL AND HORIZONTAL JUMPS IN ELITE ATHLETES.

MONTORO-BOMBÚ, R., MIRANDA-OLIVEIRA, P., SANTOS, A., RAMA, L.

UC: UNIVERSIDADE DE COIMBRA

INTRODUCTION: Plyometric is a training method that aims to improve muscle power. In this method, different ways of analyzing intensity in unilateral and bilateral jumping have been reported (1). However, little has been on spatiotemporal differences in the variables associated with training intensity. These exercises are characterized by an abrupt stretching of previously tight muscles after the brake of a free fall . However, it is not known if the duration times between the eccentric phase (EPT) and the concentric phase (CPT) are similar between DJ over HDJ. It has been reported that DJ does not show significant differences in GCT and flight time (FT) as height increases, but it is unknown if this behavior is the same for HDJ. In this sense, the purpose of this study was to compare the differences in the spatiotemporal variables of the horizontal Drop Jump (HDJ) with the vertical Drop Jump (DJ) in elite jumpers and sprinters.

METHODS: Sixteen international-level athletes were recruited. All performed 2 DJ attempts with ascending order (DJ30, DJ40, and DJ50) and after 2h completed 2 HDJ attempts (HDJV30, HDJV40, HDJV50). A research-grade platform integrated with an infrared optical system allowed to analyze in real-time: GCT, FT, EPT, CPT, and time to maximum concentric peak (T-GRF-2).

RESULTS: It was found that T-GRF-2 can take 45-55 % of the total jump time, regardless of the type of exercise. In HDJ, anteroposterior forces require more time for force production relative to DJ (T-GRF-2 DJ30 = 0.109 ± 0.003 - HDJ30= 0.158 ± 0.003; DJ40 = 0.102 ± 0.003 - HDJ40= 0.134 ± 0.003; DJ50 = 0.115 ± 0.003 - HDJ50= 0.165 ± 0.003). The other associated variables also showed significant differences ($p \leq 0.05$) benefiting DJ.

CONCLUSION: DISCUSSION. The TGRF-2 for the DJ was better than that reported in one previous study (24). We found that the time to the concentric peak of the GRF can take 45-55% of the total time of the jump, which represents that the muscles still must continue force production 45-55% longer after reaching the concentric peak force. Also, our results show that in the HDJ the anteroposterior forces need a longer time to take the peak force production relative to the vertical forces. Other results of the EPT and CPT results show that for both exercises, EPT tends to be significantly lower than CPT. Likewise, EPT is significantly lower in DJ than in HDJ. For CPT, the behavior is not the same, where significant differences are observed only for some sets of heights.

CONCLUSIONS: The findings showed differences between DJ and DHJ. It is suggested that coaches use the DJ to enhance the fast stretch-shortening cycle exercise and the DHJ for slow-type exercises (3). Because of the characteristics of GCT, the HDJ might not favour fast stimuli during the maximal speed phase of sprinting. However, the start and acceleration phase can be favourable, where more TGRF-2 is needed, and contact times are more delayed than DJ.

EXPLORING THE ACUTE AFFECTIVE RESPONSES TO RESISTANCE TRAINING: A COMPARISON OF THE PREDETERMINED AND THE ESTIMATED REPETITIONS TO FAILURE APPROACHES

SCHWARTZ, H., EMANUEL, A., ROZEN SAMUKAS, I., HALPERIN, I.

TEL AVIV UNIVERSITY

INTRODUCTION: In resistance-training (RT), the number of repetitions is traditionally prescribed using a predetermined approach (e.g., three sets of 10 repetitions). An emerging alternative is the estimated repetitions to failure (ERF) approach (e.g., terminating sets two repetitions from failure). Despite the importance of affective responses experienced during RT, a comparison between the two approaches on such outcomes is lacking.

METHODS: Twenty women (age range: 23–45 years) without RT experience completed estimated one repetition maximum (RM) tests in four exercises. In the next two counterbalanced sessions, participants performed the exercises using 70%1RM. Participants completed ten repetitions in all three sets (predetermined condition) or terminated the sets when perceived to be two repetitions away from task-failure (ERF condition). Primary outcomes were affective-valence, enjoyment, and approach-preference and secondary outcomes were repetition-numbers completed in each exercise.

RESULTS: We observed trivial differences in the subjective measures and an approximately even approach-preference split. Under the ERF condition, we observed greater variability in repetition-numbers between participants and across exercises. Specifically, the mean number of repetitions was slightly lower in the chest-press, knee-extension, and lat-pulldown (~1 repetition) but considerably higher in the leg-press (17 vs. 10, $p<0.01$).

CONCLUSION: Both approaches led to comparable affective responses and to an approximately even approach preference. Hence, prior to prescribing either approach, coaches should consider trainee's preferences. Moreover, under the ERF condition participants completed a dissimilar number of repetitions across exercises while presumably reaching a similar proximity to task-failure. This finding suggests that ERF allows for better effort regulation between exercises.

SIX WEEKS OF UNILATERAL FLYWHEEL HIP EXTENSION AND LEG CURL TRAINING IMPROVES FLYWHEEL ECCENTRIC PEAK POWER BUT DOES NOT ENHANCE HAMSTRING ISOKINETIC OR ISOMETRIC STRENGTH.

DE KEIJZER, K.L., MCERLAIN-NAYLOR, S.A., BEATO, M.

UNIVERSITY OF SUFFOLK

INTRODUCTION: Hamstring strain injuries are highly problematic and likely to re-occur. Although injury is likely multifactorial, evidence suggests development of eccentric strength may help performance and reduce likelihood of injury. The use of strength training with an eccentric emphasis and exercises based around both the knee and the hip joint have become more commonplace. Similarly, flywheel training has seen greater integration in sport for performance and rehabilitation and has therefore garnered greater research interest. Although bilateral leg curl and deadlift flywheel training have enhanced hamstring strength and showed interesting findings regarding injury prevention, little is known about unilateral hamstring flywheel training.

The present study aimed to determine whether unilateral flywheel hamstring training (a combination of hip extension and knee flexion exercises) enhances isokinetic, isometric, and flywheel measures more than a control condition.

METHODS: The study involved 11 male university athletes (age 22 ± 2 years; body mass 77.2 ± 11.3 kg; height 1.74 ± 0.09 m) with their legs randomly allocated to flywheel training or control. Eccentric knee flexion torque (60°.s-1), isometric torque (30° of knee flexion), and flywheel unilateral leg curl and hip extension peak power were measured before and after training. Training involved progressive increase in volume or intensity of knee flexion and hip extension exercises.

RESULTS: The intervention enhanced hip extension concentric ($p < 0.01$, $d = 1.76$, large) and eccentric ($p < 0.01$, $d = 1.33$, large) peak power more so than the control (significant interaction effect). Similarly, eccentric ($p = 0.023$, $d = 1.05$, moderate) peak power was enhanced for the leg curl. No statistically significant differences between conditions were found for isokinetic eccentric ($p = 0.086$, $d = 0.77$, moderate) and isometric ($p = 0.431$, $d = 0.36$, small) knee flexor strength or leg curl concentric peak power ($p = 0.339$, $d = 0.52$, small). Statistical parametric mapping analysis of torque-angle curves also revealed no significant ($p > 0.05$) time-limb interaction effect at any joint angle.

CONCLUSION: Unilateral hamstring flywheel training enhances flywheel eccentric peak power. However, coaches should consider strength to be task specific and not translate unanimously between tests. Specifically, no improvements in isokinetic eccentric or isometric (long-lever) hamstring strength were seen. Additionally, practitioners should aim to monitor and use mechanical outputs to guide training and periodisation as significant differences between exercises are evident. The large variation in eccentric overload seen between exercises (larger eccentric overload during leg curl in comparison to hip extension) and sessions supports the need to monitor mechanical outputs during flywheel training. We also present strength adaptations throughout the entire range of motion for the first time after flywheel training using statistical parametric mapping.

EFFECTS OF 8-WEEK HIGH-VELOCITY RESISTANCE TRAINING ON MUSCLE PROPERTIES AND MUSCLE FUNCTION: A RANDOMIZED CONTROLLED TRIAL

WANG, Z., TANIGUCHI, M., SAEKI, J., ICHIHASHI, N.

KYOTO UNIVERSITY

INTRODUCTION: Muscle quality declines earlier than muscle mass [1] and affects muscle function independently of muscle mass [2]. It is critical to understand how muscle quality can be effectively improved to prevent and treat muscle dysfunc-

tion; however, measures to effectively improve muscle quality remain unclear. The present study aimed to investigate the effect of different training velocities on the improvement in muscle quality by comparing the effects of high- and low-velocity resistance training on muscle quality, mass, and function before and after an 8-week intervention.

METHODS: Thirty-three healthy young women (ages; 23.1 ± 2.2 years, height; 159.2 ± 5.7cm, body mass; 20.2 ± 5.8kg) were randomly assigned into two groups: the high-velocity resistance training group (HVRT group, n = 16) and the low-velocity resistance training group (LVRT group, n = 17). Each group underwent concentric knee extension resistance training with a load of 60% one-repetition maximum (1RM), with 10 repetitions per set for 4 sets, 3 times per week for 8 weeks. Before and after the 8-week intervention, quadriceps femoris muscle echo intensity (QFEI), muscle thickness (QFMT), isokinetic strength (60°/s and 300°/s), rate of velocity development (RVD) at 300°/s, and 1RM were assessed. Split-plot factorial design analysis of variance was used to compare the interaction between groups and time.

RESULTS: For QFEI, there was an interaction between groups and time ($p < 0.01$) and a main effect of time ($p < 0.01$). The HVRT group showed a significant reduction in QFEI after the 8-week intervention; however, the LVRT group did not. QFMT revealed only the main effect of time ($p < 0.01$), and both groups showed significant increases in QFMT after the 8-week intervention.

In the results on muscle function, RVD showed a group × time interaction ($p < 0.05$) and a main effect of time ($p < 0.01$), with a significant increase in RVD only in the HVRT group. Isokinetic strength (60°/s and 300°/s) and 1RM showed a main effect of time ($p < 0.01$), both groups showed significant increases in isokinetic strength and 1RM after the 8-week intervention.

CONCLUSION: Significant improvements in QFEI and RVD after 8 weeks of intervention were observed in the HVRT group compared with the LVRT group when performing RT at the same intensity and same number of sets and repetitions. These findings suggest that HVRT is more effective in improving muscle quality than LVRT.

NEUROMUSCULAR RESPONSIVENESS DURING ACHILLES TENDON VIBRATION WHILE STANDING, IN RELATION WITH THE WALKING CAPACITY OF CHILDREN WITH CEREBRAL PALSY

PATIKAS, D.A., PAPAVASILEIOU, A., SAHINIS, C., THEODOSIADOU, A., FABRE, M., AMIRIDIS, I., LAPOLE, T., BAUDRY, S.

ARISTOTLE UNIVERSITY OF THESSALONIKI, GREECE

INTRODUCTION: Cerebral palsy (CP) is a neurodevelopmental disorder characterized by poor postural control and gait [1]. Although deficits in sensory input and processing are well documented in CP [2], the investigation of proprioception in posture and gait is rather limited. Vibration applied on the Achilles tendon (ATV) disturbs proprioceptive input, which can be used to investigate the contribution of proprioceptive inputs in postural control [3]. The purpose of this study was to assess postural and muscular responses in response to ATV while standing, and to investigate possible relation with walking ability in children with CP and typically developed (TD) children.

METHODS: Nine children with CP (12.5±1.7 yrs, 147.3±0.5 cm, 46.1±0.8 kg) and 16 children with TD (14.0±3.8 yrs, 161.2±1.2 cm, 54.8±0.9 kg) performed 10 m walking at comfortable and maximum speed tests, and 2 (for CP) or 6 (for TD) minutes walking (endurance test). Bilateral ATV was applied during standing on a force platform, with eyes closed, for 30 s, while the center of pressure (CoP), trunk acceleration (TrA) and electromyographic responses of the soleus (Sol), gastrocnemius medialis (MGas) and tibialis anterior (TA) muscles were analyzed for 5 s before/after the start and end of ATV. The rate of change of the variables after the start and before/after the end of ATV was expressed as the log2 ratio relative to values before ATV. The correlations between the performance in walking tests and the postural or electromyographic variables were examined with Pearson's r, whereas Spearman's rho was calculated when normal distribution was not granted.

RESULTS: None of the walking tests demonstrates significant correlation with changes in CoP or TrA at any time point of analysis ($p>0.05$). Performance at 10-m walking (comfortable) and endurance test was significantly correlated to the change in Sol and MGas activation after the onset of ATV and before the end of ATV ($p<0.05$). Furthermore, muscle activation did not correlate significantly for the instances before the start and after the end of ATV ($p>0.05$). Furthermore, change in TA activation was not correlated with the performance of any of the walking tests, whereas 10-m walking at maximum speed was also not correlated with any of the examined variables ($p>0.05$).

CONCLUSION: Although motor responses due to ATV were not related to performance in walking, the results of this study indicate that ATV activates more the muscles of children (CP and TD) with less walking capacity. Since walking capacity indirectly reflects the extent of motor deficit in CP, this knowledge may help us linking the effects of ATV with the clinical picture, which might be a useful tool to seek new intervention strategies in CP.

BEYOND THE LUNGS: CAN O2 SUPPLEMENTATION BE BENEFICIAL FOR CEREBRAL OXYGENATION AND FATIGUE DURING EXERCISE IN FIBROTIC INTERSTITIAL LUNG DISEASE?

MARILLIER, M., GRUET, M., BERNARD, A.C., CHAMPIGNEULLE, B., VERGÈS, S., MORAN-MENDOZA, O., NEDER, J.A.

LABORATORY OF CLINICAL EXERCISE PHYSIOLOGY - QUEENS UNIVERSITY

INTRODUCTION: Cerebral hypoxia may exacerbate the perception of fatigue during exercise.[1] We previously demonstrated that activity-related hypoxaemia, a hallmark of fibrotic interstitial lung disease (f-ILD), dose-dependently impairs cerebral oxygenation in this population.[2] The prevailing view is that supplemental O2 may improve exercise tolerance in f-ILD by lessening the hypoxic ventilatory drive and dyspnoea.[3] It remains untested, however, whether part of the ergogenic effects of O2 may be attributable to improved cerebral oxygenation and perceived fatigue in this patient population.

METHODS: Fourteen patients with f-ILD (12 men, 72±8 years, 8 with idiopathic pulmonary fibrosis, lung transfer for carbon monoxide= 44±13% predicted) performed a constant-load (60% peak work rate) cycle test to symptom limitation under medical air (Tlimair). Fourteen controls exercised up to Tlimair of their individually (age- and sex-) matched patient. Later on, patients repeated the test on supplemental O2 (fraction of inspired O2= 0.41±0.08) up to their own Tlimair. Patients were blind to the gas mixture being delivered and arterial O2 saturation by pulse oximetry (SpO2) readings during each test. We used near-infrared spectroscopy and the rating-of-fatigue (ROF) scale to respectively assess prefrontal cortex oxygenation and perceived fatigue.

RESULTS: All patients developed severe exertional hypoxaemia (Tlimair SpO2= 80±8% after 16.9±4.2 min). They showed poorer cerebral oxygenation as indicated by larger deoxyhemoglobin (HHb) [2.9±2.6 (range: 0.0 to 10.8) vs -0.5±0.9 µmol from rest] and had greater perceived fatigue (ROF= 6.2±2.0 vs 2.6±2.3) vs controls under air ($p<0.001$). Reversal of exertional hypoxaemia with supplemental O2 (SpO2= 98±1%) led to a significant decrease in HHb (-0.4±1.3 µmol from rest; no longer differing from controls) and lower ROF scores (3.7±1.2; $p<0.001$ vs air) in patients. Supplemental O2-induced changes in HHb correlated with those in ROF scores throughout exercise in f-ILD (rrepeated-measures correlation= 0.56; 95% confidence intervals= 0.37 to 0.70; $p<0.001$).

CONCLUSION: The beneficial effects of O2 supplementation during exercise in f-ILD are not limited to "the lungs": reversing cerebral hypoxia to lessen perceived fatigue is relevant to enhance exercise tolerance in this patient population.

THE USE OF THE SIX-MINUTE WALK TEST (6-MWT) TO SCREEN FOR SYMPTOMS OF ACUTE MOUNTAIN SICKNESS AND PREDICT SUSCEPTIBILITY DURING A LONG-TERM EXPOSURE IN NORMOBARIC HYPOXIA.

WILLMOTT, A.1,2, EICHHORN, G.1, SWANN, P.1, RICHARDSON, A.1, HAYES, M.1, MAXWELL, N.1

1. UNIVERSITY OF BRIGHTON, 2. ANGLIA RUSKIN UNIVERSITY.

INTRODUCTION: Individuals travelling to altitudes of >2000-2500 m are at increased risk of acute mountain sickness (AMS) and may benefit from undergoing a standardised screening assessment prior to departure. As such, a simple and time-efficient tool for predicting human physiological responses to altitude exposure (both simulated and true), is the 6-minute walking test (6-MWT). The 6-MWT also demonstrates acceptable construct validity when monitoring acclimatisation at terrestrial altitude of ~3400 m, however, it is unknown if this test can predict symptoms of AMS during a prolonged exposure to normobaric hypoxia. Therefore, the aim of this study was to: 1) compare the performance outcome and humans responses towards the 6-MWT between normoxia and normobaric hypoxia; and 2) investigate if the 6-MWT in normobaric hypoxia can predict symptoms of AMS during an 8-hour normobaric hypoxia exposure.

METHODS: Forty-four healthy participants (25 males, 19 females, 31±10 years, 73.9 ± 14.6 kg 174.1 ± 8.0 cm) visited the laboratories on three occasions to complete a normoxic and normobaric hypoxic 6-MWT, and then an 8-hour exposure to normobaric hypoxia at rest. Participants underwent a familiarisation trial and 30-mins rest in each condition before starting the 6-MWT, which was completed in a randomised order. Normobaric hypoxia occurred within an environment simulating an altitude of 4500 m (fraction of inspired oxygen [FiO2]: 12.5%).

RESULTS: A significantly impaired performance (668 ± 83 vs. 725 ± 90 m, $p<0.05$), lower pulse oxygen saturation (SpO2: 75 ± 8 vs. 97 ± 2 %, $p<0.05$) and higher AMS scores via the Lake Louise Questionnaire (1 ± 1 vs. 0 ± 0 arbitrary units, $p<0.05$) were observed following the 6-MWT in normobaric hypoxia compared to normoxia. During the 8-hour normobaric hypoxic exposure, a reduction in resting SpO2 (mean: 81 ± 4 %, end: 82 ± 6 %, pre-to-post change: -16 ± 6 %) and an increase in AMS scores were observed (mean: +1 ± 4, end: +2 ± 2, pre-to-post change: +2 ± 2 arbitrary units). Low corre-

lation coefficient values were found for post-test and pre-to-post test changes in SpO2 (r = 0.3 and 0.0) and AMS scores (r = 0.3 and 0.2) between the 6-MWT and 8-hour prolonged exposure in normobaric hypoxia, respectively.

CONCLUSION: The 6-MWT demonstrates impairment to performance, increased physiological strain and the occurrence of AMS symptoms in response to normobaric hypoxia compared to normoxia. However, it appears the 6-MWT is unable to predict AMS susceptibility, nor impairment to SpO2 during a prolonged exposure to normobaric hypoxia. Whilst the 6-MWT is useful for monitoring acclimatisation progress and provides a good tool for educational purposes to improve individuals' knowledge on the effect hypoxia has on performance and health outcomes prior to departing for an prolonged sojourn at altitude, it is not currently possible to be used in screening for, or predicting AMS susceptibility.

STRENGTH TRAINING OF THE LOWER EXTREMITIES MAY HAVE LARGER BENEFICIAL EFFECTS ON BRAIN HEALTH IN OLDER ADULTS WITH MCI THAN IN COGNITIVELY UNIMPAIRED OLDER ADULTS

LEVIN, O.

KU LEUVEN

INTRODUCTION: Physical exercise is considered a potent countermeasure against various age-associated neurodegenerative processes. We assessed the effect of 12 weeks of resistance training (RT) on neurometabolites and gray matter volume in the hippocampus. This region has a high potential to be negatively affected by aging, specifically in the preclinical phase of dementia such as in older individuals with mild cognitive impairment (MCI).

METHODS: Complete randomized controlled trial data were obtained from 37 older individuals (60-85y old) of whom 11 were diagnosed as individuals with MCI and the remaining were cathegorized as cognitively unimpaired healthy controls (HC). Participants were randomly allocated to 12 weeks of lower body resistance training (n = 23; 7 MCI) or passive control (n = 14; 4 MCI). 1H-MRS spectra were acquired from the left hippocampus (HPC) using the PRESS sequence and neurpmetabolite levels were quantified with LCModel (version 6.3.1-R). Neurometabolites of interest were the ratios to creatine (Cr) of N-acetyl aspartate (NAA/Cr) and myoinositol (mIns/Cr) and NAA/mIns. Gray matter volume (GMV) of the right and left hippocampus were estimated from 3D T1-weighted images using FreeSurfer (v7.1.1). Main outcome measures were pre-to-post changes (expressed as % of baseline values of the three neuromatabolite ratios and right and left HPC GMV. Two-way ANOVAs with Group (Exercise versus Control) and Condition (MCI versus HC) were used to compare the effect of RT intervention or no intervention on % changes in the aforementioned outcome measures.

RESULTS: A significant main effect of Condition ($F(1,33) = 5.93$, $p = 0.020$, partial $eta^2 = 0.152$) was found for NAA/mIns ratio in the total sample, showing a pre-to-post increase of NAA/mIns ratio in HC (+ 10.4 ± 25.4 %) as compared to a decrease in MCI (- 7.2 ± 15.1 %). A closer inspection of these observation suggests a mean reduction of about 20% of NAA/mIns ratio in MCI who were not included in the exercise group whereas MCI who underwent 12 week of RT showed relatively stable NAA/mIns ratios. However, the Group main effect and the Group x Condition interaction were not significant (both $F(1,33) \leq 2.08$, $p \geq 0.158$). No other main effects or interactions were found (all $p \geq 0.071$). However, a trend with a Group moderate effect size (partial $eta^2 = 0.071$) was found for right HPC GMV suggesting that the RT group showed an increase in right HPC GMV (+ 0.44 ± 2.07 %) whereas a decrease (- 0.60 ± 1.52 %) was observed for passive controls.

CONCLUSION: We showed that a 12 weeks of RT intervention may be effective for slowing or preventing neuronal loss and possibly reduce the detrimental effect of age-related glial cell overactivity. These beneficial effects appeared to be more pronounced in MCI than in cognitively unimpaired older adults.

The study was supported by funds from the Research Council of Lithuania (Grant Number S-SEN-20-5).

THE EFFECT OF ROBOTIC WALKING ON SPASTICITY, PAIN, AND QUALITY OF LIFE IN INDIVIDUALS WITH CHRONIC SPINAL CORD INJURY: A PILOT RANDOMISED CONTROLLED TRIAL

ALBERTUS, Y.

UNIVERSITY OF CAPE TOWN

INTRODUCTION: The prevention and treatment of secondary complications is a key priority for people with spinal cord injury (SCI) and a fundamental goal of SCI rehabilitation. The conceptual basis for RLT appears promising; a rehabilitation modality that removes the need for intensive assistance from therapists, whilst facilitating safe and effective over-ground ambulation. However, small sample sizes and a lack of homogeneity across studies have resulted in an underpowered evidence base supporting the efficacy of RLT for SCI rehabilitation. Thus, this randomized control pilot study aimed to investigate the effects of RLT compared to ABT on pain, spasticity, and quality of life in individuals with incomplete SCI.

METHODS: Participants with chronic motor incomplete tetraplegia (n = 16) were recruited. Each intervention involved 60-minute sessions, 3x per week, over 24-weeks. RLT involved walking in an Ekso GT exoskeleton. ABT involved a combination of resistance, cardiovascular and weight-bearing exercise. Outcomes of interest included the Modified Ashworth Scale, the International SCI Pain Basic Data Set Version 2, and the International SCI Quality of Life Basic Data Set.

RESULTS: Neither intervention altered symptoms of spasticity. Pain intensity increased from pre-post intervention for both groups, with a mean increase of 1.55 [−0.82, 3.92] ($p = 0.03$) and 1.56 [−0.43, 3.55] ($p = 0.02$) points for the RLT and ABT group, respectively. The ABT group had an increase in pain interference scores of 100%, 50%, and 109% for the daily activity, mood, and sleep domain, respectively. The RLT group had an increase in pain interference scores of 86% and 69% for the daily activity and mood domain respectively, but no change in the sleep domain. The RLT group had increased perceptions of quality of life with changes of 2.37 [0.32, 4.41], 2.00 [0.43, 3.56] and 0.25 [−1.63, 2.13] points, $p = 0.03$, for the general, physical, and psychological domains, respectively. The ABT group had increased perceptions of general,

physical and psychological quality of life with changes of 0.75 [–1.38, 2.88], 0.62 [–1.83, 3.07] and 0.63 [–1.87, 3.13] points, respectively.

CONCLUSION: Despite the increased pain ratings and no change in spasticity symptoms, there was an increase in perceived QoL for both groups over 24-weeks. This dichotomy warrants additional investigation in future large-scale RCTs. This pilot trial offers promising evidence for the effectiveness of RLT for improving functional and ambulatory capacity, secondary complications and quality of life in people with incomplete SCI.

IMPACT OF EXERCISE ON CARDIOPULMONARY AND VASCULAR HEALTH IN OLDER ADULTS WITH INTELLECTUAL DISABILITY: A 6-MONTH RANDOMIZED PILOT STUDY

OVIEDO, G.R., SIMÓN-SILES, S., FONT-FARRÉ, M., VILARÓ-CASAMITJANA, J., JAVIERRE, C., GUERRA-BALIC, M.
UNIVERSITY RAMON LLULL - INTERNATIONAL UNIVERSITY OF CATALONIA - UNIVERSITY OF BARCELONA

INTRODUCTION: Older adults with intellectual disabilities (ID) are at high risk for cardiovascular disease. They have reduced physical fitness compared to their non-disabled peers, so exercise programs are essential to improve their health and quality of life.

This study aimed to compare the effect of two types of exercise programs [continuous aerobic training (CAT) and all-out sprint interval training (SIT)] on aerobic capacity and vascular health in older adults with ID.

METHODS: Twenty-four older adults (50.58±1.44 years) with mild or moderate ID of both sexes participated. Control (n=8), SIT (n=8) and CAT (n=8) groups were randomly formed. The SIT and CAT groups performed 72 sessions of 90 min, 3 times/week on cycle ergometers. The variables analyzed were: age, weight, height, body mass index (BMI), cardiorespiratory fitness (VO2), peak power, carotid-to-femoral pulse wave velocity (PWVcf), systolic (SBP) and diastolic (DBP) blood pressure. Vascular and arterial stiffness parameters were assessed by tonometry (SphygmoCor Xcel, AtCor Medical, Sydney, Australia) and VO2 by a stress test with metabolic analysis on a cycle ergometer. Descriptive values were obtained for all variables. A one-way ANOVA was used to compare age, height, weight and BMI. To analyze the effects of the interventions, repeated measures ANOVA with Boferroni post-hoc tests were used. Statistical significance was set at $\alpha<0.05$.

RESULTS: At the beginning, the age, height, weight and BMI were similar in all groups. The SIT group significantly decreased body weight (76.4 vs 73.8 kg) and BMI (29.7 vs 28.7 kg/m2) at the end of the intervention (all p<.05). The SIT group significantly increased VO2 peak (18.7 vs 21.7 ml/kg/min) and peak workload (101.5 vs 136.3 watts) achieved during the maximal stress test (p=0.019; p=0.001 respectively). These increases were significantly higher than those of the CAT group (p=0.042; p=0.046 respectively). PWVcf was lower at the end of the intervention in both active groups (CAT: 7.67 vs 6.61 m/sec, p=0.02; SIT: 7.91 vs 7.20 m/sec, p=0.04). Only the SIT group decreased the SBP (129.7 vs 121.3 mmHg, p=0.035). DBP decreased in both active groups (CAT: 79.7 vs 72.5 mmHg, p=0.02; SIT: 78.5 vs 73.0 mmHg, p=0.013).

CONCLUSION: Both exercise programs (SIT and CAT) positively impacted central arterial stiffness and blood pressure.

The SIT program promoted better aerobic capacity, peak power, body weight and BMI results.

All-out sprint interval training interventions may be a valid tool to improve the health of older adults with ID.

THE EFFECTS OF PRESCRIBED EXERCISE ON THE PHYSICAL AND COGNITIVE HEALTH OF ADULTS WITH DOWN SYNDROME

GORDON, D.1, WELSH, T.2, CRIMI-LAMANNA, N.2, MACPHEE, A.2, BROWN, S.2, ZINK, A.2, HOEFKES, M.2, MERZBACH, V.1
1ANGLIA RUSKIN UNIVERSITY, CAMBRIDGE CENTRE FOR SPORT & EXERCISE SCIENCES, UK, 2FCB TORONTO

INTRODUCTION: Down syndrome (DS) is the result of the presence of either the whole or part of an additional duplication of chromosome-21. The countenance of this additional chromosome can be linked to chronotropic and respiratory incompetence, neuromuscular conditions, immunological suppression, impaired decision making, verbal reasoning, processing, and executive function. Recent works showed that American adults with DS that they engaged in just 10.1 ± 13.5 min of moderate intensity activity, coupled with 1.7 ± 9.8 min of vigorous activity. Indeed, they were shown to engage in 412.7 ± 216.6 min of sedentary time per day. Additionally, the burden to the health care sector associated with DS equates to an additional $78,500,000 per annum. Therefore, the purpose of this study was to examine the effects of 8-weeks of prescribed exercise and/or cognitive training on the physical and cognitive health of adults with DS.

METHODS: Following ethics approval 84 participants (age 27.0 ± 8.0) from 5 countries volunteered and agreed to participate. Measures of physical fitness and cognitive function were obtained using a modified version of the 6-minute walk test, (completed twice) as well as a modified version of the talk test, while cognitive and executive function were assessed using the Corsi block test, Stroop task, and the Sustained-Attention-To-Response Task (SART) test. All tests were completed pre and post intervention. Based upon distance completed across the 6-minute walk test, participants were assigned to 8-weeks of either 3 x 30 min of walking (EXC), 6 x 20 min of cognitive training (COG), combined group of EXC and COG (COM) or no intervention (CON). Data expressed as mean ± SD.

RESULTS: Reputed measures ANOVA showed a significant increase (P< 0.05) in 6-min walk distance for both EXC (55.6 ± 66.4 m) and COM (51.7 ± 65.0 m). Number of correct responses in the SART showed significant (P= 0.000) increases for EXC (9.1 ± 5.0), COG (P= 0.000) (8.5 ± 7.5) and COM (P= 0.03) (10.0 ± 23.3). STROOP non-compatible correct responses increased by 6.1% (P= 0.02) for EXC and 35.3% (P= 0.001).

CONCLUSION: These findings show that prescribed exercise can have a profound effect on both the physical and cognitive health of adults with Down syndrome. The changes in cognitive function show evidence of for enhanced decision making and critical thinking.

EFFECT OF HATHA YOGA IN PATIENTS WITH EATING DISORDERS: A CLINICAL STUDY.

TOUTAIN, M., MOSCONE, A.L., LECONTE, P., GAUTHIER, A.

UNIVERSITY OF CAEN AND UNIVERSITY OF PARIS-SUD 11

INTRODUCTION: Eating Disorders (ED), such as anorexia and bulimia, affect about 10% of young people [1]. Physiological and psycho-cognitive comorbidities are commonly associated with ED, including interoceptive deficit [2]. Interoceptive awareness (IA) is the ability to identify, access, understand, and respond appropriately to internal cues (digestive system, muscle tension, heart rate, etc.) [3]. IA can be improved by mind-body practices such as meditation or yoga [2]. To our knowledge, the effect of yoga on IA has not yet been studied in ED patients. The aims of this study are 1) to assess the effect of yoga on IA of ED patients and 2), on body mass index (BMI), eating attitudes, mood, exercise motives and sleep quality, in a clinical setting.

METHODS: After 8-weeks of three Hatha yoga sessions per week, 11 inpatient participants (age = 25.91) completed the multidimensional assessment of IA (MAIA) scale, the eating attitude test (EAT-26), the hospital anxiety and depression scale (HAD), the exercise motivation inventory-2 (EMI-2) and the Pittsburgh sleep quality index (PSQI).

RESULTS: A non-parametric analysis showed a significant improvement in the MAIA score after the 8 weeks of yoga ($p<.05$), with a pre-program score of 63/160 and a post-program score of 84/160. Significant improvement were also found in BMI (18.37 to 19.44), EAT-26 score (39 to 25), HAD depression score (7 to 4) and EMI-2 body-related motivations score (7.75 to 6.56).

CONCLUSION: The decrease observed in the EAT-26 score as well as the increase in BMI confirmed that yoga is suitable for ED patients and does not affect treatment [2]. The decrease in the depression score confirmed the positive effect of yoga on mood observed in other studies [2]. The decrease in body-related motivations score suggests that yoga contributed to shift from an exercise-related mindset, to a less body-oriented goal. It shows a new vision of yoga for patients with ED and could be a new therapeutic lever to address problematic exercise in ED treatment. The increase in MAIA score revealed a positive effect of yoga on IA and highlights that IA may be an important target for yoga intervention in ED. However, these results need to be taken with caution, as the sample size remains small. Additional data are needed as well as a control group.

CARDIAC AUTONOMIC MODULATION AND FITNESS RESPONSES TO A 6-MONTH MULTICOMPONENT SPRINT INTERVAL TRAINING INTERVENTION IN OLDER ADULTS WITH INTELLECTUAL DISABILITY: A RANDOMIZED CONTROL TRIAL

FONT-FARRÉ, M., GUERRA-BALIC, M., SILVA FARCHE, A.C., DE MEDEIROS TAKAHASHI, A.C., OVIEDO, G.R.

BLANQUERNA, UNIVERSITY RAMON LLULL, BARCELONA, SPAIN AND FEDERAL UNIVERSITY OF SÃO CARLOS, SÃO CARLOS, BRAZIL

INTRODUCTION: Persons with intellectual disability (ID) present many conditions and diseases, such as cardiovascular diseases, obesity, and diabetes [1]. Physical and functional improvements have been described after implementing aerobic and/or sprint interval training protocols in people with ID [2]. Nevertheless, whether these interventions may affect the cardiac autonomic modulation at rest, during and after a submaximal exercise test in older adults with an ID is unknown. Therefore, the aim of this study was to investigate if there is an enhancement in cardiac autonomic modulation (HRV, rest-to-exercise HR's delta and HR off-kinetics) after 6 months of two multicomponent interventions in older adults with an ID.

METHODS: In this randomized control trial, participants with ID (age: 50.58 ± 7.25) were allocated into three groups [multicomponent aerobic training group (MATG), multicomponent sprint interval training group (MSITG) and control group (CG)]. The programs included aerobic (on cycle ergometers), resistance, balance, and flexibility training. Participants trained 3 times/week, 75-90 minutes/session during 24 weeks. The MSITG performed bouts of 5 to 10-min of exercise consisting of 5 to 20-s all-out sprints followed by 15 to 60-s of low cadence recovery. The MATG performed aerobic bouts of 5 to 10-min and the intensity was progressively increased from 55% to 85% of the HR reserve. The 6-min walking test has been used to assess the submaximal exercise performance. The cardiac autonomic modulation was evaluated by using the linear and non-linear parameters of the HRV, the analysis of rest-to-exercise HR delta and HR off-kinetics. Models include DS as covariate and Bonferroni adjustments were used for comparisons.

RESULTS: A group x time interaction was observed for the variables Δ0-30s ($F(2)=3.694$; $p<0.05$) and physical capacity ($F(2)=6.115$; $p<0.01$). The MSITG showed a significant increase of HR deltas between rest and the first 30s of exercise

($p<0.05$) and a significant increase in aerobic capacity ($p<0.05$). In contrast, CG significantly reduced physical performance ($p<0.01$).

CONCLUSION: The MSITG improved the physical performance and the vagal removal at the beginning of the submaximal exercise. In addition, these results show an attenuation of the aggravation of autonomic reflex response capacity suffered by the influence of aging. These improvements could be due to the positive effects of high-intensity exercise on baroreflex function. The MSIT intervention could be used to enhance baroreflex sensitivity in older adults with ID.

VERTICAL CENTER-OF-MASS BRAKING AND MOTOR PERFORMANCE DURING GAIT INITIATION IN HEALTHY ADULTS AND PARKINSON'S DISEASE PATIENTS: A COMPARISON BETWEEN FORCE-PLATE AND MARKERLESS MOTION CAPTURE SYSTEM

SIMONET, A.1,2,3, DELAFONTAINE, A.2,3,4, FOURCADE, P.2,3, YIOU, E.2,3

1 LADAPT LOIRET, CENTRE DE SOINS DE SUITE ET DE RÉADAPTATION 2 CIAMS, UNIVERSITÉ PARIS-SACLAY 3 CIAMS, UNIVERSITÉ D'ORLÉANS 4 UNIVERSITÉ LIBRE DE BRUXELLES, BELGIQUE

INTRODUCTION: Gait initiation (GI) is a locomotor task that is classically used in the literature to investigate stability control and motor performance (MP) in healthy subjects and neurological patients (1). The quantification of these biomechanical parameters requires the recordings from force-plate(s) (FP) and/or motion capture system (MCS). Conventional MCS necessitate 38 markers to compute whole-body center-of mass (CM) kinematics. It is therefore time-consuming and, as FP, requires highly trained operators (2). Markerless MCS is a recent innovative technology that facilitates motion analysis and that does not require any preparation of experimental participants. It may therefore drastically reduce the duration of experiments/data treatment, which may be relevant for researchers, clinicians and patients. This study questioned the ability of markerless MCS to evaluate accurately stability control and MP during GI in healthy subjects and patients with Parkinson's disease (PD). Values provided by FP were considered as the gold standards1 against which values provided by markerless MCS were compared.

METHODS: Ten young healthy adults (YH), 10 healthy elderly (EH) and 10 PD participated in the study. All performed series of GI at a spontaneous and fast velocity. Signals from FP and markerless MCS were simultaneously recorded to compute CM kinematics. Experimental variables were the peak of CM velocity along the anteroposterior axis and the "braking index" (BI), which correspond to indicators of MP and stability control, respectively. BI was computed as the ratio [peak downward CM velocity (VzMIN) minus vertical CM velocity at foot-contact]/VzMIN. BI reflects the capacity of participants to brake their CM fall under gravity (1). To investigate the agreement between the two systems, a Bland and Altman (BA) analysis was conducted for both variables under each velocity condition and group. Repeated-measures ANOVA with the Velocity (spontaneous vs. fast) and System (FP vs. markerless MCS) as within-subject factors, and the Group (YH, EH, PD) as between-subject factor were carried out. Newman-Keuls post hoc tests were conducted when necessary.

RESULTS: BA plots showed that the absolute and relative biases for MP and BI were virtually zero in each velocity condition and group. 95% of the relative MP differences between the two systems ranged between +10% and -10% for MP and +40% and -40% for BI. ANOVA revealed a significant main effect of Group and Velocity (but not System) for both variables ($p<0.05$), and a Group*Velocity interaction. Post hoc tests further showed that the two systems detected similar significant differences between groups and velocity conditions for both variables.

CONCLUSION: These results suggest that markerless MCS are sufficiently accurate to compare BI and MP across groups and velocity conditions, which might be useful in a research and clinical context.

EXPLORING THE INTERPLAY BETWEEN ELITE ATHLETES AND SPORT EQUIPMENT IN THE QUEST FOR PERFORMANCE: A CASE STUDY IN SAILING

TERRIEN, E., HUET, B., SAURY, J.

NANTES UNIVERSITY

Introduction

From a phenomenological perspective, it is classically assumed that when sport equipment is used by expert athletes, it is so well incorporated to the athlete's body that it becomes transparent, disappearing from the athlete's awareness. How-

ever, few studies have investigated the perceptual experiences of expert athletes using their equipment to challenge this assumption. These studies focus on small equipment such as backpacks or ice axes, showing that even these types of equipment can have a significant presence in elite athlete's experience. We pursued this exploration in the sport of windsurfing and more specifically in IQfoil (i.e. the Olympic windsurfing class). Indeed, in IQfoil, the size and characteristics of the equipment contrasts with those of the previous studies, creating a favorable situation of research to contribute to the understanding of the interplay between human and sport equipment.

Methods

We collected data during a training session of two elite IQfoil riders. Both had a long record of international victories and were part of the national team. We collected data in two steps: (a) in-situ audio-video recording of the training session; and (b) individual self-confrontation interviews. We conducted the data analysis using the Course of Experience framework methodologies to identify and categorize the meaningful elements of the riders' own worlds.

Results

The analysis revealed eight typical meaningful elements in the riders' own worlds: flight height, physical effort, position in the fleet, sail movements, sail power, speed variations, transmission balance, wind variations. These findings reveal that when riders try to optimize their speed, their attention is distributed between the environment (i.e., wind variation, position in the fleet), their relation with the equipment (i.e., transmission balance, physical effort), and the relation between the equipment and the environment (i.e., sail power, flight height, speed variation).

Discussion

Our findings contribute to the understanding of expert use of sport equipment in two complementary ways: (a) by contributing to apprehend distinctions between classes of equipment in function of their autonomy of movements in relation to the athletes' activity; and (b) by suggesting a fundamental distinction between the experience of using sport equipment in an activity of performance optimization versus in a daily routine activity.

QUALITATIVE AND QUANTITATIVE RESEARCH FOR SPORTSPERSONSHIP OF UNIVERSITY STUDENT-ATHLETES

OSADA, T., SEKIYA, H.

HIROSHIMA UNIVERSITY

INTRODUCTION: The Multidimensional Sportspersonship Orientation Scale (MSOS) [1] has been often used to measure sportspersonship attitudes but is characterized by a small number of question items regarding negative attitudes. Other measures related to sportsmanship attitudes include the Moral Disengagement in Sport Scale (MDSS) [2], which measures only negative attitudes, and the Attitude to Moral Decision-making in Youth Sport Questionnaire (AMDYSQ) [3], which measures youth attitudes. On the other hand, there's none of the scales all-embracing measure sportspersonship attitudes among student-athletes in university. The Prosocial and Antisocial Behavior in Sports Scale (PABSS) [4] provides a balanced measure of sportspersonship behavior, however, the behavior is influenced by factors other than attitudes. That is, comprehensive research investigating both positive and negative aspects of sportspersonship attitudes is necessary. Therefore, the purpose of this study was to examine sportspersonship attitudes comprehensively among university student-athletes.

Method:

In study 1, a focus group interview was conducted to identify unsportsperson-like attitudes involving 5 (4 female and 1 male, Mage=24.6 ± 3.88) university students majoring in sport psychology in Japan. The statements were analyzed qualitatively and grouped into categories. In study 2, a 100-item online questionnaire was developed to measure sportspersonship attitudes of university student-athletes in Japan. We used 5 scales for question items developed based on study 1, MSOS, PABSS, AMDYSQ, and MDSS. A total of 488 (211 female, 274 male, and 3 unknown, Mage= 20.10 ± 1.14) athletes completed the questionnaire.

Results and CONCLUSION: The qualitative analysis of the interview data in study 1 resulted in 5 categories. The exploratory factor analysis in study 2 found 5 factors consisting of 43 items of sportspersonship. The 5 dimensions of sportspersonship consisted of 4 negative dimensions; selfish behavior, disturbing opponents, cheating, and revenge, and a positive dimension; respect for surroundings. The cluster analysis revealed that there are two types of sportspersonship among university student-athletes. Cluster 1 (N=321) is the athletes who agree to sportsperson-like attitudes but not to unsportsperson-like attitudes. Those who are in cluster 2 (N=167) tend to think sportsperson-like attitudes are bad, but unsportsperson-like attitudes are good. Furthermore, more males belonged to cluster 2 than females, suggesting that males possibly tend to judge agreeable to unsportsperson-like attitudes more than females in sport.

THE TRANSFORMATIONAL PROCESS IN ATHLETES WHEN LONG-TERM COUNSELING LEADS TO IMPROVED PERFORMANCE AND PERSONALITY DEVELOPMENT

OKUDA, A.1, SHIRO, N.2

1.BIWAKO-GAKUIN UNIVERSITY, 2. PROFESSOR EMERITUS, UNIVERSITY OF TSUKUBA

Introduction

Psychological support for athletes through counseling deals not only with psychological problems related to performance enhancement (external issues) but also with the psychological issues of personality development and psychological maturation (internal issues). By clarifying the transformational process of counseling for the resolution of these two (internal/external) issues, the way in which psychological development in athletes is interrelated with their athletic and physical experiences in competitive situations.

Purpose

The aim of this study was to clarify the transformational process that occurs when counseling carried out for resolving problems in competition also leads to psychological development in athletes. In other words, the purpose was to understand the reciprocity between reality adaptation (performance enhancement) and individualization (psychological development) in athletes.

Methods

The narrative record of a client was carefully reviewed. His main complaint was of "a big gap between my performance in practice and competitions. And the bigger the competition, the less control I have over myself." The client was a male athlete in his 20s who specialized in target-shooting. His counseling sessions consisted of paid interviews of 50 minutes every two weeks, except for when he was unable to come due to competitions or training camps. The analysis of his interview records follows the synchronic (chronological) changes in his movement-narratives, internal- experience narratives, and performance-change narratives in 72 interviews conducted over a four-year period.

Results and Discussion

The interview material can be roughly divided into four phases: Phase I, in which the client underperformed in competitive situations; Phase II, in which the client showed awareness of mind and movement in competitive situations; Phase III, in which the client reconsidered the meaning of each movement; and Phase IV, in which the client discovered, established, and consolidated his unique style. In the counseling sessions, the client deepened his self-understanding and clarified important issues (Phase I and Phase II) by reflecting in front of his counselors on his movements during competitions. He then reconsidered the meaning of his own physical movements and went through a trial-and-error process to resolve his problems (Phase III), eventually leading to the establishment of his own style (Phase IV). The transition into each phase was not linear, but rather a series of forward and backward steps. This series of processes also promoted individualization (psychological development) in the client, resulting in improved and stable performance. It is considered that clients retelling their stories in counseling can bring about a qualitative change in athletic experience and facilitate the process of individualization.

ACCEPTANCE BY COACHES OF IMMERSIVE VIRTUAL REALITY FOR IMPROVING SPORT PERFORMANCE

DEVRIÈSE-SENCE, A., CHOMIENNE, L., BOSSARD, M., VERHULST, E., KULPA, R., MONTAGNE, G., MASCRET, N.

AIX-MARSEILLE UNIVERSITY / RENNES UNIVERSITY / GUSTAVE EIFFEL UNIVERSITY

Under certain conditions, immersive virtual reality (VR) has shown its effectiveness in improving sport performance. However, the psychological impact of VR on athletes is often overlooked, even though it can be deleterious (e.g., decreased performance, stopping the use of VR). Mascret et al. (2022) have recently highlighted a significant intention of athletes to use a VR Head Mounted Display (VR-HMD) designed to increase their sport performance. Whatever their level and before a first use, they all initially considered it as quite useful (except for recreational athletes), quite easy to use, and quite pleasant to use. Coaches are also concerned by using the VR-HMD: If athletes accept the VR-HMD but coaches do not, there is a risk that the VR-HMD will never be used despite its potential benefits. In this context and based on the Technology Acceptance Model, this study aims to identify possible blockages by measuring coaches' acceptance of VR-HMD device before the first use.

After reading a short text introducing the VR-HMD and its benefits for improving sport performance, a total of 239 coaches, from different sports and from local to international level, filled out a questionnaire assessing perceived usefulness to improve training, perceived usefulness to improve athletes' performance, perceived ease of use, perceived enjoyment, job relevance, and coaches' intention to use it. Structural equation modeling analysis, one-sample t-tests, and one-way ANOVAs were used to examine the data.

The main results show that (1) coaches' intention to use the VR-HMD is positively predicted by perceived usefulness to improve athletes' performance, perceived enjoyment, and job relevance, but not by perceived ease of use, (2) coaches significantly consider the VR-HMD useful to include in their training and to improve their athletes' performance, easy to use, pleasant to use, and relevant for their job, and (3) no significant differences appear on the previous scores according to coaches' levels, except for job relevance: international and national coaches find the VR-HMD more relevant to their job than local level coaches. All these results highlight that the VR-HMD is rather well accepted by the coaches before a first use. No contraindication appears from this point of view for the coaches to use the VR-HMD for performance optimization purposes.

EFFECTS OF SIDE-BY-SIDE PARTNER ON ENJOYMENT AND SPEED IN SELF-PACED TREADMILL RUNNING

HOSHINO, S., KOBAYASHI, A., KONISHI, S., KUNIDA, K., SUGAWA, M., KOMORI, K.

NARA WOMEN'S UNIVERSITY

INTRODUCTION

The phenomenon in which performance is improved by the presence of others is called social facilitation (Zajonc, 1965), and the phenomenon that occurs in the situation of simultaneously performing the same task as others is called the co-action effect. This refers to one's performance being more on task, merely because there are other people doing the same task. According to Zajonc, perceiving the presence of others increases arousal and drive, and evokes a dominant response, which is promoted if the task is well learned and suppressed if it is unfamiliar. While there are many studies that have focused on performance in the presence of partner, few studies have examined the psychological effects necessary to facilitate physical activity. Therefore, in this study, we physiologically and psychologically examine the influence of the presence of a running partner on women who are not practiced runners and do not have a habit of exercising in terms of co-action effect.

METHOD

Subjects: 19 female university and graduate students (21.4 ± 1.5 yr.) who do not exercise regularly.

Tasks and conditions: Flat treadmill self-paced running for 30 minutes under two conditions (1) Solo condition: SC: running alone and (2) Partner condition: PC: running side by side with a partner.

Measurements: (a) Behavioral indices: total running distance, running speed, and rate of speed increase every 5 minutes (actual speed/initial speed), (b) physiological index: heart rate, and (c) psychological indices: Feeling Scale: FS, Exercise Enjoyment Scale: EES, Excitement, Anxiety, RPE (Borg's scale). Speed's change and heart rate were measured continuously and psychological indices were reported at the base line (B), every 5 minutes (R5-R30), and twenty minutes after the end (A20).

RESULT and DISCUSSION

The total running distance for 30 minutes in PC (3639.91m) was significantly longer than in SC (3471.38m) (Wilcoxons signed-rank test, $Z=-3.351$, $p<.001$). The running speed was always significantly higher in the PC (R5-R30). As a result of two-way ANOVA for heart rate, a significant main effect was shown for time factor ($F(2.105, 29.474)=58.387$, $p<.001$, $\eta 2=.807$). Perceived exertion: No significant difference between two conditions. The results suggest that under the PC, the participants ran longer distances and faster despite the same exercise load and the perceived exercise intensity.

Running in the PC was shown to be significantly more exciting than running in the SC at R20-R30, and A20. In the PC, excitement increased significantly at the end. Anxiety was rated higher in the SC than in the PC in R20-R30. In the PC anxiety reduced 20 minutes after the running and then after running low anxiety state lasted. Compared with the SC, the PC showed a significantly higher enjoyment (EES) at R25-A20. The SC was reported more comfortable (FS) at the beginning (R5), but after 30 minutes running (R30), a more comfortable feeling was reported in the PC.

CONCLUSION

Results show that excitement increased, and anxiety decreased at 20 minutes after running, and these effects persisted for 20 minutes after 30 minutes of running, leading to feelings of enjoyment. Running with a partner showed social facilitation. Furthermore, an improvement in positive emotions during running was observed. Since it is said that experiencing fun and excitement during exercise enhances intrinsic motivation (Teixeira et al., 2012), increased excitement due to the presence of a partner is thought to be effective in facilitating exercise behavior.

POSITIVE IMPACT OF SPORTS EXPERIENCES ON WORKPLACE PERFORMANCE: A STUDY OF FORMER ATHLETES AND THEIR MANAGERS IN JAPAN

NAMIKI, N., HIROYUKI, H.

WASEDA UNIVERSITY

Introduction

The transition from athletic retirement to the workplace is a topic of growing interest among researchers. Transferable skills is pivotal in advancing an athletes career development and facilitating a smooth transition into the workforce (Bernes et al., 2009). A lack of comprehension exists regarding how the skills acquired from competitive experience have positively impacted their workplace performance. Therefore, this study aimed to identify the strengths that former athletes acquired through their athletic careers as perceived by both the athletes themselves and their managers in the workplace.

Methods

Semi-structured interviews were conducted with ten former athletes who had successfully transitioned to the workplace and six of their managers in Japan. Athletes played soccer, basketball, rugby, skiing, swimming, and track and field. Each interview lasted nearly 50 minutes and focused on the strengths that the athletes brought from their sports careers to their current workplaces, and the challenges they faced during the transition. Thematic analysis (TA; Boyatis, 1998) was used to analyze the interview data. The study was approved by the Waseda University Ethics Review Committee on Research with Human Subjects (Approval number: 2022-104).

Results

The results of the study revealed that the majority of the former athletes felt that their sports experience had a positive impact on their work lives. Several strengths were identified, including goal-setting, problem-solving, assertiveness, teamwork, patience, responsibility, ability to cope with changes in the environment, optimism, and expertise in exercise. Additionally, they found similarities between the workplace and athletics in goal-setting and problem-solving. When he was an athlete, he looked back on himself to find and solve problems to succeed. They established a good cycle to produce results and applied it to work. Managers highly valued the strengths of athletes, not only those mentioned above but also their positive impact in the workplace. Their enthusiastic attitude and approach to work could inspire their coworkers. From a managerial perspective, athletes were also seen as valuable contributors to a cohesive and productive team dynamic.

Discussion

This study contributes to the existing body of research on the transferable skills athletes bring to the workplace, offering unique insights. The strengths cultivated as athletes vary among individuals. For instance, some enhance their problem-solving abilities by observing others, while others improve their competitiveness through new and unique training methods. This demonstrates that even when facing a common challenge, individuals may approach it differently, leading to diverse skill sets in the workplace. Additionally, athletes and managers possess unique perspectives, highlighting the importance for athletes to be aware of and understand the highly valued strengths in the workplace.

MIRROR, MIRROR, AM I THE BEST PLAYER AT ALL? DEVELOPMENT OF PSYCHOMETRIC INSTRUMENTS ASSESSING FANTASY PRONENESS AND DEFLATED REALITY IN SPORT

ZHANG, S.1, BOARDLEY, I.2

1. UNIVERSITY OF DERBY; 2. UNIVERSITY OF BIRMINGHAM

Background: Competitive sport offers an excellent environment for an individual to fulfil the lionization of the self as one can have tremendous opportunities to beat opponents, dominate the competition, or at least fantasize about being an exceptional performer. Competitive sport is also a rocky way – one would not become a 'talent' or an 'elite' without thousands of hours of deliberate practice and training in a relatively tiring and tedious environment, whereas investing greater effort and working harder do not necessarily lead to more positive outcomes or a more promising career. In this research, we developed and validated two relevant psychometric instruments, namely the Sport Fantasy Proneness Scale (SFPS) and the Deflated Reality in Sport Scale (DRSS), to assess the important but overlooked context-specific constructs.

Methods: We established a working definition for sport fantasy proneness and deflated reality in sport and generated an initial item pool of the SFPS and DRSS from well-established, relevant measures assessing the two constructs in general life domains, prior to a rigorous process of content validity assessment involving an expert panel. We then examined factorial, convergent, discriminant, and concurrent validity and measurement invariance, as well as internal consistency and test-retest reliability of the two new scales, through two cross-sectional samples (Study 1: Sample 1 N = 255, Sample 2 N = 260) and one longitudinal sample (Study 2: Sample 3 N = 118) of competitive athletes in the UK.

Results: Aligning with the conceptualizations in general life domains, one's disposition of engaging in sport fantasy and perception of deflated reality in sport both appear to be a unidimensional construct. Evidence supported the convergent, discriminant, and concurrent validity whilst demonstrating very good consistency, test-retest reliability, and measurement invariance of the two new scales. A weak, positive correlation exists for scores of the two new scales, and a mixed profile of sport fantasy proneness and sense of deflated reality in sport could exist (i.e., low-low, low-high, high-low, high-high). Thus, the two constructs may interactively influence training- and performance-related outcomes in sport.

Conclusion: The SFPS and the DRSS demonstrated robust psychometric properties in assessing athletes' sport fantasy and perception of deflated reality. The new scales provide researchers and practitioners with new, reliable instruments to examine new research questions and tackle issues relevant to the two important but previously overlooked psychological constructs.

INTEGRATIVE PROPERTIES OF SUBJECTIVE VERSUS OBJECTIVE SPORTS MONITORING

MONTULL, L., BALAGUÉ, N.

INEFC PIRINEUS, UNIVERSITY OF LLEIDA

In sporting contexts, the use of objective monitoring tools and physical activity trackers based on collecting massive biomechanical, physiological and performance data has recently expanded. Objective monitoring integrates multiple internal and external variables through mathematical algorithms and makes predictions on the basis of artificial intelligence. Predicated on mechanistic assumptions, such algorithms cannot capture and assess properly athlete's states and consequently cannot promote athletes health and performance. Contrarily to these mechanistic assumptions, athletes are com-

plex adaptive systems, featured by nonlinear dynamic behaviours that cannot be accurately predicted from a particular variable or set of variables (Balagué et al., 2020). Furthermore, while focusing on collecting and processing large amounts of data, analysts, scientists and coaches may forget the outstanding potential of the human neurobiological system to continuously, and rapidly, integrate massive information about performer-environment interactions. Such integrative properties offer exceptional possibilities of subjective monitoring for outperforming any objective monitoring system. Understanding and valuing subjective-based monitoring strategies is crucial to enhance athletes' awareness and promote their self-consciousness, autonomy and self-regulation. Future research should investigate how to enhance this human potential to contribute further to athletes health and performance. This line of argument, based on a recent opinion article (Montull et al., 2022), is not intended to advocate for the elimination of objective assessments, but to highlight and discuss the integrative possibilities of subjective monitoring.

Montull, L., Slapšinskaitė-Dackevičienė, A., Kiely, J., Hristovski, R., & Balagué, N. (2022). Integrative Proposals of Sports Monitoring: Subjective Outperforms Objective Monitoring. Sports Medicine - Open, 8(1), 41. https://doi.org/10.1186/s40798-022-00432-z

THE CONSTRUCTION AND VALIDATION OF THE CHARTING PHYSICAL LITERACY JOURNEY MATRIX: A PILOT STUDY

CHOI, S.M., SUM, R.K.W., HUANG, M.

THE CHINESE UNIVERSITY OF HONG KONG

Introduction

Physical literacy is an attitude toward an individual's physical activity experience, including four attributes motivation, confidence, physical competence, and knowledge and understanding (Whitehead, 2019). Despite the assessment, evaluation, and measurement of physical literacy have been debated among academia (Edwards et al., 2018), the notion of the term 'charting' was suggested by the idealist perspective. Therefore, this study employed the philosophical-discussed Charting Physical Literacy Journey (CPLJ) Matrix and used the quantitative technique of questionnaire construction and validation. The CPLJ Matrix could then serve as an additional battery to reflect one's current perception of participating in physical activity.

Methods

A 60-item Matrix using a 5-point Likert scale was developed for the pilot study. A total of 276 participants (175 male, 96 female, and 5 unknown genders) were adults who were an average age of 26.62 ± 10.67. They were asked to respond to the statements of CPLJ Matrix through an online survey platform. After the normality and reliability data analyses, exploratory and confirmatory factor analyses were conducted through the employment of IBM SPSS Statistics and AMOS version 28 for Windows.

Results

The exploratory factor analyses discovered an 18-item, 2-factor scale with loadings ranging from 0.71 to 0.85, and Cronbach's alpha ranged from 0.92 to 0.94. The confirmatory factor analyses provided standardized estimates for all significant paths and showed that the construct reached acceptable fit indices for the model of $\chi2(134) = 484.032$, $\chi2/df = 3.612$, $p < .001$, CFI = .902, ILI = .903, TLI = .889, RMSEA = .097, SRMR = .077 (Hu & Bentler, 1999). The factor loading of all items ranged from 0.68 to 0.90 which is above the standard of 0.45, suggesting that observed variables sufficiently represented the latent variables.

Discussion

This study suggested an initial 2-factor (dismissing and maximising) matrix for individuals perceiving current physical activity experience with the consideration of four physical literacy elements. A matrix-shaped report was also generated through the system for participants' charting progress, which could reflect the fluctuation progress over the life span. While the research team is in the progress of translating the CPLJ Matrix into several languages (currently with nine languages), the direction of future study should expand the inspection to cross-age groups and cross-national levels.

ACUTE EFFECTS OF A PRE-SEASON SPEED TRAINING PROGRAM ON SAND VS. HARD COURT IN PROFESSIONAL BASKETBALL PLAYERS

RAASCH, K., HEIL, J., VUONG, J.L., FERRAUTI, A.

FACULTY OF SPORTS SCIENCE, RUHR UNIVERSITY BOCHUM

INTRODUCTION: Basketball is known as a fast paced team sport, characterized by constant changes of direction as well as speed with acceleration and deceleration. Recently, sand as a training surface has gained in importance and an increasing amount of research is focused on the beneficial long-term effects on speed related training on sand [1; 2]. Considering that long-term effects are based on the acute internal and external loads, little research investigated the short-term effects of sand training. Therefore, the aim of this study was to compare the acute effects of a pre-season speed training on sand versus hard court on physiological load and neuromuscular performance in professional basketball players.

METHODS: Twenty-two healthy competitive male basketball players (age 24.8±3.9 years; height 193.3±8.7 cm; weight 93.5±12.9 kg) completed one training session on sand (n=7) or on hard court (n=15). Training sessions were part of a seven week pre-season training intervention and were realized during the sixth week of this intervention. Sessions were identically applied on both surfaces, lasted 40 min and consisted of four different speed related drills, including sprint and jumping exercises. Pre-training (PT), post warm-up (PW) and post exercise (PE) measurements were taken for counter movement jump performance (CMJ), blood lactate concentrations (LA), heart rate (HR) and ratings of perceived exertion (RPE). Data are presented with mean±SD. T-tests for independent samples were used to verify surface depending differences. Significant levels were set at $p<0.05$.

RESULTS: LA was significantly higher on sand compared to hard court PW (2.6±1.2 vs. 0.9±0.3 mmol/l, $p<0.001$) as well as PE (3.7±1.8 vs. 1.5±0.6 mmol/l, $p<0.001$). RPE values and HR were correspondingly higher on sand PW (139±7 vs. 121±12 b·min-1, $p=0.002$) as well as PE (153±12 vs. 137±15 b·min-1, $p=0.021$). No significant differences were found in CMJ performance on sand compared to hard court at PE (41.8±5.41 vs. 40.9±7.60 cm, $p=0.769$).

CONCLUSION: Training on sand comes along with a higher metabolic and cardiorespiratory load compared to hard court which can be attributed to a longer coupling time between eccentric and concentric muscular action, a longer foot contact time and a less efficient power output. This might have caused an increased energy demand on sand compared to hard court. Under this conditions a reduction in the elastic energy potentiation and muscle tendon can be expected but interestingly, neuromuscular performance is not affected. Future studies should investigate if these acute effects might be helpful to have positive long-term effects.

CHANGES IN COUNTERMOVEMENT VERTICAL JUMP PERFORMANCE METRICS DURING A PROFESSIONAL MEN'S BASKETBALL GAME

CABARKAPA, D., PHILIPP, N., ESERHAUT, D., FRY, A.

UNIVERSITY OF KANSAS

INTRODUCTION: While multifaceted in physical performance parameters influencing success, basketball is a sport that is largely dictated by an athlete's ability to efficiently use their stretch-shortening cycle. One of the non-invasive testing modalities used to quantify this neuromuscular phenomenon, as well as identify fatigue and athletes' readiness status, is the countermovement vertical jump (CVJ) performed on a force plate. Thus, the purpose of this study was to examine how some of the most commonly studied CVJ performance metrics respond to on-court competitive demands.

METHODS: Eight professional male basketball players ($\bar{x}$±SD; hgt=192.7±10.6 cm, wgt=88.9±12.4 kg; age=27.5±2.5 yrs) volunteered to participate in the present study. After arrival at the gym, all participants completed the standardized warm-up protocol consisting of a set of dynamic stretching exercises and 15 min of partner shooting. Upon completion of the warm-up, the baseline (BS) CVJ performance was assessed. Each participant stepped on a portable force plate system (ForceDecks Max, VALD Performance, Brisbane, Australia) sampling at 1000 Hz, and performed three maximum-effort CVJ without arm swing. The participants were instructed to hold their hands on the hips during the entire movement. Also, to minimize the possible influence of fatigue, each jump trial was separated by a 30 sec rest interval. Then, the participants proceeded with a simulated 5x5 basketball game (i.e., 4x10-minute quarters with Elam Ending). By following the identical testing procedures, each participant performed one CVJ post-first (P1Q) and third quarter (P3Q), and three CVJ post-second (P2Q) and fourth quarter (P4Q). Repeated measures analysis of variance with Bonferroni post-hoc adjustment was used to examine statistically significant changes ($p<0.05$) in the following force plate metrics: vertical jump height (VJH; impulse-momentum calculation), modified reactive strength index (RSI-mod; jump height/contraction time), and peak concentric force (PCF).

RESULTS: No statistically significant differences were observed in VJH [cm] (F[4,28]=2.947, p=0.110; BS=16.8±2.6, P1Q=17.0±3.0, P2Q=15.3±3.1, P3Q=15.5±3.4, P4Q=15.4±4.1), RSI-mod [m/s] (F[4,28]=1.347, p=0.291; BS=0.62±0.13, P1Q=0.66±0.12, P2Q=0.58±0.13, P3Q=0.57±0.19, P4Q=0.58±0.20), and PCF [N] (F[4,28]=1.381, p=0.284; BS=2408.3±412.7, P1Q=2539.0±372.3, P2Q=2441.8±414.6, P3Q=2449.1±400.4, P4Q=2411.6±335.5) across five testing time points.

CONCLUSION: The findings of the present study indicate that VJH, RSI-mod, and PCF did not exhibit notable changes during a simulated basketball game. Although further research including the amount of internal and external load that the athletes are exposed to is warranted, we can conclude that the aforementioned force plate metrics were either not sensitive enough to detect fatigue-influenced changes in the neuromuscular performance throughout a game span or that the athletes were already adequately trained to properly respond to on-court competitive demands.

ANTHROPOMETRY AND BODY COMPOSITION IN ELITE YOUNG BASKETBALL PLAYERS ACCORDING TO THEIR MATURITY STATUS

MAURO, M., GRIGOLETTO, A., TOSELLI, S.

UNIVERSITY OF BOLOGNA

INTRODUCTION: Basketball is a high-intensity team sport that requests both anaerobic ability (speed, vertical jump, explosive power, agility) and aerobic capacity [1]. Although power-quickness and strength appeared as great components in looking for future on-court performance, a study that analysed elite players involved in the NBA draft identified the length-size (set of anthropometric measures) component as the best predictor [2]. However, anthropometric features and somatotypes of players could vary with ageing and role [3, 4]. Examining maturational characteristics could help in selecting elite and non-elite basketball players [5]. So, coaches and trainers need to consider both chronological age and maturation in scouting and should compare adolescent players' progresses to appropriate profiles. Therefore, this study aimed to establish the anthropometric characteristics of adolescent basketball players and draw somatotype and bioimpedance vector (BIVA) profiles according to their maturation.

METHODS: Sixty-six adolescent basketball players of an elite team (Vitus Segafredo® Bologna 1927) from U12 to U15 were enrolled in a cross-sectional study design. All players performed many anthropometric measures such as weight, height, sitting height, upper and lower limbs length, nine circumferences, three diameters, nine skinfold thickness (Lange skinfold caliper, Beta Technonoly Inc., Houston), and Bio-impedance analysis (BIA 101 BIVA®PRO, Akern, Italy). Maturity status was estimated according to the Mirwald equation [6] and the subjects were classified according to their maturity status. %Body Fat (%BF), Fat Mass (FM) and Fat-Free Mass (FFM) were estimated by Slaughter equation [7]. One-way ANOVA was used to detect anthropometric changes between players who were classified as early (E), on time (OT) or late (L). The significance level was set at $P<0.05$.

RESULTS: Weight, Height, trunk length, thorax circumference, thigh circumference, total thigh area and thigh mass area showed significant differences between E, OT, and L in all the categories. Greater differences appeared in earlier players' FFM of U13, U14, and U15 than later and youths on time. Longer arm spam (U13: $F=9.94$, $p<0.01$; U14: $F=10.35$, $p<0.01$; U15: $F=8.02$, $p<0.05$) and upper limbs (U13: $F=9.94$, $p<0.01$; U14: $F=10.44$, $p<0.01$; U15: $F=8.36$, $p<0.01$) appeared in elder early players than in later and on time. Also, resistance was lower in U12 (641.4 ± 65.48), U13 (507.38 ± 54.01), and U15 (491.57 ± 45.45) early players than in later (677.75 ± 80.68; 648.07 ± 62.07; 570.65 ± 58.34), respectively.

CONCLUSION: The findings of this study confirmed that several differences could appear in adolescents with similar chronological ages with different maturation statuses, despite they competed at the same level. Coaches may monitor youths' maturation to get the best results.

ATHLETIC PERFORMANCE DEVELOPMENT IN ADOLESCENT VOLLEYBALL PLAYERS IN SPORT ACADEMY

KISLEV-COHEN, R., HARAT, I.

WINGATE INSTITUTE

INTRODUCTION: Volleyball is heavily based on fast and explosive movements which play a critical role in performance. Sex-specific differences that arise during puberty are known to have an effect on the training process of adolescent athletes. Therefore it's essential to track longitudinal athletic performance to evaluate development and progress, and effectiveness of the training programs. The aim of the study was to compare athletic development of adolescent male and female volleyball players over time in the Academy of Excellence in Sports at Wingate Institute.

METHODS: Athletic performance test data of female (FVB, n=86) and male (MVB, n=88) indoor volleyball players was collected between 2013 and 2022. Tests were conducted up to 3 times per year and longitudinal changes were analyzed. The test battery included speed (5m,10m), agility and power (countermovement jumps and medicine ball throws) tests. Data was grouped into 3 age categories: 14 years or less (U14), 15-16 (U16), and 17-18 (U18).

RESULTS: In FVB group, no significant differences were found between age groups in 10m (U14: 2.05+0.16, U16: 1.99+0.12, U18: 1.98+ 0.08) and countermovement jump (CMJ) (U14: 35.7+5.0, U16: 37.0+5.4, U18: 37.4+4.8), a similar trend was found for the other tests performed. Conversely, in the MVB group significant differences ($p<.01$) were found in 10m between the U14 to U16 and U18 groups (U14: 1.94+0.15, U16: 1.85+0.09, U18: 1.76+0.06). Significant differences ($p<.01$) were also found in the CMJ performance between U14 group to U16 and U18 groups (U14: 40.5+7.3, U16: 47.5+7.0, U18:

50.7+5.7). Similar differences were also found in the other tests performed. In both groups, when expressed as percentages, the rate of change was greater between U14 and U16 compared to U16 and U18 for CMJ (MVB: 17.2% vs. 8.0% respectively; FVB: 3.5% vs. 1.0%) and for 10m (MVB 5.7% vs. 3.6%; FVB 2.7% vs. 0.7%).

CONCLUSION: Males demonstrated a noteworthy development in the parameters that were tested. The greatest improvement was apparent between U14 and U16 groups, reflecting the training process during the first years at the academy and possibly the time where peak development occurred. However, no significant differences were apparent in the females. This could be due to the fact that on average they reach their peak height velocity and biological maturation earlier than males, which has been known to affect training adaptation and physical development. For the athletes tested this period most likely occurred prior to entering the academy.

These results compare with previous studies assessing physical development of adolescent male and female athletes, reporting a decline in the rate of performance development with increasing biological age and possibly increase in training experience. These findings emphasize the need for coaches to understand the effects of growth and maturation on athletic abilities, and highlights the importance of longitudinal monitoring of young players through their early development years.

THE INFLUENCE OF STRENGTH LEVEL ON SPORT-SPECIFIC SKILLS BETWEEN STRONGER AND WEAKER PROFESSIONAL HANDBALL PLAYERS

KYRIACOU-ROSSI, A., HADJICHARALAMBOUS, M., ZARAS, N.

UNIVERSITY OF NICOSIA

INTRODUCTION: Handball is a complex team-sport that requires high-level of physical abilities and sport-specific skills in order to attain success [1]. Handball players spend a large part of their training in resistance training programs in order to enhance strength-power and as a consequence performance in the field [2]. However, the role of muscle strength on handball specific skills and whether stronger players may have a greater performance compared to weaker players remains largely unclear. The purpose of the study was to investigate the influence of muscle strength on handball specific skills and to examine the correlation between strength and handball specific skills.

METHODS: Twenty-one male professional handball players (height 1.81±0.08m; body mass 87.9±13.9kg), participated in the study. Experimental procedures were performed six weeks before the official initiation of the in-season period. Measurements included body composition, countermovement jump (CMJ), leg extension isometric peak torque (IPT) and rate of torque development (RTD), 0-20m linear sprint, T-Test agility, throwing velocity from 7 and 9 meters distance from the goal and one repetition maximum (1-RM) in bench press and squat. Players were separated into strong (SG) and weak (WG) groups according to their 1-RM strength in bench press and squat. T-Test was used to explore differences between SG and WG while r-Pearson correlation coefficient was used to investigate the relationship between variables. Statistical significance was set at $p \leq 0.05$.

RESULTS: No significant difference was found for body composition between SG and WG ($p>0.05$). However, SG had significantly higher CMJ height (21.5%, p=0.002), IPT (22.4%, p=0.008) and RTD relative to body mass from 0-100 to 0-250msec ($p<0.05$) compared to WG. Moreover, SG had lower 0-20 linear sprint (-6.3%, p=0.012) and agility time-trial (-7.3% p=0.001), while throwing velocity from 7m and 9m was significant higher for SG compared to WG (7.4%, p=0.011 and 8.2%, p=0.009, respectively). When all players considered as one group, 1-RM strength and IPT were significantly correlated with fat free mass (r=0.518-0.774), CMJ power production (r=0.649-0.823) and throwing velocity (r=0.639-0.819). In addition, RTD was significantly correlated with CMJ power (r=0.829), fat free mass (r=0.760) and throwing velocity (r=0.780 and 0.835).

CONCLUSION: The main finding of the study was that muscle strength has a significant influence in handball specific skills while stronger players may have a greater advantage in the field compared to their weaker counterparts. These results suggest that strength training should be a vital part for handball players as it leads to significant higher increases in performance.

DEVELOPMENT OF THE KOREA HANDBALL ACADEMY PHYSICAL FITNESS TEST MODEL FOR YOUTH HANDBALL PLAYERS

PARK, S.1,2, KIM, M.1, PARK, J.2,3, KWON, S.2,4, HAN, T.5, AHN, J.2,4

1 KOREA INSTITUTE SPORTS OF SCIENCE, 2 HANDBALL ACADEMY KOREA, 3 PUKYOUNG NATION UNIVERSITY, 4 KOREA HANDBALL FEDERATION, 5 ANDONG NATIONAL UNIVERSITY

INTRODUCTION: The purpose of this study was to develop a Korea Handball Academy Physical Fitness Test Battery for youth handball players considering their characteristics using Delphi/AHP technique.

METHODS: After reviewing previous studies, this study held an expert meeting to draft a battery. To select physical fitness variables, 17 experts with more than 10 years of research or coach experience in the related field were invited. The content validity of each test item was verified through the 1st and 2nd Delphi surveys. A decision-making method based on the analytic hierarchy process (AHP) was used to assign weights to each factor in the final physical fitness test battery selected based on the results of the Delphi survey.

RESULTS: As a result, 10 physical fitness factors, length (CVR=1.00), weight (CVR=0.67), muscle strength (CVR=0.67), muscular endurance (CVR=0.83), cardiorespiratory fitness (CVR=0.83), flexibility (CVR=0.67), power (CVR=1.00), agility (CVR=1.00), speed (CVR=0.80), coordination (CVR=1.00) were determined. As test variables for physical fitness, height (CVR=0.83), am span (CVR=0.67), lean body mass (CVR=0.64), handgrip strength (CVR=0.83), push-up (CVR=0.67), 20m shuttle run (CVR=1.00), sit-and-reach (CRT=0.83), standing long jump (CVR=0.67), countermovement jump (CVR=0.67), ball speed (CVR=0.67), rollercoaster run (CVR=0.83), visual reaction (CVR=0.83), 20m sprint (CVR=0.83) and ball handing (CVR=0.67) were found to be valid respectively. Weight was calculated according to the relative importance of the variables.

CONCLUSION: The present findings indicate that the Korea Handball Academy Physical Fitness Test Battery can be used to evaluate the physical fitness of youth handball players and select players with potential power.

RELATIONSHIP BETWEEN RATE OF FORCE DEVELOPMENT (RFD) AND REACTIVE FORCE (RSI) WITH THE RISK OF INJURIES AND REHABILITATION PROCESS IN HANDBALL: A SYSTEMATIC REVIEW.

CARRASCO-FERNÁNDEZ, L.1, GARCÍA-SILLERO, M.2, GARCÍA-ROMERO, J.1, BENÍTEZ-PORRES, J.1

UNIVERSIDAD DE MÁLAGA

INTRODUCTION: Handball is characterized as a team sport subjected to high intensity actions that require high physical demands on the player. It is a sport that includes physical efforts such as massive changes in movements and impacts and frequent contact between athletes that are related to the development of repetitive injuries (1-3). Previous studies indicate the importance of studying parameters such as the concentric and eccentric Rate of Force Development (RFD) and Reactive Strength Response (RSI) in order to improve sport performance and decrease the development of sport injuries. This is due to the direct and indirect relationship with the elastic energy of the muscle-tendon system (4, 5). Therefore, the purpose of this study was to analyze the benefits of strength training program on injury risk and the rehabilitation process in order to improve the sport performance in handball.

METHODS: A systematic review was conducted in PubMed, Scopus, Web of science and Sport Discus databases. The PRISMA methodology was considered in order to achieve more specific results. We included published studies in which strength variables will be included in training programs for handball teams with the aim of reducing the development of injuries or accelerating the process of rehabilitation. In addition, we focus on studies that include RFD and RSI parameters in lower limb training programs.

RESULTS: A total of 11 studies were included in the final systematic review. The selected studies were published between 2015-2023 and varying follow-up from 1 week to 12 months. In all the studies, programs for the prevention and rehabilitation of lower limb injuries were included in elite category female and male handball players. It was observed that RFD and RSI parameters are essential markers in elite handball teams. Training focused on eccentric actions such as change of direction, jumping or landing have shown an increase in power, muscle activation and leg stiffness level. A decrease in functional asymmetries, obtaining better results compared to with concentric and isometric training for injury prevention and rehabilitation programs was reported. Furthermore, they demonstrate the effectiveness of plyometric training, specific exercises, and a rest period after the competition season in rehabilitation programs for sports injuries.

CONCLUSION: Plyometric and eccentric exercises based on the improvement of RDF and RSI are fundamental in training programs of elite handball players due to the results observed increasing sports performance and optimizing rehabilitation programs for lower limb injuries. A multidisciplinary work focused on an individualized way taking into account the characteristics of each player is essential in elite handball teams to reduce the risk of injuries and accelerate the rehabilitation process.

PHYSIOLOGICAL AND BIOMECHANICAL LOADS IN SMALL SIDED FIELD HOCKEY GAMES

WILMES, E., DE RUITER, C., VAN LEEUWEN, R., BANNING, L., VAN DER LAAN, D., SAVELSBERGH, G.

VRIJE UNIVERSITEIT AMSTERDAM

INTRODUCTION: When assessing training load, a distinction can be made between physiological and biomechanical load [1]. The physiological load of field hockey is known to vary with different formats of small sided games (SSGs) [2]. However, little is known about the biomechanical loads of field hockey SSGs. Therefore, the aim of present study was to gain a more thorough understanding of biomechanical loads in field hockey SSGs in comparison to physiological loads.

METHODS: Two different SSGs (small: 5 versus 5, ~100 m2 per player; large: 9 versus 9, ~200 m2 per player) were performed by sixteen female elite field hockey athletes of the Dutch U-21 team during two experimental training sessions. Players were equipped with a global navigation satellite system worn between the scapulae, which measured player position, and three inertial measurement units on the pelvis and thighs, which measured lower body kinematics. The effects of SSG format on a variety of physiological (i.e., distances covered in various speed ranges) and biomechanical (i.e., mean absolute acceleration/deceleration, and time spent in several demanding body postures) load metrics were assessed using linear mixed models (significance level of $p<0.05$).

RESULTS: The physiological loads were higher for the large SSG. In contrast, most biomechanical load metrics were higher for the small SSG.

CONCLUSION: This study has shown that changing SSG format affects physiological and biomechanical load differently. Physiological loads appear to be higher for large SSGs, whilst biomechanical loads seem to be higher for small SSGs.

INTRODUCTION: To improve players' performance in team sports such as rink hockey, it is important to manage the training process ensuring positive adaptation according to competitive demands. Therefore, monitoring training load (TL) to appropriately adjust between stress and recovery during training microcycles and minimize the risk of developing non-functional overreaching is crucial to develop athletes' physiological adaptations. This research aimed to investigate the training load through external (EL) and internal load (IL) dynamics across the preparation and competition of a top-level national team during the 2021 Rink Hockey European Championship.
