METHODS: An observational study was carried out during the preparation and competition phases of the 2021 Rink Hockey European Championship from the 1rst until the 20th of November 2021. A non-experimental descriptive method was used to characterize the training sessions and training matches during the two (2) preparation weeks (TW-2 - two training weeks preceding the competition and TW-1 – one week before the competition) and the competitive games of the competition week (CW). The preparation weeks were characterized by training sessions (TMD-3, TMD-2, TMD-1) and 2 training matches (TMD). In total, players participated in 12 rink training sessions, 4 training matches, and 3 international competitive games during the three weeks of the study. A two-way mixed design ANOVA was utilized to compare EL and IL across microcycles during training sessions and competitions. A Spearman-Rho correlation test was used to understand the relationship between players' EL and IL during training sessions and competitive matches.

RESULTS: In general, results revealed significantly higher values between training match day -3 (TMD-3) to TMD-1 for Player Load (PL) ($p \leq 0.05$) distance covered (DT) and high-speed skating (HSS; ≥18 km) ($p \leq 0.001$). Competition weeks (CW) also revealed significantly higher values in comparison with training weeks (TW-2 and TW-1). Interestingly, during competition, high impacts (Himpt; 8-10 g) ($p \leq 0.001$, $r=0.64$) and decelerations (DEC; [-10 -3]m/s2 (n)) ($p \leq 0.001$, $r=0.43$) had a greater influence on players' session RPE (s-RPE) than in training weeks.

CONCLUSION: Our results suggest that training sessions do not represent the game demands, for example, HImpt and DEC appear to induce physiological impacts in players, but the same does not occur in the training sessions. Such results highlight the need to understand the competitive dynamics of the sport and the use of the most appropriate metrics to monitor the preparation process.

PLAYING POSITION EFFECTS ON TECHNICAL AND PERFORMANCE CHARACTERISTICS IN MALE FUTSAL PLAYERS

SOUGLIS, A.1, KALIARNTAS, K.2, APOSTOLIDIS A.1, ANDRONIKOS, G.2, GELADAS N.1, TRAVLOS A.3, BOGDANIS, G.1

<1> NATIONAL AND KAPODISTRIAN UNIVERSITY OF ATHENS, ATHENS, GREECE <2> EDINBURGH NAPIER UNIVERSITY, EDINBURGH, UK <3> UNIVERSITY OF PELOPONNESE, GREECE

INTRODUCTION: Futsal or five-a-side indoors soccer is an intermittent high-intensity sport characterized by high physical, technical, and tactical demands. Although there are several studies evaluating the effects of playing position on technical and performance characteristics in soccer, there is limited evidence in futsal. Therefore, the current study aimed to examine the positional differences in terms of technical and performance characteristics in male futsal players.

METHODS: Sixty-two futsal players were randomly allocated into four groups: control group (n=16, age: 23.6±0.7 y), wingers (n=18, age: 23.1±0.5 y), defenders (n=16, age: 22.4±0.4 y) and pivots (n=12, age: 24.1±0.5 y). Technical (i.e., passes, dribbles, ball touches shots, headers, possessions) and performance characteristics (final 3rd court entries, heart rate, total distance covered, sprint distance) were measured during the match. Also 30-meters sprinting time, countermovement jump (CMJ), delayed onset muscle soreness (DOMS) of the knee flexors/extensors and dominant knee joint range of movement (KJRM-DL) were measured before, immediately after, and 24h, 48h, 72h, 96h, 120h, and 144h post-match. A mixed-model ANOVA was used for statistical analyses.

RESULTS: Wingers touched significantly more times the ball but performed significantly less headers compared to pivots and defenders ($p<.05$). Defenders received less passes but lost the ball significantly less times and performed significantly more headers compared to wingers and pivots ($p<.05$). Wingers had significantly higher HR in both halves of the game. Overall, wingers covered significantly longer distance during the game and more so in the first half and were standing and walking less compared to the other groups ($p<.05$). The distance covered significantly reduced in the second half in all groups ($p < .05$) with wingers indicating a more marked decrease (6.3%). Similarly, wingers performed significantly more sprinting whereas defenders sprinted significantly less ($p<.05$). Performance in 30-m sprint and CMJ significantly decreased immediately after the game and retuned to baseline at 72h later in wingers and pivots. Defenders returned to baseline at 144h and 96h respectively. DOMS symptoms peaked 24h after and returned to baseline 96-120h post-match in both dominant lower limb flexors and extensors. KJRM-DL decrease peaked at 24h (with wingers experiencing the larger decrease) and returned to baseline 72h post game ($p<.05$).

CONCLUSION: Futsal playing positions have different technical and performance demands. Wingers touch the ball more frequently, sprint and cover significantly more distance and this is reflected in their higher HR compared to the other positions. Sprinting, jumping and KJRM-DL performance is significantly impaired in the first 24h whereas DOMS symptoms

significantly increase in all positions. It seems that DOMS lasts longer in defenders and KJRM-DL is more prominent in wingers. This evidence can be used to improve current futsal training practice.

INFLUENCE OF REDUCED FIELD AREA ON TACTICAL BEHAVIOUR IN 11VS11 FOOTBALL PRACTICE GAMES

WITTKUGEL, J., DEUKER, A., JAKOBS, J., BRAUNSTEIN, B., REIN, R., VOGT, T.
DEUTSCHE SPORTHOCHSCHULE KÖLN

INTRODUCTION: The behaviour of players in team sports is substantially influenced by the ecological context in which they are constantly perceiving and acting [2]. Thereby, the collective behaviour of the competing teams is shaped by the environmental conditions like the available playing area. In football practice, it is common for coaches to adjust the environmental layout in comparison to the formal 11vs11. For example, practice games are played on smaller goals or without goals at all, with fewer players or additional players for the team in possession, or with defined zones that arise with specific tasks. In practice the most common training adjustment is called Small-Sided-Game. This notion is defined by the reduction of the field area and area per player in the chosen practice game design [1, 4]. Therefore, the present study aims to examine the adaptions of collective tactical behaviour as a consequence of a reduction of the field area in a 11vs11 practice game.

METHODS: Four different field conditions were played and examined. Each condition was played with eleven players per team. Each team played five attacks per condition (a total of 40 attacks). Every attack started with the goalkeeper in possession. Conditions were played in the following order: 105m long x 68m wide (325 m2 per player, formal); 86m x 56m (219 m2 p. p., large); 74m x 48m (162 m2 p. p., half) and 59m x 38m (102 m2 p. p., small), respectively. Each player was equipped with a GPS unit (Catapult) to collect positional data and calculate the parameters distance-to-nearest-opponent, convex hull, and relative field usage [3].

RESULTS: The mean areas of the convex hulls were formal: 1412±139, large: 1210±115, half: 978±81.6, and small: 672±76 square meters. Significant differences were found across all conditions with an ANOVA ($F=88.16$; $P<0.001$; effect size=0,88) and post hoc ($P<0.001$) test. Thus, significant differences across all conditions were also found for the 'distance-to-nearest-opponent' parameter. Relative field usage also showed significant differences ($F=40.4$; $P<0.001$; effect size=0.72). This value was significantly lower in the formal game than in all three smaller field conditions ($P<0.001$).

CONCLUSION: Our findings suggest that scaling of the field sizes has a significant impact on the collective behaviour of teams practicing 11vs11 and should be chosen with care by the practioners. As the findings show, not only distances between the players and the convex hull change, but also the relative field usage. Reduction of field size results in less space outside the convex hull and therefore less opportunities left for players to find goal-directed solutions.

CHANGE OF DIRECTION AND CHANGE OF DIRECTION DEFICIT IN DANISH ELITE FEMALE AND MALE SOCCER PLAYERS PERFORMING 505 AND ARROWHEAD TESTS

FRANCH, J., KOEFOED, N.S.2
1.AALBORG UNIVERSITY, 2.UNIVERSITY OF COPENHAGEN, DEPARTMENT OF NUTRITION, EXERCISE AND SPORTS, COPENHAGEN, DENMARK

INTRODUCTION: In soccer, the ability to 'cut' and change direction during running is considered an important factor and occurs frequently during a game (1). The basic ability of players to change direction (without ball possession) is often evaluated through sprint running involving one or multiple changes of direction (COD) tests with time as an outcome (CODt), i.e. the 505t or the arrowhead test (AHt). A recent approach to this is to eliminate the linear sprint by calculating the change of direction deficit (CODd) in the 505 (505CODd) (2). The present study investigates this approach in elite Danish female soccer players. The same approach of using CODd in combination with AHt (AHCODd) is investigated in elite Danish male soccer players.

METHODS: Two groups participated, with one group being further divided in three age-groups. The groups consisted of 21 top-level female players (EW; age: 19.6±4.9 years, height: 171.6±7.3 cm, bodyweight: 61.8±6.1 kg) and 48 elite male players (EM). The EM group contained players at different age groups; under-17 (EM17; n=17, age: 15.5±0.5 years, height: 180.5±6.7 cm, bodyweight: 70.4±7.9 kg), Under-19 (EM19; n=14, age: 17.2±0.7 years, height: 181.0±7.9 cm, bodyweight: 68.8±7.76 kg) and senior (EMS; n=17, age: 23.5±4.17 years, height: 183.5±6.0 cm, bodyweight: 78.6±5.7 kg).

All groups performed a 30 m sprint test, with EW also recording a 10 m split time. Additionally, EW performed the 505t and 505CODd. The male players performed the AHt and the AHCODd. For CODd calculations 10m and 30m linear sprint time was subtracted from 505t and AHt, respectively.

Split and final times were recorded using infrared photocells. Witty (Microgate, Bolzano, Italy and Ci; Brower Timing, Draper, UT, USA, for EM and EW respectively).

All time comparisons were performed using one way ANOVA. Correlation between CODt and CODd was performed with 'Pearson's r correlation' or 'Spearman Signed Rank Test' and all male players were pooled for correlation analysis.

RESULTS: Across groups EMS was significantly faster in the 30 m sprint compared to EM19 and EM17 and EW was significantly slower than all other groups ($p < 0.05$). For EW, positive correlation was found for 10 m sprint and 505t ($r = 0.67$), and an insignificantly negative relationship between 10 m sprint and 505CODd. For EM 30 m sprint and AHt correlated ($r = 0.68$), and an insignificantly negative relationship between 30 m sprint and 505CODd.

CONCLUSION: In Danish elite soccer players, the present study shows high correlations between CODt and linear sprint times, in both male and female players, indicating that linear sprint ability, and not COD is evaluated in the COD tests used. The results therefore support similar results in experienced cricketers (2) however, the observed insignificant negative relationship between linear sprint time and CODd needs further research on order to qualify player performance.

TRAINING AIMS FOR SMALL-SIDED GAMES: THE EFFECTS ON SMALL-SIDED GAME DESIGN AND LOCOMOTOR DEMANDS IN WOMEN'S ACADEMY SOCCER

OLTHOF, S., MCQUILLIAM, S.

LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: Small-sided games (SSGs) are training formats played in a soccer practice and played with the intention to induce physical, technical, and tactical training stimuli[1,2]. Coaches use varying pitch dimensions, team sizes, and playing rules to emphasise a desired training outcome. Where manipulations in SSG constraints shape the demands for players, it remains unclear what the influence is of the intended training aim on the design and consequently the demands in SSGs. Therefore, the aim is to investigate the effect of the intended training aim on the SSG design and players' locomotor demands.

METHODS: Training plans and locomotor demands of an under-21 women's academy team were monitored. Eighteen players played a total of 186 SSGs during 64 practice sessions over five months. Training plans were completed by the coach before the training and included the intended training aim (i.e., physical, technical and/or tactical), pitch size (as the relative pitch area [RPA]), team size, and duration for each SSG. Locomotor activities were obtained with player tracking technology (Catapult S7, Melbourne, Australia) during the training and analysed on total distance (TD), high-speed running distance (HSRD; 12.5-19.0km/h), very high-speed running distance (VHSRD; 19.0-22.5km/h), sprint distance (SD; >22.5km/h)[3], and accelerations and decelerations (ACC-DEC). Locomotor variables were normalised for the SSG duration. Differences in the training design and locomotor demands were evaluated for training aim (ANOVA with post-hoc tests with Bonferroni corrections; $p<.05$).

RESULTS: The intended training outcome had a significant effect on the SSG design and demands ($p<.001$). SSGs with a technical aim were played in a smaller RPA, with less players, and for a shorter duration than in SSGs with a (combination of) tactical and physical aim ($p<.05$). Further, SSGs with a physical aim demanded greater TD, HSRD, VHSRD, and SD from the players than with a (combination of) technical and tactical aim ($p<.05$). In SSGs with a technical aim, players covered less TD, HSRD, VHSRD, and SD, but performed more ACC-DEC than in SSGs with a (combination of) physical and tactical aim ($p<.05$).

CONCLUSION: The training aim significantly influenced how coaches designed SSGs prior to practice and consequently affected the players' locomotor demands. SSGs with small pitch sizes and number of players and a short duration are typically played for a technical outcome, but also evoked more ACC-DEC. In contrast, SSGs with greater pitch sizes and number of players and a longer duration are often used for physical and tactical outcomes. This induced greater running demands and aligned with the physical aim of the SSG[2]. Coaches' intentions for a SSG determine the format, and will consequently stress the locomotor demands, alongside technical and tactical demands[1].

DIFFERENTIAL EFFECTS OF SMALL-SIDED GAME LOAD ON NEUROMUSCULAR AND PERCEPTUAL-COGNITIVE PERFORMANCE OF YOUTH SOCCER PLAYERS

SKALA, F., ZEMKOVÁ, E.

FACULTY OF PHYSICAL EDUCATION AND SPORT, COMENIUS UNIVERSITY IN BRATISLAVA

INTRODUCTION: Physical and psychological load of small-sided games (SSGs) can affect players' neuromuscular and cognitive performance [1,2]. The question remains which of load variables are responsible for the impairment of performance in youth soccer players. This study investigates players' neuromuscular and perceptual-cognitive performance i) response to SSG, ii) relationship with external load and perception of fatigue.

METHODS: Sixteen academy soccer players (13.6±0.5y, 163.4±5.9cm, 50.4±7.1kg) underwent SSG 4v4 + GK (40x25m) consisting of six 4-min intervals separated by 1-min recovery. Exercise intensity was monitored by the tracking system Polar Team Pro (Polar, Kempele, Finland). Before and after SSG a 100-mm visual analog scale (VAS-F) determined subjective perception of fatigue, followed by planned (PA) and reactive (RA) agility tests, countermovement jump (CMJ), divided attention task (DA), and go/no-go task (GNG). Paired t-test and Wilcoxon signed-rank test were used to analyze performance changes. Individual pre-post differences (Δ) were aligned with load variables to calculate Pearson's (r) or Spearman's (rs) correlation coefficients.

RESULTS: Players achieved 87±4% HRmax with a relative distance covered of 92±7 m/min. Subjective perception of fatigue increased after SSG (41.56±14.02%, p=.001). Further, CMJ height decreased (-6.67±6.64%, p=.014, d=.56), whilst PA time (3.71±2.50%, p=.002, d=.97), RA time (6.60±7.36%, p=.003, d=1.78) and errors in GNG increased (46.43±138.3%, p=.039, d=.59). There were no significant changes in DA task errors (3.66±16.81%, p=.362, d=.22) and speed of response in GNG task (-3.36±8.04%, p=.119, d=.29). Additionally, significant correlation was found between ΔPA and ΔVAS-F (r=.60, p=.014), and moderate between ΔPA and low to medium intensity decelerations (r=.48, p=.061). ΔRA correlated significantly with ΔCMJ height (r=-.54, p=.031) and moderately with ΔGNG errors (rs=.47, p=.123). Sprinting distance (≥21 km/h) and maximal speed in SSG correlated with ΔCMJ height (rs=.66, p=.006; r=.54, p=.032) while high-intensity accelerations correlated with ΔPA (r=-.76, p=.002).

CONCLUSION: Fatigue induced by SSG load affects youth players' agility, explosive strength, and decision-making in visual inhibition task. PA time was associated with fatigue perception and low to medium intensity decelerations. In addition, there was a relationship between explosive strength decrement and RA time. This variable was moderately associated with increased errors in GNG task. However, players who covered a longer sprinting distance and achieved higher maximal speed in SSG had smaller decrement in CMJ height, and those producing a higher number of high-intensity accelerations had smaller increase in PA time. High-intensity actions in SSG may, to some extent compensate for neuromuscular performance decline in young players.

TRAINING LOAD COMPARISON BETWEEN SMALL, MEDIUM, AND LARGE-SIDED GAMES IN PROFESSIONAL FOOTBALL

BEATO, M.

UNIVERSITY OF SUFFOLK

INTRODUCTION: Football training aims to develop physical capacities, tactical and technical skills to compete during matches. In the latest years, sided-games, which are categorized as small (SSG), medium (MSG), and large (LSG) formats, have been commonly used by coaches for simultaneously training these capacities and skills. This study aimed to assess if internal and external load parameters were different between sided-game formats, secondly, if these parameters were influenced by players' positions, and finally, if load parameters were different among sided-game types (from 2vs2 to 10vs10) in professional football players.

METHODS: Twenty-five male professional football players of the same club were enrolled in this study (age = 27 +- 9 years and body mass = 78 +- 14 kg) during the 2022-23 season. Sided-games were categorized in formats as SSG (n =145), MSG (n = 431), and LSG (n = 204). Players were divided into roles such as central backs (CB), fullbacks (FB), central midfielders (CM), attacking midfielders (AM), and strikers (ST). STATSports 10 Hz GNSS Apex units were used to monitor external load parameters such as distance, high-speed running (HSR), sprinting distance, accelerations, and decelerations. The internal load was quantified using the rate of perceived exertion (RPE).

RESULTS: The linear mixed model analysis found differences between formats ($p < 0.001$) for RPE, distance, HSR, sprinting, accelerations, and decelerations. Differences were found between positions for HSR ($p = 0.004$), sprinting ($p = 0.006$), and decelerations ($p < 0.001$). Moreover, a significant difference was found between sided-game types ($p < 0.001$) for RPE, distance, HSR, sprinting, accelerations, and decelerations.

CONCLUSION: This study found that some specific sided-games formats were more suitable to load some parameters than others, specifically, the distance, HSR, and sprinting distance covered were greater during LSG compared to MSG or SSG. The number of accelerations and decelerations was higher in MSG compared to SSG. The players' positions influenced some external load metrics, specifically, HSR and decelerations but not RPE or distance per minute. LSG 8vs8 was found to be the most demanding drill for distance covered and LSG 10 vs 10 was found to be the most demanding drill for HSR and sprinting. On the other hand, acceleration and deceleration demands were greater in MSG 5vs5 and MSG 6vs6 compared to other formats.

ASSESSING THE INDIVIDUAL RELATIONSHIP BETWEEN PHYSICAL FITNESS IMPROVEMENTS AND EXTERNAL LOAD MATCH PERFORMANCE IN MALE PROFESSIONAL FOOTBALL PLAYERS – A CASE STUDY

SPENCER, M.1, BYRKJEDAL, P.T.1, LUTEBERGET, L.S.1,2, IVARSSON, A.1,3, BJØRNSEN, T.1

1UNIVERSITY OF AGDER, DEPARTMENT OF SPORT SCIENCE AND PHYSICAL EDUCATION; 2DEPARTMENT OF PHYSICAL PERFORMANCE, NORWEGIAN SCHOOL OF SPORT SCIENCES; 3SCHOOL OF HEALTH AND WELFARE, HALMSTAD UNIVERSITY

INTRODUCTION: Coaches and practitioners may interpret improvements in physical capacity via fitness tests as coinciding with improvements in external load match performance, based on the assumption of a causal relationship between these variables. However, numerous factors, including reliability and validity of different measures, must be considered before making such an interpretation (1,2). Currently, there is limited research investigating these match related effects following an improvement in relevant physical fitness assessments. The aim of this study was to investigate if a meaningful improvement in physical fitness tests following an in-season strength training period can be related to and affect external load match performance at an individual level in professional male football players.

METHODS: Eight professional football players (25.4 ± 3.1 yrs, 184.1 ± 3.4 cm, 79.3 ± 2.2 kg) completed an in-season 10-week strength intervention period and participated in >2 matches with >60 min playing time pre- and post-intervention, to be included in the analysis. Physical fitness tests were undertaken pre- and post-intervention and included: 10-, 30-m and

peak speed sprint times, countermovement jump (CMJ) and leg press power. External load match performance was recorded pre- and post-intervention and included: total distance, peak speed, high (19.8-25.2 km/h) and sprint (>25.2 km/h) intensity running distance, PlayerLoadTM, and high intensity events (>2.5 m/s) consisting of accelerations, decelerations and change of directions. Physical fitness improvements had to exceed the measurements typical error (TE) and the smallest worthwhile difference (SWD) to be considered meaningful (1,2). A non-overlap of all pairs analysis (NAP; 3) was performed to assess external load match performance pre- and post-intervention and Bayesian pairwise correlation analysis was performed to assess the relationships between changes in physical fitness and external load match performance.

RESULTS: Three players displayed meaningful improvements in 2-5 physical fitness tests. However, NAP analysis showed positive effects in external load match performance for all 8 players. Kendal's Tau correlation analysis showed evidence (Base factor >3) for only one correlation (peak speed – decelerations, τ = -.62) between the changes in physical fitness and external load match performance, while the remaining comparisons were unrelated.

CONCLUSION: Our findings suggest that improvements in physical fitness may not necessarily translate to improved external load match performance. Further research is required to understand the potential relationships between physical fitness improvements and changes in football external load match performance.

PHYSICAL PERFORMANCE DIFFERENCES BETWEEN GROUP AND FINAL STAGES IN THE 2022 FIFA WORLD CUP

CAVACA, M.L.1,2, FATELA, P.1, REIS, J.F.2,3, PASSOS, P.3, BRITO, J.2, VALAMATOS, M.J.2,3

1FACULTY OF HUMAN KINETICS – LISBON UNIVERSITY, PORTUGAL; 2 PORTUGAL FOOTBALL SCHOOL, PORTUGUESE FOOTBALL FEDERATION, OEIRAS, PORTUGAL; 3CIPER - FACULTY OF HUMAN KINETICS – LISBON UNIVERSITY, PORTUGAL

INTRODUCTION: Soccer is a sport characterized by a great number of high-intensity actions where players must display great sprinting abilities, leg muscular power, and technical skills in order to be successful. The aim of this study was to compare the physical performance of finalist teams in the 2022 FIFA World Cup Qatar, between group and final stages.

METHODS: A total of forty matches (n=24 matches in the group stage and n=16 matches in the final stage) of the 2022 FIFA World Cup were analyzed. All data were accessed through the official FIFA website considering the official statistic report of each analyzed match. For group stage analysis only successful teams (teams cleared to the final stage) were considered. A total of eight physical metrics were considered: total distance covered, total distance in different intensity zones (zone 1: 0-7 km/h; zone 2: 7-15 km/h; zone 3: 15-20 km/h; zone 4: 20-25 km/h; zone 5: more than 25 km/h), number of high-speed runs (i.e., HSR – performed between 20-25 km/h) and number of sprints. All variables were normalized to game time.

A mixed-effects model was used to compare the variables behavior between the different World Cup stages. The significance level was set to $p < 0.05$ for all statistical analyses.

RESULTS: Significant differences were found for all physical metrics analyzed between final and group stages ($p<0.001$). In all variables teams cleared to the final stage presented higher levels of physical performance during group stage comparing to final stage ($p<0,01$) meaning high total distance covered, distance covered in all intensity zones (zone 1, zone 2, zone 3, zone 4 and zone 5), and high number of sprints and high-speed runs, in group stage.

CONCLUSION: Our finding suggest that teams perform differently along the championship. From the group stage to the final stage, mean team values decreased in all variables of performance, in distance covered and in high intensity actions. A possible reason to this decrease in performance is the cumulative fatigue, since the game calendar imposed a match at every 3 days, hampering a full recovery between matches. However, more information regarding the athlete perception of fatigue, objective measurements of fatigue and recovery are needed to support this suggestion. Another topic of interest is specific climatic characteristics of this particular world cup (Qatar), as it was a championship characterized by high temperature and humidity. Therefore, the knowledge about the physical behavior in different stages of FIFA World Cup Championships should be considered in the future.

PREVALENCE OF POOR SLEEP QUALITY, SLEEPINESS, AND INSUFFICIENT SLEEP DURATION IN SOCCER PLAYERS

CUNHA, L.A.1, BRITO, J.2, LASTELLA, M.3, FIGUEIREDO, P.1,2,4

1. CIDESD, UNIVERSITY OF MAIA, PORTUGAL; 2. PORTUGAL FOOTBALL SCHOOL, PORTUGUESE FOOTBALL FEDERATION; 3. CENTRAL QUEENSLAND UNIVERSITY, AUSTRALIA; 4. UNITED ARAB EMIRATES UNIVERSITY, ABU DHABI

INTRODUCTION: It is well-known that sleep is essential for optimal recovery and performance for athletes. Despite that, they are often exposed to some sport and non-sport factors that can negatively affect sleep. Therefore, this study aimed to analyze sleep habits in soccer players, describing the prevalence of poor sleep quality, excessive daytime sleepiness, habitual sleep duration and self-assessed sleep needs.

METHODS: The study included 682 soccer players (n = 73 females) of various age groups (mean age: 18.5 ± 7.0; range: 51 years old). The participants completed the Pittsburgh Sleep Quality Index (PSQI), the Epworth Sleepiness Score (ESS), and answered the question: "how many hours of sleep do you need to feel rested?". For each player, a sleep deficit index (SDI) was calculated by subtracting their habitual sleep duration (reported in the PSQI) from self-assessed sleep needs. It was

considered relevant if the SDI was ≥ 1 hour. The groups were defined and compared based on sleep recommendations for each age category: 8-13 years old; 14-17 years old; ≥18 years old. Correlations were computed between the PSQI and ESS scores and sleep duration.

RESULTS: Excessive daytime sleepiness was present in 71% of the players (8-13 years old: 22%; 14-17 years old: 79%; ≥18 years old: 87%), 28% reported poor sleep quality (8-13 years old: 8%; 14-17 years old: 18,5%; ≥18 years old: 44%), 29% did not achieve the minimum recommended sleep duration (8-13 years old: 39%; 14-17 years old: 36%; ≥18 years old: 20%), and 44% had an SDI ≥ 1h (8-13 years old: 25%; 14-17 years old: 42%; ≥18 years old: 48%). Significant differences were found in sleep duration, PSQI and ESS scores between age groups ($p<0.01$). Negative correlations between sleep duration and PSQI ($rs=-0.55$, $p<0.01$) and ESS ($rs=-0.32$, $p<0.01$) scores were found. There was a positive correlation between PSQI and ESS scores ($rs=0.40$, $p<0.01$).

CONCLUSION: The results showed that the ≥18 years age group, in general, had poorer sleep quality, more prevalence of excessive daytime sleepiness, and higher prevalence of not achieving the amount of sleep that satisfied individual needs, compared with younger players. An extremely high proportion of players aged 14-17 and ≥18 years had excessive daytime sleepiness (79% and 87%, respectively). It was found that players with poorer sleep quality had a higher level of sleepiness during the day, and shorter sleep duration was associated with lower sleep quality and greater sleepiness. These results showed that a large proportion of players suffer from sleep disturbance. Since sleep is crucial for optimal recovery and subsequent performance, athletes should be aware of the importance of adopting behaviors that could result in better sleep.

INTERSTATE TRAVEL HAS MINIMAL IMPACT ON MEAN AND INDIVIDUAL SLEEP VARIABILITY IN ELITE MALE AUSTRALIAN FOOTBALLERS

SPENCE, A.L.1, KEMP, S.M.1, KELLER, B.S.2, DUCKER, K.J.1, MCVEIGH, J.1, GUCCIARDI, D.F.1

1 CURTIN UNIVERSITY, 2 FREMANTLE FOOTBALL CLUB

INTRODUCTION: Regular travel is an expectation for professional athletes competing at national or international level. Travel fatigue and jet lag symptoms are likely consequences for athletes engaged in frequent domestic travel. Recurrent time zone crossings may result in disruption to sleep behaviours, impacting recovery and subsequent performance. We conducted a pre-registered examination of sleep metrics in elite male Australian Football players, from the same professional club, over two weeks and compared players who travelled for interstate competition (away fixture) to those who remained at home (home fixture).

METHODS: Using wrist-worn actigraphy, nightly sleep metrics including sleep duration (minutes), sleep efficiency (%) and sleep onset (time of day) were recorded in 15 athletes (22.7±3.5 years) over 13 consecutive nights. Data collection aligned with the start of the competitive season where the team had consecutive away and home fixtures, enabling a quasi-randomisation based on club player selection. Players travelled eastward on Day 3 (Night 4: GMT+8 to GMT+10.5) and returned on Day 4 (Night 5), the evening of match day. The subsequent home fixture was played on Night 12. Raw accelerometer data analysis was performed using GGIR with resulting metrics analysed using a location-scale model within a multilevel framework, to estimate the effect of travel on mean-level and intra-individual variability of sleep indices. Results are reported as mean and 95% credibility interval (CI).

RESULTS: Overall, players averaged 500 minutes of sleep per night (95%CI = 489, 510), with 86% sleep efficiency (95%CI = 83.7, 88.8) and fell asleep (sleep onset) at 22:30 (95%CI = 22:12, 22:42). Inferentially, players who travelled interstate (n=7) for competition slept for shorter periods (-0.04, 95% CI = -0.43, 0.31), had a later sleep onset (+0.38, 95%CI = -0.52, 1.24) but had a greater sleep efficiency (+3%, 95% CI = -6.70, 12.98) compared to those who remained home (n=8). Players who travelled interstate experienced less variability in sleep duration (-0.08, 95% CI = -0.45, 0.27) and efficiency (-0.74, 95% CI = -2.37, 0.93), but experienced greater variability in sleep onset (+0.39, 95% CI = -2.15, 2.98) compared to those who remained at home.

CONCLUSION: Existing research on sleep dynamics within sport have typically relied on mean-level estimates, yet this limited focus is insufficient due to the complexity of individual sleep behaviours. Integrating both mean-levels and intra-individual variability estimates of sleep indices, we observed small, statistically inconsequential effects of travel on sleep metrics, most likely due to the small sample. Nevertheless, the inclusion of intra-individual variability alongside mean-level estimates of sleep metrics, both statistically and visually, provides a holistic approach to understanding sleep behaviours in the context of elite sport. This would further enable the development of personalised interventions to optimise sleep hygiene in athletes.

ENVIRONMENTAL CHALLENGES, OBSTACLES AND WISHES IN EQUESTRIAN SPORTS: CONSUMPTION, LACK OF POWER, AND KNOWLEDGE

SÄTRE, A., HEDENBORG, S., PALMQUIST, T.G., RADMANN, A., KRONBORG, M.

MALMÖ UNIVERSITY

Introduction

Addressing issues under the umbrella of the climate crisis is arguably the business of every sector and every individual. Sport science research has, however, been focused on how the human body has been affected by the environment (eg., Timpka et al., 2020; Gale et al., 2020; Sandford, et al., 2021) rather than vice versa and the environmental effects of (mega) events (McCullough, 2017). Less is known about behavior and attitudes regarding environmental issues in the sport sector (cf. Mistra Background Paper, 2018). In collaboration with riding schools, federations and higher education institutions in the sector, this study aims to gain a deep understanding of how people in equestrian sport perceive environmental challenges, obstacles and solutions.

Methods

Data consists of 30 semi-structured interviews with representatives of riding schools, >400 responses to an online survey (still open), educational plans and environmental policies from riding schools, federations and higher education institutions in Sweden and Norway. In the survey, respondents answered multiple choice and free text questions on perceptions of main challenges, obstacles, and solutions to an environmentally sustainable equestrian sport. Free text answers were focused and analysed using data-reduction, coding, and conclusions. The material was organized in three categories: challenges, obstacles and wishes. To validate the data analysis, we circled back to the original answers to control that chosen parts matched the context and answers in a representable way.

Results

Results show that people in equestrian sports identify consumption as a main challenge to a pro-environmental transformation of the sports. A main obstacle is the 'lack of power', in relation to becoming a part of environmental improvement and structural change. Furthermore, they answered that this obstacle could be met by knowledge.

Discussion

Similar to what Beames et al has shown regarding adventure sports (Beames et al 2019; Beams et al 2022), consumption patterns is seen as a main challenge to an environmentally sustainable equestrian sport. Representatives of riding schools describe an increased consumption of supplies, for example in relation to seasonal trends. Respondents single out 'lack of power' as the obstacle, saying the board and the industry must be open for a transformation for a positive change to happen. However, action is being taken, for example by repairing instead of buying new, and arranging opportunities for consuming second hand riding clothes and supplies. To overcome the obstacle, the respondents wish for increased knowledge reaching all levels in equestrian sports; from riding classes to the board, and with contribution and follow up-initiatives by higher institutions.

ATTITUDES TO ENVIRONMENTAL CHANGE IN EQUESTRIAN SPORTS

KRONBORG, M.

NORWEGIAN SCHOOL OF SPORT

Attitudes to Environmental Change in Equestrian Sports

Kronborg, M., Hedenborg, S., Palmquist, T. G., Radmann, A., Sätre, A

Norwegian School of Sport Sciences

Introduction

Studies show that the equine sector emits more carbon dioxide than domestic aviation, the main issues being food and transport (Müller, 2021). Other studies show that nutrient leakage from manure piles and paddocks and pastures are major problems (Blomberg &Välimaa, 2016). These challenges are important to overcome to develop a sustainable equestrian sport. The purpose of this study is, first, to understand obstacles to a pro-environmental sport and, second, how interventions can be built to transform the sport using the COM-B model for behavior change. The presentation will focus on the obstacles.

Method

Data consists of survey answers (>400) and 30 semi-structured interviews in Norway and Sweden. The COM-B model was used to analyze the data. Trustworthiness was ensured through several processes being (reflexivity, audio traits, dependability, conformability)

Results

In the COM-B model for behavior change capability (C), opportunity (O), and motivation (M), are three key factors capable of changing behavior (B) (Barker et al 2016). Results of this study show that although stakeholders in equestrian sports are aware of and motivated to change their behavior (M), they lack knowledge and skills (C). In addition, they point to challenges related to economy and simultaneously fulfilling other sustainability goals (O). Furthermore, although motivation for change is present it is expressed as something they have to do (rather than want to do). There are, in other words, obstacles to change in all three categories.

Discussion

Knowledge of obstacles to change related to the COM-B model can, in conjunction with the 'behavior change wheel' (Michie, S et al 2014) be used as a base for interventions. To initiate successful interventions, it is important to identify the categories of intervention that should be included in the behavior change strategy such as education, persuasion, incentivization, coercion, enablement, training, restriction, environmental restructuring, and modelling. As a result of this study, we would suggest that the Equestrian Sport Federations and local governments in Sweden and Norway start with interventions targeted at education and enablement.

ANALYSIS OF TENNIS CADDIES CULTURE

LIU, L.H., LIU, Y.D.

CHINA UNIVERSITY OF GEOSCIENCES, WUHAN

Introduction

Tennis caddies refer to the personnel who provide corresponding services such as ball picking and ball supply for players under the guidance of the referee in accordance with tennis rules in tennis tournament. As a part of the tournament, especially the Grand Slam, tennis caddies have developed a distinctive caddie culture over the centuries, which is a combination of material, institutional, spiritual and behavioral culture. In modern tennis, the use and number of caddies is directly determined by the level of the tournament. There are no caddies at the lower levels of the game, but the larger the tournament, the greater the number of caddies used.

Methods

To explore the different cultural phenomena of tennis caddies contained in large-scale tennis tournaments, the methods of literature review and comparative research are used to compare Chinese and western tournaments, including material culture, system culture, spiritual culture, behavior culture and other aspects of the tennis caddies.

Conclusions

Western culture is thick with a strong sense of independent innovation and emphasis on tradition and change with the time. China is also seeking for innovation and change after introducing and absorbing the western tennis caddies culture.

Discussion

To form a tennis caddies culture with Chinese characteristics, it is suggested to promote tennis culture from aristocratic style to civilian and popular style, improve the level of public tennis culture and etiquette, build brand names, solidify characteristics, pay attention to the cultivation of humanistic spirit, form a diversified competition culture, and improve the status of tennis caddies.

GENDER-EQUAL ON THE COURT. THE VALUE SYSTEM OF FEMALE AND MALE KORFBALL PLAYERS

WAWRZYNIAK, S.1, WEGRZYN, M.1, DOLINSKI, W.2, PEZDEK, K.1

<1> WROCLAW UNIVERSITY OF HEALTH AND SPORT SCIENCES, POLAND; <2> UNIVERSITY OF WROCŁAW, POLAND

INTRODUCTION: Korfball is the world's only mixed team game with ball where players (4 females and 4 males) play the same roles in the court during the match (Crum, 2021). As sport is a carrier of universal values and players are expected to strive for excellence, perfection, respect, friendship and fair play and korfball is gender-equal discipline, therefore the aim of this study is to determine the hierarchy of the value system of Polish female and male players, and factors and experiences influencing the perception of the discipline.

METHODS: The participants were 27 players of Polish Senior National Team in korfball, including 14 women (23.21 ± 3.98 years old) and 13 men (26.92 ± 5.91 years old). The research was conducted during the National Team training camp in the 2021/2022 season. The study involving human participants was reviewed and approved by Ethics Committee of the Wroclaw University of Health and Sport Sciences, Poland (No. 10/2022). Written informed consent to participate in this study was provided by the participants' or the participants' legal guardian/next of kin.

The Rokeach Values Survey (RVS) in Polish adaptation and the author's questionnaire "Values in Korfball" were used to determine the hierarchy and importance of values of the athletes. The RVS consists of two lists of values: 18 terminal and 18 instrumental, which respondents ranked according to importance, from the most important for them (rank 1) to the least (rank 18) (Jaworska, Matczak, Bitner, 2011). The questionnaire consisted of 13 complementary questions about korfball experiences.

All statistical analyses were carried out using IBM SPSS Statistics. The results were analyzed for the group by gender, age, place of residence, education and training experience. Non-parametric Mann–Whitney U-test, Kruskal-Wallace Test and Spearmans rank correlation coefficient were applied.

RESULTS: Health and Family Security were the most important terminal values for players, both women and men. National Security and Equality were significantly higher in the hierarchy of women and Pleasure was more important for men. The korfball players' highly regarded instrumental values like Honest, Responsible and Loving (Ambitious, Honest, Loving for women; Honest and Responsible for men). A statistically significant difference was found only for Forgiving, which was more valued for women than men. Mature Love and A Comfortable Life were significantly more valued for athletes with higher education (also True Friendship), living in cities and working. For studying players Equality was significantly more important. For male players the importance of 4 values increases with the years of play: Self-Respect, Wisdom (terminal), Capable and Courageous (instrumental).

CONCLUSION: There is a lack of similar research in sport sciences, thus more research is needed to determine if gender-equal factor influences the value system of players comparing to the others team or individual sports.

GENDER-SPECIFIC CHARACTERISTICS OF PHYSICAL PERFORMANCE DURING SPEED AND STRENGTH EXERCISES

NAGORNA, V., MYTKO, A., OBERHOFER, K., ACHERMANN, B., LORENZETTI, S.

SWISS FEDERAL INSTITUTE OF SPORT MAGGLINGEN

INTRODUCTION: Performing specific speed and strength exercises, such as a squat with a barbell, requires the athlete to have an impeccable technique of performing a motor action from a biomechanical point of view and high indicators of the athletes balance function coefficient. That is why, the purpose of this study was to identify elite athletes` gender-specific characteristics of physical performance during speed and strength exercises.

METHODS: The method of expert evaluations was used to determine the modern problems of female elite sports (n=20). To determine the model characteristics of the optimal psychophysiological state and balance function of elite male versus female athletes during physical exercises, two independent groups, including 17 women (age 20,11± 3,12) and 24 men (age 19,83± 3,06), were compared.

The participants were elite athletes from different sport games, including: basketball (women, n=10 and men, n=14), handball (women, n=3 and men, n=5) and volleyball (women, n=4 and men, n=5). Mathematical and statistical processing and data analysis were carried out using the computing and graphic capabilities of the computer programs "Statistica".

RESULTS: The analysis of the literature in modern sports science and the results of the interviews with 20 experts made it possible to highlight the main gender problem in sports that is: transferring male athletes` training models and loads to the female preparedness. The statistical analysis of the psychophysiological tests` results showed that, for men, it is an attention predominance, and for women, is mobility and strength of nervous processes, respectively. The female athletes in the group were 5,88 cm shorter in height and 19,08 kg lighter in weight. Statistically significant differences with $p < 0.01$ were observed in male athletes' dynamometry of the dominant (53,54±4,75 kg) and non-dominant (50,67±5,26 kg) hands compared to female athletes who presented with a dominant hand strength of 30,59±3,54 kg and a non-dominant hand strength of 29,06±3,42 kg. Based on the comparison of stabilograms of two samples, we determined the degree of visual stability in standing using the Romberg coefficient, with significant differences in the results for men (173% ± 2,62) versus women (216% ± 2,32). The higher the percentage, the better the athlete was coordinated and/or trained. As for the ratio of the quality of the equilibrium function of elite athletes without and with visual control, significantly higher indicators were observed for women (0,98 ± 0,02) compared to the group of men (0,78 ± 0,06).

CONCLUSION: The present research results provide new information and scientific insights into the need to build different approaches in planning special physical loads for female compared to male athletes. The outcome of the expert evaluation is expected to affect recommendations on efficient speed and strength training design (e.g. exercise "squat with a barbell") for women versus men to be further investigated in ongoing research.

META-SYNTHESIS OF WOMEN'S EXPERIENCES OF GENDER-BASED INTERPERSONAL VIOLENCE IN SPORT

FORSDIKE, K.

LA TROBE UNIVERSITY

Introduction: Violence against women and girls in sport is a pervasive issue, with prevalence rates of interpersonal violence ranging from 26% to 74% across psychological, physical, and sexual violence. This is despite sport being championed as a site for women's empowerment and equality, and as a key setting for addressing the drivers of gender-based violence. Whilst prevalence studies show a high rate of interpersonal violence, they rarely examine gender-based violence beyond sexual violence, and often focus on elite or youth sport populations. There is a need to examine all forms of gender-based violence in sport and to seek to understand women's diverse lived experience to inform appropriate policy and practice responses. Our meta-synthesis reviewed and synthesised qualitative studies that had explored women's experiences of gender-based interpersonal violence in sport.

Methods: We searched five databases across four categories of search terms: gender-based violence/abuse/harassment; sport/exercise; woman/female; qualitative. We followed a meta-ethnographic approach. We developed an interpretation of a selection of studies, using reflexive thematic analysis to create a new interpretation (third-order construct) beyond the individual studies reviewed. We applied a feminist socio-ecological lens to our analysis, remaining cognisant of gendered power as it runs through and between the socio-ecological levels.

Results: We included 25 records representing 24 studies. Participants experienced many forms of gender-based violence: sexual, physical, psychological, economic, drug and technology facilitated, perpetrated by coaches, intimate partners (sometimes one and the same), peers and their own family. These often appeared as composite forms of abuse, intersecting and overlapping. We co-constructed five themes: the normalisation of abusive behaviours in the sports context; sport family violence; women's status in a patriarchal system; women's safety work; and organisational impotence and hostility.

Discussion: Women described a variety of forms of abuse, often composite and over time, perpetrated by a broad range of abusers that included people from within and outside of sport. Across the studies, women's experiences of abuse could be mapped within and across the individual, relational, organisational and cultural levels of the socio-ecological model, with (lack of) power being a central factor in women's experiences within each level as well as flowing between the levels. We also constructed a fifth level pertaining to the context of gender-based violence in sport – that of the sport family. This sits between the relational and organisational levels as the sport context provides both intense familial relationships as well as a patriarchal familial organisational structure that facilitates and silences the abuse. These foundational insights will be key to developing appropriate prevention and response initiatives to gender-based violence in sport.

CP-SH08 Coaching

HOW IS MUSCLE TYPOLOGY ESTIMATED AND USED IN SPORT SCIENCE PRACTICE? A QUESTIONNAIRE IN 446 COACHES.

LIEVENS, E., DE BLOCK, F., VAN VOSSEL, K., VAN DE CASTEELE, F., VANDENBOGAERDE, T., SANDFORD, G., BELLINGER, P., MINAHAN, C., BOURGOIS, J.G., STELLINGERF, T., MUJIKA, I., DERAVE, W.

GHENT UNIVERSITY

INTRODUCTION: On average, most humans dispose of an equal number of slow-twitch and fast-twitch muscle fibers. However, a large inter-individual heterogeneity in muscle typology exists, having important implications for talent identification and training individualization. Though, it is unclear to what extent these muscle typologies are used in coaching practice. We expect that the invasiveness of the gold standard to measure the muscle typology, a muscle biopsy, lowers the use in the daily guidance of athletes. We assume that coaches circumvent this problem by using non-invasive estimators of the muscle typology. Yet, it is unclear which estimators are used and for which purposes coaches use muscle typology information.

METHODS: An online questionnaire was sent to coaches and members of the scientific/medical staff through e-mail and social media in 4 languages and was completed by 446 respondents from 49 nationalities. The survey examined opinions regarding muscle biopsies, how the muscle typology is estimated and its perceived importance for coaching. Differences according to coaching group (individual (n=290); team sport (n=104) and multiple (n=52; coaching both individual and team sports)) were further analyzed using Chi-square tests.

RESULTS: The majority of respondents were high level coaches as 57% trained world class or elite athletes. Forty percent of all coaches already used the muscle typology in coaching practice. Furthermore, 50% would use this information if they would be able to measure it. Despite high interest, only 18% of the coaches thought their athletes would be willing to undergo a muscle biopsy. Therefore, other non-invasive techniques were used. In general, 65% used their experience/observation during training and competition to estimate the muscle typology, moreover individual coaches used their experience more than team sport coaches (68% vs. 51%; P=0.009). Jump tests were the second most used method to estimate the muscle typology (56%). Team sport coaches relied more on these tests than individual coaches (68% vs. 48%; P=0.001). Strength tests (33%), visual inspection of athletes' morphology (25%) and muscle biopsies (13%) completed the top 5. Interestingly, more than 80% of the coaches use the muscle typology to individualize training volume (87%) and intensity (84%). Moreover, more than half of the coaches used muscle typology to individualize duration of recovery (62%), training frequency (60%), taper strategy (54%), to decide on tactical issues (54%) and to identify talent (49%).

CONCLUSION: Previously, it was acknowledged that muscle typology is relevant for talent orientation, but this questionnaire shows that coaches value its importance even more for training individualization. As muscle biopsies are probably not ideal in elite athletes, coaches use other methods to estimate the muscle typology. Some of the used non-invasive estimators of muscle typology are not sufficiently supported by science, opening opportunities for further research and education.

TALENT SELF-ORIENTATION IN YOUTH SOCCER

ZHAO, K.

CHINA INSTITUTE OF SPORT SCIENCE

INTRODUCTION: Talent orientation is one of the early step stones in many talent identification (TID) models and national TID campaigns derived from these models. In the recent years the development of expert-level performance in sports was primarily discussed against the background of two different pathway: the early specialization approach and the diversification approach.In regard to the timing of the training start and the layout of the early phase of training activities many researchers advocate the strategy of a late specialization in one particular sport combined with a broad sampling of

different sports.At the same time, numerous sport academics claim for the opposite that is an early orientation of youth athletes towards a specific sport that fits best to their personal talent make-up, because longer learning time, more appropriate personal dispositions and early success contribute to the optimal development of exceptional performance and expertise.This study examines the way in which young soccer players manage the conflict between specialization and diversification.

METHODS: To clarify the specific patterns of the early sports sampling strategies between the poles of early specialization and diversification the competition performances of 276 youth soccer players were systematically documented in the sports they played from the U6 to the U21 age group. Univariate ANOVAs and regression analyses were used to analyze whether later successful athletes differed from non-elite soccer players in their self-orientation strategies.

RESULTS: ANOVA showed that three sampling strategies during childhood and adolescence lead to different performance outcomes at early adult age. A high level of the soccer performance is seen at the less frequent strategy of participating in one or more other competitive sports before taking part in soccer competitions. Nevertheless, the highest performing soccer players, are those who had focused almost exclusively on playing soccer from the beginning.

CONCLUSION: Thus, the results are in line with the latest differentiated model of talent development, and confirm that successful youth soccer players prefer early and in-sport specialization.

THE EFFECT OF THE GOSEONG-GUN SOOMCHI COMPLEX MARINE HEALING PROGRAM ON IMPROVING LUNG HEALTH

SHIN, J.

KYUNGNAM UNIVERSITY

INTRODUCTION: The study to verify the effectiveness of the Soomchi combined marine exercise healing program by analyzing the physical composition of the subjects, their blood lipids, and the effects of the program on their lung health-related variables, and heart rate variability variabvariables.

METHODS: In the experiment, the Soomchi combined marine exercise healing program was conducted for 5 hours a day, 5 days a week. on 15 participants. The results of their body composition, blood lipids, lactic acid, blood pressure, PEF, FEV1 and maximum oxygen intake were analyzed before and after the subjects completed the Soomchi program. For the statistical analysis, the mean and standard deviation (M±SD) of each variable were calculated using SPSS version 20 and an independent t-test was conducted to test for the amount of change in the participants before and after the Soomchi combined marine healing program. All significant levels were set to α=.05. As a result of the experiment

RESULTS: First, no statistically significant differences were found in the changes in body composition after the 5-day combined marine healing program was completed

Second, regarding the changes in blood component after the program was conducted, statistically significant differences were found in the lactic acid ($p<.05$). That is, the experimental group showed a significant decrease in lactic acid after the program whereas the control group showed a significant increase.

Third, systolic blood pressure decreased significantly and while in PEF and FEV1 increased significantly in the experimental group after the program.

Fourth, the LF of the control group significantly decreased after 5 days

CONCLUSION: After the five-day soomchi lung health marine exercise healing program, there was a group difference in the amount of change in lactic acid, a fatigue substance in the blood, and the experimental group significantly decreased after the program.

There was a significant difference between groups in the change in systolic blood pressure, PEF, and FEV1 of lung health variables. Systolic blood pressure in the experimental group decreased significantly after the program, and PEF and FEV1 in the experimental group increased significantly after the program.

As a result of heart rate variability analysis, LF was significantly decreased after 5 days in the control group.

In summary, this study showed positive physical changes in lung health variables (blood pressure, PEF, FEV1) and heart rate variability (LF), a stress-related variable, after participating in the Soomchi Lung Health Marine Healing Program. It can be said that the effectiveness of the program has been demonstrated.

However, the fact that there was no change in body composition and blood lipid variables was that the breath health marine healing exercise program was lacking for a period of time, and it is believed that there will be clear effects when implemented in the long term, so it is suggested to implement a long-term marine healing program in the future.

HOW VARIABILITY COULD SHAPE PERCEPTUAL-MOTOR EXPERTISE IN 4X100 M RELAY?

EGIZIANO, M.1, CHOMIENNE, L.1, BOSSARD, M.2, VERHULST, E.3, KULPA, R.3, MASCRET, N.1, MONTAGNE, G.1

AIX MARSEILLE UNIV, CNRS, ISM, MARSEILLE, FRANCE <1> / UNIV GUSTAVE EIFFEL, COSYS-PICS-L, F-77454 MARNE-LA-VALLÉE, FRANCE <2> / UNIV RENNES, INRIA, M2S - EA 7470, RENNES, FRANCE <3>

INTRODUCTION: The optimization of perceptual-motor expertise is a very challenging issue for both coaches and athletes. A recurring question that can be asked is to what extent training sessions must be performed in stable conditions, in which the athlete is exposed to task constraints mimicking those encountered in competition, or conversely under extremely variable conditions, to be more effective? In this study we were interested in a very specific skill, namely the synchronization of runners' race in 4x100 m relay. Relay performance is based on the ability of the team to coordinate the

race of the athletes to maximize the speed of the baton exchange. To optimize the passing of the baton, athletes can place a go-mark on the ground approximately 8 m from their starting position to initiate their run when the giver crosses this mark. This synchronization task is not trivial and relies on the ability of athletes to anticipate the passage of the partner on the go-mark. Moreover, to our knowledge, no feedback-based procedures were proposed to train this task. The aim of our study is precisely to investigate the influence of the variability of training conditions on athletes anticipation abilities, in an immersive virtual environment.

METHODS: The athletes were equipped with a virtual reality headset to be immersed in a virtual stadium at the receiver's position. They were instructed to initiate their race when the avatar of their partner passed over the go-mark. A learning protocol including a pre-test, an acquisition phase and both retention and transfer tests (assessments done under conditions different from those for which they had been trained) have been used. Two groups of participants, namely 'stable' and 'variable', practicing athletics at a regional level, have been tested. The first group performed the task under stable conditions, i.e., with the go-mark always placed at the same distance and in the presence of an avatar always arriving at maximum speed. The second group performed the task under variable conditions, i.e., with a variable go-mark position and in the presence of an avatar whose speed varied. Both groups received systematic extrinsic feedback about their performance after each trial in the acquisition phase. Several dependent variables have been used to characterize the participants' behavior, including the timing error and the gaze strategies.

RESULTS: The results revealed that the 'stable' group learned the task better than the 'variable' group when tested in the reference task. Conversely during the transfer tests, the 'variable' group outperformed the 'stable' group.

CONCLUSION: These results reveal the added value associated with the use of variability in practice conditions to acquire robust perceptual-motor skills.

FEMALE ATHLETE CONSIDERATIONS: IMPROVING COACH KNOWLEDGE AND CONFIDENCE VIA AN ONLINE SHORT COURSE

CLARKE, A., LEABEATER, A., SUPPIAH, H., ROBERTS, A.

LA TROBE UNIVERSITY

INTRODUCTION: With a growing awareness and recognition of female-specific considerations when training athletes, there is a requirement for coaching and support staff to be educated on current best practice guidelines when working with female athletes. The aim of this study was to assess the effectiveness of an online short course aimed at improving the knowledge of coaching and support staff working with female athletes.

METHODS: This study used a mixed-methods survey design, where participants completed three instances of an online survey (pre-course, post-course, and 6 months post-course) before and after an online 8-week short course involving both content delivery and an applied practice block. Questions involved both quantitative (numeric) and qualitative (textual) responses. Open-ended survey questions were analysed thematically to explore two a priori themes of 'Course expectations' and 'Changes in practice'. The data were explored inductively within these pre-determined thematic areas. Finally, overall course feedback was analysed deductively to provide guidance for future course delivery.

RESULTS: Of the 92 participants who completed both pre- and post- surveys, 72% (n=66) were female and 67% (n=62) were from a team sport. The perceived knowledge and confidence of participants both improved following the course ($p<0.001$) and were still above pre-course values 6-months post ($p<0.001$). Two sub-themes were generated within the 'Course expectations' theme: Empowering [me] to empower and support [them], and Sharing knowledge and experiences. Within the 'Changes in Practice' theme the subthemes Relaxing into it and Embedding support structures were observed. Feedback from participants indicated that they enjoyed learning from a variety of content experts as well as each other, and that the online learning format was suitable.

CONCLUSION: Future educational courses aimed at coaching and support staff are encouraged to apply our learnings to design and deliver programs in a way that is accessible and aligned with the learning styles and preferences of these individuals. When delivering specific education regarding supporting female athletes, directly targeting and encouraging men to participate may also be beneficial.

TO AGREE UPON VOCABULARY FOR THE GENERAL ADAPTATION SYNDROME AND SUPERCOMPENSATION MODELS

GARLAND, S.W.

MALMÖ UNIVERSITET

INTRODUCTION: Words to describe aspects of training are often used incorrectly or inconsistently. The original General Adaptation Syndrome model by Selye (1950) talked of "stressors" that produce "defence", "damage", "actions" and "reactions" [1] but Yakolev (1967) used "stimulus", "fatigue", "compensation" and "supercompensation" [2] and Fry (1998) "stimulus", "resistance" and "adaptation" [3]. Other words included in training models include "depletion", "restitution", and "involution" [2, 4]. Some of these words don't have a precise scientific meaning, and some don't have a scientific meaning at all.

METHODS: Published training models, and other terms used to describe training, were surveyed, and the most common and precise terms were used to build a new training model.

RESULTS: A training model is proposed that precisely defines the following terms:

Training: A period of physical activity that has a goal of improving or maintaining physical function

Rest: A period without training

Fatigue: A process that occurs during training; a disturbance in a system's homeostasis resulting in a reduction in performance

Recovery: A process whereby the reduction in performance due to fatigue returns to normal

Adaptation: A process of change by which the body becomes better suited to a task

Effect: The improvement in performance that results from adaptation

De-training: The process by which effects wear off due to lack of training

Dose: A quantity of training

Overload: A training dose sufficiently high to cause adaptation

Stimulus: Training is a stimulus, and in this context stimulus and training are synonyms

Response: The response to a training stimulus is fatigue, recovery and adaptation. "Response" therefore means the processes of fatigue, recovery and adaptation.

Note that training and rest are time periods, and fatigue, recovery, adaptation, response and de-training are processes.

CONCLUSION: This model provides clear definitions of terms commonly used in exercise science, and can help those of us in the exercise science community to speak the same language and communicate effectively.

DISCREPANCIES BETWEEN INTENDED AND ACTUAL TRAINING LOAD – REASONS AND IMPLICATIONS FOR PERCEIVED STRESS AND RECOVERY

OTTER, R.T.A., BAKKER, A.C., KERKHOFF, M., STOTER, I.K., DE JONG, J.

HANZE UNIVERSITY OF APPLIED SCIENCES GRONINGEN

INTRODUCTION: Coaches strive to enhance performance of their athletes by prescribing an effective and well-balanced training program. The intended training load sometimes deviates with the perceived training load by the athletes (Otter et al 2022). However, underlying causes and possible consequences are still unknown. This study aimed to explore 1) reasons for differences in training load 2) discrepancies between intended training set by the coaches and actual training perceived by junior speed skaters and their relationship with changes in stress and recovery.

METHODS: First, nine speed skaters and their coach were interviewed about their methods for determining duration and intensity of training sessions, in order to explain any potential mismatches. Second, during a 4-week training period, 2 coaches and their 23 speed skaters monitored the intended and perceived training intensity (RPE) and duration (minutes) for each session. Coaches filled it out prior to training sessions and athletes after each session. Both intended and perceived training load were calculated by multiplying RPE by duration. Perceived stress and recovery levels were measured using RESTQ-sport questionnaires before and after the 4-week period. Differences between intended and perceived training load and perceived stress and recovery were calculated over the 4 weeks.

RESULTS: Overall, there were large individual variations in (mis)matches between intended and perceived training load. Results from the interviews revealed that there were several causes for differences in training load between coaches and athletes such as discrepancies in the interpretation of the RPE scale, personal and external influences of the athlete and deviance in expected and actual fitness. The second part analyzed 438 planned training sessions and 378 actual training sessions. The planned training sessions had a moderately longer duration per week (52:37h) compared to the perceived duration (45:16h), with skaters completing 4±6 sessions less. Perceived training load was lower than intended for both skating (-532±545AU) and strength (-1276±530AU) sessions, due to lower RPE scores for skating (-0.6±0.7) or shorter/fewer sessions for strength (-04:13±02:06h). Differences in intended-perceived training parameters had a strong positive correlation with changes in RESTQ-sport for success ($r=0.57$), physical recovery ($r=0.58$), self-regulation ($r=0.60$), and personal accomplishment ($r=0.59$). All described differences and correlations were significant ($p<0.05$)

CONCLUSION: These findings show that speed skaters demonstrate a (mis)match with the coach's intended training load for different reasons. In general, there is a relationship between the mismatch in training load and the perception on recovery scales of the RESTQ-sport. This implies that athletes who approach or exceed intended training load perceive more personal accomplishment, physical recovery, success and self-regulation.

DIFFERENCES IN PROFICIENCY LEVEL OF THE STRADDLE VAULT MOVEMENT IN JAPANESE ELEMENTARY SCHOOL CHILDREN

SANO, T.

CHUKYO UNIVERSITY

INTRODUCTION: Gymnastics is positioned in the physical education curriculum of some countries, but it has been pointed out that the childrens proficiency and the quality of instruction may depend on the experience or knowledge of the teacher (Kovač et al., 2020). In Japanese elementary schools, it is not uncommon for a homeroom teacher to teach all subjects, and he/she doesn't necessarily have expertise in exercise instruction. Therefore, we focus on the straddle vault of the vaulting box exercise, and aim to clarify the actual state of the skill proficiency of children in Japanese elementary school.

METHODS: The subjects were 486 children aged 9-12 from four elementary schools in Japan. There were 120 3rd graders (5 classes), 127 4th graders (5 classes), 129 5th graders (5 classes), and 110 6th graders (4 classes). We evaluated the childrens proficiency using five proficiency movement patterns of the straddle vault (Sano et al., 2022). The straddle vault movement was filmed by two video cameras from the front and side, and the images were evaluated by two evaluators based on the following six evaluation points: (1) Adjusting; free leg flexion, (2) Rebound jump, (3) Push-off, (4) Rotating backward, (5) Closing legs, (6) Stopping firmly. Latent class analysis was applied to the evaluation results to extract five proficiency patterns of the straddle vault, and the pattern with the highest membership probability was judged as the proficiency level of the subject. In order to investigate the difference in proficiency between grades, we compared the composition ratio of patterns by chi-square test and residual analysis. Additionally, the composition ratio of pattern of each class within the same grade was compared by Fishers exact test. Significance was set $P<0.05$.

RESULTS: As a result of the latent class analysis, five proficiency patterns (Failure vaulting, Arm dependent vaulting, Unstable landing vaulting, Stable vaulting, and Strong push-off vaulting) were extracted. A significant difference was observed in the composition ratio of proficiency patterns among grades ($X2=46.9$, $P<0.01$, Cramers $V=0.18$). Residual analysis revealed that there were many Failure vaultings in the 3rd, many Arm dependent vaultings in the 4th and 5th, and many Unstable landing vaultings in 6th grades. Furthermore, as a result of comparing the composition ratio of the pattern between each class in the same grade, a significant difference was observed among the classes in 3rd, 4th, and 5th grades. Especially among the 4th grade, there was a wide range of percentages: 3-35% for Failure vaulting, 6-42% for Arm dependent vaulting, and 8-47% for Stable vaulting.

CONCLUSION: The proficiency of the straddle vault in elementary school children is influenced not only by grade, but also by class (instruction by the homeroom teacher). It is thought that sharing more specific and practical evaluation and instruction methods will be effective for improving the quality of instruction and learning of movements in physical education.

THE EFFECT OF AN 8-WEEK STRUCTURED FOOTBALL TRAINING PROGRAMME ON SELF=PERCEIVED LEVELS OF SKILL, PSYCHOLOGICAL AND PHYSICAL ACTIVITY RELATED MEASURES IN HONG KONG BOYS

OREILLY, J., HUI, S.C., SIT, C.H.P., LU, Y.J.

THE CHINESE UNIVERSITY OF HONG KONG

INTRODUCTION: Hong Kong is facing the public health concern of childhood obesity (Huang et al., 2018). Involvement in team sports promotes a more active lifestyle, enhances physical fitness and improves clinical health (Hills et al., 2015). Very few studies in Asia have placed emphasis on the use of team sports, such as soccer, among youth groups as an intervention strategy to increase physical activity levels, as well as physical and psychosocial status.

METHODS: Male Participants from the Hong Kong Football Association development programme were recruited. Pre- and post-programme evaluation was conducted. Questionnaires were composed of 19 questions, including football and psychological-related items. In the post-programme evaluation, 5 additional questions on the effectiveness of the football participation were added. Measures of self-perceived football skills, interest in sports, life satisfaction, self-esteem, self-efficacy and the Physical Activity Rating for Children and Youth (PARCY) were also assessed. The Cantril Ladder of Life was adopted for self-rating of life satisfaction. The Rosenberg Scale was adopted to assess the participants' self-esteem. Enjoyment levels and self-efficacy was assessed by using the 7-item PA Enjoyment scale (Motl et al., 2001), and 8-item PA Self-efficacy Questionnaire (Motl et al., 2000). Semi-structured focus group discussions were conducted to obtain more in-depth feedback. Paired sample t-tests were adopted for the statistical analysis.

RESULTS: 641 participants from 3 rounds with mean ages of 11.6, 9.6 & 9.6 respectively, completed all evaluations. Numbers of weekly football sessions in the past month of averaged 1.1 to 2.1 at pre- and 1.6 to 2.7 at post-programme evaluation. The reported mean duration for each session ranged from 68.8 to 76.1 minutes at pre- and 67.1 to 76.5 minutes at post-programme evaluation. In round 3, the average duration for each session dropped by 5.5 minutes at the post-programme stage. In all rounds, "improvement in football skills" and "having fun" were the 2 most important reasons that maintained football participation. Most players reported themselves as "beginner" at the pre-programme stage for rounds 2 & 3. After the scheme ended, the percentage of "beginners" decreased by 4 to 12 points for all the 3 rounds.

Enjoyment scores in round 3 decreased by 2.9 points ($p=0.026$). In the same round, a 2.7-point increment ($p=0.03$) was detected in players with low/moderate PA level at the pre-programme stage. All samples perceived a higher level of football skills at the end of the scheme. For those whose initial PA levels were not high, improvement was also found at the post-programme stage.

CONCLUSION: This football programme enhanced indicators for each of football-, psychological- and physical activity-related measures. This offers practical implications as an indicator for the optimisation of physical and psychological health through a soccer training programme and a strategic application of sports-programme promotion.

EXPLORING THE USE OF STORIES TO TRANSLATE KNOWLEDGE ABOUT SELF-REGULATORY PROCESSES DURING GOAL STRIVING IN RUNNING

JACKMAN, P.C., WADEY, R., BRICK, N.E., WHITEHEAD, A.E.

UNIVERSITY OF LINCOLN

Introduction

Despite substantial growth in literature on sport psychology, a 'gap' between research and practice has been identified as a longstanding issue in this field, and more broadly in sport science. To address the research-practice gap, alternative ways are needed to increase the transfer and uptake of research in practice. Research-informed stories have showed promise as a knowledge translation tool in sport and physical activity, yet little research has explored how athletes, coaches, and sport psychology consultants (SPCs) act on stories that seek to translate sport psychology knowledge. The aim of this study was to explore the utility of evidence-based stories as a KT tool for sharing knowledge about self-regulatory processes during goal striving in endurance running.

Methods

Guided by the knowledge-to-action model (Graham et al., 2006), we developed evidence-based vignettes portraying athletes' stories in running races and shared these stories with runners, coaches, and SPCs. We explored participants' responses to, and the impact of, the stories, through a longitudinal, integrated methods approach. Eleven runners, three of whom were also running coaches, and two sport psychology consultants (SPCs) read and/or listened to the four research-informed stories and subsequently completed a qualitative survey and two semi-structured interviews exploring their short-term and long-term responses to the stories. Data were analysed using reflective thematic analysis.

Results

Our reflexive thematic analysis yielded five themes: "bridging the gap between research and practice", "the stories (did not) resonate with me", "stories stimulate reflection", "a portal to new ways of knowing", and "putting knowledge into action". Collectively, these themes portrayed how the stories were useful for translating knowledge into practice, the reasons why, and how the stories acted on participants.

Discussion

The participants' perceptions of, and responses to, the vignettes were overwhelmingly positive and suggested this form of representation is a promising approach to translate sport psychology knowledge into action in runners, coaches, and SPCs. Our findings methodologically extend past research in sport on the use of stories as a KT tool by examining the impact of stories on athletes, coaches, and SPCs over time. By generating data at three timepoints over a 6-month period, the current study demonstrated both the conceptual (i.e., changes in levels of knowledge) and instrumental (i.e., changes in use of mental strategies, use of stories by coaches with athletes) use of knowledge presented in the stories. Overall, the findings demonstrate that stories hold potential for translating sport psychology research into practice and enhancing the likelihood that knowledge users benefit from research findings.

UPPER LIMB STRENGTH ASYMMETRY ON A BALLISTIC ERGOMETER BETWEEN SEATED PARALYMPIC ATHLETES AND ABLE-BODIED ATHLETES

BRASSART, F.1,3, FAUPIN, A.1, HAYS, A.2, WATELAIN, E.1, WEISSLAND, T.3

1IAPS - N°201723207F & UNIVERSITÉ DE TOULON, LA GARDE, FRANCE; 2 ISM, UMR 7287, CNRS & AIX MARSEILLE UNIVERSITÉ, MARSEILLE, FRANCE 3 IMS, UMR 5218, PMH_DYSCO & UNIVERSITÉ DE BORDEAUX, PESSAC, FRANCE

INTRODUCTION: Upper limb asymmetry could increase the risk of injuries in able-body athletes [1] as in manual wheelchair users [2] on strength asymmetry particularly. Paralympic sitting athletes overused their upper limbs in daily life and physical activities, so they could developpe more strength asymmetries than able-bodied people. In this study, we hypothesize that Para-athletes are more asymmetric in strength than able-bodied athletes.

METHODS: Paralympic athletes (PA) were composed of wheelchair tennis, basketball, rugby, and cycling athletes (n = 54, 17 women and 37 men) divided into two groups (with abdominal capacities (PAAC), n = 31 (10 women and 21 men), and without abdominal capacities (PANAC), n= 23 (7 women and 16 men). Able-bodied athletes (AB) were judokas and sports court athletes (n = 42, 13 women and 29 men). was performed seated on a frictionless sledge and consisted of measuring the force during ballistics push-ups at 4 load levels. The force of the right and left upper limbs was measured using two Kistler force plates. The Instantaneous Symmetry Index (ISI) was calculated, according to the method proposed by Chénier et al. (2017) [3] and applied to the push phase for all loads. T-test was used to compare ISI between groups.

RESULTS: The mean strength asymmetry from all loads, calculated with ISI value was significantly higher in men PA compared to AB (respectively 0.057±0.038 and 0.033±0.013; p = 0.001) but also in both paralympic groups (PAAC (p = 0.003) and between AB and PANAC (p = 0.045). However, there is no significant difference between PAAC and PANAC (respectively 0.056±0.031 and 0.058 ± 0.046, p = 0.884). No significant differences were found between all women populations (PAAC 0.054±0.026 or PANAC 0.050±0.014, and AB 0.048±0.043 , p >0.05). Finally, there is no significant difference between PA and AB males and females (respectively p = 0.703 and 0.231).

CONCLUSION: With a graded load push-up exercise, this study aimed to compare the strength symmetry with ISI between the upper limbs of paralympic and able-bodies athletes. Our main results show that in the men's group, PA present greater asymmetry than AB, which is not observed in the women's group which tends to be more asymmetrical than men. But this result may be due to a smaller woman population in all subgroups. The abdominal capacities do not seem

to be the reason for a lesser asymmetry given the non-significant differences between PAAC and PANAC. From push-up exercise, ISI applied to the force is relatively low compared to results on wheelchair propulsion from Chénier et al. 2017 (ISI = 0.2±0.09), but we observe for PA an ISI greater than 0.05 regardless of gender. This value could be an interesting indication threshold of the asymmetry with this index on this test to pay attention to para-sports practice.

EPIDEMIOLOGICAL STUDY OF SPORTS INJURIES OF CHINESE WINTER PARALYMPIC ATHLETES IN DAILY TRAINING

CAN, G., CHEN, L., JIANHONG, Z.

INTERNIST OF SPORT MEDICINE RESEARCH INSTITUTE

INTRODUCTION: There are quite few injury studies in Paralympic winter sports athletes compared to abundant ones in healthy winter sports athletes. Thus, the present study aims to investigate injury epidemiology in Chinese para-athletes preparing for the 2022 Paralympic Winter Games and provide necessary reference information for para-athletes participation safety and injury prevention.

METHODS: We monitored daily training of 174 athletes from para ice hockey, snowboarding, alpine skiing, cross-country skiing and biathlon, who have been preparing the 2022 Beijing Paralympic Winter Games, with monitoring periods varied from 20-68 days(a total of 8,307 athlete days), and each team had professional medical support staff that performed data collection.

RESULTS: 78 out of 174 handicapped athletes (44.8 per cent) reported 123 cases of injuries with a rate of 14.8 cases per 1,000 training days. In terms of sports, we found that injury incidence of snowboard skiing was the highest (62.0%) among sports, corresponding to injury prevalence of snowboard skiing, which had also been the highest among sports, in Pyeongchang Winter Paralympic Games in 2018. We assume this might be caused by the difficulty finishing the moves, specifically, athletes might be highly likely losing body control when completing certain moves. Para ice hockey had the highest injury incidence (IR 25 per 1,000 training). We suppose this might be because the duration of daily monitoring was too short (only 20 days). In terms of sex, the injury prevalence of female athletes (46.4%) was slightly higher than that of men (44.1%), while the injury incidence of women (15.3 per 1,000 training days)was also slightly higher than that of men. In terms of age, the injury prevalence (48.5%)and the injury incidence (15.2 per 1,000 training days)of athletes aged 26-34 were both the highest. In terms of course of sports injury, athletes with chronic injury had higher injury prevalence, which might be due to training overload, leaving athletes with insufficient time for recovery. In terms of types injury, the highest injury percentage was the overuse (63.4%), followed by contusion (13.8%) and sprain (11.4%). In addition, skin abrasions were regularly observed in training, and common causes include contact with venues, prosthetic limbs and equipment during training.

CONCLUSION: In the course of preparation for the 2022 Beijing Winter Paralympic Games, the injury prevalence of snowboard skiers ranked first, which needs immediate attention. The rate of Athletes seeking for medical help due to overuse was relatively high, which indicated that athletes might not be fully recovered before the next training day. The injury prevalence of female athletes was slightly higher than that of male athletes, indicating that female athletes had higher risk of acquiring injury, which needs immediate attention.

DEVELOPMENT OF IMU SYSTEM FOR MEASURING 100-M RACING WHEELCHAIR KINEMATICS

SUWANMANA, S.1, JAMKRAJANG, P.1, INTHIAM, J.2, NARASETTHAKUL, A.2, BUNJING, P.2, SAWAENGWAISAYASUK, S.3, LIMROONGREUNGRAT, W.1

1MAHIDOL UNIVERSITY; 2KING MONGKUT'S UNIVERSITY OF TECHNOLOGY NORTH BANGKOK, 3SPORTS AUTHORITIES OF THAILAND

INTRODUCTION: Wheelchair racing is one of the major sports events particularly in the Paralympics games. Kinematics analysis of racing wheelchair propulsion (RWP) is critical for improving performance and preventing injury. Previous study investigated RWP kinematics during 100-meter race using 2 video cameras (1). As technology advances, inertia measurement unit (IMU) has currently gained popularity in wheelchair research (2-3) due to its portable, low-cost, and easy to implement. However, no previous study has employed IMU sensors to measure RWP kinematics in the field. Therefore, the purpose of this study was to develop IMU system to measure spatiotemporal parameters during 100-meter distance.

METHODS: Ten wheelchair racing athletes were volunteered to perform 100-meter race simulation. IMU sensors were attached to the wheelchair frame and both wrists to collect acceleration data for the analysis of RWP kinematics. Furthermore, the traveling distance was measured using an Odometry Measurement Unit (OMU) equipped with an adjustable mechanism for attachment to various sizes of front wheel forks. The acceleration data and traveling distance were collected simultaneously at a sampling frequency of 100 Hz. Three simulated race trials were collected and analyzed. Spatiotemporal data including push frequency, propulsion and recovery phase were obtained from IMU data. Data from a total of 100 meter and each 20-meter interval were analyzed. Repeated measure ANOVA was performed to determine significant differences among the five phases. Holm post hoc tests were completed when a significant main effect was found.

RESULTS: Significant main effect was found in push frequency ($p<0.001$) and propulsion phase ($p=0.02$), except for recovery phase. Post hoc analyses revealed that there was significant increase in push frequency and propulsion phase when going from first 20 to 20-100 m ($p<0.05$). Similarly, significant increases were also noted with propulsion phase during 0-20 m, however, only when compared to 20-80 m ($p<0.05$).

CONCLUSION: This study displays the feasibility of IMU system for measuring RWP kinematics in the field. The result shows high push frequency and long propulsion phase in the first 20-meter because athletes need to overcome the inertia from the stationary and gain more velocity. This data can be used to provide feedback to coach and athletes.

DIETARY INTAKE AND SERUM VITAMIN D LEVELS AMONG WHEELCHAIR USERS WITH INITIAL LOW BONE MINERAL DENSITY

MOBERG, E.1,2,3, RISVANG, L.C.1, KOLSET, S.O.2, GARTHE, I.3, JONVIK, K.L.1

1: NORWEGIAN SCHOOL OF SPORT SCIENCES, OSLO, NORWAY. 2: UNIVERSITY OF OSLO, OSLO, NORWAY. 3: NORWEGIAN OLYMPIC AND PARALYMPIC COMMITTEE

INTRODUCTION: Wheelchair users may face nutritional challenges due to reduced mobility and complications associated with their disability. The potential nutritional deficiencies, and low mechanical loading of bones, may lead to an increased risk of low bone mineral density (BMD) and consequently osteoporotic fractures. Furthermore, adequate energy intake, vitamin D and calcium are important factors in prevention and treatment of low BMD. Therefore, the aim of this study was to investigate dietary intake in relation to serum levels of vitamin D (S-vitamin D) and BMD among wheelchair users with an initial low BMD of the lumbar spine (Z-score<0.0).

METHODS: Prior to a 24-week Randomized Controlled Trial (RCT) on the effects of resistance training on bone health, energy, calcium and vitamin D intake, S-vitamin D, BMD and body composition were assessed in 8 wheelchair users (4 females/4 males; 3 athletes; 36 (22-47) yrs;72.9 (58.9-84.6) kg). Dietary intake was assessed with 3 unannounced 24-hour dietary recalls within a 2-week period. BMD (lumbar spine and hip) and body composition were measured by Dual-energy X-ray absorptiometry (DXA) and S-vitamin D by a fasted, venous blood sample. The subjects answered the "International Physical Activity Questionnaire – Short Form", which estimated individual physical activity level (estPAL), and the Cunningham equation was used to estimate resting metabolic rate (estRMR). Estimated energy requirement was calculated by estRMR and estPAL. Due to non-normality, data are presented as median (25th-75th percentiles), and Spearman correlation analyses were performed with significance level $\alpha=0.05$.

RESULTS: Daily energy intake (EI) was 2517 (1727-3458) kcal and 61 (54-68) kcal/kg lean body mass (LBM). The EI/estRMR ratio was 1.8 (1.5-2.1), which for all subjects was above their estimated energy requirements. None of the EI parameters correlated with Z-score of lumbar spine or hip ($P>0.05$). Both calcium intake (1305 [751-1500] mg/d) and protein intake (1.4 (1.1-1.8) g/kg/d) were in line with dietary recommendations. Daily vitamin D intake was 16 (7-27) ug/d, and 38 % of the subjects had an intake below Norwegian recommended daily intake (RDI; 10 ug/day). The 3 subjects with the lowest hip Z-scores used vitamin D supplements. As such, vitamin D intake was negatively correlated with hip Z-score (rsp=-0.79, $P=0.02$), S-vitamin D was 42 (35-56) nmol/l and 75% of the subjects presented suboptimal values <50 nmol/l. There were no significant correlations between S-vitamin D and Z-score of lumbar spine or hip ($P>0.05$), or with vitamin D intake ($P=0.18$).

CONCLUSION: Despite a sufficient energy and calcium intake, 1 of 3 had vitamin D intakes below RDI, and suboptimal S-vitamin D levels were present in 3 of 4 wheelchair users with initial low BMD. Further research is needed to conclude whether vitamin D is the driving nutritional factor for bone health in wheelchair users.

SLEEP IN PARALYMPIC ATHLETES AND ITS RELATIONSHIP WITH INJURIES AND ILLNESSES

SILVA, A., PINHEIRO, L.S., SILVA, S., ANDRADE, H., PEREIRA, A., SILVA, F.R., GUERREIRO, R., BARRETO, B., RESENDE, R., MELLO, M.T.

UNIVERSIDADE FEDERAL DE MINAS GERAIS

INTRODUCTION: The popularity of Paralympic sports has grown exponentially in the past years. With more athletes competing at high levels, injury rates have become a worrying issue (1). A recent systematic review warned about the high prevalence and incidence of injuries found in para athletes (2) and achieving optimal recovery in the training process is important in improving physical performance (3). To evaluate sleep characteristics of Paralympic athletes and investigate the relationship of sleep with health problems, including injuries and illnesses, in Paralympic athletes.

METHODS: This was a transversal study with 20 Paralympic athletes who had competed at the highest level of Brazilian competitions in the following modalities: athletics, swimming, and weightlifting. A specific database of health problems recording was collected in conjunction with the medical team for two weeks through the Brazilian version of the Oslo Sports Trauma Research Center questionnaire (OSTRC-BR) concurrently with the evaluation of chronotype, sleep quality, sleep complaints and sleep behavior. The sleep-wake patter was monitored using a wrist activity monitor in conjunction with self-report sleep diaries for 15 consecutive days.

RESULTS: Sleep latency (r=-0. 46; p=0.04) and duration of naps (r= -0.46; p=0.04) were associated with occurrence of health problems; insomnia (r= -0.46; p= 0.04), frequency of insomnia, Pittsburgh Sleep Quality Index score (r= 0.45; p=0.04), and frequency of awakenings at night (r= 0.58; p= 0.01) were associated with severity of health problems on week 2; frequency of movements during sleep was associated with OSTRC-BR cumulative score (r= 0.58; p=0.00); and frequency of nightmares was associated with OSTRC mean score. A high prevalence of poor sleep quality and poor sleep behavior was also found.

CONCLUSION: Paralympic athletes tend to report poor sleep quality and to have a poor sleep behavior. Some sleep complaints such as insomnia symptoms, awakenings at night, movements during sleep and poor sleep quality were associated with the occurrence and severity of health problems We recommend practitioners consider the sleep characteristics of athletes in their injury prevention planning for Paralympic athletes.

HANDCYCLING WITH CONCURRENT LOWER BODY LOW-FREQUENCY ELECTROMYOSTIMULATION INCREASES ACUTE OXYGEN UPTAKE IN ELITE WHEELCHAIR BASKETBALL PLAYERS: AN ACUTE CROSSOVER TRIAL

MICKE, F., RAPPELT, L., HELD, S., WIEDENMANN, T., DEUTSCH, J.P., KLEINÖDER, H., DONATH, L.

GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: Acute increases in oxygen uptake (VO2) during exercise are crucial for aerobic training adaptations and depend on the amount of muscle involved. VO2 capacity is limited during wheelchair handcycling due to restricted muscle involvement of the impaired lower body muscles. Handcycling with concurrent complementary low-frequency electromyostimulation (LF-EMS), applied to major lower limb muscles might lead to relevantly increased passive muscle involvement with higher oxygen uptake in elite wheelchair basketball (WCB) athletes.

METHODS: The squad of the German national WCB team (n=12, age: 25.6 ± 5.6 years, height: 1.75 ± 0.16 m, mass: 74.0 ± 21.7 kg, classification: 2.92 ± 1.26 a.u. (1.0 - 4.5 from least to most mobility)) completed 2×5 minutes of handcycling (60 rpm, ¾ bodyweight as resistance in watts) (HANDCYCLE) and handcycling with concurrent EMS of the lower extremities (EMS_HANDCYCLE). During EMS_HANDCYCLE, LF-EMS (impulse frequency: 4Hz, impulse width: 350µs, continuous stimulation) was applied to gluteal, quadriceps and calf muscles. The stimulation intensity (buttocks: 69.5 ± 22.3 mA, thighs: 66.8 ± 20.0 mA, calves: 68.9 ± 31.5 mA) was individually adjusted based on reported comfort tolerance for 5 minutes.

RESULTS: Large and significant mode-dependent differences in VO2 responses were found between HANDCYCLE and EMS_HANDCYCLE (17.60 ± 3.57 vs. 19.23 ± 4.37 ml·min-1·kg-1, p = 0.001, ηp2 = 0.69). Furthermore, ΔLactate was significantly lower in HANDCYCLE compared to EMS_HANDCYCLE (0.04 ± 0.28 vs. 0.31 ± 0.26 mmol·l-1, p = 0.036, ηp2 = 0.37). Although perceived effort did not differ between conditions (2.7 ± 0.9 vs. 2.9 ± 0.9 a.u., p = 0.293, ηp2 = 0.100), discomfort was rated lower during HANDCYCLE compared to EMS_HANDCYCLE (1.4 ± 1.3 vs. 3.9 ± 2.1 a.u., p = 0.002, ηp2 = 0.58).

CONCLUSION: Concurrent and complementary LF-EMS of the lower extremities during submaximal handcycling notably increases acute oxygen uptake and thus may serve as an additional cardiocirculatory training stimuli for improvements in aerobic capacity in wheelchair athletes. Future studies on tissue response and preservation when concurrently using LF-EMS in the long term are suggested.

A STATISTICAL APPROACH TO SELECT WHICH PLAYERS TO PUT ON THE FIELD DURING A WHEELCHAIR BASKETBALL CHAMPIONSHIP.

CAVEDON, V.

SCHOOL OF EXERCISE AND SPORT SCIENCES

INTRODUCTION: Game performance in Wheelchair Basketball (WB) is represented by season statistics in terms of winning records, average points from both field-goals and free throws, rebounds, assists, and steals per match. How to optimize the factors contributing to the success of game performance and how to select players are primary concerns of the coaches and the technical staff. In order to explore the factors contributing to the success of the match, Cluster Analysis was applied in WB game performance data.

METHODS: Data related to a complete regular season of the top Italian WB Championship 101 athletes of 8 different teams and 56 matches) were considered for analysis. Based on seven scores of the athletes' performance normalized by the time spent by each player in the field during each match (i.e., the number of free-throw points made [FTM], number of two-point field-goals made [P2M], number of three-point field-goals made [P3M], total points made per match [PTS = FTM + P2M + P3M], number of steals [ST], number of rebounds [REB] and number of assists [AS]), the suitable number of clus-

ters was determined by the hierarchical ward clustering method. The k-means clustering technique with the defined number of clusters was then performed to determine cluster membership for each participant.

RESULTS: Based on data related to the first round of the Championship (i.e., 28 matches), two cluster solution to explaining about 35% of the total variance was considered to produce the optimal cluster size for detailed groups whilst maintaining meaningful differences between the clusters. Cluster 1 was composed by high performing athletes, while Cluster 2 is composed by low performing athletes. Based on data related to the second round of the Championship, the regression analysis conducted with the performance of each team (winning or losing), showed that teams where players belonging to the Cluster 1 had played more time during the second round of the championship were also those with the better team performance (Adjusted R-squared = 0.48 and P = 0.035).

CONCLUSION: The results of the present study provided a practical tool for WB coaches based on statistical techniques to support their tactical decisions in order to answer the coach's question: "By what criteria can I select which players to put on the field during a WB championship?".

THE EFFECTS OF PRE-COOLING ON CORE TEMPERATURES AND PHYSIOLOGICAL INDICATORS IN BLIND MARATHON RUNNERS USING ICE SLURRY INGESTION - A CASE STUDY OF JAPANESE ELITE ATHLETES

NAKAMURA, M.1, NAITO, T.1,2, AKAZAWA, N.1, TAKAHASHI, A.1, MURAISHI, K.1,3, YASUDA, K.4, KINOSHITA, H.4

1> JAPAN INSTITUTE OF SPORTS SCIENCES; 2> HOKKAI-GAKUEN UNIVERSITY; 3> KANTO GAKUEN UNIVERSITY; 4> JAPAN BLIND MARATHON ASSOCIATION

INTRODUCTION: The Tokyo 2020 Games were held in a hot environment, and blind marathon runners, such as athletes in other events, needed to prepare for the heat during the event. Although body cooling strategies to control excessive increases in core body temperature are extremely important to ensure safety and high exercise performance in hot environments, the thermoregulatory responses and effects of body cooling in visually impaired marathoners in hot environments remain unclear. The purpose of this study was to investigate the effects of pre-cooling with ice slurry ingestion on the core temperatures and physiological and subjective indicators in blind marathon runners during outdoor distance running in hot environments.

METHODS: Four elite blind marathon runners (2 males and 2 females; age, 41 ± 17 years; height, 158.2 ± 9.0 cm; weight, 49.4 ± 7.8 kg; T11–T12 classes), aiming to compete in the Tokyo 2020 Games, participated in this study before the Games. During the training camp in early September 2019 (Wet Bulb Globe Temperature (WBGT), 29.9 ± 1.4 °C), two 15–30 km running sessions were performed. All runners ingested 7.5 g· kg −1 of ice slurry (ICE), or an ambient temperature sports drink (CON) during the 30-minute warm-up before running. The two conditions, ICE and CON, were performed in a crossover fashion, with the two runs spaced three days apart. Core body temperature (gastrointestinal temperature, Tgi), skin temperature (Tsk), and heart rate (HR) were measured before warm-up (Pre), after pre-cooling (Post Pre-cooling), at the start, and at the 5, 10, 15, 20, 25, and 30 km distance points. Body weight (used to calculate sweat loss and dehydration rate) was measured before and after running. An effect size (Cohens d) was calculated to indicate the degree of difference in each physiological index between the two groups. The standard effect size was set as small (0.20), medium (0.50), and large (0.80).

RESULTS: The average time per kilometer was similar in both conditions (ICE, 0:04:30 ± 0:00:42; CON, 0:04:33 ± 0:00:39; d = 0.07). The decrease in Tgi from Pre to Post Pre-cooling was greater for the ICE group than that for the CON group (ICE, Δ-0.86 ± 0.2 °C; CON, Δ0.05 ± 0.4 °C; d = 2.88). However, the difference in Tgi between the two groups disappeared at the 5-km mark from the start of the race. The other physiological parameters, such as Tsk, HR, total water intake volume, total sweat loss, and dehydration rate, were similar in both conditions.

CONCLUSION: The results of this study showed that pre-cooling by ice slurry ingestion decreased core temperature, but had little effect on the skin temperature, HR, or dehydration rate of blind marathon runners. The difference in the core temperatures between the CON and ICE groups observed during precooling disappeared at the 5-km mark of the run. Therefore, in addition to pre-cooling, it would be necessary to consider the introduction of cooling during marathon races.

QUANTIFICATION OF PULLING FORCE DURING A INCREMENTAL ROWING TEST IN PARA-ATHLETES: PILOT STUDY

PRADON, D.1, DIRY, A.2, MAHIEU, M.1, LI, T.3, AMELON-PETIT, C.1

<1> PÔLE PARASPORT SANTÉ APHP - ISPC SYNERGIES, <2> FÉDÉRATION FRANÇAISE D'AVIRON, <3> KINVENT, MONTPELLIER

INTRODUCTION: The scientific literature identifying the physiological and biomechanical factors of performance in able-bodied rowers allows for the characterization of expectations in both novice and high-level rowers (Lawton 2012, Smith 2012). This work allows the identification of indicators associated with cardiorespiratory, muscular, and gestural capacities during muscle, boat, and rowing tests. Despite this work, few have focused on the development of pulling force during rowing tests. Indeed, only Curtler (2016) reports a decrease in strength when the athlete is found to be able to use only their arms, or only their arms and trunk compared to the arms, trunk, and legs condition. Although not focused on para-athletes, this study questions the impact of muscle deficit on athletic performance. The objective of this study is to characterize the pulling force developed by the national and elite para-athletes during incremental rowing VO2 max Test.

METHODS: 6 para-rowers of national and elite level perform a 3-minute incremental test with 30 seconds of recovery on a rowing machine (RowErg, Concept C2, USA). The pulling force is recorded during the test (K-Pull, Kinvent, France). The temporal parameters of the cycle as well as the maximum pulling force and its onset were calculated for each cycle at

each level. The percentage difference between the penultimate and the last level was calculated for each biomechanical parameter [median Q1-Q3].

RESULTS: The 6 athletes achieved 4 or 5 validated landings. Concerning the biomechanical performance parameters, we observed a 13% [10-15] decrease in cycle time between the penultimate and the last stage, which was accompanied by a 13% [10-14] increase in cadence. Logically, the pull phase increases (5% [5-7]) less than the return phase decreases (17% [12-22]). While the pull force also increases (5% [4-8]), the analysis of the onset of peak force remains almost identical at all levels (14±1.3%). This last parameter underlines that despite the different motor deficits, the athletes have the capacity to develop a quasi reproducible force at each cycle of each level.

CONCLUSION: This pilot study identifies that the adaptations of the performance parameters are in agreement with the literature. The analysis of the pulling force highlights a low variability of the appearance of the peak in the cycle. These results seem to indicate a technical reproducibility of the para-rammers independently of their level of motor deficit. This last point may allow the identification of the expected level of motor expertise.

VALIDITY AND RELIABILITY OF PREDICTION EQUATIONS BASED ON ANTHROPOMETRIC INDICES TO ESTIMATE BODY COMPOSITION IN ATHLETES WITH AN AMPUTATION

RIVERA-AMÉZQUITA, L.V., SAAVEDRA-BERNAL, X., ESCORCIA-GÓMEZ, D.C., RAMOS-CABALLERO, D.M.

UNIVERSIDAD DEL ROSARIO

INTRODUCTION: Body composition needs to be monitored in athletes with amputation because these parameters are related with their performance and health. The most common method of evaluation is the prediction equations based on anthropometric indices. However, they assume body symmetry; this is not the case of athletes with amputation. Consequently, the use of anthropometry and the prediction equations might not be adequate. Therefore, the aim of this study is to explore the validity and reliability of predictive equations based on anthropometric indices to estimate body composition in athletes with unilateral lower limbs amputation, compared with the gold standard Dual-energy X-ray absorptiometry (DEXA).

METHODS: Body composition was measured in 28 paralympic athletes with unilateral amputation using DEXA and anthropometry at the same day. Wilcoxon test was used to estimate the differences between DEXA and prediction equations. Pearson's correlation coefficient was estimated to determine the association between techniques. Absolute agreement was assessed using the Intraclass Correlation Coefficient (ICC).

RESULTS: Statistically significant differences ($p<0,001$) were found in all of the variables between DEXA and the predictive equations. Anthropometry significantly overestimated fat mass by 3.38 Kg, fat mass index by 1.23 Kg/m2, lean mass index by 5.70 Kg/m2 and bone mass by 12.15%. Also, anthropometry significantly underestimated fat percent (by 10.6% with Slaughter, by 8.87% with Faulkner and by 13.44% with Carter equation), lean mass by 11.78 Kg and lean mass percentage by 26,72%. Only fat mass index had an excellent agreement between the equations and DEXA (ICC= 0.81). Lean mass (ICC= 0.63) and fat percent estimated with Slaughter (ICC= 0.47) and Faulkner (ICC= 0.49) had good agreement. For the other variables, this agreement was poor. Very strong correlations were found for fat mass index (r= 0.82) and lean mass (r= 0.86), and strong associations for fat mass (r= 0.79), fat percent (r= 0.7 for Slaughter, 0.64 for Faulkner and 0.79 for Carter) and lean mass index (r= 0.69 compared to Appendicular muscular mass index given by DEXA) between instruments. Other variables reported weak to moderate associations.

CONCLUSION: Prediction equations based on anthropometric indices are valid to measure fat mass, fat mass percentage (Slaughter, Faulkner and Carter equations), fat mass index, lean mass and lean mass index compare to DEXA on athletes with lower limb unilateral amputation. But this method is not valid for the estimation of lean mass percentage, fat free mas index and bone mass percentage. The precision of the equations is excellent only for fat mass index compared to DEXA, which means that they will give biased results for the rest of the parameters. Therefore, we do not recommend to use of the traditional equations based on anthropometric indices for the estimation of body composition in athletes with unilateral lower limb amputation. Specific equations for them should be developed.

EFFECTS OF TAI CHI AND CONVENTIONAL EXERCISE ON SUBJECTIVE SLEEP PARAMETERS IN OLDER ADULTS WITH CHRONIC INSOMNIA AND DEPRESSIVE SYMPTOMS: PRELIMINARY RESULTS OF A RANDOMIZED CONTROLLED TRIAL

RECCHIA, F., YU, A.P., NG, T.C., SIU, P.M.

UNIVERSITY OF HONG KONG

INTRODUCTION: Insomnia occurs in nearly 50% of older adults, and has been associated with several chronic diseases, including heart disease, osteoporosis and depression. Depression and insomnia are highly comorbid, as sleep difficulties can arise prior to or after the onset of a depressive episode. Exercise has been endorsed by international guidelines as an effective treatment for insomnia and depression. However, whether different exercise modalities induce differential responses on subjective sleep remains to be elucidated. In this study, we present the preliminary findings of a randomized controlled trial designed to compare the effects of conventional exercise and Tai Chi versus control on subjective sleep quality in older adults with chronic insomnia and depressive symptoms.

METHODS: In this three-arm randomized controlled trial, thirty-six older adults (67±5y) with a diagnosis of chronic insomnia and depressive symptoms were randomly assigned in a 1:1:1 ratio to a conventional exercise intervention consisting of aerobic and strength training (EX), a Tai Chi intervention (TC), or a Health Education control (HE) for 12 weeks. Outcomes included the Pittsburgh Sleep Quality Index (PSQI), and sleep efficiency, sleep onset latency and total sleep time assessed through a sleep diary. Generalized estimating equations were used to compare the changes in sleep parameters from baseline among groups, where a P value <0.05 was considered statistically significant. Data are presented as means±SD.

RESULTS: At the end of the intervention, the PSQI values were significantly reduced in all groups (TC, -3.3±3; EX, -2.9±3; HE, -2.6±3; Time effect, P=0.04) but no differences were observed among groups (Time x Group, P=0.5). No significant Time (P≥0.25) or Time x Group (P≥0.11) interactions were observed for sleep efficiency, sleep onset latency and total sleep time, although all interventions improved sleep efficiency (TC, 14%±21; EX, 11%±16; HE, 9%±10), sleep onset latency (TC, -35±47min; EX, -38±85min; HE, -11±29min) and total sleep time (TC, 100±107min; EX, 58±102min; HE, 64±81min) from baseline.

CONCLUSION: Our preliminary findings suggest that exercise, Tai Chi and health education are effective for improving subjective sleep quality in older adults with chronic insomnia and depressive symptoms. Participants in the intervention groups experienced greater improvements on sleep quality when compared to control, however these differences did not reach statistical significance. Further analyses based on a larger sample size are needed.

ACUTE EFFECTS OF ECCENTRIC VERSUS CONCENTRIC EXERCISES ON EXECUTIVE FUNCTION OF OLDER ADULTS

HUANG, M.1, CHEN, T.C.2, SINGH, F.1, NOSAKA, K.1

1 EDITH COWAN UNIVERSITY, 2 NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: Cognitive function could be improved acutely after performing a bout of aerobic and/or resistance exercise [1]. It is possible that muscle contraction types in the exercise affect the acute changes in the cognitive function differently. For example, Fang et al. [2] reported greater movement-related cortical potential during eccentric (lengthening) than concentric (shortening) muscle contractions. However, no previous studies have compared between eccentric and concentric exercises for acute changes in cognitive function. We tested the hypothesis that eccentric exercises would improve cognitive function greater than concentric exercises. Thus, we compared descending stair walking (DSW) and ascending stair walking (ASW), as well as eccentric resistance exercise (ERE) and concentric resistance exercise of the knee extensors (CRE) for changes in some cognitive function test scores before and after the acute exercise bout performed by older adults.

METHODS: Twenty healthy older (66-75 y) adults performed DSW, ASW, ERE and CRE for 20-25 minutes each with a week interval between exercises in a randomised order. They performed Stroop test, symbol digit modalities test, digit span test and two types of trail making test (TMT-A, TMT-B) before and after sitting for 20 minutes (control condition), two occasions before the first exercise session, and before and after each exercise bout. Two exercises (DSW vs. ASW, ERE vs. CRE) were compared for changes in the cognitive function scores before and after the exercise by two-way repeated-measures ANOVA to test the hypothesis that DSW and ERE (eccentric exercises) would increase the scores greater than ASW and CRE (concentric exercises).

RESULTS: A significant ($p<0.05$) improvement of the test scores was found from the first to the second control sessions, and after sitting for 20 minutes. No further improvement of the scores was evident from the second control session to the baseline of the next four exercise sessions. When comparing pre- and post-exercise test scores, no significant changes were observed for Stroop, symbol digit modalities and digit span tests. However, TMT-A (-16.1±4.7 ~ -22.9±10.1 s) and TMT-B (-20.3±10.3 ~ -30.4±22.1 s) showed improvement ($p<0.05$) from pre- to post-exercise, without significant differences among the four exercise sessions.

CONCLUSION: These results showed that the exercises did not improve cognitive function except for the TMT performance. However, a similar improvement of the TMT scores was also found in repeating the tests in 20 min, thus the effect was not likely due to the exercise. Contrary to the hypothesis, no significant difference between eccentric and concentric exercises existed for post-exercise changes in cognitive function, and cognitive function was not improved by an acute exercise for older adults whose cognitive function was not impaired.

ACUTE PROGRESSIVE WHEELED MOTORIZED SLED-PUSH EXERCISE IN OLDER ADULTS: FEASIBILITY AND PHYSIOLOGICAL QUANTIFICATION

SEBASTIAO, E., BAUMANN, M., HILL, C., CAMIC, C., CHOMENTOWSKI, P., SIQUEIRA, V.

NORTHERN ILLINIOS UNIVERSITY

INTRODUCTION: The potential of the novel XPO Sled Trainer (XST) - a wheeled motorized sled-push device, has not been systematically tested in older adults. This study examined the feasibility and physiological effects resulting from an acute progressive sled-push exercise session using the XST device in older adults and compared it to a walking session.

METHODS: Thirty-six older adults (Age: 69.2±4.7 years; BMI: 27.3±5.9 kg/m2; 61% women) were randomly allocated into the sled-push (SLP; n=18) or walking (WKG; n=18) group. We assessed: heart rate (HR) using a HR monitor, blood pressure (BP), blood lactate (LAC) using handheld blood lactate meter device, and rate of perceived exertion (RPE) using the Omni scale. The protocol involved participants pushing the XST device, which provides low rolling resistance at low speeds with an instant and automatic equivalent increment in resistance with increased speed, six times on a 30-meter course with 2-minute rest periods in between. The exercise for the SLP was based on normal average speed for pushing the sled with the motor disconnected (i.e., no resistance). Normal average speed was then used to create three different exercise intensity/speed zones: subnormal (75 and 85%), normal (100%), and supranormal (125%); with the 100% and 125% speed being completed twice each and the average used for the analysis. An online metronome connected via Bluetooth to a speaker was used to pace and monitor speed during each of the six trials. Data were collected during all 2-minute rest periods. The WKG condition performed the same task but without the sled. Data were analyzed using Mixed-Factor ANOVAs with significance level set at $P<0.05$, with holm correction.

RESULTS: No adverse events occurred during the exercise sessions, and participants of both groups successfully completed the exercise protocol as prescribed. Mixed-factor ANOVAs revealed a significant group x speed interaction for HR $F(2, 66) = 25.92$, $P<0.001$, $\eta p2=0.44$, systolic BP $F(2, 68) = 8.81$, $P=0.001$, $\eta p2=0.21$, blood LAC $F(2, 68) = 19.61$, $P<0.001$, $\eta p2=0.37$, and a significant main effect for group $F(1,34) = 32.92$, $P<0.001$, $\eta p2=0.49$ and velocity for RPE $F(2,68) = 48.27$, $P<0.001$, $\eta p2=0.59$. Test of simple effects for speed showed that the SLP group demonstrated significantly ($P<.001$) higher HR (subnormal: mean difference (MD)=22.28 b·min-1; normal: MD=36.1; supranormal: MD=40.41, systolic BP (subnormal: MD=11.1 mmHg; normal: MD=13.5; supranormal: MD=18.1), and blood LAC (subnormal: MD=1.1; normal: MD=1.9; supranormal: MD=3.5) compared to the WKC for all three defined speed categories.

CONCLUSION: The findings support the viability and safety of the XST exercise in older adults. Such exercise modality demonstrated an intensity driven modality that may have potential to elucidate positive adaptations in the cardiovascular system of older adults. In addition, our findings demonstrated that the XST session resulted in higher physiological demand compared to walking as demonstrated by the assessed parameters.

AGE- AND SEX-RELATED DIFFERENCES ON MUSCLE STRENGTH OF THE TIBIOTARSAL JOINT AND ITS ASSOCIATION WITH PHYSICAL AND FUNCTIONAL FITNESS

BOVOLINI, A.1,2, RÚA-ALONSO, M.1,2,3, MARQUES, M.1, COSTA-BRITO, A.R.1, SERRA, N.1, VILA-CHÃ, C.1,2

1: POLYTECHNIC OF GUARDA;2: RESEARCH CENTER IN SPORTS SCIENCES, HEALTH SCIENCES, AND HUMAN DEVELOPMENT;3: PERFORMANCE AND HEALTH GROUP, UNIVERSITY OF A CORUNA

INTRODUCTION: Ageing, even without chronic conditions, is associated with several changes and declines in neural and musculoskeletal systems (1). Along with low physical activity levels in older populations, these declines might lead to distinct losses of physical and functional fitness between older men and women (2). Moreover, studying physically active older and young adults may help to understand the isolated impact of ageing. This study aimed to evaluate the impact of age and sex on muscle performance of plantar flexion and dorsiflexion of the tibiotarsal joint and their association with physical and functional fitness.

METHODS: The sample included 42 participants: 22 young (11 men, 22.09 ± 2.02 years; and 11 women, 22.27 ± 3.35 years); and 20 older adults (10 men, 68.60±4.99 years; and 10 women, 63.50 ± 12.65 years). Participants were evaluated for muscle performance of the plantar flexors and dorsiflexors of both tibiotarsal joints (peak torque and work) and physical and functional fitness. The assessments included normal and fast gait speed at 4 and 10 metres (GS), time up and go (TUG), handgrip (HG), sit to standing tests (STS-5r and STS-30s), and functional reach test (FR).

RESULTS: Regarding physical fitness, only a main effect of age was observed in TUG, HG, STS-5r and -30s, and FR ($P \leq 0.017$). For muscle performance, all evaluated variables (peak torque and work) showed age main effect ($P < 0.001$). A main effect of sex was observed in HG and STS-30s ($P \leq 0.038$). An interaction age*sex was observed in fast GS during the

4- and 10-meter tasks (P ≤ 0.030), with older women being slower than older men and younger women (P ≤ 0.031). Peak torque and work of the tibiotarsal joint flexors were both moderately to strongly correlated to TUG, STS-5r and STS-30s (P ≤ 0.043).

CONCLUSION: Age-related muscle performance decline appears to affect men and women similarly. Some functional and physical tests (HG and STS-30s), which is associated with better muscle performance, were affected by sex but not by age (except for GS). Both GS test (4- and 10-metres) showed no association with muscle decline, being worse in older women. Since physical activity levels are affected by age (2), developing public strategies to promote physical activity and strength training is necessary for older adults, especially women.

HIGH INTENSITY INTERVAL TRAINING HAS POSITIVE EFFECT ON FUNCTIONAL MOVEMENT IN OLDER ADULTS.

STERN, G., PSYCHARAKIS, S., PHILLIPS, S.

UNIVERSITY OF EDINBURGH

INTRODUCTION: One of the most important exercise training goals, particularly for older adults, is the preservation of functional movement: fundamental movement patterns that require a balance of mobility and stability (including neuromuscular/motor control) used in the performance of basic locomotor, manipulative, and stabilizing movements (Cook et al., 2014). While functional movement has been positively associated with physical activity and increases in muscular power, it is not clear whether high intensity interval training (HIIT) or moderate intensity continuous training (MICT) are more effective for preserving and promoting functional movement. A large body of research has determined that both types of exercise programme are effective for improving measures of aerobic and anaerobic fitness in older adults. However, the effect of the two exercise modalities on functional movement has most often been a secondary outcome, with a range of observational techniques applied for measurement.

METHODS: A search strategy of terms locating studies of HIIT interventions, functional movement outcome measures, and older adult population samples was executed on seven digital databases. Randomized and pair matched trials of > 2 weeks were considered for inclusion. Studies of participants with neurological impairment or studies using combined exercise modality were rejected. Standardized mean difference for functional movement outcome measures were calculated. A meta-analysis of the included studies and sub-groups was performed along with study quality (risk of bias and publication bias) evaluation.

RESULTS: A total of 18 studies were included for random effects model pooled analysis. HIIT showed a medium, statistically significant favourable effect on functional movement versus non-intervention control (ES = 0.60 95% CI [0.24, 0.95] p = 0.001). However, sub-group analysis of HIIT versus MICT on functional movement showed a trivial effect in favour of HIIT (ES 0.13, 95% CI [-0.06, 0.33] p=0.18) and did not achieve statistical significance.

CONCLUSION: This meta-analysis indicates that HIIT interventions in older adults may be effective at promoting improvements in functional movement, though it is unclear whether HIIT is superior to MICT. Most importantly, the results indicate that future research should utilize more standardized HIIT protocols equalized to the comparator for work, time, or energy expenditure, include HIIT interventions on healthy, physically active populations and measure functional movement with more comprehensive assessments than those designed to assess the frail elderly.

MECHANISM OF AEROBIC EXERCISE IMPROVING SOCE-MEDIATED CORONARY CONTRACTION IN AGING RATS

HUANG, J., DENG, W.

GUANGZHOU SPORT UNIVERSITY

INTRODUCTION: Studies have shown that aging can cause the dysfunction in vasoconstriction. Store-operated Ca2+ entry (SOCE) and its constituent proteins Orai and STIM play a critical role in the regulation of vascular tone. The present study aimed to explore the effects and the underlying mechanism of aerobic exercise on SOCE-mediated coronary contractile function in aging rats.

METHODS: Ten young rats were set as the Young group. Twenty aging rats were randomly divided into the Old group and Old+Exercise group, with ten rats in each group. Old+Exercise group received 11 weeks of treadmill aerobic exercise intervention. The SOCE-mediated coronary artery contraction of rats in each group was detected by isometric tension measurement. The expressions of Orai and STIM in the coronary smooth muscle of three groups were detected by the immunohistochemical method. The expressions of microRNAs were screened by transcriptome sequencing technology.

RESULTS: There was no significant difference in the vasoconstriction induced by high potassium solution among three groups. In the vasoconstriction induced by endothelin-1, compared with the Young group, there was a significant en-

hancement in the coronary artery contraction in the Old group, and this effect was restored after 11 weeks of aerobic exercise training in aging rats. Furthermore, SOCE-mediated coronary contraction in Old group was significantly higher than that in the Young group, and this effect was significantly inhibited by exercise training in aging rats. Our immunohistochemical results showed that, the expression of Orai2 was abundant in myocardium and coronary smooth muscle layer. Compared with Young group, the expression of Orai2 protein in Old group and Old+Exercise group was significantly lower. Additionally, the expression of Orai2 in Old+Exercise group was significantly lower than that in Old group. The expression of Orai3 protein in Old group was significantly lower than that in Young group, and the expression of Orai3 in Old+Exercise group was higher than that in Old group. The expression of STIM1 in Old group and Old+Exercise group was significantly lower than that in Young group, and the expression of STIM1 in Old+Exercise group was higher than that in Old group. However, the expressions of Orai1 and STIM2 in the smooth muscle layer of coronary artery were low. High throughput sequencing of rat serum was executed and a total of 114 different expressions of microRNAs was found, in which rno-miR-298-5p was the target microRNA of Orai2, novel_miR_1079 was the target microRNA of STIM1, and rno-miR-27a-5p was the target microRNA of STIM2 and Orai3.

CONCLUSION: Aerobic exercise can effectively improve the abnormal enhancement of coronary artery contraction induced by aging, which is related to the down-regulation of SOCE-related proteins Orai and STIM. The microRNAs may be involved in the regulation of the expression of Orai and STIM. Among them, rno-miR-298-5p, rno-miR-27a-5p, and novel_miR_1079 are potential target microRNAs of Orai and STIM.

THE EFFECT OF 10WEEK FOREST WALKING EXERCISE ON KNEE STABILIZATION IN MIDDLE-AGED FEMALE

SON, J.H.1, KIM, K.H.1, KIM, B.K.1, JEONG, H.J.1, PARK, J.S.1, KEUM, H.H.2, CHOI, J.H.2, KIM, A.R.1, KANG, J.1, HAN, K.M.3, MIN, J.W.1

1.DANKOOK UNIVERSITY 2.KOREA INSTITUTE OF INDUSTRIAL TECHNOLOGY 3.CALIFORNIA STATE UNIVERSITY

INTRODUCTION: The purpose of this study was to compare the indoor resistance exercise group using elastic bands and the forest exercise group using forest slopes for middle-aged female in order to investigate the effect of walking exercise on muscle strength improvement in forest environment.

METHODS: Twenty-four female were randomly assigned to an indoor group (n=11, mean±SD: age 53.38±10.78 years, height 160.54±4.99cm, body mass 61.71±5.69kg) and a forest group (n=13, mean±SD: age 56.73±7.06 years, height 162.55±4.55cm, body mass 63.14±10.04kg). In the indoor group, the exercise was performed mainly on the lower extremity using an elastic band, and the forest group performed a walking exercise to uphill and downhill the sloping forest environment. Both groups were carried out twice a week for a total of 10 weeks. The RPE intensity was gradually increased to 13-14 intensity for the first 1-2 weeks, 15-16 intensity for 3-6 weeks, and 16-17 intensity for 7-10 weeks. Before the start of exercise and after the end of the exercise period, Biodex System 4 was used to perform left and right extension and flexion at 60°/sec speed five times in total, and the knee strength measured at 30° was analyzed by Two-way mixed design ANOVAs. If there was a significant difference, it was post-hoc by the bonferroni method.

RESULTS: There was no significant difference in right extension according to group and time (group: p=.827, Time: p=.813), and there was no interaction effect (p=.111). There was no significant difference in the right flexion according to the group (p=.789), but there was a significant difference according to the time (p=.027), and there was an increase in the forest exercise group (p=.020). There was no significant difference in left extension(p=.281), significant difference in time(p=.002), and increased in forest exercise group(p=.005), and no interaction effect(p=.507). There was no significant difference in the left flexion according to the group (p=.476), and there was a significant difference according to the time (p=.000), and both the indoor exercise group (p=.007) and the forest exercise group increased (p=.002). There was no interaction effect (p=.833).

CONCLUSION: Walking exercise in forest environment is thought to have brought improvement of knee muscle strength by giving load to uphill and downhill lower extremities, and it was confirmed that forest walking exercise can be suggested as an activity to improve muscle strength for middle-aged female knee stabilization.

EFFECTS OF MICROCURRENT THERAPY WITH RESISTANCE EXERCISES ON STRENGTH, FUNCTIONAL CAPACITY, AND MUSCLE THICKNESS IN MIDDLE-AGED ADULTS: A PILOT STUDY

KOLIMECHKOV, S., LAZA-CAGIGAS, R., SEIJO, M., SWAINE, I., THIRKELL, J., COLADO, J.C., LARUMBE-ZABALA, E., NACLERIO, F.

UNIVERSITY OF GREENWICH

INTRODUCTION: Microcurrent therapy (MCT) is a non-invasive method that transmits a sub-sensory electrical current through the skin within the range of milliamperes (1-999mA). MCT has been suggested as an effective treatment for sarcopenia. The aim of this study was to analyse the effects of adding MCT to a resistance exercise programme on strength, functional capacity, and muscle thickness in middle-aged adults.

METHODS: The study involved a double-blind randomised controlled design. Eight participants (mean ± SD: age 54.4 ± 7.4 years, BMI 23.1 ± 3.8 kg/m2, height 168.7 ± 12.3 cm) were randomly assigned into a microcurrent (MCT, n = 4; 1 man and 3 women) or a sham (SH, n = 4; 1 man and 3 women) group. All participants completed a 6-week resistance training programme with elastic bands (2 sessions per week, 12 workouts). Participants performed 3 sets of 12 to 15 maximal repetitions, with 1.5 to 2 min of rest between sets, of the following exercises: shoulder press-squat, biceps curl, back squat, lateral pull down, deadlift, triceps extension, lunge, and upright row. The rating of perceived exertion (RPE) was determined by the OMNI-Resistance Exercise Scale (OMNI-RES) for elastic bands (0-10 scale) to determine the increment of

the training load over the 6-week intervention period. An RPE of 6 to 7, 7 to 8, and 8 to 9 rated immediately after the completion of each set was required during weeks 1, 2, and 3 to 6 respectively. If participants did not reach the required RPE after 12 reps, they were instructed to (i) increase the number of reps up to 15 and (ii) if this was not enough for obtained the wanted RPE, they had to increase the resistance offered by the elastic band by reducing its grip width or changing it to a less viscoelastic band. Participants wore a microcurrent or a sham device on their dominant upper arm during the 3 hours immediately after the workout or in the morning on non-training days. The microcurrent device delivered a current with an intensity between 50 and 400 μA in a ratio of 2:1 (on:off) and a frequency of 1.03 kHz. Measurements of strength (handgrip and 90° isometric leg press), functional capacity (30s chair stand test), and muscle thickness were conducted before and after the intervention. Pre-post changes were analysed to calculate effect sizes.

RESULTS: A significant increase in the post-assessment 90° isometric leg press test was determined in the MCT group (+3.9 kg, p = 0.03, d = -1.85). No other significant, pre-post or between-group differences were observed. Nonetheless, compared to SH, the MCT group showed more favourable effect sizes in 90° isometric leg press (d = -1.20), handgrip strength (d = 0.66), 30s chair stand test (d = -0.99), and vastus lateralis muscle thickness (d = -0.68).

CONCLUSION: Adding a 3-hr post-workout microcurrent treatment appears to favour the positive effects of resistance exercise in middle-aged adults.

IMPROVEMENT IN FUNCTIONAL, CLINICAL SCORE AND QUALITY OF LIFE AFTER A SPECIFICALLY DESIGNED EXERCISE PROGRAM IN PEOPLE WITH TOTAL HIP REPLACEMENT: A PILOT STUDY

PINELLI, E.1, ZINNO, R.1, MAZZOTTA, A.2, SCOPPOLINI MASSINI, M.1, BARONE, G.1, DALLARI, D.2, BRAGONZONI, L.1

1 UNIVERSITY OF BOLOGNA; 2 IRCCS ISTITUTO ORTOPEDICO RIZZOLI

INTRODUCTION: Hip osteoarthritis (OA) are highly prevalent age-related chronic condition among older people. The end-stage treatment for OA is the total hip replacement (THR). Despite the high impact of physical activity and an active lifestyle on peoples quality of life (QoL) and joint health, the majority of people remain inactive, especially those who suffer from osteoarthritis. The aim of this study was to improve the clinical and functional status of people who have undergone THR as well as their QoL through a specifically designed exercise program

METHODS: A cohort of 10 patients (mean age of 64.1±7.9) was enrolled for participating in the study. The patients were recruited at Rizzoli Orthopedic Institute at the moment of the pre-surgery medical check-up. The participants were randomly assigned to the intervention Group (IG) or control group (CG). The IG followed a 3-month exercise program specifically designed for people with hip arthroplasty. The CG followed the usual care for such patients. Both groups were assessed three times: within 2 weeks pre-surgery (PreSA), 6 months after surgery (PostSA), and after the 3-month exercise (3MA). The outcomes assessed were: Health-related Quality of Life (SF-36 questionnaire), functional (Timed up and go, 30sec chair stand test, single leg stance test) and clinical outcomes (WOMAC and HOOS), strength parameters (handheld dynamometer), and joints mobility. The Student's t-test for unpaired samples was used for parametric quantitative variables and the Chi-square test for qualitative dichotomous ones. A post-hoc analysis with Bonferroni correction was used for the comparison between groups and between the assessment time. The significance level was set at $p < 0.05$

RESULTS: From the initial cohort of participants, 2 of the control group dropped out. Hence, 8 participants completed the assessments (3 in IG and 5 in CG). In the IG group, the "physical function" domain of SF-36 showed statistically significant improvement from PreSA to PostSA ($p<0.01$) and 3MA ($p<0.01$). Concerning the strength assessment, the IG showed a significant improvement in hip extension strength from PreSA to 3MA ($p<0.05$), while the GC showed no significant improvements in strength parameters. Regarding the functional tests, the IG showed a significant improvement in TUG from PreSA to 3MA ($p<0.01$). The other outcomes showed improvement in both groups from PreSA to PostSA and 3MA, however, they were not statistically significant ($p>0.05$).

CONCLUSION: The overall clinical and functional score and QoL parameters improved from the first (PreSA) to the last evaluation (9 months after surgery). However, the IG showed greater improvement in lower limb strength, reduced risk of falls (measured through TUG), and higher self-reported physical function (SF-36) than the CG. Interventions based on exercise programs specifically designed for people with THR have the potential to improve the quality of life of these individuals.

ESTROGEN-TREATED POSTMENOPAUSAL WOMEN HAVE INCREASED MUSCLE MITOCHONDRIAL RESPIRATORY CAPACITY AND THIS IS ENHANCED BY ACUTE EXERCISE

KLEIS, A., FARLOV, J., SCHMÜCKER, M., BLOM, I., FLENSTED, M., HASSØ, R., LINDTOFTE, S., PEDERSEN, E., DELA, F., LARSEN, S.

INSTITUTE OF BIOMEDICAL SCIENCES, COPENHAGEN UNIVERSITY

INTRODUCTION: Estrogen is recognized to exert a protective effect on mitochondrial function, by mediating processes as mitochondrial biogenesis and antioxidant defenses against free radicals. Likewise, loss of estrogen is associated with decreased mitochondrial respiratory capacity (MRC) in rodents [1]. Since menopause causes a rapid decline in circulating estrogen this on-going study investigated if mitochondrial function was affected by estrogen-treatment in postmenopausal women. It was hypothesized that estrogen-treated postmenopausal women showed superior mitochondrial function than non-treated women.

METHODS: Biopsies from vastus lateralis were obtained from 11 hormone-treated (HT) postmenopausal women (55±4 years, BMI: 22±2 kg/m2, VO2max: 36.9±5 ml/kg/min) and 10 non-treated controls (C) (55 ± 6 years, BMI: 23±2 kg/m2,

VO2max: 35.2±6 ml/kg/min) at rest and immediately post exercise on bicycle ergometer (45 min @65%VO2max). MRC and H2O2 emission in permeabilized fibers were measured by high-resolution respirometry and fluorometry (Oxygraph-2 k, Orobros, Austria). HT and C were matched for VO2max and years after last menstrual bleeding. 3-way ANOVA was used to analyze respirometry and fluorometry to compare treatment (HT/C), time (pre/post exercise) and addition of substrates (mitochondrial respiratory states).

RESULTS: A main effect of treatment was found in respiration (p=0.0216), as HT showed higher MRC for both complex I (pre/post HT vs. C (malate, pyruvate, glutamate): 50±13/55±16 vs. 46±8/41±6 pmol/s/mg), complex I+II (+succinate: 84±12/85±15 vs. 70±15/66±25 pmol/s/mg) and uncoupled respiration (+FCCP: 98±18/99±28 vs. 81±14/76±23 pmol/s/mg) than C. No differences were observed in ADP sensitivity measured as Km, though Vmax was significantly increased post exercise in HT compared to post exercise in C (p=0.0444; post HT: 48±18 vs. post C:33±9 pmol/s/mg), with no differences in pre values between groups. ROS production was higher in HT than C (p=0.0318) in all respiratory states (MP, MPS, MPS+ADP) and was not affected by acute exercise.

CONCLUSION: HT exerted higher MRC and uncoupled respiration than C, which could support the idea of estrogen as an important enhancer of mitochondrial function. Simultaneously HT showed increased ROS production, which may serve as intracellular signalling molecule, but may also have a negative impact on the occurrence of metabolic diseases such as type 2 diabetes [2]. The antioxidant properties will therefore be further investigated.

THE RELATIONSHIP OF PROACTIVE PERSONALITY, ATHLETIC IDENTITY AND FUTURE WORK SELF AMONG STUDENT ATHLETES

WU, Y.T.1, WU, Y.F.2

1.SOOCHOW UNIVERSITY 2.MING CHI UNIVERSITY OF TECHNOLOGY

Introduction

Student athletes represent a unique population of universities and colleges. Student athlete's career transition is an important life issue that every athlete must face. However, little attention has focused on student athlete's cognitive representations and their future-oriented possible selves. Thus, to understand student athletes' personality and psychological aspect, this study adopts career construction theory to discover how student athletes' proactive personality relates to athletic identity and how it is reflected in their future work self.

Method

In this study, a quantitative approach was adopted using questionnaire survey, a total of 272 valid questionnaires were collected from student athletes currently studying in a university. Confirmatory factor analysis was used to analyze the current data to reconfirm the validity of the instruments. This study examined the relationship of proactive personality, athletic identity, and future work self among the student athletes with structural equation modeling (SEM).

Results

The result consisted of 137 Male 50.5% and 135 Female 49.6% participants from different student athlete from university in Taiwan, 5-point Likert scale was used in this study with 4 items for proactive personality, 5 items for athletic identity and 5 items for future work self, with a CFA, the Chi square showed 2.5, 5.5, and 2.9. The reliability and validity all met the requirement, according to CR > 0.7 : acceptable (Hair, 1997) with .807; .859; .907 and the AVE > 0.5 : acceptable (Fornell, and Larcker, 1981) .510; .552; .711 and the Cronbachs α >0.6: acceptable (Byrne, 2001) .806, .854, .903.

Discussion

The study results showed that proactive personality, future work self and athletic identity were positively related; while athletic identity was also positively related to future work self. These findings suggest that proactive personality and athletic identity are more likely to develop salient future work self. These results suggested that to develop adaptive abilities, individuals need to continuously gain insights of their own characteristics and the complexity of working environments through various exploring experiences (Savickas, 2013). Future work self is important in student athletes career transitions, counselors and educators can use these personalities to identify challenges that student athlete face throughout their career development.

ENHANCING LEARNING PROCESSES WITH THE FUNCTIONAL ADAVANCED DIDACTIC. A PILOT STUDY BASED ON EMBODIED THEORIES.

CICCARELLI, S., FERRARO, F.V., ARUTA, L., ARELLANO, W., GUTIERREZ, K.P., CAMPO, K.C., IAVARONE, M.L.

UNIVERSITÀ DEGLI STUDI DI NAPOLI PARTHENOPE

INTRODUCTION: The intensity of technology use in the aftermath of the pandemic and the restrictions imposed by the pandemic have encouraged a reduction in physical activity levels for children and adolescents, causing negative consequences for their health and well-being over time. Hence the need to experiment with innovative teaching protocols that integrate curricular subject study with motor activity. In this sense, in accordance with embodied theories and gamification theory, FAD (Advanced Functional Didactics) is experimented.

METHODS: The following contribution aims to present the results of a research project carried out in Cartagena de Indias (Colombia), in a public school, on a sample of 120 students attending the third year of primary school. This sample was divided into an experimental group (EX) and a control group (CG). The aim of the research was to measure the effectiveness of FAD on learning ability and certain aspects pertaining to the cognitive axis.

For data collection, a battery of tests validated in Colombia was administered to both the EXs and CGs, in phase T1 (pre-intervention) and phase T2 (post-intervention), with the aim of measuring certain aspects related to cognitive functions, such as: graphic and visuo-constructive abilities, immediate verbal memory, deferred verbal memory, deferred visual memory, spatial abilities, planning and organization, and visual attention. Learning, on the other hand, was assessed with tests constructed in collaboration with the teachers as they were ascribable to the acquisition of curricular knowledge also covered by the FAD.

The intervention lasted 3 months with 2 meetings per week, 2 hours each.

RESULTS

With the FAD, significant changes were observed in the experimental group with regard to learning attributable to some curricular subjects (mathematics, geometry, history and English) and some cognitive skills (handwriting and visuo-construction). Specifically for geometry, reference is made only to shape recognition, whereas with regard to English, the change is particularly significant in male subjects. Female subjects report more significant changes in graphical and visuo-constructive skills.

DISCUSSION

The results encourage the experimentation of experimental teaching protocols that, like FAD, integrate motor activity with the study of curricular subjects. Clearly, such experimentation is only feasible through the construction of environments conducive to the performance of such activities, furnished with gymnastic equipment, teaching aids and stationery materials. The results of the following study are an encouraging starting point for refining the proposed activities in order to improve their educational effectiveness to be tested in new experiments.

ENHANCING PARTICIPATION OF BLIND AND VISUALLY IMPAIRED STUDENTS IN PHYSICAL EDUCATION THROUGH DIGITAL TECHNOLOGY – A PARTICIPATORY APPROACH

HÖGER, B., MEIER, S.

UNIVERSITY OF VIENNA

Introduction

For children with blindness and visual impairment (BVI), participation in Physical Education (PE) can serve as an important facilitator of physical and mental health as well as life satisfaction (Labudzki & Tasiemski, 2013; Penedo & Dahn, 2005). Research points towards manifold participation barriers for children with BVI in PE, however, these barriers and possible solutions have so far mainly been investigated from the perspectives of sighted parents, teachers and fellow students (Haegele et al., 2020).

Methods

In the project "Smart Sport Assistance", we adhere to the postulation of the CRPD (2006) "nothing about us without us" and reconstruct participation barriers and possible digital solutions in terms of assistive technology for PE from the perspective of BVI persons using a participatory research approach. Following the Mosaic Approach (Clark, 2005), we collected a variety of data (interviews, school tours, images of significant elements) from 19 BVI students aged 14-21 (7m, 12w) from a school specializing in BVI in Austria to reconstruct the socio-material reality of PE from the perspective of those affected through data analysis with thematic content analysis (Braun & Clarke, 2022).

Results

We identified numerous ways in which spacial, material and interpersonal conditions prohibit BVI students from participation, even in a specialized school. At the same time, students imagined manifold technologies to enhance participation in a digitized future. From these imaginations we derived 15 specific concepts for assistive technologies across several sports disciplines that represent the requirements of BVI students.

Discussion

As an outlook, we present how sighted students from technical schools and their teachers can be involved in participatory research processes to not only develop these technologies but also become more aware of the perspectives of BVI people and their needs.

THE EFFECTIVE CHARACTERISTICS OF PE-BASED INTERVENTIONS ON SOCIAL BEHAVIOURS

MARIC, S., COTTON, W., CRADDOCK, J., WHITE, R.

UNIVERSITY OF SYDNEY/ MACQUARIE UNIVERSITY

Despite the well-known benefits of participation in physical education (PE), rates of disengagement continue to climb in high school- aged students. It is therefore unsurprising to find that PE-based interventions have become so prevalent in literature. Of the theoretical frameworks that have emerged, Cooperative Learning theories have demonstrated success in this field due to the social benefits explored within studies. The Sport Educational Model (SEM) and Teaching Games for Understanding Model (TGfU) have been embraced by researchers as basis for attempting to establish the positive effects of social theories on students in PE and used as theoretical frameworks within interventions. Within this review, SEM and TGfU, amongst others, have demonstrated positive effects on students' social interactions within PE lessons. Furthermore, studies have shown positive impact on students through improvements in academic performance, student wellbeing, teacher-student relationships, problem solving, and intrinsic motivation. A systematic review of literature was used to identify the effective characteristics in intervention design. A systematic review is required due to its meticulous nature and due to the scope of the research available on Cooperative Learning.

Methods: 16 articles were identified through a review of ERIC, Web of Science, ProQuest and SportsDiscuss. The title and abstract fields were searched for the following terms: 1. School* OR "secondary college" OR "secondary education" OR primary education" OR "elementary education" 2. "physical education" OR "phys ed" OR PE 3. Teach* OR Educat* OR Lead* OR Instruct* 4. Test or RCT or randomi* or control or trial or evaluat* or quasi-exper* or cluster or intervention* Social competenc*" OR Cooperat* OR "Social skill*". The search included articles published between the year 2000 to 2020 and studies were included if they; were published in English, delivered during PE lessons to school aged children, delivered by a specialist PE teacher, focused on evaluating the interventions as opposed to how it affected specific population groups, examined effects of social cohesion, and/or, reported outcomes using independent group difference values.

Results: The current systematic review of literature has found that at present 'effective' characteristics of PE based interventions have found mixed results due to numerous contributing factors. These results indicate that future interventions should include stakeholders, such as parents, teachers as facilitators, and to include interventions in both primary and secondary school settings. The impact of the teacher is important, and results suggest that interventions with a theoretical framework presented more favourable results. The duration of interventions yielded mixed results and in order to demonstrate long term benefits in the future, it was concluded that more research in this area is needed.

STIMULATING ACTIVE STUDENTS THROUGH

ISNANTA, R., FERDINANDUS, M.E., KUSUMA, D.W.Y., SETYAWATI, H.

UNIVERSITAS NEGERI SEMARANG

Introduction

The phenomenon in which a gadget becomes the Z-generations daily need caused 1/5 of children aged 5-12 years, and 1/7 of adolescents aged 13-18 years in Indonesia are overweight and obese. Obesity has known as a non-communicable disease that links to various degenerative diseases such as diabetes mellitus, lipidemia, cardiovascular diseases, etc. On the other hand, physical education (PE) is aimed to improve active behavior by present various forms of games that can stimulate children to be more physically active. This study was conducted to introduce "Move n Fun" (MnF), an android game-based that requires physical movement to play it. This game is an intervention to increase student participation and active time.

Methods

This is a Pretest-Posttest One-Group Study. A total of 150 students in the fifth and sixth grades of 4 elementary schools have participated. Pre and Post intervention assessments measured student subjective attitudes toward PE classes. The Physical Activity Questionnaire for Adolescents (PAQ-A) was used to assess students for personal opinions about their PE class before and after playing MnF. The teacher's comment was also part of the evaluation process.

Results

A paired samples t-test was conducted to evaluate whether students (n = 150) increased their participation in PE class after intervention. The results indicated that the postintervention students (M = 18.55, SD = 1.99) were significantly more active in PE class than before the intervention (M = 16.97, SD = 2.02). Significant findings included an increase in the mean of: (1) How often were you very active for last 7 days; (2) Statement your best for last 7 days; (3) Mark how often you played MnF after school; (4) Which one do you often play category in MnF. Contrary findings were noted for How you feel about PE class significant decrease after intervention.

Conclusion

This study has proved that playing MnF in PE class can increasing student activity as measure to decrease the obesity epidemic. The intervention also suggest that positive behaviors proposed in school can encourage positive behavior at home.

CHANGING ORGANISATIONAL STRUCTURES IN SKATEBOARDING – ETHNOGRAPHY OF A SUBCULTURES LEARNING AND TEACHING ENVIRONMENT

BÜSCHER, B.

TU DORTMUND

Theory

As an ongoing subject in sports pedagogical research Skateboarding is genuinely described as an informal sport with alledgedly open accesses to urban spaces, where sport activites are performed according to the often juvenile actors' capabilites and needs (Beal, 2013). Thereby, particular competences concerning movement, spatial and stylistic practices are acquired and continually discussed concerning its practical relevance in everyday life as well as specific vocational fields (Borden, 2019). However, on the background of its ongoing "sportification" (Kilberth & Schwier, 2019) the contexts of learning and teaching become continually differentiated between competitive and school sports. Of particular pedagogical interest are those settings that originate from the subculture itself, when ex-perienced scene members pass on selected cultural content to beginners at all ages.

Method

In the course of an "organizational ethnography" (Ybema et al., 2009) a total of 45 field visits were carried out in such a setting in order to investigate its internal structures, rules and processes. A participant observation initially consisted of skateboarding with the group as well as the gradual immersion in its organizational and social forms, which finally led to in-depth field interviews as familiarity increased. The data set of 250 pp. observation protocols and 150 pp. interview transcripts was evaluated by means of a "Grounded Theory" (Corbin & Strauss, 2008) and was increasingly put into a praxeological perspective.

Results

The open codings of ritualization, regulation and sanctioning are illustrated by means of essayistically elaborated data-anchors. On the level of an axial category, the field-specific organizational structure can be discussed both in terms of cultural theory with regard to its orgin in skateboarding subculture. In the context of "the changing landscape of urban youth sports" (Atencio et al., 2018), it also needs to be compared to referential institutions of sports.

COGNITIVE MOTOR INTERFERENCE IN DAILY LIFE SITUATIONS

WOLLESEN, B.

UNIVERSITY OF HAMBURG

Many daily life situations integrate cognitive tasks, such as remembering a phone number, discussing certain topics, or planning cer–tain tactics in team sports. In many cases, however, we have to deal with other cognitive or motor tasks running in parallel, such as remembering a shopping list while navigating through a crowded supermarket. The assumption is that in these multitasking situations that performance is e.g. limited by the capacity of each single process but also depends on how effectively we manage process interactions. Typically, limitations in processing of multiple tasks as compared to processing a single task (ST) are described. These processing limitations become even more obvious when the overall capacity is limited, like in novices or older adults. Getting rid of the limitations or at least pushing the limits to some extent in order to either (a) maintain performance despite disrupting/simultaneous secondary tasks (dual-task scenarios) to optimize performance in specific multitasking settings or (b) to counteract decline in relevant processing capacity has a high functional rele–vance for different target groups (e.g., athletes, older adults, employees) and has therefore been the target of many research studies. This talk will address the conduction of suitable training regimes, integrating particular processing components which actually cause the limitation and try to modify the functionality of these processes through specific interventions.

HOW FAR DOES VIRTUAL REALITY ALTER THE NEUROMUSCULAR SYSTEM?

GROSPRÊTRE, S.

C3S - EA4660

Virtual Reality (VR) is the computer simulation of a three-dimensional environment that a person can interact with in a seemingly real or physical way, using special electronic equipment such as a headset with integrated screens. VR is used in many fields, being used for instance to simulate real-life situations while remaining in a safe context, such as to train future surgeons to perform complex operations. Because it is well known that VR induces a great activation of the autonomic nervous system (ANS), as shown for instance by an increase in heart rate and electrodermal activity, this modality is often used as a way to maximise ANS activation and to improve stress management. However, there is more and more evidence that VR also has benefits for the motor system. For instance, adding the simulation of a virtual environment to a motor task performed in laboratory conditions may increase the impact of the task on the corticospinal excitability, reflecting voluntary motor system efficiency. Adding VR to a fitness training program, by displaying a playful and dynamic background, may increase the gains of the training as compared to a standard fitness program. Regardless of the type of population and type of intervention, a large majority of authors agree that VR increases the benefits of physical practice. However, the effects of VR are highly dependent on both the nature of the simulated environment (considered stressful/stimulating or relaxing), but also on the individuals receptivity to the intervention. The way a person reacts and interacts with the various virtual environments thus depends on a number of technological and psychological characteristics. The degree of immersion is determined by the technological characteristics of VR such as resolution, frame rate, etc. For example, more photorealistic graphics in a virtual environment have a positive effect on immersion. Another factor is the amount of sensory stimulation. The immersion effect is greater in the case of simultaneous stimulation of more sensory systems, congruence of stimulation of different modalities and its intensity. The ability to freely navigate the virtual environment and interact with virtual objects, when their bodies are realistically modelled, contributes greatly to the sense of realism. Therefore, VR needs to be smartly implemented to hope for benefits in sport training or rehabilitation contexts, as its effects might be specific according to the way it is used.

Here, we will discuss the potential benefits of adding VR to physical exercise, on cognitive function as well as on motor performance, based on the very recent literature. Practical recommendations will also be provided, based for example on the current knowledge on dose-response effect, or optimal modalities to induce gains in motor-related performances.

ADAPTATIONS IN MOTOR CONTROL STRATEGIES WEARING A STATE-OF-THE-ART EXOSKELETON OR PROSTHESIS

DE PAUW, K.

VRIJE UNIVERSITEIT BRUSSEL

Even though companies collaborate with ergonomists, prevalence of work-related musculoskeletal injuries exceeds 50% for back, shoulder and neck disorders in the industry (Govaerts et al, 2021). A possible solution to reduce the risk of a musculoskeletal disorder is via the implementation of wearable technologies, such as occupational exoskeletons, exosuits and collaborative robots.

Literature shows that these devices assist the operator during industrial work by reducing muscle activity (e.g. De Bock et al, 2021) and muscle fatigue (De Bock et al, 2022). However, following questions remain 1° What is the impact of using wearable technologies on mental fatigue?; 2° Do wearable technologies impact posture during industrial work?; 3° Is the use of wearable technologies accepted by industrial workers?

In line with abovementioned, individuals with a lower-extremity amputation might improve their quality of life using motorized prosthetics devices. It is known that this population face difficulties during daily activities (less mobility, friction wounds, falling). Nowadays stiff, passive prosthetic devices evolved to flexible motorized prostheses including advanced sensory control systems using machine learning algorithms (mainly reinforcement learning). These novel devices intend to substantially improve daily functioning and comfort, and thus the quality of life of the wearer. Indeed, literature shows that compared to passive ankle-foot prostheses, quasi-passive and active prostheses significantly enhance the quality of life (Lathouwers et al, 2023). However, it still remains to be determined whether the use of advanced technology results in long-term therapeutic benefits. One of the major hurdles in robotics technology is improving human-robot interaction. Customization of robotics technology might be achieved through human-in-the-loop optimization strategies. During this lecture, all abovementioned will be further discussed in detail.

IS-PN04 Exogenous Ketone Supplementation: Can we hack metabolism to improve health and performance?

IMPACT OF EXOGENOUS KETONE SUPPLEMENTATION ON EXERCISE PERFORMANCE: A FOCUS ON SKELETAL MUSCLE RECOVERY

STEPHENS, F.

UNIVERSITY OF EXETER

Following the landmark paper published by Cox and colleagues' in Cell Metabolism in 2016, which showed the exogenous ketones could improve endurance exercise performance, research on the performance-enhancing effects of exogenous ketones has been more muted. The majority of publications, highlighted by recent meta-analyses, tend to report no benefit (or detriment) of exogenous ketones on exercise performance. However, there does appear to be some influence of exogenous ketones on adaptation to exercise training with recent studies focusing on how regularly consuming exogenous ketones can impact the exercise training response. Professor Stephens will provide a thorough yet concise overview of the literature on exogenous ketones and exercise performance and then focus his talk on recent studies exploring how exogenous ketosis impacts recovery and adaptation to training with a specific emphasis on skeletal muscle. This will include the theoretical and experimental evidence, including his own published studies, on how the direct anti-inflammatory and anti-catabolic effects of ketones might interact to impact skeletal muscle protein synthesis and recovery from resistance exercise training and/or muscle damage. The lecture will conclude with a discussion of some novel and thought-provoking potential clinical applications of exogenous ketones in trauma and surgery. The target audience includes exercise physiologists, applied and clinical exercise practitioners, skeletal muscle biologists, and clinicians.

EXPLORING THE THERAPEUTIC POTENTIAL OF EXOGENOUS KETONE SUPPLEMENTS

LITTLE, J.
UNIVERSITY OF BRITISH COLUMBIA

Due to their dual function as an alternative metabolic fuel and a hormone-like signalling molecule, ketones have emerged as an intriguing therapeutic tool with potential to improve cardiometabolic and cognitive health. Professor Little will begin by presenting the series of studies conducted in his laboratory, starting in healthy young participants and progressing to individuals with obesity and type 2 diabetes, demonstrating that exogenous ketone supplementation can acutely lower blood glucose and improve glucose tolerance. He will also present a recent meta-analysis he led summarizing the literature on how exogenous ketone supplementation impacts blood glucose regulation. After covering the underlying physiological/metabolic mechanism(s) that may explain how ketones lower blood glucose, he will highlight how the glucose-lowering, anti-lipolytic, and anti-inflammatory effects of ketones could be harnessed using exogenous ketone supplementation as a potential therapy for type 2 diabetes. His talk will finish by exploring some of the other emerging clinical conditions where exogenous ketones are producing encouraging therapeutic findings, including age-related cognitive decline, Alzheimers disease, and heart failure. This talk will be of interest to researchers and practitioners with interests in nutrition, metabolism, diabetes, cardiovascular disease, cognitive/brain health, and immunology/inflammation.

HISTORY, CHALLENGES, AND OPPORTUNITIES IN THE FIELD OF EXOGENOUS KETONE SUPPLEMENTATION

CLARKE, K.
UNIVERSITY OF OXFORD

Professor Kieran Clarke was co-leader of an international team supported by the United States Defense Advanced Research Projects Agency (DARPA) that developed the first, and most potent, exogenous ketone supplement, the ketone monoester (R)-3-hydroxybutyl (R)-3-hydroxybutyrate. Designed as a supplement that would allow soldiers to maintain their physical and mental performance across multiple days in the battlefield, the ketone monoester was the result of over two decades of research on the basic and applied science of ketones. With her international collaborators, Professor Clarke has now published over 40 peer-reviewed research papers describing how exogenous ketones influence metabolism, exercise performance, cognitive function, resilience, and longevity. She will provide a historical perspective to the field of ketosis, teach attendees the basic biochemistry of ketosis and ketolysis, and describe the challenges and opportunities of exogenous ketone supplementation for improving physical and mental health. This talk will provide all attendees, whether new to the field or published experts, with new insights on how the history of ketone research might shape the future application of exogenous ketone supplementation for performance and health.

OP-PN10 Cardiovascular Physiology I

EFFECTS OF HEAT AND EXERCISE ON CAROTID AND RETINAL HAEMODYNAMICS

CADDY, H.T., CARTER, H.H., CRIDDLE, J.L., DOYLE, B.J., GREEN, D.J.
THE UNIVERSITY OF WESTERN AUSTRALIA

INTRODUCTION: It is unclear if the microvasculature in the brain, such as that leading to the eye, is autoregulated or whether it is responsive to the systemic impacts of heat and/or exercise. We hypothesised that common (CCA), internal (ICA) carotid and central retinal (RA) artery haemodynamics would change significantly in response to passive heating (PH), or heating during exercise (HE), and that responses to these challenges would be associated between arteries.

METHODS: Healthy participants (n=11, 26.1±3.7yrs, body mass index 22.5±2.3) underwent 50 minutes of testing in a climate-controlled chamber (40ºC, 50% relative humidity) under PH (seated upright) and HE (ergometer cycling at 45% VO2max) conditions. Using duplex ultrasound pre and post testing, time averaged blood flow (BF) was calculated in the CCA and ICA from diameter and blood flow velocity (BFv) measurements, with BFv also assessed in the RA using Doppler ultrasound. Differences in haemodynamic responses from baseline were assessed using paired t-tests, and interaction effects between variables were assessed via two-way repeated measures MANOVA and Hotelling T-square analysis. $P < 0.05$ was deemed statistically significant. Data are presented as mean±SD.

RESULTS: In response to PH alone, CCA and ICA BF did not significantly change, while RA BFv significantly decreased (3.92±0.51 vs 3.42±0.53 cm/s, P=0.034). No significant interactions between CCA, ICA and RA data to PH were observed. In response to HE, CCA BF significantly increased (584.15±137.04 vs 750.33±177.49 ml/min, P=0.007), ICA BF remained unchanged, and RA BFv significantly decreased (3.77±0.59 vs 2.89±0.47 cm/s, P<0.001). A significant interaction was present between ICA and CCA BF ($F(1,10)=8.06$, P=0.018), and between RA BFv and CCA BF ($F(1,10)=11.37$, P=0.007) in response to HE. No interaction was observed between the RA and ICA data.

CONCLUSION: Under challenging environmental conditions blood flow distribution is altered to favour systemic thermoregulation. Whilst gross brain blood flow is not compromised in absolute terms, we found evidence of diminished flows in the RA which may reflect microvascular flows in the brain.

THE MIDDLE CEREBRAL ARTERY BLOOD VELOCITY RESPONSE TO MODERATE INTENSITY CYCLING IN CHILDREN, ADOLESCENTS AND ADULTS

WESTON, M.E., BARKER, A.R., COOMBES, J.S., BAILEY, T.G., BOND, B.

UNIVERSITY OF EXETER

INTRODUCTION: Age-related differences in the cerebral blood flow response to incremental exercise have previously been observed in children, adolescents and adults, but this has yet to be investigated during constant work-rate exercise. The purpose of this study was to investigate the middle cerebral artery blood velocity (MCAv) response to constant work-rate moderate intensity cycling exercise in 21 children (aged 9.3±0.8 years, 10 males), 17 adolescents (12.3±0.4 years, 10 males) and 20 young adults (23.6±2.4 years, 10 males).

METHODS: Participants completed an incremental ramp test to exhaustion on a cycle ergometer, to determine maximal oxygen uptake and gas exchange threshold (GET), before completing three 6-minute transitions at a moderate-intensity (90% GET), on separate visits. Bilateral MCAv was measured by transcranial Doppler ultrasonography on each visit, and ensemble-averaged for each participant into 1-s data. Data were analysed using a mono-exponential model with a time delay, except for in 3 children, who did not display an exponential rise in MCAv during exercise. Differences in kinetic parameters between age groups were analysed using one-way ANOVAs.

RESULTS: Baseline MCAv was significantly higher in children (99.3±12.2 cm/s) compared to adolescents (87.2±10.0 cm/s, P<0.01), and both were significantly higher than adults (68.4±9.3 cm/s, P<0.01). The time constant of the exponential rise of MCAv was significantly slower in adults (27±9 s) compared to both children (14±9 s) and adolescents (14±8 s, P<0.01), but no differences were observed in the time delay (P=0.09). The absolute amplitude of the exponential increase in MCAv was significantly greater in adolescents (17.8±5.0 cm/s) compared to adults (13.1±4.4 cm/s, P=0.01), but not children (14.5±6.6 cm/s, P=0.08). However, when expressed as a relative change from baseline (Δ%), the increase in MCAv during moderate intensity exercise was significantly smaller in children (14.6±6.4%) compared to both adolescents (20.5±5.6%) and adults (19.7±7.6%, P<0.05). One striking feature of the MCAv response was an absence of a steady-state across all age groups following the initial exponential rise. The fall in MCAv occurred earlier in children (140±53 s) and adolescents (165 ± 77 s), compared to adults (242 ± 92 s, P<0.01), and MCAv fell by a greater magnitude in children (6.4±3.6 cm/s) and adolescents (7.3±4.4 cm/s), compared to adults (3.3±3.7 cm/s, P<0.05).

CONCLUSION: These novel findings are the first to identify smaller relative increases in MCAv during moderate intensity exercise in children, compared to adolescents and adults. Furthermore, this study is the first to find a slower adjustment of MCAv during moderate intensity exercise in adults, compared to children and adolescents. These amplitude and time-based differences in the cerebral blood velocity response to exercise may suggest differences in the mechanisms of regulation of cerebral blood flow during exercise throughout the transition from childhood to adulthood.

BLOOD OXYGEN IN THE NON-EXERCISING HUMAN FOREARM DURING DYNAMIC EXERCISE IN THE HEAT: IMPLICATIONS FOR SKIN BLOOD FLOW CONTROL

TRANGMAR, S.J.1, GONZÁLEZ-ALONSO, J.2

1 LEEDS BECKETT UNIVERSITY, LEEDS, UK; 2 BRUNEL UNIVERSITY LONDON, UXBRIDGE, UK

INTRODUCTION: Based on classical estimations (1), it is widely considered that incremental exercise through to volitional exhaustion invokes a substantial vasoconstriction in the skin vasculature, attenuating skin blood flow. This process appears to occur in parallel to the exponential rise in sympathetic nerve activity and circulating catecholamines (2–5). There is, however, no direct empirical evidence to support the assumption that skin perfusion declines at near-maximal aerobic exercise in the heat. We measured non-exercising forearm blood O2 contents, a surrogate for skin blood flow, during incremental exercise in the heat.

METHODS: Nine endurance-trained males (29±5 yrs, 184±5 cm, 79±9 kg, and VO2peak: 59±7 ml·kg-1·min-1) performed three incremental exercise tests (INC1, INC2 & INC3; 20, 40, 60, 80 & 100% of Wmax) with INC2 being preceded by 2 h of submaximal exercise and 5 min of rest (5). Exercise was performed in the semi-recumbent position in the heat (35°C, rH 50%). Regular fluid ingestion afforded maintenance of euhydration status. Regular blood samples were obtained from the median cubital vein with the arm maintained inactive throughout exercise. Blood samples were drawn into pre-heparinized syringes and rapidly analysed for haemoglobin (Hb), oxygen saturation (SO2%), oxygen tension (PO2) and other blood metabolites. Arterial (estimated from (5)) and venous O2 contents, and a-vO2 diff were calculated. Data are expressed as mean+SD.

RESULTS: During INC1, all blood variables remained unchanged from rest to 40% Wmax. Between 60-100% Wmax, however, venous Hb (peak vs. rest; ~154±11 vs. ~141±10 g/L), SvO2% (88±8 vs. 67±9%, P<0.001), PvO2 (66±19 vs. 42±15 mmHg, P<0.001) and forearm venous O2 content (183±32 vs. 135±18 mL/L, P<0.001) increased and then stabilized, whilst arterial O2 content stayed essentially unchanged (198±13 mL/L). Forearm a-vO2 diff decreased from 56±27 mL/L at baseline rest, to a nadir of ~25±27 mL/L at 80% Wmax (P<0.05), remaining stable thereafter. The pattern of response and end exercise values were similar among the three incremental tests, despite the higher baseline forearm venous O2 content values in INC2 (~181±21 mL/L). Similar responses were seen during prolonged, submaximal exercise in the heat.

CONCLUSION: We observed a marked elevation in inactive-forearm venous blood O2 content during prolonged submaximal and incremental exercise, leading to a substantial decline in inactive-forearm a-vO2 diff. These findings suggest that skin perfusion and oxygen delivery remain elevated during incremental cycling exercise to volitional exhaustion in the heat in the face of profound increases in sympathoadrenal activity.

SEX DIFFERENCES IN THE IMPACT OF EXERCISE ON VASCULAR FUNCTION: A WITHIN-SUBJECT RANDOMISED CROSS-OVER TRIAL OF TWINS

THOMAS, H.J., MARSH, C.E., LESTER, L., SCURRAH, K.J., HAYNES, A., NAYLOR, L.H., GREEN, D.J.

THE UNIVERSITY OF WESTERN AUSTRALIA

INTRODUCTION: Physical activity reduces cardiovascular risk, in part via direct effects of exercise on arterial wall function. Response to exercise can be idiosyncratic, however, and may depend upon the type of exercise performed, sex differences, or the genetic predisposition to vascular adaptation. The current study utilised a classical twin paradigm, in a randomised cross-over design of distinct exercise modalities (endurance [END] vs resistance [RES]). We hypothesised that 1) vascular function responses would be modality-specific; 2) most individuals would not respond similarly to both training modalities; 3) vascular responses to exercise would be sex dependent; and 4) vascular responses to each training mode would express a high degree of heritability.

METHODS: This study recruited 90 same-sex twins (31MZ and 14DZ pairs; 25.8±6.0yrs) to complete, as pairs, 3 months of RES and END training, separated by a 3-month washout. Vascular function was assessed with high-resolution ultrasound in the brachial artery via endothelium-dependent vasodilation (flow-mediated dilation (FMD)) and endothelium-independent vasodilation (glyceryl-trinitrate induced dilation (GTN)).

RESULTS: FMD% and GTN% increased following END (1.46%, P<0.001 and 1.76%, P=0.004, respectively) and RES (1.73%, P<0.001 and 1.68%, P=0.045). Females showed significant increases in both FMD% and GTN% in response to both modes of training (RES: FMD% 2.19%, P<0.001; GTN% 2.25%, P=0.043, END: FMD% 1.91%, P<0.001; GTN% 2.38%, P=0.003), whereas male responses yielded smaller average increases (RES: FMD% 0.97%, P=0.146; GTN% 0.73%, P=0.555, END: FMD% 0.82%, P=0.073; GTN% 0.91%, P=0.328). Around 1/3 of participants did not respond to one of the two modes and only 10% and 17% did not respond to both forms of training for FMD% and GTN%, respectively. For FMD%, a larger proportion of females than males responded positively to RES (78% and 56%, respectively) and END (78% and 70%). For GTN%, this sex difference was less apparent (RES 63% and 52%; END 72% and 65%). Twin analysis revealed that following RES training both FMD% and GTN% were highly correlated for MZ pairs (rMZ=0.58, P=0.003 and rMZ=0.61, P=0.001, respectively), and GTN% was also highly correlated in MZ pairs following END (rMZ=0.75, P<0.001), indicating that both modalities were dependent on factors shared only by MZ twins and that a large contribution from genetic effects is unlikely.

CONCLUSION: Our findings indicate that different forms of exercise training (END and RES) can enhance vascular function in young healthy subjects and that responses in females are more marked. Most individuals respond to one or other form of training, with few unresponsive to both; this finding has implications for optimising exercise-based approaches to vascular health for individualised benefit. Focusing on characteristics of exercise prescription may be more important than the impact of distinct candidate genes when considering exercise as a form of vascular medicine.

POST-EXERCISE BLOOD PRESSURE AFTER AEROBIC CONTINUOUS AND INTERVAL EXERCISE IN YOUNG HEALTHY SUBJECTS

YLINEN, V., VALTONEN, R., TULPPO, M.

UNIVERSITY OF OULU

INTRODUCTION: Post-exercise hypotension (PEH) revels appropriate vascular responsiveness to exercise. However, a large interindividual differences has been observed in PEH after acute aerobic exercise. The minimal detectable difference, counting typical and random errors in interpretation of PEH, have been published recently for systolic blood pressure (sBP), defined as PEH1 (post-exercise sBP–pre-exercise sBP). This allows the identification of responders (PEH1<-7.0 mmHg) and non-responders (PEH1≥-7.0 mmHg) after aerobic exercise. We hypothesized that aerobic training mode modifies PEH in healthy young subjects

METHODS: Twenty subjects (female n=8, 28±5 years; male n=12, 26±6 years) performed an incremental maximal exercise test by bicycle ergometer until exhaustion, starting from 40 W and increasing load at every 2 min 15 W for female and 20 W for male. Furthermore, subjects performed 3 exercise sessions, 30 min each and all in separate days, by bicycle ergometer with BP measurements at sitting position before and 1 h after exercise. First exercise was treated as a familiarization session. Thereafter, continuous and interval aerobic exercises were performed in a random order. The intensity of continuous exercise was 60% of maximal Watts. Interval training was 8x1 min high intensity exercise (80-90% of maximal Watts) with 2 min recovery between intervals (50% of maximal Watts). The average Watts over 30 min exercise was 60% of maximal Watts for both. Rating of Perceived Exertion (RPE from 0 to 20) and BP were measured at every 5 min during

continuous exercise and during high intensity and recovery phases during interval exercise. Heart rate was recorded continuously during exercises.

RESULTS: Maximal oxygen uptake was 43±6 (range 35-50) and 47±7 (range 36-60) ml/kg/min for female and male, respectively. Baseline BP was 124±12/72±6 and 123±12/72±6 mmHg (p=ns) before continuous and interval exercise, respectively. The average values for sBP were 166±22 and 172±23 mmHg (p=ns), heart rate 74±6 and 76±5 % of maximal heart rate (p=ns) and, RPE 12±1 and 13±1 (p<0.01) during continuous and interval exercises, respectively. PEH1 was -9±10 (range -30-+8) and -9±5 (range -17-+5) mmHg (p=ns), after continuous and interval exercises, respectively. PEH1 did not correlate with maximal oxygen uptake, sBP or RPE during exercise in either condition. Ten subjects after continuous (50%) and fourteen subjects (70%) after interval exercise were categorized as responders according to PEH1 analysis. Most importantly, 6 subjects (30 %) were responders regarding PEH1 only after interval exercise according to minimal detectable difference analysis.

CONCLUSION: Aerobic exercise training mode such as continuous vs. interval modifies PEH in healthy young subjects. This was obvious even performing the exercise at the same average workload, heart rate and sBP. Thirty percent of young subjects results in measurable PEH only after interval exercise favoring activation of fast skeletal muscle fibers during exercise.

OP-AP26 Football: Analytics

PHYSIOLOGICAL PROFILES AND ACTIVITY PATTERNS OF AMPUTEE SOCCER PLAYERS DURING AMPUTEE SOCCER MATCH PLAY

ESATBEYOGLU, F., HAZIR, T., KIN-ISLER, A.

BOZOK UNIVERSITY

INTRODUCTION: There is a wealth of research investigating on the match characteristics of regular soccer whereas match demands of amputee soccer game is scarce. Therefore, the objective of this study was to analyse the match demands of amputee soccer game.

METHODS: Ratings of perceived exertion, heart rate (HR) and blood lactate were analyzed as physiological responses and peak speed, total distance covered (TD), TD at five speed categories (SC), percentages of TD at five SC and time spent in four maximal heart rate (HRmax) zones were analyzed as activity patterns during amputee soccer matches (n=22). The Kolmogorov-Smirnov test was used to analyze the normality of the variables. The deviation from the normal distribution is insignificant for all variables (p>0.05) and they are presented as means and standard deviations unless otherwise stated. A paired sample t-test was conducted to determine the differences in activity patterns and physiological parameters between the halves. Cohen's d effect size (ES) (trivial=< .19; small= .20–.59; medium= .60–1.19; large=1.20–1.99 and very large=> 2.0) was used to measure the paired effects.12,13 Differences between the halves in TD at five SC and percentages of TD at five SC were determined with 2 x 5 (half x SC) two-way ANOVA with repeated measures. Differences between the halves in time spent at HRmax% was determined with 2 x 4 (half x HRmax) two-way ANOVA with repeated measures. In case of significant difference, Bonferroni's post-hoc tests were used. Data were analyzed using SPSS (v. 22.0) with the level of significance at p≤ .05.

RESULTS: The mean HR in the first half was higher than the second half (p=.049) whereas other physiological responses were not statistically different between the halves (p>0.05). TD in the first half was higher than the second half (p=.000) and players covered more distance at lower SC in both halves and during matches. TD at very low SC accounted for ~73 % whereas low, moderate, high and very high efforts accounted for ~27 % of the TD. Amputee soccer players spent ~46 min at moderate and high intensity HRmax zones whereas these accounted only about ~4 min at very low and low intensity HRmax zones during 50 min matches.

CONCLUSION: The results of the current study showed that physiological responses during amputee soccer game were not differed between the halves except HRmean response. Results of the activity profiles revealed similar Speedmax attained in the halves whereasTD, percentage of the mean TD at various SC and time spent at HRpeak% during amputee soccer game were differed according to the halves. These results confirm that exercise intensity in amputee soccer is high and amputee soccer players are under high physiological loads and they play amputee soccer at higher percentages of individual HRmax.

ENERGY INTAKE, TRAINING AND MATCH LOAD OF ADOLESCENT FEMALE SOCCER PLAYERS OF INTERNATIONAL STANDARD

MCHAFFIE, S.J.1, LANGAN-EVANS, C.1, MOREHEN, J.C.1, STRAUSS, J.1, ARETA, J.L.1, ROSIMUS, C.2, EVANS, M.2, WAGHORN, R.2, MORTON, J.P.1

LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: Elite female adult soccer players of international (1) and club level standard (2) under-consume carbohydrate in relation to nutritional guidelines. In addition, we also qualitatively explored a culture of "under-fuelling" that was

related to a fear of consuming carbohydrates in the belief that it would lead to gains in fat mass (3). In contrast to adult players, however, the habitual nutritional practices of elite adolescent players have not yet been objectively assessed. Therefore, the aim of the present study was to quantify the energy intake (EI) of elite adolescent female soccer players during a training and game schedule of international standard.

METHODS: Elite adolescent players from the English national team (n=23, age: 16.6 +/- 0.6y, body mass: 61.6 +/ 6.1 kg) took part in a 10-day international training camp comprising two match days, five training days and three rest days. All players self-reported their EI via the remote food photography method and pitch-based training and match load were measured using GPS technology. Comparisons in EI and physical loading indices between days were assessed using mixed linear models. Data are reported in proximity to the match with a minus symbol (-) indicative of the days before the match day (MD).

RESULTS: Total distance covered was greater (all $p<0.001$) on MD-4 (6121 ± 1400 m) and both MDs (6582 ± 4133 m; 6753 ± 3352 m) when compared with all other training days: MD-5 (3004 ± 280 m), MD-2 (2963 ± 604 m) and both MD-1s (2822 ± 953 m; 3491 ± 413 m). Total daily EI was greater (all $p<0.05$) on both MD-1s (2413 ± 486 kcal-1; 2004 ± 521 kcal-1) and both MDs (2314 ± 484 kcal-1; 2165 ± 479 kcal-1) when compared with both MD+1s (1776 ± 471 kcal-1; 1697 ± 394 kcal-1), MD-5 (2164 ± 440 kcal-1), MD-4 (2059 ± 425 kcal-1) and MD-2 (2057 ± 313 kcal-1). Similarly, relative CHO intake was greater (all $p<0.05$) on both MD-1s (4.1 ± 0.8 g.kg-1; 4.3 ± 1.1 g.kg-1) and both MDs (4.8 ± 1.2 g.kg-1; 4.8 ± 1.4 g.kg-1) in comparison to both MD+1s (3.6 ± 1.1 g.kg-1; 3.1 ± 0.8 g.kg-1) , MD-5 (3.7 ± 0.8 g.kg-1), MD-4 (4.1 ± 1.1 g.kg-1), MD-3 (3.6 ± 0.8g.kg-1) and MD-2 (4.0 ± 1.0 g.kg-1). Furthermore, only 15% of players consumed greater than 6g/kg of CHO on MD-1, 17% on MD and 2% on MD+1.

CONCLUSION: In summary, we report for the first time that adolescent female soccer players competing at international standard do not adjust daily CHO intake to levels (i.e. >6 g/kg body mass) that are recommended to prepare for and recover from soccer match play (4). In addition, players also under-fuel on training days, thus presenting a culture of "under-fuelling" that is comparable to adult female players. From a practical perspective, these data highlight the requirement for relevant education and behaviour change strategies that aim to promote increased CHO intake before, during and after exercise.

CHANGE OF DIRECTION DEMANDS IN GERMAN HIGH-PERFORMANCE SOCCER

DEUTSCH, J., RIEKE, M., REIN, R., HELD, S., DONATH, L.

INSTITUTE FOR EXERCISE TRAINING UND SPORT INFORMATICS

INTRODUCTION: This study aimed to compare the change of direction (COD) demands of German Bundesliga soccer match play relative to playing position using an optical-tracking-system. COD data were collected from German Bundesliga soccer teams (2017–2018 season; 17 matches). The findings of this study would give further insights into soccer match play demands and could therefore influence load management, physical training and rehabilitation process of soccer practitioners.

METHODS: An event in which a player completed a deceleration (≤-2 m·s-2), an angular change in the direction of motion (≥20°), and a subsequent acceleration (≥2 m·s-2) within a duration of 1 second was defined as a COD. These thresholds have typically been used to classify accelerations and decelerations above a moderate intensity level during a team sports match (Delves et al., 2021; Newans et al., 2019). Directional changes were subdivided by entry velocity (<3.0 m·s-1 (COD3), 3.0-5.5 m·s-1 (COD3_5.5), 5.5-7.0 m·s-1 (COD5.5_7) and >7.0 m·s-1 (COD7)) and rotation angle (Low: 20-59° (COD60); Medium: 60-119° (COD120); and High: 120-180° (COD180)). The frequency of total COD, the subcategories of entry velocity and rotation angle for each playing position (Goalkeeper (GK), Centre Back (CB), Full Back (FB), Central Midfield (CM), Winger (WI) and Striker (ST)) and the average, standard deviation, maximum and minimum values were calculated.

RESULTS: ANOVA revealed significant group effects for COD60 ($p<0.001$; $\eta2 = 0.08$), COD120 ($p<0.001$; $\eta2 = 0.63$), COD180, ($p<0.001$; $\eta2 = 0.05$) between positions. Post hoc tests revealed significant differences between positions for all angles. Further, ANOVA revealed significant group effects for COD3 ($p<0.001$; $\eta2 = 0.07$), COD3_5.5 ($p<0.001$; $\eta2 = 0.20$), COD5.5_7 ($p<0.001$; $\eta2 = 0.14$) and COD7 ($p=0.034$; $\eta2 = 0.02$). Post hoc test revealed significant differences for all entry velocities, except COD7. Approximately, 90% of COD during matches were performed with entry speeds <5.5 m·s-1 and about 70% were low (~40%) and moderate (~30%) angled turns.

CONCLUSION: This study provides insights into the COD demands of German Bundesliga soccer matches, which can be used to guide position-specific physical preparation strategies, to monitor player load, to develop performance tests and to give recommendations for rehab and return to play standards.

CLUB ATHLETICO PARANAENSE

INTRODUCTION: The difficulties of the Brazilian professional soccer schedule are known worldwide. The teams often compete during the year for state, nationals and internationals championships, being able to lead 75 games a year. Thus, the objective of the present study was to follow the 2022 season of an elite Brazilian soccer professional team and observe whether the different levels of competition - state, national and international - also present different levels of physical demands: for the whole team such as for the player positions.

METHODS: The study included 37 athletes (24.3±3.9 years; 180.2±4.9cm; 76.0±6.9kg; 15.8±2.3%BF) from the main team, divided into fullbacks (n=6; 22,3±2,7years; 179,0±3,9cm; 72,8±5,2kg; 15,1±2.1%BF), defenders (n=7; 24,4±4,3years; 185,6±1,8cm; 85,9±9,9kg; 17,6±1,7%BF), midfielders (n=13; 25,5±4,9years; 177,6±4,3cm; 74,0±5,3kg; 15,9±2,3%BF) and forwards (n=11; 23,5±4,9years; 180,5±4,3cm; 75,4±5,3kg; 15,3±2,3%BF). The athletes played 5 state games, 44 national games and 15 international games during the season. Players were monitored in all games by a global positioning device at 10 Hz and with inertial motion sensors at 100 Hz (S7 Catapult System). The total distance (TD), the distance covered in high intensity (HSR), the distance covered in sprint (SD), the density (DEN) of the team and of the positions in the field at different competitions were evaluated. After collecting the information, the normality of the data was verified and they proved to be non-parametric, thus, the Kruskal-Wallis test was performed and later the Dunns multiple comparison test was used ($p<0.05$).

RESULTS: The most relevant results founded in the present study were detected in DEN and SD. In the DEN we found a statistical difference between the state championship (105.0±11.6 m/min) and the international championships (100.3±10.8 m/min), as well, we founded a difference in this variable for the midfielders between the state (113.2±7.7 m/min) and international (107.2±8.5 m/min) championships. Regarding the SD, a difference was found for forwards between the state (195.5±77.4 m) and national (242.5±130.1 m) championships.

CONCLUSION: From the data found, we can infer that international championship games have a higher number of fouls and interruptions in the game and this causes a decrease in the DEN of the game, especially when we observe this same variable in the state championship, in which the team is technically superior and can have a higher ball possession, making the distance covered per minute greater. When we observe the SD variable, we find significantly higher values in national championships. Sometimes the team plays more compactly in these competitions, favoring the counterattack and having space to develop this variable when compared to the state championship.

OP-BM10 Strength training

ESTIMATION OF NEUROMODULATORY AND INHIBITORY INPUTS TO MOTONEURONS IN CHRONICALLY STRENGTH TRAINED INDIVIDUALS

ŠKARABOT, J., BEAUCHAMP, J.A., PEARCEY, G.E.P.
LOUGHBOROUGH UNIVERSITY

INTRODUCTION: Strength training (ST) is accompanied by neural adaptations that augment muscle force production (1). All motor commands are transformed into muscle fibre twitches via motor units (MUs) as a result of excitatory and inhibitory ionotropic inputs, which are modified by neuromodulatory inputs. The way in which these commands are altered as a result of ST is not well-studied, but chronically ST individuals exhibit lower antagonist muscle coactivation at various force levels (2), which suggests that chronic ST might lead to adaptations in the motor commands that transform neural inputs to superior mechanical outputs. Here, we compared estimates of neuromodulatory inputs and patterns of inhibitory inputs to motoneurons from MU discharge patterns in chronically ST and untrained (UT) individuals.

METHODS: Chronically ST (8±3 years of ST experience) and UT individuals (n=15 in each group, 4 females per group) performed isometric dorsiflexion forces of a triangular shape up to 30, 50, and 70% of maximal voluntary force (MVF) whilst high-density surface EMG signals were recorded from tibialis anterior. EMG signals were decomposed into individual MU discharges (3) that were subsequently smoothed using support vector regression (4). Delta F (onset-offset hysteresis of pairs of discharging MUs) was calculated to estimate the persistent inward current magnitudes. A quasi-geometric approach (5) was used to garner further insights into the neuromodulatory inputs (brace height) and the inhibition pattern (MU discharge acceleration, and post-acceleration [attenuation] slopes). Linear mixed models were used to assess whether outcome variables were predicted by group, contraction level, and their interaction.

RESULTS: ST were 50% stronger than UT (413±117 vs. 275±88 N, $p=0.0011$), and exhibited greater peak MU discharge rates during 70% (34±1 vs. 29±1 Hz, $p = 0.0157$), but not 30% and 50% MVF ($p\geq0.0869$). Delta F and MU acceleration slope increased with contraction level ($p<0.0001$) but were similar between groups ($p=0.8370$). Brace height was modulated differently between groups across contraction intensities ($p<0.0001$), with it being lower for ST compared to UT at 50%

(p=0.0235) and 70% MVF (p=0.0090). The post-acceleration slope of the MU discharge attenuation phase was greater in ST compared to UT (p=0.0104).

CONCLUSION: Our results suggest that the neural networks responsible for generating the motor commands that govern MU discharge patterns are modulated with chronic ST. In particular, chronically ST individuals exhibit modifications in the pattern of inhibition, one that is more reciprocal in nature, which is likely associated with greater MU discharge rates and superior muscle force production.

THE USE OF BLOOD FLOW RESTRICTION DOES NOT ENHANCE ADAPTATIONS OF CORTICOSPINAL EXCITABILITY OR INTRACORTICAL INHIBITION AFTER ACUTE RESISTANCE TRAINING

KELLER, M., VOROBIOVA, A., FAUDE, O.

UNIVERSITY OF BASEL

INTRODUCTION: Resistance exercise with blood flow restriction (BFR) is considered a safe and powerful training tool. Low-load (LL) resistance training with BFR results in comparable hypertrophy compared to conventional heavy-load (HL) resistance training (Centner et al. 2019). Additionally, LL training with BFR (LL-BFR) induces comparable (Grønfeldt et al. 2020) or slightly lower (Centner et al. 2019) effects on muscle strength than HL training. It is generally accepted that increases in maximum strength are mediated by muscular hypertrophy and/or neural adaptations. However, the effect of BFR on neural adaptations is scarcely investigated. The aim of this study was therefore to investigate the effects of BFR on acute neural adaptations following a single bout of resistance training.

METHODS: Fifteen male participants (21-35 years) volunteered to participate in this study. On three separate days, participants performed a strength training session of the right elbow flexors with either LL, LL-BFR or HL. Neuromuscular adaptations were investigated before and after each resistance training session by means of transcranial magnetic stimulation (single- and paired-pulse TMS) and peripheral nerve stimulation (Mmax). Data were acquired during submaximal sustained isometric contractions. During LL-BFR, the cuff was inflated to 50% of the individual arterial occlusion pressure to restrict venous outflow in the working musculature during exercise.

RESULTS: The preliminary data analysis with mixed linear models revealed that, compared to baseline values, normalized MEPs (% of Mmax) from the trained biceps brachii were enhanced for HL (Cohen's d = 0.51) but not LL-BFR (Cohen's d = 0.03) when compared to LL. Changes in short-interval intracortical inhibition (SICI) and intracortical facilitation (ICF) were very inconsistent and did not differ between training session.

CONCLUSION: This is the first study that investigated neural adaptations after a single bout of resistance training with and without BFR. We observed augmented MEP amplitudes after HL when compared to LL what is in line with previous evidence (Colomer-Poveda et al. 2020). Adding BFR to LL training did not alter corticospinal responses. The data therefore indicate that training with BFR less likely affects cortical neural adaptations.

COMPARISON OF MOTOR UNIT FIRING RATE DURING HIGH-LOAD VS. LOW–LOAD BLOOD-FLOW RESTRICTION RESISTANCE TRAINING

MACGREGOR, L.J.

UNIVERSITY OF STIRLING

INTRODUCTION: Chronic low-load resistance training with the addition of blood-flow restriction (BFR) leads to greater adaptation compared to comparable load exercise without BFR. Indeed low-load BFR resistance training leads to increases in muscle mass, and possibly in strength, that are similar to those observed with high-load resistance training [1, 2]. The aim of this research was to assess early adaptations in strength, muscle mass, and muscle contractile properties to resistance training using low loads with BFR compared to high loads, and to explore potential neural mechanisms underlying these adaptations by examining motor unit firing rate during each training condition.

METHODS: Seven healthy-active, but previously non-resistance trained individuals completed seven training sessions involving unilateral leg press and leg extension. One leg was trained using low-load (40% of 1-RM) with BFR, the other was trained using high-load (80% of 1-RM). Pre- and post-training: 1-RM leg press and leg extension, and MVC knee extension were measured to assess strength; and thigh circumference and volume were measured to estimate quadriceps mass. Tensiomyography was used to measure muscle stiffness and contraction velocity of vastus lateralis pre-, mid-, and post-

training. Electromyogram (EMG) was captured from vastus lateralis throughout all training sessions using a 4-channel surface array. EMG was decomposed into individual motor unit action potential trains [3].

RESULTS: Mean motor unit firing rate was greater during high-load training than during low-load BFR training (P = 0.016). Leg extension 1-RM (P = 0.001), knee extension MVC (P = 0.019), and thigh circumference (P = 0.001) and volume (P = 0.001) increased following both resistance training conditions. Leg press 1-RM (P = 0.103), and vastus lateralis stiffness (P = 0.483) and contraction velocity (P = 0.585) did not change with training.

CONCLUSION: Despite greater motor unit firing rates during high-load training, seven resistance training sessions increased strength and markers of muscle mass to a similar extent in both training conditions. Greater relative demand of leg extension exercise may explain the improved 1-RM and knee extension MVC observed, while leg press 1-RM remained unchanged. Precise mechanisms underlying the early adaptations to resistance exercise with BFR remain to be elucidated.

COMPARISON OF PERSISTENT INWARD CURRENTS IN LOWER LIMB MUSCLES OF RESISTANCE TRAINED, ENDURANCE TRAINED, AND INACTIVE YOUNG INDIVIDUALS

GOREAU, V., HUG, F., JANNOU, A., DERNONCOURT, F., CROUZIER, M., CATTAGNI, T.

NANTES UNIVERSITY

INTRODUCTION: Physical training is known to induce neural adaptations in the motor pathways, resulting in changes to the output of α-motoneurons. Persistent inward currents (PICs) have a substantial influence on α-motoneuron output and have been found to increase with resistance training in older adults. However, the adaptations of PICs related to physical training in young adults remain unknown. Additionally, since monoaminergic drive is believed to be diffuse within α-motoneurons of an individual, it is possible that physical training promotes PICs in all muscles. The aim of this study is to compare the PICs of individuals with different physical training experiences by assessing several muscles in the lower limb.

METHODS: Twelve resistance-trained (RES), twelve endurance-trained (END), and thirteen inactive (INA) individuals participated in one experimental session. Surface electromyographic signals were collected using 64-channel electrodes placed over the soleus (SOL), gastrocnemius medialis (GM), tibialis anterior (TA), vastus medialis (VM), and vastus lateralis (VL). Motor unit discharge rates of each muscle was extracted from these signals. Paired-motor unit analysis was used to calculate delta frequency (ΔF) as an estimate of PICs amplitudes during triangular-shaped contractions to 20% of maximum torque capacity. A linear mixed-effect model was used to compare ΔF values, with physical training and muscles as fixed factors and random intercepts and slopes for participants. Pearson correlations were performed between each pair of muscles.

RESULTS: Regardless of the muscle, there was no significant difference in ΔF between the physical training groups (RES: 3.5 pulses per second (pps), END: 3.7 pps, INA: 3.4 pps, $p = 0.35$). There was no significant interaction between the physical training group and muscle ($p = 0.45$). ΔF differed significantly between muscles (SOL: 3.1 pps, GM: 3.4 pps, TA: 4.8 pps, VM: 2.2 pps, VL: 2.0, $p < 0.001$). There were only significant correlations between VL and VM ($r = 0.60$, $p < 0.001$), SOL and GM ($r = 0.35$, $p = 0.041$), and TA and GM ($r = 0.49$, $p = 0.03$).

CONCLUSION: Contrary to our hypothesis, the results suggest that there is no difference in PICs between physical training groups, despite substantial differences in physical training experiences. As the ΔF values obtained in this study are derived from lower threshold motor units recruited at a low force level, it cannot be ruled out that PICs adaptation occurs but is constrained to higher threshold motor units. The correlations observed in ΔF between certain pairs of muscles are noteworthy, as they suggest the existence of individual profiles in the amplitude of PICs.

OP-BM27 Swimming

TORSO MOVEMENT AT SPRINT FRONT CRAWL AND BACKSTROKE SWIMMING SHARE SIMILAR PATTERNS BUT ALSO HAVE DISTINCT DIFFERENCES.

NIKODELIS, T., GOURGOULIS, V., LOLA, A., NTAMPAKIS, I., KOLLIAS, I.

ARISTOTLE UNIVERSITY

INTRODUCTION: Front crawl and backstroke, due to the alternating movements of the limbs facilitate a distinct roll of the torso along the longitudinal axis of the body. The torso also rotates around its sagittal axis (yaw rotation). These rotations are usually analyzed by breaking the torso in two segments (upper and lower trunk). Due to the fact that these two swimming techniques share similar characteristics (e.g. almost horizontal body position, extending – bending – extending the elbow, flutter kick, etc.), in practice of teaching coaches and swimmers often intuitively transfer tips and parts of teaching from one style to the other. Yet, this may have a scientific base only if the parts of technique that facilitate a positive transfer of learning are identified and discriminated. This study investigated coordination of the pelvis and the upper trunk area, 7th cervical vertebrae (C7), regarding the participants' yaw and roll rotation, at sprint front crawl and backstroke.

METHODS: Thirty-four swimmers performed a 25m sprint at each stroke. Segmental rotations of pelvis and upper trunk (C7) were assessed, using gyroscopes (Kapa-Swim sensor, K-Invent, © 2014). From the whole trial the following parameters were calculated: angular amplitudes of each segment, their mean autocorrelation values, the max cross correlation coefficient between the two segments, its phase lag and percent of total power at the main frequency. Normal distribution was verified using the Shapiro–Wilk test. Repeated measures ANOVAs were applied with three within subjects' factors (style: backstroke vs. front crawl, segment: pelvis vs. C7, direction: yaw vs. roll) for angle amplitude, auto-correlation and relative power, for cross-correlation the segment factor was omitted.

RESULTS: Pelvis yaw and roll as well as C7 roll amplitudes were greater in backstroke, while C7 yaw was greater in front crawl. In backstroke, C7 had greater values than pelvis in both directions, while in front crawl C7 had greater values than pelvis only in yaw. Mean peak values of the autocorrelogram were high except the one of pelvis at front crawl in yaw. Cross correlation between pelvis and C7 rotations yielded higher values in roll compared to yaw. Front crawl had higher values than backstroke only in yaw. The power spectral density analysis showed that relative power amplitude of angular displacement at the main frequency was larger in backstroke compared to front crawl.

CONCLUSION: Both strokes share similar characteristics in roll but the coupling of the two segments in yaw is different between them. These findings imply that proper focus should be given from instructors to enhance only a positive transfer of learning between the two strokes. More comparative research is needed for yaw rotation in conjunction with stroke kinematics and propulsive forces to understand the role of the torso in these bilateral swimming techniques and embody the findings in the teaching process.

STROKE REGULATION TIMING ACCORDING TO FINAL PERFORMANCE DURING INTERNATIONAL OPEN-WATER RACES : A RACE ANALYSIS USING EMBEDDED SENSORS

BOUVET, A.1,2,3, PLA, R.4,5, DELHAYE, E.1,2, NICOLAS, G.1,2, BIDEAU, N.1,2

1 M2S LABORATORY, UNIVERSITY RENNES 2, ENS RENNES, FRANCE ; 2 MIMETIC, INRIA RENNES, FRANCE ; 3 CREST, ENSAI, BRUZ, FRANCE ; 4 FRENCH SWIMMING FEDERATION, FRANCE ; 5 INSERM, PARIS, PARIS

INTRODUCTION: Race analysis of open-water swimming is of crucial interest to provide valuable feedbacks on performance that drive construction of further training plans or race strategies. Thus, some studies look at pacing during these events but were restricted to split time and rank [1, 2, 3, 4] or intermediate stroke rate (SR) [5]. Then, there is a need for continuous monitoring of biomechanical aspects during open-water swimming associated with performance, especially because timing of kinematical regulation along the race remain unclear. The aim of this study was to analyze cycle-to-cycle SR and jerk cost (JC) profiles and identify the dependency of biomechanical regulations timing on final performance during international open water races.

METHODS: 12 elite swimmers were analyzed during 18 races of two legs of LEN European open water cup including both a 10km, and a 5km race for one leg, with an Inertial Measurement Unit (Xsens DOT, The Netherlands) on the sacrum. Data were divided into 4 segments of 25% (S1 to S4) and swimmers were pooled on 3 balanced group according to final rank (G1 to G3). Cycle-to-cycle SR and JC were computed [6] and fitted using 3rd order polynomials to defined kinematical profiles. A two-way mixed ANOVA was used to compare SR and JC values using segments as within and group as between-subjects factor and Bonferroni post-hoc procedures for significant effects. Significance was set at $p<0.05$.

RESULTS: Kinematical profiles displayed specific regulations as J-shape, U-shape and reverse L-shape for G1, G2 and G3 with significant effect of segment on SR and JC for G1 ($p<0.001$, $\eta^2=0.24$ and $p<0.05$, $\eta^2=0.15$) and G2 ($p<0.001$, $\eta^2=0.46$ and $p<0.01$, $\eta^2=0.02$). We highlighted two tipping-points (TP1 and TP2) at respectively 30% and 75% of the race related to final performance because they were greater in G1: ΔG1: -0.04 ; ΔG2: +0.10 g²/s²x10^3 for TP1 and ΔG1: +2.25 ; ΔG2: +0.87 cycles/min and ΔG1: +1.06 ; ΔG2: +0.13 g²/s²x10^3 for TP2.

CONCLUSION: This work provided the first cycle-to-cycle monitoring of stroke parameters coming from in-situ data collection during full international open water events. We showed the importance of SR and JC control to support effective pac-

ing leading to open water performance through two tipping-points. Such points led to a typical J-shape profile of best performers driven by milestones in stroke regulation. Then, TP1 reflected the end of a stroke economy period (0-30%) and TP2 the end of a progressive increase in kinematics (30-75%) towards end-spurt (75-100%). Results indicated that open water races followed high-grading dynamics requiring specific timing of biomechanical regulation. Best swimmers displayed a stroke rate reserve and a specific management of stroke smoothness to follow the both tipping-points respectively related to preserving energy and launching decisive end-spurt.

RESISTED SWIMMING: COMPARISON BETWEEN THRUST FORCE EXERTED BY THE HAND AND APPLIED TO THE TETHERED DEVICE

CORTESI, M.1, COLORETTI, V.1, RUSSO, G.1, FANTOZZI, S.2

UNIVERSITY OF BOLOGNA

INTRODUCTION: The thrust force (FT) is only a fraction of the overall force exerted by the swimmer to move his body (1). The capability to maximize FT is a key factor to improve swimming performance. In the last decades, the hand pressure measurement technique has been implemented to support the understanding of FT mechanism (2). However, because the direct assessment during free swimming remains difficult to quantify, the FT measurement during tethered swimming was proposed as an alternative tool. To our knowledge, the relationship between FT exerted by the hand and FT applied to the tethered device has never been tested, and an agreement between these techniques is needed (3). Thus, the aim of this study was to compare FT assessed during fully-resisted swimming by two approaches: the differential pressure and the dynamometrical one.

METHODS: Ten young swimmers (7 F, 15.3 ± 0.5 years, 75.5 ± 7.1 % of WR) performed one full tethered test only-arms wearing a wireless pressure sensor (SEAL, Platysens) on the palmar and dorsal side of each hand. FT applied to the load cell (FTtet; Globus Ergometer, Globus) was assessed during the tethered trial as the average value of 10-s maximal effort in front-crawl. Based on pressure sensors data, the resultant force exerted by each hand to move the water (Fhand) was calculated as the product of differential hand pressure (palmar minus dorsal, PRdiff) and the hand surface (A). Assuming that the hand kinematics was circle-shaped, the instantaneous FT exerted by the hand to propel the body (FThand) was the horizontal component of the force at the hand and was estimated as Fhand • sin(α), where α was the angle in the underwater phase between the trunk and the upper arm considered as a single rigid segment.

RESULTS: PRdiff was 4.099 ± 0.381 Kpa, A was 0.0155 ± 0.0005 m2, and stroke frequency was 1.12 ± 0.09 Hz. Positive associations were observed between FTtet and FThand ($r = 0.641$, $p = 0.023$), FTtet and Fhand ($r = 0.613$, $p = 0.030$) and FThand and Fhand ($r = 0.977$, $p < 0.001$). FThand (43.4 ± 4.4 N) and Fhand (63.5 ± 6.2 N) were significantly lower than FTtet (74.2 ± 9.6 N; $p < 0.001$, Holm's post-hoc test).

CONCLUSION: The swimmer's thrust force assessed by the differential pressure approach during fully-resisted swimming is lower than the force collected by the dynamometrical approach (- 41%). This finding is supported by a previous review comparing different studies using these approaches singularly (3). Because the differential pressure approach can only measure the thrust force exerted by the last segment of the upper limb, and because the hand contribution to the propulsion decreased when the stroke frequency was ≥ 1.1 Hz (4), this difference could be partly imputable to the contribution of the forearm that was not considered.

WEARABLE PRESSURE SENSORS FOR SWIMMING THRUST ANALYSIS: A VALIDATION STUDY

COLORETTI, V., RUSSO, G., FANTOZZI, S., CORTESI, M.

ALMA MATER STUDIORUM, UNIVERSITÀ DI BOLOGNA

INTRODUCTION: The swimmer can increase his velocity by decreasing hydrodynamic resistance and/or increasing thrust force (1). To assess thrust force, indirect techniques (video-based analysis or computational fluid dynamic) are more time-consuming than direct ones (tethered swimming with load cell or pressure sensors system). According to Takagi et al. (2), the pressor sensor systems calculate the forces exerted through the hands surface (A) as F = A • Pdiff where Pdiff is the hydrodynamic pressure (PD) difference between the palmar and dorsal side excluding the hydrostatic pressure influence (PS). Due to the greater ecological features of modern wearables technologies, this study aims to validate the first wireless pressure sensor system in terms of PS and PD accuracies compared with theoric static pressure (tPS) and theoric dynamic pressure (tPD).

METHODS: The validation was conducted as: i) PS vs. tPS (calculated as $P = Patm + \rho \bullet g \bullet h$) through the static immersion of the wearable pressure sensor (SEAL, Platysense) down to a depth of 34 cm with a constant step of 1cm; ii) PD vs. tPD (calculated as $P = 0.5 \bullet \rho \bullet v2$) by towing 4 SEALs using an electromechanical towing system at constant velocities of 0.5,

1.0, 1.6, 1.9 ms-1 and constant depth of 10 cm. Bidimensional video analysis was used to confirm the correct depth. Within-trials (3 trials), between-sensor (10 sensors), and day-by-day reliability (2 days for 6 sensors) were analyzed in terms of ICC, CV%, TE, SEM, and MDC. Bias, standard error of estimate (SEE) and T-test/ANOVA were calculated to test the accuracy for PS and PD considering the theoric gold standard. The sensitivity of the pressure sensor was 0.1 KPa.

RESULTS: PS showed excellent agreement for within-sensor, between-sensor, and day-by-day reliability regarding ICC (0.99, 0.99, >0.96), CV% (0.1, 0.1, 0.2), TE (0.1, 0.1, 0.1 KPa), SEM (0.1, 0.1, 0.1 KPa), and MDC (0.1, 0.1, 0.4 KPa). No differences ($p < 0.05$) were found between PS and tPS and between PD and tPD. Small bias and small SEE were found for PS vs. tPS (0.2 KPa and 0.1 KPa, respectively), which increase with depth according to the equation PS = 0.968 • tPS + 3.182. Furthermore, PD vs. tPD comparisons revealed a small bias at each different velocity (0.3, 0.1, 0.3, 0.4 KPa).

CONCLUSION: The present results suggest that hydrostatic and hydrodynamic pressures acquired by wearable wireless devices demonstrate a small amount of error compared to theoric pressures, despite its increases as a function of depth (always lower than 0.4 %). The proposed instrument seems suitable for future studies in swimming propulsion analysis due to its ecologic features and lower impact on swimming technique.

PERFORMANCE DESCRIPTORS IN ARTISTIC SWIMMING TECHNIQUE: THE RELATIONSHIP BETWEEN PROPULSION, SYMMETRY, STABILITY, AND HEIGHT IN DIFFERENT STATIC FIGURES

FANTOZZI, S.1, COLORETTI, V.2, CHIMIERI, S.2, RUSSO, G.2, CORTESI, M.2

UNIVERSITY OF BOLOGNA

INTRODUCTION: Biomechanical parameters allow the quantitative description of the performance in artistic swimming technique. Few studies investigated the kinematics and the dynamics of different sculling using underwater cameras, load cell, and/or wired sensor pressure (1,2). Thanks to the advances in wearable technology, it is now possible to evaluate propulsion and stability ecologically during daily training sessions. The present study aimed to investigate the relationship between force exerted by the hands during sculling motion, the symmetry of this force between the hands, the stability of the leg and pelvis, and the body level height with respect to water surface during the flamingo (FLA), gru (GRU), and vertical (VER) static figures.

METHODS: Sixteen female synchronized swimmers (19.1±3.0years, 163.7±4.3cm height, 56.3±6.0kg mass) were analyzed. FLA, GRU and VER figures were randomly executed 3 times during a single trial (each figure held for 5s, followed by 10s paused). Using the differential approach (3), the force exerted by the hands was estimated by means of 2 wireless pressure sensors (SEAL, Platysens). Mean value (Fmean) and symmetry index (Fsym) were estimated for the 5/trial central sculling. The stability of the pelvis (STABpel) and of the vertical leg (STABleg) were estimated considering all 3 axes using 2 inertial sensors (Wavetrack, Cometa) (4). The height (HGT) corresponded to the level of the water surface with respect to 3 thigh zones (proximal, central and distal part) using a camera.

RESULTS: Variables between figures showed strong associations: Fmean, Fsym, STABleg, STABpel and HGT obtained during GRU were significantly correlated ($p < 0.05$) with the corresponding variables during FLA ($r = 0.748$, $r = 0.955$, $r = 0.630$, $r = 0.968$, $r = 0.615$) and VER ($r = 0.916$, $r = 0.666$, $r = 0.650$, $r = 0.747$, $r = 0.632$). Significant correlations ($p < 0.05$) for Fmean, Fsym, STABleg, STABpel and HGT between FLA and VER were also found ($r = 0.721$, $r = 0.571$, $r = 0.724$, $r = 0.804$, $r = 0.783$). No correlation was observed between any variables within the figures.

CONCLUSION: The results supported the technical coherence in terms of propulsion, stability, symmetry and height among the artistic swimming figures of flamingo, gru, and vertical. However, these descriptors were not correlated within the single figure, probably due to the low variability of the quantities among the athletes.

OP-AP28 Talent Identification

NON-INVASIVE ESTIMATION OF HUMAN MUSCLE FIBER TYPE COMPOSITION; A MULTIDIMENSIONAL APPROACH

VAN DE CASTEELE, F., LIEVENS, E., VAN DER MEULEN, L., SABLAIN, M., VAN VOSSEL, K., HARDEEL, J., VERCAMMEN, B., VAN THIENEN, R., DERAVE, W.

GHENT UNIVERSITY

INTRODUCTION: Muscle fiber type composition (MFTC) is a sport performance determinant with potential for talent orientation and training individualization. However, its use in sports practice remains limited, because the current gold standard to measure MFTC requires a muscle biopsy. There is no consensus regarding the optimal non-invasive method to estimate MFTC, since most studies are limited to relating one test to a single biopsy-based MFTC in a small male-only sample. Therefore, our aim was to determine the best (combination of) non-invasive method(s) by addressing these limitations.

METHODS: Forty young, recreationally active participants (20 men, 20 women) were subjected to two muscle biopsies in vastus lateralis, two in gastrocnemius medialis and multiple non-invasive tests. Test selection was based on 1) how well measurements were related to MFTC in literature (overview of 80 studies), 2) how often they were used in the field (survey on 446 coaches) and 3) capturing different MFTC dimensions: metabolism, power, fatigue and contractility. Subjects performed 30 m sprints, squat jumps, a Wingate test, isokinetic and isometric knee extensions, electrostimulation of the n. femoralis, a maximal incremental cycling exercise test and a proton magnetic resonance spectroscopy scan to measure muscle carnosine. Muscle cross-sections were stained for myosin heavy chain type I, IIa and IIx and analyzed in ImageJ. Average relative type I area of four biopsies across two muscles was our MFTC criterion variable. Pearson correlations (all subjects) examined the relationship between tests and MFTC and the largest significant correlation for each test is shown. The predictive value of test combinations was assessed by multiple linear regression.

RESULTS: The multi-biopsy typology, as relative type I area, ranged from 39.1 to 79.6 % and was based on the analysis of 3590 ± 1059 fibers per individual. For metabolic parameters, blood lactate 3 min after the Wingate ($r=-0.67;p<0.001$) and average carnosine concentration in the vastus lateralis and gastrocnemius ($r=-0.48;p=0.002$) showed criterion validity. For power, we found best correlations for maximal torque during 300°/s knee extensions ($r=-0.47;p=0.002$), 15m sprint time ($r=0.42;p=0.007$) and squat jump height ($r=-0.36;p=0.022$). The fatigue index during a Wingate also showed significant correlation ($r=-0.48;p=0.002$). For contractility, rate of torque relaxation after electrical stimulation of the knee extensors was correlated with MFTC ($r=0.39;p=0.013$). When combining methods, MFTC could be estimated for 45% (adj. R^2; $p<0.001$) in all subjects and for respectively 52% and 66% (adj. $R^2;p<0.001$) in men and women separately.

CONCLUSION: Several non-invasive estimators, covering different MFTC dimensions, were each related to MFTC, but a multivariate approach led to superior estimations at the individual level. Therefore, to bring more accurate MFTC assessments to sports science research and practice, we should move to a multidimensional combination of tests.

ORIENTING ADOLESCENTS AND INCREASING TALENT POOLS IN TRACK AND FIELD, VOLLEYBALL AND CYCLING.

PION, J.1,2, TEUNISSEN, J.W.1,2

1 HAN UNIVERSITY OF APPLIED SCIENCES AND 2 GHENT UNIVERSITY

INTRODUCTION: Keeping children active during adolescence is proving to be a challenge. This has implications for sports participation and the pathway to elite sport. A better connection between schools and sports clubs can prevent sports dropouts and increase talent pools. For this purpose, a new project was set-up in which schools, sports clubs and municipalities work together to support talent detection/orientation among adolescents in three sports: athletics, volleyball and cycling. However, previous studies show that talent detection can be distorted by (temporary) differences in maturity status. The research question is whether those with the greatest potential are more likely to be detected.

METHODS: In total 420 adolescents (13.62y ± .45y) were assessed by means of the "(SportKompas I Like" survey that mapped which activity they liked and an adapted "SportKompas I Do" test battery that charted participants performance profiles. The maturity status was measured with the Khamis-Roche method. Assessing the results was done in three ways: First, seven sports were presented to each participant based on personal exercise preferences. Second, a generic test battery was assessed in both age and maturity groups and ranked into a list of better movers. Third, the organisers wanted to improve inflow in 3 sports where the infrastructure in the area offers opportunities, namely athletics (running), volleyball and cycling (track).

RESULTS: Out of 196 girls, 81 were late mature, 71 on-time and 44 early mature. Among the 214 boys, 29 were late mature, 108 on-time and 77 early mature. Both discriminant analyses with 2 grouping variables i.e., early and late mature girls/boys were significant (girls: rcan = .827 and Wilks' Λ = .316 and $P < .001$; boys: rcan = .883 and Wilks' Λ = .220 and $P < .001$). The cross validated analysis classified 89.6% of the girls and 97.2% of the boys correctly. Early mature girls ($F=103,142$ and $P<.001$) and boys ($F=205,152$ and $P<.001$) were significantly taller than their late mature peers. Early mature girls also outperformed late mature peers for standing broad jump ($F=5,297$ and $P<.023$), sprint 30m ($F=4,118$ and $P<.045$), knee push-ups ($F=5,635$ and $P<.019$), curl-ups ($F=4,807$ and $P<.030$), endurance shuttle run ($F=12,117$ and $P=.001$)

and KTK balance beams (F=5,758 and P<.018), while early mature boys scored better for shuttle run (F=6,342 and P=.013), KTK balance beams (F=7,460 and P=.007) and KTK jumping sideways (F=5,026 and P=.027).

CONCLUSION: Sport professionals from schools and municipalities try to give a quality impetus to the talent pool in clubs. All adolescents received sports promotion recommendations. However, detecting potential at the age of 13 is biased by maturity status. Using only the ranking of performance on tests to estimate potential is not sufficient because false positives are detected while false negatives are forgotten. When evaluating the data for selection towards the sports in the region, it is important to consider differences in maturity status.

PHYSICAL FITNESS AND MOTOR COMPETENCE TESTS AS PREDICTORS OF TALENT IN SOCCER? THE CORRELATION OF JUVENILE TEST RESULTS AND LATER SUCCESS VIEWED STEPWISE OVER 12 YEARS – A LONGITUDINAL STUDY

SIENER, M., HOHMANN, A.

GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: There are already several studies on talent identification in youth soccer. However, only a minority of these studies have a longitudinal design or observe the complete performance trajectory of young athletes all the way to adulthood. The few studies that investigated associations between youth performance and later success in senior competitive sports showed that the validity of talent predictions steadily decreased with increasing time periods. However, the data available to date is very limited. Therefore, the aim of this study was to analyze the correlations of early test performance (physical fitness and motor competence tests) of young soccer players with their later successes stepwise over 12 years until adulthood.

METHODS: Over the past 12 years, about 100 male soccer players aged 8 years (U9) were tested annually (N = 1,266) in various physical fitness and motor competence tests. The test tasks included a 20m sprint, push-ups, sit-ups, standing long jump, standing bend forward, balancing backward, 6min endurance run, change of direction agility, hand grip, sideward jumping, soccer dribbling, agility run, and ball throw. For each participant, a 20-point performance scale was used to determine and assess the playing and competition success achieved in the following years in the respective age groups (up to U21). Using correlation analysis, it was examined whether juvenile test scores were significantly related to playing performance achieved later on.

RESULTS: The findings show significant correlations with later achieved performance for almost all juvenile test tasks. Nevertheless, in early adolescence (U11–U15), mostly no or only weak correlations ($|r|<0.17$) of playing success with the test results can be demonstrated. However, it is noticeable that all correlation values become higher with an increasing prediction period. Thus, the highest correlation values are reached between U9 test performance and U21 playing success. However, the effects are predominantly moderate ($|r|<0.35$). The soccer-specific test items showed the largest correlations.

CONCLUSION: Contrary to the results of other studies, the findings show that the correlations become stronger over a longer period. This is surprising since it can be assumed that performance parameters such as strength or endurance do not remain stable over such a long period of time (12 years) or can first become apparent later, e.g. during puberty. However, the reason that the correlations increase over time could be due to the fact that the league structure in soccer is not yet fully developed at a young age. Only at the adult level exists a distinctive league system that facilitates the differentiation between better and weaker soccer players, which facilitates the assessment of performance success. As expected, the two high-fidelity tests soccer dribbling and agility run performed best. Both tests have been practiced by the German Football Association (DFB) for many years.

OP-MH19 Ageing and exercise interventions

APPLICABILITY OF A CONTROLLED SUPRAMAXIMAL HIT PROGRAM AMONG NON-EXERCISING OLDER ADULTS

SIMONSSON, E., FRYKHOLM, E., SANDSTRÖM, S., HEDLUND, M., HOLMBERG, H., JOHANSSON, B., LINDELÖF, N., BORAX-BEKK, C.J., ROSENDAHL, E.

FACULTY OF MEDICINE, UMEÅ UNIVERSITY

INTRODUCTION: Supramaximal High-Intensity Interval Training (HIT) is effective and time-efficient for older adults. Still, concerns about the safety and applicability warrant development and evaluation of adapted exercise programs. This study aims to evaluate the applicability of the supramaximal HIT program (Hedlund et al., 2019) applied in the randomized controlled Umeå HIT Study (NCT03765385).

METHODS: Sixty-eight non-exercising older adults (66 to 79 years old, 44% males) were randomised to 25 sessions of controlled supramaximal HIT (10x6-seconds) or moderate-intensity training (MIT) (3x8-minutes). The training was supervised and performed on stationary bicycles at a local gym in groups of 8-10 participants. The exercise intensity was individualized and watt-controlled. Standardized escalation criteria were used to allow gradual and individual escalation of the target intensity. Applicability outcomes were attendance, target intensity compliance and escalation, and positive and negative events related to the training sessions.

RESULTS: Participants in HIT attended 748 of 850 sessions with a participant mean (SD) attendance rate of 88% (12). Corresponding numbers in MIT were 749 of 850 sessions and 88% (17), respectively. The most common causes of non-attendance were pre-announced absence (56% in HIT, and 54% in MIT) or being ill (28% in HIT, and 24% in MIT). The mean stipulated interval intensity increased from 235 to 428 watts in HIT, and from 54 to 84 watts in MIT. The most common criteria for not increasing the intensity in HIT was the participant not feeling ready to escalate, while in MIT it was that the participant's heart rate exceeded 70% of heart rate reserve. Participants' mean compliance to the stipulated intensity across sessions was 81% (11) in HIT, and 98% (4) in MIT. In total, 112 positive and 52 negative events were expressed in HIT, with a participant median (range) of 2 (0-12) positive and 1 (0-10) negative events across sessions. Corresponding numbers in MIT were 74 positive and 94 negative events, with a participant median of 1 (0-9) positive and 2 (0-14) negative events. The most common type of positive event was general vitality ("more energetic/happier") in HIT, and musculoskeletal ("muscle soreness/stronger muscles") in MIT. In both groups, the most common type of negative event was musculoskeletal ("muscle soreness/pain"). No negative event was considered a serious adverse event.

CONCLUSION: This exercise program of watt-controlled supramaximal HIT seems applicable and enjoyable in non-exercising older adults. Attendance was high, with fewer negative events and more positive events in HIT. The participants in HIT could comply to the stipulated intensity and its progression over time. Consideration of the participant's own readiness to increase intensity seems important.

HOW DOES OLDER ADULTS' FITNESS LEVEL IMPACT THE ASSOCIATIONS BETWEEN BORGS RPE SCALE AND PHYSIOLOGICAL MEASURES OF EXERCISE INTENSITY?

FOSSTVEIT, S.H.1, LOHNE-SEILER, H.1, FERON, J.F.2, LUCAS, S.J.E.2, BERNTSEN, S.1

1 UNIVERSITY OF AGDER, KRISTIANSAND, NORWAY, 2 UNIVERSITY OF BIRMINGHAM, BIRMINGHAM, UK

INTRODUCTION: A vast amount of research indicates strong validity for Borgs (6-20) Rating of Perceived Exertion (RPE) scale using physiological measures (e.g., heart rate, blood lactate concentration, and respiratory exchange ratio (RER)) as criterion measures.1 However, a recent study by Kossi et al.2 showed that older adults reported higher RPE than younger individuals at the same training intensity. In light of these findings, it is of interest to investigate if older adults' fitness level could impact the associations between Borgs RPE scale and physiological measures of exercise intensity.

We hypothesized that peak oxygen consumption (VO2peak) would be negatively associated with RPE and physiological intensity measures at the lactate threshold, and positively associated with physiological intensity measures at exhaustion.

METHODS: 138 older adults (68.5±5.7 yrs) completed an incremental maximal treadmill test to exhaustion, using a modified Balke protocol, combining measures of lactate threshold and VO2peak.3 General linear regression analyses, taking into account age and sex/gender, were performed to examine associations between Borgs RPE scale and physiological measures of exercise intensity at lactate threshold and exhaustion.

RESULTS: VO2peak was positively associated with RPE (β=0.79 [0.33, 1.25], and negatively associated with % of VO2peak (β =-32.72 [-46.43; -19.01] at the lactate threshold, but not with % of peak heart rate (p>0.05). At exhaustion, VO2peak was positively associated with both RPE and RER (β =0.91 [0.16, 1,66], β =22.99 [7.63, 38.34]), respectively, but not with peak blood lactate concentration (p>0.05).

CONCLUSION: The present studys findings contradict our hypothesis, as the participants with the lowest fitness level did not report a higher RPE at the lactate threshold but instead reported lower RPE than their fitter counterparts. Moreover, a higher RER was observed for participants with higher fitness levels, in addition to reporting a higher RPE at exhaustion. Thus, fitness level may impact the associations between Borgs RPE scale and physiological measures of exercise intensity in older adults, although further research is needed to explore these associations.

A LONGITUDINAL STUDY ON CARDIOPULMONARY FUNCTION OF OLDER ADULT CYCLISTS

FATHI, A., NEWTON, E., SIEGEL, L., FRANCIS, T., MILBOURN, E., DUGGAL, N., LORD, J., LAZARUS, N., POLLOCK, R., HARRIDGE, S.

KINGS COLLEGE LONDON

INTRODUCTION: The relationship between ageing, exercise and disease is obscure. This longitudinal study of older amateur road cyclists, who were extensively physiologically characterised nine years ago(1), provides an opportunity for new

insights into this relationship. Thus, the aim of the study was to investigate the effects of 9 years of active ageing on cardiopulmonary function in relation to any change in health status.

METHODS: Eighty older road cyclists were re-tested after nine years and categorised according to i) no declared health issues (Group 1, 21=M (males), 10=F (females)), ii) exhibiting new but well-controlled health condition(s) unlikely to affect exercise (Group 2, 17=M, 12=F) or iii) having any poorly controlled underlying condition(s) that may compromise exercise tolerance (Group 3, 13=M, 7=F). Blood pressure and heart rate (RHR) were measured at rest along with pulmonary function (Forced Vital Capacity, FVC; Forced Expiratory volume, FEV1). An incremental exercise test was performed on a cycle ergometer to determine maximal aerobic power (VO2peak), maximum heart rate (MHR), and ventilatory threshold (VT). O2 kinetics (TAU) was also determined. Statistical analysis: i) one-way ANOVA assessed for differences at baseline, ii) paired T-test assessed for change over time, and iii) multiple regression analysed between-group differences over time.

RESULTS: Results are mean group changes±SD (*denotes significant change over time, $p<0.05$,) for groups 1, 2 and 3 respectively. The age of participants after nine years were 71±5, 73±6, and 72±6 (yrs). With the exception of FVC, there were no between-group differences at baseline for any indices. Cycling volume declined in two groups (km month−1; -242±276*, -242±339*, -125±296),. SBP increased in group 2 only (mmHg; -0.4±15.3, 7.0±15.7*, 7.3±27.5), whereas DBP increased in all groups (mmHg; 6.7±11.0*, 10.7±10.2*, 12.4±14.8*). Groups 2 and 3 saw an increase in RHR (bpm; 1.5±5.0, 3.4±6.1*, 5.1±8.6*), whilst lung function declined in all groups (FEV1: L; -0.7±0.4*, -0.5±0.6*, -0.8±0.4*; FVC: L; -1.6±0.9*, -1.4±0.7*, -1.9±0.9*). MHR (bpm; -8.8±8.0*, -11.6±8.3*, -13.4±10.1*), VO2peak (ml kg−1 min−1; -7.8±4.6*, -8.5±4.8*, -11.0±5.5*), and VT (ml kg−1 min−1; -3.6±4.0*, -5.4±5.1*, -5.6±4.3*) have declined in all groups. TAU increased in group 2 (s; 1.8±7.9, 7.4±12.3*, 6.6±15.1). The data show a significant interaction between groups over time across all indices ($p<0.01$), except for TAU, with Group 3 showing the greatest change in function.

CONCLUSION: The development of disease over nine-years of active ageing appears to impact global cardiopulmonary function. Despite this, the cyclists maintain high levels of physiological function. Thus, whilst ageing increases susceptibility to some diseases, their impact on function may be ameliorated by exercise.

MUSCLE STRENGTH AND METABOLIC HEALTH IN MASTER ENDURANCE RUNNER: DO THEY DIFFER FROM YOUNG RUNNERS AND SEDENTARY ELDERLY?

ORESKÁ, L.1, SEDLIAK, M.1, CERNÁCKOVÁ, A.1, BUZGÓ, G.1, HAMAR, D.1, CVECKA, J.1, VAJDA, M.1, OKULIAROVÁ, M.2, ZEMAN, M.2, KERN, H.3

1 FACULTY OF PHYSICAL EDUCATION AND SPORTS, BRATISLAVA, SLOVAKIA; 2 FACULTY OF NATURAL SCIENCES, BRATISLAVA, SLOVAKIA 3 INSTITUTE FOR PMPR, ST. PÖLTEN, AUSTRIA

INTRODUCTION: Lower levels of physical activity in old age contribute to the natural decline in an individual´s muscle strength and metabolic health. However, master athletes, who maintain high levels of regular physical activity, may affect the extent to which these physical functions decline, as they are ageing. Yet, there are still some differences in physical functioning between master and young athletes. The study aims to examine the effect of ageing and lifelong endurance running in master athletes on metabolic health and muscle strength, compared to their elderly sedentary counterparts and young endurance runners.

METHODS: The cross-sectional study involved totally 42 healthy males split into 4 groups: 1) young endurance runners (YR: n=11, age: 28.2±2.05 yrs); 2) young sedentary (YS: n=11, age: 28.2±2.34 yrs), 3) master endurance runners (MR: n=10, age: 69±3.09 yrs); 4) elderly sedentary (ES: n=10, age: 71.1±3.64 yrs).YR and MR involved only the active marathon runners, according to the following inclusion criteria: 1) above 300 mins per week of endurance running, 2) regular participation of YR (at least 3 years) and MR (at least 25 years) in running competitions (in 10 km, half, and full marathon), 3) to have their personal best time on 10 km run in last season under 35 mins in YR and under 55 mins in MR.

To compare the differences in metabolic health and muscle strength among the abovementioned groups, the venous blood was collected (blood glucose, insulin, TAG, LDL, HDL and total cholesterol), the body composition (body weight, skeletal muscle mass and body fat) by bioimpedance was measured, and the muscle strength of lower limbs was tested via maximal voluntary contraction of both isometric extension and flexion on the knee dynamometer.

RESULTS: Blood glucose was significantly higher in ES and YS (4.11±0.22 mmol/l; P=.003). Insulin was significantly higher in ES (9.32±3.77 IU) compared to MR (5.16±2.32 IU; P=.005) and YS (10.01±6.52 IU) vs. YA (3.39±1.02 IU; P=.001). HDL cholesterol was significantly higher in both YR (1.51±0.20 mmol/l) compared to YS (1.22±0.25 mmol/l; P=.007) and MR (1.61±0.30 mmol/l) compared to ES (1.04±0.19 mmol/l; P=.001). LDL cholesterol was significantly in YR (2.09±0.60 mmol/l) compared to MR (3.33±0.60 mmol/l; P=.001) and in YS (2.50±0.73 mmol/l) vs. ES 3.20±0.99 mmol/l; P=.037). No significant differences were observed in triacylglycerol. Similarly there were observed differences between YR and YS and MR and ES.

CONCLUSION: The results proved, there are some differences in the parameters of metabolic health according to age as well as the effect of regular exercise. Lifelong endurance running may positively affect the process of ageing due to maintaining higher levels of muscle strength and slowing down metabolic alterations.

The study was funded by the INTERREG V-A Slovakia—Austria (acronym CAA, ITMS2014 + 305041X157) and by the Slovak Research and Development Agency (Grant no. APVV-21-0164).

EFFECTS OF OLD AND VERY OLD AGE ON NEUROMUSCULAR FATIGUE DURING ISOMETRIC, CONCENTRIC AND CYCLING FATIGUING TASKS IN MEN AND WOMEN

ROZAND, V., VARESCO, G., BERTRAND, M., LUNEAU, E., MILLET, G.Y., FÉASSON, L., LAPOLE, T.

UNIVERSITÉ JEAN MONNET

INTRODUCTION: The effects of aging on performance fatigability (decrease in maximal force) has been extensively studied during local (i.e. single-joint) isometric and dynamic fatiguing tasks. However, the experimental setup are usually far from ecologically valid conditions, with workloads set in percentage of maximal capacities and fatigability evaluated at exhaustion. The aim of the present study was to investigate performance fatigability during isometric, dynamic and cycling incremental fatiguing tasks across age with absolute workloads.

METHODS: Twenty-six young (13 women), 27 old (14 women) and 23 very old (11 women) adults randomly performed an isometric (ISO) and a dynamic (DYN) quadriceps intermittent fatigue tests on an isokinetic dynamometer and a similar test on a validated cycle ergometer (BIKE). This test consisted of incremental stages of 75 contractions (0.8-s on/0.8-s off; ISO and DYN) or 120-s cycling at 37.5 rpm (BIKE) with increments relative to the participants body weight. Maximal voluntary force, voluntary activation (VA) and amplitude of the resting twitch (Tw) were assessed using the interpolated twitch technique with percutaneous electrical nerve stimulation before, after each stage and at exhaustion.

RESULTS: Performance (number of stages) decreased with age for men and women in the three conditions. For men, maximal force decreased earlier in old and very old adults compared to young adults during BIKE but not during ISO and CON. However, the decrease in maximal force at exhaustion was greater for young than very old adults after ISO ($P<0.001$), but similar across age in CON and BIKE. For women, maximal force decreased earlier for very old adults compared to young adults during CON but not during ISO and BIKE. At exhaustion, the decrease in maximal force was similar across age and fatiguing tasks. For both men and women, impairments in VA and Tw amplitude were similar across age and fatiguing task, except a larger decrease in Tw amplitude for young men after BIKE compared to older groups ($P<0.05$).

CONCLUSION: These results showed that young men and women were more performant than old and very old adults independent of the task when the load was set relative to individual body weight. Fatigability (decrease in force) occurred earlier in old and very old men during cycling, and earlier in very old women during the concentric task. At exhaustion, no age-related difference were observed for men and women independent of task, except for the isometric task in which young men had greater fatigability than very old men. Fatigability was mainly driven by impairments in contractile function. These results suggest that fatigability should not only be evaluated at exhaustion but also at sub-maximal levels that are closer to the intensity of activities of daily living.

OP-AP29 Body Composition

NEW BIOELECTRICAL IMPEDANCE VECTOR REFERENCES AND PHASE ANGLE CENTILE CURVES IN 4,367 HEALTHY MALE AND FEMALE CAUCASIAN ADULTS: THE NEED FOR AN URGENT UPDATE AFTER 30 YEARS

CAMPA, F., CORATELLA, G., CERULLO, G., STAGI, S., PAOLI, S., GRIGOLETTO, A., MORONI, A., PETRI, C., ANDREOLI, A., DEGAN, R., IZZICUPO, P., SERGI, G., MASCHERINI, G., MICHELETTI, M., MARINI, E.

UNIVERSITY OF PADOVA: UNIVERSITA DEGLI STUDI DI PADOVA

Toselli, S., Moro, T., Paoli, A.

INTRODUCTION: The bioelectrical impedance vector analysis (BIVA) represents a qualitative analysis of body composition. Starting from the bioelectrical characteristics, the vector can be evaluated compared to 50%,75%, and 95% tolerance ellipses representative of reference populations. The tolerance ellipses for healthy adults have been provided in 1995 and were developed by mixing underage, adult, and elderly subjects.

METHODS: The current study aimed to provide new tolerance ellipses for healthy adults and as a secondary aim to present centile curves for the bioelectrical phase angle. Bioelectrical resistance (R), reactance (Xc), and phase angle were measured in 2,137 and 2,230 Caucasian males and females using phase-sensitive foot-to-hand analyzers at 50 kHz. A minimum of 35 subjects were included for each age category from 18 to 65 years.

RESULTS: The new mean vectors showed a shift to the left on the R–Xc graph with respect to the former reference values (males: $F=75.3$; $p<0.001$; females: $F=36.6$, $p<0.001$). The results provided new 5th, 10th, 25th, 50th, 75th, 90th, and 95th percentile curves for phase angle, identifying time point phases of decrement (males: -0.03° per year at 33.0-51.0 years and -0.05° per year after 51 years; females: -0.03° per year from 37.2 to 57.9 years).

CONCLUSION: Compared to the references provided along with the BIVA invention, the present study showed that the tolerance ellipses of the adult population are shifted to the left within the R-Xc graph, also suggesting a higher phase angle. After 30 years, the current study presents new BIVA and phase angle reference values for the healthy Caucasian adult population.

SOMATOTYPE AFFECTS LEAN BODY MASS ESTIMATION WITH BIOELECTRICAL IMPEDANCE ANALYSIS

UTCZÁS, K., TRÓZNAI, ZS., KALABISKA, I., PÁLINKÁS, G., PETRIDIS, L.
HUNGARIAN UNIVERSITY OF SPORTS SCIENCE

INTRODUCTION: Body composition measurements, particularly using bioelectrical impedance are quite common among athletes. However, when evaluating the results, we need to know the limitations of this method, furthermore potential influencing factors. The aim of the study was to examine the effects of the individual somatotype on body composition estimated by bioelectrical impedance analysis, especially on lean body mass and to investigate how body proportions affect the variability of estimates.

METHODS: 719 male athletes were measured aged between 10 and 20 years (mean age: 15.6±1.9 years). The athletes were all players from sport clubs or academies in Hungary. Body composition was estimated by bioelectrical impedance analysis (InBody 720) and by dual-energy X-ray absorptiometry (Lunar Prodigy). Somatotype was determined with regression equations using the Heath&Carter method (1967). Groups based on the trunk to limb ratio were calculated by the ratio of sitting height to hip height. The effect of somatotype components and body ratio on lean body mass estimation was examined by multivariate linear regression. The differences between groups were analyzed by one-way analysis of variance (ANOVA).

RESULTS: On average, BIA underestimated body fat percent by 7.6% compared to DXA. Further, the average difference in lean mass between BIA and DXA was -3.9 kg. The smallest difference between the two methods was found in the mesomorphic dominant group, for both lean body mass (-3.3 kg) and fat percentage (6.4%). The mean difference in fat percentage estimation was the largest in the ectomorphic dominant group (8.6%), while the mean difference in lean body mass estimation was the largest in the endomorphic dominant group (-5.4 kg). Regarding segmental lean body mass analyses, we found significantly larger difference in the lean body mass estimation of the lower limbs in the ectomorphic dominant group. Based on the trunk-to-limb length groups, fat percentage was underestimated, while lean body mass was overestimated for athletes with proportionally longer limbs. The difference between BIA and DXA decreased with increasing trunk-to-limb ratio. Multivariate linear regression revealed that individual somatotype and trunk-to-limb ratio together explained 27% of the differences in lean body mass estimation.

CONCLUSION: As both the BIA and DXA provide estimates of body composition, it is important to understand any factors that may affect the results of the measurements. Our findings suggest that body composition measurements and somatotype are related. Therefore, it can be assumed that lean body mass estimates are influenced by the dominant component that determines somatotype and this should be considered when using BIA analysis. Overall, body proportions affect BIA measurements, with a lower trunk to limb ratio being associated with an overestimation of lean body mass.

RELATIONSHIP BETWEEN MAXIMUM FAT OXIDATION DURING A GRADED CYCLING TEST AND SUBCUTANEOUS ADIPOSE TISSUE MEASURED USING ULTRASOUND IN ELITE TRIATHLETES

MATHY, A., SENGEIS, M., ERNST, J., SOUKUP, C., SCHARNER, M., TRISKA, C.
LEISTUNGSSPORT AUSTRIA

INTRODUCTION: In endurance sports, such as triathlon, body mass and fat are of great importance. On the one hand, carrying low body mass and fat as well might be an advantage, on the other hand providing sufficient energy for high amount of training hours and multiple competitions is essential. Consequences of insufficient energy availability may have adverse effects on performance and long-term health of athletes. Therefore, an accurate (1) and reliable (2) measurement method for measuring subcutaneous adipose tissue (SAT) may provide relevant data to enhance athletes` performance. The aim of this study is to analyse a potential relation between SAT and parameters of fat oxidation in elite triathletes.

METHODS: A sample of 12 male national team triathletes (age 22.3±2.9y, body height 1.85±0.06m, body mass 73.7±4.9kg, BMI 21.7±1.1kgm-2, VO2peak 4922.1±313mL) performed a graded exercise test with measurement of respiratory gases. The last 90 s of oxygen uptake and carbon dioxide production for each stage were averaged and fat oxidation was calculated using stoichiometric equations (3). Using this data, maximal fat oxidation (MFO) and FATmax (expressed as % of VO2peak) was calculated for each participant. SAT thickness was measured at eight defined body sites using ultrasound according to a published protocol (1). SAT thickness sums of all sites (in terms of DI; I fibrous structures incl.) were used: upper-and lower abdomen, front-and lateral thigh, medial calf, erector spinae, distal triceps, and brachioradialis. Further, SAT thickness sums of the lower limbs (DI,LL; front-and lateral thigh, and medial calf) were used. Ultrasound images were calculated using a semi-automatic image evaluation software (NISOS-BCA Fat Analysis Tool, v.4.2, nisos.at). To assess strength of the relation between parameters Pearson moment correlations have been used (GraphPad Prism version 9.0.0).

RESULTS: Results showed non-significant correlations between DI (14.83±7.67 mm) and MFO (0.57±0.13 g/min; r=-0.347, p=0.269) and for DI and FATmax (2.4±0.2 W/kg; r= 0.08, p=0.808). Moreover, non-significant correlations were found between DI,LL (6.34±3.80 mm) and MFO (r=-0.484, p=0.111) and FATmax, (r=0.553, p=0.062). Five of 12 males had 'extremely low' and four had 'very low' DI values according to a preliminary assessment schedule (4).

CONCLUSION: The main findings indicate that thickness of adipose tissue does not predict the athlete's capability to maximise fat oxidation. Also, SAT of lower limbs, which might be more specific in the type of physical load, did not show a relationship to parameters related to fat oxidation during exercise. A transfer of SAT values on interpretation of training zones and training recommendations in concern of fat oxidation might not be justified. However, the influence of SAT values on performance in competition should be observed and SAT changes should be noted for each athlete individually.

DOES THE ULTRASOUND THICKNESS REPRESENT AN ACCURATE METHOD TO PREDICT LEAN MASS IN RESISTANCE TRAINED MEN?

VALAMATOS, M.J.1,2,3, CAVACA, M.L.1,3, MATIAS, C.N.4, REIS, J.F.2,3, TEIXEIRA, F.J.2,5, MONTEIRO, C.P.2,3
1-FACULDADE DE MOTRICIDADE HUMANA, UNIVERSIDADE DE LISBOA, PORTUGAL; 2-CIPER, FMH, PORTUGAL; 3-PORTUGAL FOOTBALL SCHOOL, FPF, PORTUGAL, 4-CIDEFES, UNIVERSIDADE LUSÓFONA, PORTUGAL; 5-UATLA, PORTUGAL

INTRODUCTION: Increasing muscle mass is the main objective of individuals engaged in resistance training(RT) programs. Ultrasound (US) can play an important role in monitoring such musculoskeletal adaptations because it provides objective measures of muscle mass and muscle quality. Furthermore, US is a non-ionizing imaging technique, as well as being portable and highly accessible, contrary to dual-energy X-ray absorptiometry(DXA), traditionally used in this research context. However, the literature does not provide an adequate US-based model to estimate total and appendicular lean mass (LM) in RT adult men. Thus, the main purpose of the present study was to develop a model to estimate the whole body (WB) and thigh LM based on ultrasound measurements of the vastus lateralis (VL) and rectus femoris (RF) thickness in resistance-trained men.

METHODS: Men (N = 79,31 ± 7.0 years, 76.3 ± 10.2 kg and, 174.3 ± 6.0 cm), previously engaged in RT for at least 1 year and at least 3 times per week, participated in this study. Each participant performed body composition assessments by DXA to calculate WB and regional (thigh) LML. Muscle thickness of VL and RF of the dominant leg were assessed at rest using B-mode US imaging. Longitudinal and transversal scans were taken from the muscles mid-belly corresponding to 39%(VL) and 56%(RF) of the distance from the proximal edge of the patella to the anterior superior iliac spine.

Mathematical models, based on anthropometric and US measurements, were developed using stepwise multiple regression analyses, and new developed models were cross-validated using the PRESS approach.

RESULTS: The muscle thickness of RF and VL showed a positive correlation with weight, WB and thigh LM assessed by DXA. Regression analysis showed that RF alone explain 18.9% and 19% of the WB and thigh LM, respectively, while VL by itself explain 26.5% and 20.1% of the WB and the thigh LM, respectively. Four models were developed (two for WB and two for thigh, each one including a measure of ultrasound thickness (RF or VL). After validation, the best equation to predict lean mass in WB is: Lean mass (kg) = -1.657 + 0.719* Weight (kg) + 0.416* VL (mm), where R2=0.882 and a standard error of estimate (SEE)= 2.99kg. If considering only the thigh, the best approach for LM estimation based on ultrasound thickness is: Lean mass (kg) = -0.354 + 0.146* Weight (kg) + 0.047* VL (mm) where R2=0.849 and SEE=0.667 kg.

CONCLUSION: The present study provides a valid and useful mathematical model based in US measurements, more specifically based on vastus lateralis thickness, that can be used as a practical and ecological approach to assess lean mass at a whole-body level as well as for thigh only, in RT men. These mathematical models represent an important tool to assess body composition, monitor RT adaptations and identify possible asymmetries between thighs.

OP-MH18 Physical activity promotion

BECOMING A CYCLIST TO BE ACTIVE: A SYSTEMATIC REVIEW OF THE EFFECT OF CYCLING EDUCATION AND BUILT ENVIRONMENT ON PHYSICAL ACTIVITY

DERIGNY, T., MEKKAOUI, L., LENIG, T., MEISTERMANN, L., GANDRIEAU, J., POTDEVIN, F., SCHNITZLER, C.
UNIVERSITY OF LILLE

Introduction

According to the high level of sedentary behaviour, physical activity (PA) is a public health issue (Guthold et al., 2020). Cycling, as an active transport, makes it possible to maintain sustainable daily activity (Khan et al., 2020). However, many children stopped their PA when they became adults, and it seems interesting to understand how cycling can overcome this.

Following the ecological framework of human development (Bauman et al., 2012), the aim of this systematic review is to evaluate the effectiveness of school-based interventions (interpersonal determinant) or built environment (environmental determinant) to promote sustainable engagement in PA by cycling. The research question is: 'among school-aged children, ages 6 to 18 years (P), what are the characteristics of cycle educational and environmental interventions (I) that promote engagement in PA (O), compared with children and adolescents of the same age who do not receive these interventions (C)?'

Methods

The PICO method was used to define the research question, and PRISMA checklist searched for articles in 11 databases (WOS, Embase, Psychinfo, Cochrane, Pubmed, ScienceDirect, Proquest, ERIC, Lilacs, Sportdiscus, and Scopus). Eligibility criteria were (1) English language, (2) population of school-based aged, (3) intervention study design on education and on

built environment, and (4) results related to PA engagement. The risk of bias was assessed. Inverse variance meta-analyses using random effects models are in progress.

Results

Results showed relatively poor number of studies included which try to promote PA through cycling (n=8). Despite various measurement tools: questionnaire (n=1), accelerometers (n=4) and GPS (n=3), all studies were unanimous about the benefits of built environments (n=6) or school-based interventions (n=2) on PA levels.

Discussion

This systematic review provides a consensus on the positive effects of (a) school-based interventions which are open to environmental factors, and (b) build environment facilities, on the amount of PA practiced by children and adolescents. However, no studies considered the interaction of these interpersonal and environmental variables. In the future, we encourage interventional studies with would be systemic with the interaction of the ecological variables to promote PA practices across the life course.

THE BENEFICIAL EFFECT OF 12 WEEKS OF RESISTANCE TRAINING ON MEMORY AND EXECUTIVE COGNITIVE FUNCTION OF MILD COGNITIVELY IMPAIRED OLDER ADULTS

KUŠLEIKIENE, S., VINTS, W.A.J., MASIULIS, N., CESNAITIENE, V.J., LEVIN, O.

LITHUANIAN SPORTS UNIVERSITY

INTRODUCTION: Promotion of healthy ageing is one of the major challenges for health care systems in current times. Mild Cognitive Impairment (MCI) prevalence increases with age with a risk to turn into dementia. Older adults with MCI are at a higher risk of developing impaired balance behavior because of impaired executive function integrity. Exercise training is likely to improve cognitive measures and balance [Wu J. et al, 2021]. Nevertheless, studies on the effects of physical exercise in older adults with MCI are still insufficient and vary in efficacy, exercise protocols, compliance, and interpretation of the results. This study we investigated the effects of therapeutic structured lower limb resistance training (RT) intended to improve memory, executive function, and posture in adults with MCI.

METHODS: We assessed the effect of 12 weeks resistance training to cognitive function in older adults (age: 60–80 years (completed the intervention n=53))) with intact memory (n=35) and MCI (n=18). Participants either underwent two times weekly RT program which consisted of 4 lower limbs resistant exercises performed for 3 sets of 6–10 repetitions at 70–85% of 1 repetition maximum or served as the passive control group. Posturography, Purdue Pegboard Test (PPT), ANAM test battery and Montreal Cognitive Assessment (MoCA) were collected before and after the intervention.

RESULTS: At Week 12, the MCI subjects in RT intervention group achieved significantly improved MoCA scores executive functions (before 3.96 ± 1.04 after 4.36 ± 0.95), and delayed recall (before 3.46 ± 1.37 after 4.25 ± 1.01) ($p \leq .005$). Participants in the control group also showed an increase in total MoCA score, but improvement was observed only in delayed recall ($p < .005$). Moreover, MCI subjects in the experimental group exhibited significant increases in the balance task (Sway velocity (mm\s) before 23.34 ± 8.95 versus after 19.97 ± 8.21), indicating that limb exercise training positively influenced their balance ($p < 0.05$). Performance on the ANAM test battery and PTT were not statistically different before and after the RT training intervention.

CONCLUSION: The results conclude that twelve weeks of twice-weekly lower limb resistance training intervention can effectively improve executive function and memory in elderly with MCI. Since effective balance control requires attention, we propose that improved executive function may lead to better balance control in MCI.

Tailored interventions might target physical performance to maintain cognitive state and to prevent dementia. Larger studies are required to examine the effects of exercise and the possible moderators.

This project has received funding from the Research Council of Lithuania, grant No P-SEN-20-05.

PREVENTING PHYSICAL PERFORMANCES DURING ISOLATION PERIODS IN COMMUNITY-DWELLING OLDER ADULTS: ONLY ONE ONLINE REMOTE PHYSICAL ACTIVITY INTERVENTION MODE AS SOLUTION?

AUBERTIN-LEHEUDRE, M.

UNIVERSITÉ DU QUÉBEC À MONTRÉAL

INTRODUCTION: Periods of involuntary isolation (such as lockdown; heat or cold waves) increase the risk of physical inactivity, which can contribute to physical decline among older adults. Online technology could be an innovative solution to promote physical activity habits in this context. However, the effects of these adapted remote web-based interventions (live or video or combined) remain unclear in older adults. Thus, we aimed: 1) to examine the acceptability, feasibility and

potential benefits of 2 modalities of web-based PA interventions (study-1); 2) to explore which recorded-live sessions ratio leads to the best implementation and benefits (study-2).

METHODS: Non-physically active community-dwelling older adults (>60yrs) were recruited during the 2 first covid-19 lock-downs and randomized by block period to a 12-week web-based PA intervention [study-1: Live Group (LG; n=38) vs. Recorded Group (RG; n=45) /study-2: Live-Recorded-Live group (LRL; n=22) vs. Recorded-Live-Recorded group (RLR; n=24)]. Acceptability, feasibility as well as physical performance [muscle endurance (30sec STS); muscle power (10 STS); SPPB] quality of life (EQ-5D) and PA level/motivation were assessed pre- and post-intervention.

RESULTS: 1st study: Fewer dropouts in LG than RG (LG:16% vs. RG:46%) were found. Adherence rate (LG:89%; RG:81%), level of satisfaction (LG:77%; RG:64%) and enjoyment (LG:68%; RG:62%) were similar across groups. Physical performance and quality of life improved significantly in both groups. Only LG showed significant improvements in perceived health and PA levels. Finally, LG showed greater physical performance and quality of life improvements than RG.

2d study: Dropout rate (LRL:14% vs. RLR: 29%) and adherence (>85%) were similar between groups. Both groups reported similar levels of satisfaction (>70%), enjoyment (>75%) and perceived exertion (>60%). Both groups increased physical performances with greater improvements in muscle power (p=0.010) and endurance (p<0.001) in the LRL group.

CONCLUSION: Web-based PA interventions using a decisional tree to prescribed adapted levels are safe, feasible, acceptable and beneficial for improving physical performance during isolation periods. However, PA programs which included full or more interactive web and live sessions (LLL or LRL) appear to be more effective for maintaining or improving physical health. Further research is needed as well as longitudinal follow-up (in process).

"HEALTHY ACTIVE LEARNING": 1-YEAR FOLLOW-UP EVALUATION TO INFORM LOCAL CO-DESIGN OF A NATIONAL CROSS-GOVERNMENT PHYSICAL ACTIVITY INITIATIVE

ALI, A., SNOWLING, N., RICHARDS, J., TAYLOR, Z., THORBY, R., ADAMS, J.

MASSEY UNIVERSITY

INTRODUCTION: Healthy Active Learning (HAL) is part of the New Zealand governments Wellbeing Budget, with $47m (€28m) provided to Sport NZ, Ministry of Health and Ministry of Education to undertake a 5-year initiative in 800 schools (children aged 5-13 years) in NZ to improve the wellbeing of students through healthy eating and drinking and quality physical activity. Prior to implementing HAL, little was known about existing opportunities and teacher capability to deliver physical education (HPE) in these schools. There was also limited understanding of how physical activity was valued and prioritised by schools and teachers.

METHODS: We analysed the 1-year follow-up results from a longitudinal quasi-experimental evaluation. This included a school leader/teacher survey about physical activity opportunities and the delivery of HPE. Pre-post descriptive data were calculated for 'intervention' schools (n=528 teachers) in addition to a comparative analysis with 'control' schools (n=502 teachers).

RESULTS: Experienced teachers demonstrated better teaching practices than inexperienced teachers across all schools. At follow-up, 88% of respondents from intervention schools agreed that physical activity is a key part of student wellbeing. There was a higher proportion of intervention schools with visibility of physical activity in their school charters/plans (55% vs. 39%) and that rated HPE as a high priority (21% vs. 10%). Teachers in intervention schools were more likely to run their own HPE lessons (35% vs. 28%), plan HPE lessons to meet student needs (47% vs. 38%) and assess student progress in HPE (46% vs. 39%). Intervention schools also reported improved physical activity opportunities, with 78% of teachers agreeing their school provides physical activity experiences that meet the needs of all students. The changes from baseline in all of the outcomes listed above was statistically significant in the intervention schools (p<0.05).

CONCLUSION: These results highlight the short-term difference the HAL approach can have on the school environment and teaching practices. System-wide change takes time and embedding these early changes within the whole-school is key to improving the physical activity experience and participation levels of students. There is also a clear indication of the value of improved teacher training in HPE planning and delivery.

OP-MH28 Health and fitness (mixed)

HIGH INTENSITY INTERVAL TRAINING ENHANCES CARDIOPULMONARY FITNESS IN PREGNANT WOMEN WITHOUT ADVERSE EFFECTS ON THE LEVELS OF PLACENTAL GROWTH FACTOR (PLGF)

SZUMILEWICZ, A.1, SANTOS-ROCHA, R.2, KWIATKOWSKA, E.3, KWIATKOWSKI, S.3, RADZIMINSKI, L.1

1. GDANSK UNIVERSITY OF PHYSICAL EDUCATION AND SPORT, POLAND, 2. ESDRM SPORT SCIENCES SCHOOL OF RIO MAIOR - POLYTECHNIC INSTITUTE OF SANTARÉM, PORTUGAL., 3. POMERANIAN MEDICAL UNIVERSITY, POLAND

INTRODUCTION: High intensity interval training (HIIT) has become one of the most popular fitness trends, improving health and fitness outcomes in general, special or clinical populations. However there is limited data on the effects of HIIT im-

plemented during pregnancy (1). There are still unjustified opinions that intense maternal physical effort can negatively affect the development of the foetus.

First, we aimed at answering how HIIT programme will affect cardiopulmonary parameters in pregnant women; secondly, will the levels of placental growth factor (PlGF), which has key pro-angiogenic impact on the foeto-placental circulation (2), remain normal after HIIT intervention?

METHODS: It was an experimental trial (3) in 39 Caucasian women in uncomplicated, singleton pregnancy (age 32 ± 4 years, week of gestation 24 ± 3, mean ± SD). 21 women attended an 8-week supervised, online high intensity interval training programme (HIIT group). There were 18 pregnant women in the comparative (EDU) group who completed an educational programme. We encouraged them to perform moderate to vigorous physical activity by their own. Before and after the interventions we measured maternal cardiopulmonary parameters during a progressive maximal exercise test on a cycloergometer with respiratory gas analyser. On the days of the exercise tests we assessed the levels of PlGF from the blood samples in fasting conditions. Both groups presented similar values of analysed parameters at baseline.

RESULTS: In the HIIT group compared to the EDU group we observed substantially higher post-intervention values of maximal oxygen consumption (VO2max; 25.14 ± 4.48 vs. 19.67 ± 3.36 mL/kg/min; $p < 0.001$), maximal minute ventilation (VEmax; 66.48 ± 9.96 vs. 54.33 ± 13.87 L/min; $p < 0.001$) and maximal heart rate (HRmax; 167 ± 9 vs 155 ± 16 beats/min; $p = 0.005$). In both groups, the levels of PlGF significantly increased, achieving normal ranges for particular stage of gestation (HIIT: pre intervention 296.87 ± 157.27 and post intervention 585.29 ± 391.11 pg/mL, $p = 0.002$; EDU: pre 348.88 ± 208.29, post 473.12 ± 299.07 pg/mL; $p = 0.02$); insignificant difference between groups: $F = 2.98$; $p = 0.09$). We have not observed any adverse obstetric and neonatal outcomes in either group.

CONCLUSION: Both supervised HIIT and self-performed moderate to vigorous physical activity can be recommended during pregnancy to prevent disorders in the production of PlGF. However, to improve maternal cardiopulmonary fitness pregnant individuals should perform high intensity exercise.

ACUTE EFFECT OF PSYCH UP ON MUSCULAR PERFORMANCE

KREKOUKIA, M.1, PSYCHOUNTAKI, M.1, SPILIOPOULOU, P.1, METHENITIS, S.1, ZARAS, N.2, MPAMPOULIS, T.1, TSITKANOU, R.1, BOGDANIS, G.1, TERZIS, G.1

1 NATIONAL AND KAPODISTRIAN UNIVERSITY OF ATHENS; 2 UNIVERSITY OF NICOSIA, CYPRUS

INTRODUCTION: Muscular performance depends on components of fitness such as maximal force, muscular power, rate of force development, and muscular endurance [1]. These fitness components rely on several biological and psychological attributes, such as the muscle fiber type composition and self-efficacy. In addition, several psychological techniques have been recently promoted for acute improvement of sport performance, with psyching up being one of the most popular, yet the physiological mechanism for performance improvement remains unknown [2]. Aim of this study was to examine the acute psyching-up influence on maximum force production, rate of force development, jumping performance and muscular endurance. It was hypothesized that individuals with higher percentage of type II fibers in their quadriceps muscles would be benefited more in explosive movements from psyching up, while individuals with higher percentage of type I fibers in their quadriceps muscles would be benefited more from psyching up in tests demanding muscular endurance.

METHODS: Twelve young moderately trained men (height 177±5cm, body mass 74±9kg), with no strength training and mental preparation experience, underwent a non-psych up and a psych-up trials, with a week interval between them. Tests included: maximal isometric leg press for measurement of the rate of force development (RFD) and maximal isometric force (MIF), counter movement jump for jump height (CMJh) and power (CMJp), and 45o incline leg press to evaluate the maximum number of repetitions with a load 50% of the MIF (LPRM). Self-talk, goal setting and self-efficacy techniques, were applied in the psych-up trial, 30 minutes before the second session of performance tests. Muscle fiber type composition and fiber cross sectional area (fCSA) of vastus lateralis estimated through muscle biopsies.

RESULTS: MIF ($p<0.025$), CMJh ($p<0.001$), CMJp ($p<0.001$), LPRM ($p<0.003$) and exercise volume (LPv, load x repetitions) ($p<0.001$) after psyching up were significantly higher by 9.73%, 9.25%, 4.30%, 54.35% and 66.65%, respectively, than baseline. RFD did not change after the psych up intervention. A significant positive correlation appeared between the percentage of type I muscle fibers and the percentage change in LPRM ($r=0.62$, $p<0.05$) and LPv ($r=0.69$, $p<0.05$). Low and non-significant correlations were found between the percentage of type II muscle fibers and the percentage change in all performance indices.

CONCLUSION: Self-talk, goal-setting and self-efficacy techniques, can acutely improve maximal strength, muscle power and muscular endurance. Individuals with higher type I muscle fibers in their protagonist muscles may be benefited more by these techniques during muscular endurance demanding tasks. The acute performance improvement in explosive tasks by these psych up techniques is not influenced by the fiber type composition, in moderately trained men.

CLOSING THE GAP: IDENTIFYING SEX-SPECIFIC MITOCHONDRIAL RESPONSES TO HIGH-INTENSITY INTERVAL TRAINING (HIIT) IN HUMAN SKELETAL MUSCLE

TAYLOR, D.F., REISMAN, E., ZAREKOOKANDEH, Z., HOFFMAN, N., HAWLEY, J., BISHOP, D.J.
VICTORIA UNIVERSITY

INTRODUCTION: Mitochondria are energy generating "powerhouses" that help regulate various cellular processes. Impairments in mitochondrial function are heavily associated with type 2 diabetes (T2D), a disease characterised by impaired energy metabolism that affects nearly 500 million people worldwide. Although men are more likely to receive a diagnosis of T2D, the varying pathological presentation and societal pressures has led to worse clinical outcomes for women with T2D (1). Exercise has arisen as a powerful non-pharmacological treatment for T2D through its ability to improve mitochondrial function in skeletal muscle. However, providing an adequate training prescription for women remains a challenge due to most exercise studies recruiting only men. To address this gap, the aim of our study was to identify sex-specific changes to mitochondrial function in response to exercise.

METHODS: High-resolution mitochondrial respirometry was performed on skeletal muscle biopsies taken from 18 healthy untrained young men (26.9 ± 6.3 y; 179.9 ± 10.4 cm; 82.3 ± 12.4 kg) and 13 healthy untrained women (28.0 ± 5.8 y; 167.5 ± 7.4 cm; 68.7 ± 11.0 kg) prior to and following 8-weeks of HIIT (values indicated as mean ± SD). The HIIT consisted of four sessions per a week of 4 x 4 min with 2 min of rest between each interval. The intensity of each interval was set at WLT + x (Wpeak – WLT), with x increasing from 45% in week one (x=0.45) to 75% in week eight (x=0.75), with WLT representing power at the lactate threshold and Wpeak representing peak power.

RESULTS: Skeletal muscle mitochondrial ADP sensitivity was unchanged after HIIT in both men and women, however, when both sexes were examined as a single cohort a decrease in ADP sensitivity, and therefore increase in substrate utilisation, was detected (p=0.008). All measures of mitochondrial respiration (Complex I peak, Complex I+II peak, and Complex I+II capacity) were increased after 8-weeks of HIIT in both men and women (p<0.05), but no difference (p>0.05) was observed between sexes. This contrasted to VO2max values, with men improving significantly more (p=0.013) compared to women with an average increase of 22.4% and 16.6% respectively after 8-weeks of HIIT.

CONCLUSION: Our sample size was likely inadequate to detect differences in mitochondria ADP sentivity following 8-weeks of HIIT within and between men and women. In spite of this, our study does indicate ADP kinetics in healthy populations may be improved by exercise. Due to no differences observed between the sexes, our results indicate HIIT is equally as effective at improving mitochondrial respiratory function in healthy men and women. The further validation of these findings in T2D populations will enhance clinical exercise prescription and improve outcomes for patients with mitochondrial dysfunction.

SPORT-SPECIFIC TRAINING DOES NOT ENHANCE IMPROVEMENT IN NEUROMUSCULAR PERFORMANCE IN RELATION TO GROWTH

PETRIDIS, L., PÁLINKÁS, G., TRÓZNAI, ZS., UTCZÁS, K.
HUNGARIAN UNIVERSITY OF SPORT SCIENCE

INTRODUCTION: Periods of natural improvement in neuromuscular performance have been reported around the age at peak height velocity (APHV) in young athletes. However, there is a lack of evidence that specific training stimuli may further enhance improvement rates. In this study we examined the developmental pattern of neuromuscular performance in relation to maturity status in three sports. We tested the hypothesis that training effects may increase the adaptation in neuromuscular performance beyond the degree, which is attributed to growth and maturity.

METHODS: Data from 716 athletes were analysed (from 11 to 16 years) from three sports (soccer, handball, basketball). The athletes performed countermovement jump on a force platform (HUR labs), including in the analysis also the mechanical properties of the jump (force, power) and the modified reactive strength index. Maturity was estimated by calculating APHV. According to the years from PHV we divided the athletes to groups of one year interval. Descriptive statistics and two-way ANOVA (maturity status x sport) was used for inter-group comparisons.

RESULTS: From the least (-2 years from PHV) to the more mature group (+2 years from PHV) in the entire sample, vertical jump performance increased from 26.9±3.4 to 36.4±3.9 cm (+35.3%). The largest increase (>60%) occurred ±1 year around APHV. Further, maximal relative power increased by 22% (from 39.2±4.7 to 47.9±4.5 w/kg) with the two-third of this increase taken place again around (1 year) APHV. Regarding sport group comparisons, significant differences were found, with basketball players exhibiting lower values, particularly one and two years after APHV. Similarly, after APHV the initial differences in relative power diminished and there was not any difference between the three groups.

CONCLUSION: Findings support the hypothesis that a period of accelerated adaptation in neuromuscular performance exists ±1 year from APHV. We expected that basketball players will demonstrate larger improvement compared to soccer and handball players as a result of their training, particularly in the period within and after APHV. However, the results did not confirm our assumption since we could not provide evidence that specific training may enhance improvement rates in

neuromuscular performance beyond to the improvement attributed to growth. The results are limited by the nature of the examined sports, which show several similarities in their everyday training. Data from more different sports and from non-athletes could give a better understanding of this phenomenon.

RELATIONSHIP BETWEEN MODERATE-TO-VIGOROUS, LIGHT INTENSITY PHYSICAL ACTIVITY AND SEDENTARY BEHAVIOR IN A PROSPECTIVE COHORT OF OLDER FRENCH ADULTS: A 18-YEAR FOLLOW-UP OF MORTALITY AND CARDIOVASCULAR

DUPRÉ, C., BRÉGÈRE, M., BERGER, M., PICHOT, V., CELLE, S., GARET, M., FUNDENBERGER, H., BARTH, N., GUYOT, J., BONGUE, B., BARTHÉLÉMY, J.C., ROCHE, F., HUPIN, D.

UNIVERSITY HOSPITAL OF SAINT-ETIENNE

INTRODUCTION: It is well documented that moderate-to-vigorous intensity physical activity (MVPA) is effective in the prevention of major chronic diseases. Even though the current international physical activity (PA) guidelines still mainly focus on MVPA, the topic of the most recent epidemiological studies has shifted from MVPA to light intensity physical activity (LPA), owing to the necessity of promoting all activities vs. sedentary behavior (SB). However, the evidence remains currently limited. Thus, the clarification of the effects of LPA and the close relationship with SB is crucial to promote public health.

Aim: To investigate the associations of assessed MVPA, LPA and SB with all-cause mortality, mortality from cardiovascular disease (CVD) and cardiovascular (CV) events in an elderly French population-based cohort with 18 years of follow-up.

METHODS: PA and SB were assessed by a validated self-administered questionnaire (POPAQ) investigating 5 different types of PA during the 7 previous days. PA was measured in metabolic equivalent of task (MET)-h, which refers to the amount of energy (calories) expended per hour of PA. SB was measured in hour/day. Medical histories and examinations were taken during each clinical visit to determine clinical events. All-cause mortality was established using the same procedure and by checking local death registries.

The relationships between the intensity of PA (light, moderate to vigorous) and mortality and between the periods of SB and mortality or CV events were analyzed by splines and COX models, adjusted for sex and year of birth.

RESULTS: From the 1011 65-year-old subjects initially included in 2001 (60% women), the last 18-year follow-up has been currently completed since 2019. A total of 197 deaths (19.2%, including 77 CV deaths) and 195 CV events (19.3%) were reported. Averages (standard deviation) of MVPA, LPA and SB were respectively 1.2 h/d (0.3), 5.8 h/d (1.1) and 6.6 h/d (2.3). For all-cause deaths, as well as CV deaths, the splines were significant for LPA ($p=0.04$ and $p=0.01$), and MVPA ($p<0.001$ and $p<0.001$), but not for SB ($p=0.24$ and $p=0.90$). There was a significant reduction in CV events when SB was decreasing from 10.9 to 3.3 h/d.

CONCLUSION: The PROOF cohort study shows a clear dose-response between the dose of LPA, MVPA, SB and risk of mortality. These findings provide additional evidence to support the inclusion of LPA in future PA guidelines.

CREATINE KINASE LEVELS IN PLASMA CAN PREDICT MUSCLE TISSUE DAMAGE FOLLOWING ELECTRICAL MUSCLE STIMULATION

KARLOG, K., HØJFELDT, G., HELGE, B.W., DAMGAARD, A., KJÆR, M., MACKEY, A.

BISPEBJERG HOSPITAL

INTRODUCTION: The musculoskeletal system can withstand large loads, however excessive sudden loading and lengthening of the muscle often results in muscle strain injury, the most common muscle injury type (Baker BA, J Sport Rehabil, 2017). Following a muscle injury there will be period of loss of strength and an increase in plasma creatine kinase (CK) (Paulsen et al., Exerc Immunol Rev, 2012), both of which are often used as indirect markers of damage. To directly assess damage, a tissue sample is needed, where post injury muscle biopsies reveal direct markers of damage and the following regeneration. However, it is currently unclear whether there is a correlation between the indirect markers and the direct markers of muscle damage, therefor also if indirect markers of muscle injury can predict the degree of injury.

In this study we examined if the direct and indirect markers of muscle damage are correlated, which would potentially ease the accessibility of evaluating the presence and degree of muscle damage.

METHODS: 40 males aged 18-50 were included in this 8-day study, where repeated electrical stimulated eccentric contractions (EMS) were used to induce a muscle injury in the vastus lateralis muscle. Participants were randomized to EMS in either the dominant or non-dominant leg. Isometric muscle strength and plasma CK were measured prior to EMS as well 2, 4 and 8 days following the injury. Muscle biopsies were taken prior to EMS in the non-stimulated leg and after injury in the stimulated leg as well as 4 and 8 days after injury. The biopsies were analysed for myogenin positive cells and dystrophin negative fibres.

A Spearman Rank's Correlation analyses were done between indirect markers (strength and plasma CK) measured 4 days post EMS and direct markers of muscle damage (dystrophin) and muscle regeneration (myogenin) measured 8 days post EMS.

RESULTS: Following one single bout of EMS the highest drop in strength was a 14 (± 3) % drop in strength seen at day 4. Similarly, the CK peaked 4 days after EMS, with a 122 (± 21 SEM) fold increase in plasma CK and a mean value of 17475 (± 2697 SEM) U/l, ranging from 1070 U/l - 72300 U/l. The direct markers of muscle damage and regeneration peaked 8 days after EMS with 17 (± 3 SEM) % dystrophin negative fibres and 0.18 (± 0.04 SEM) myogenin positive cells/fibre. We found no correlation between loss of strength and neither dystrophin negative fibres nor myogenin positive cells. However, plasma CK at day 4 correlated with both dystrophin negative fibres (P=0.0004) and myogenin positive cells/fibre at day 8 (P=0.0006).

CONCLUSION: To our surprise, plasma CK level measured 4 days after an injury can in this setting predict presence and degree of muscle tissue damage as assessed in a muscle biopsy. This might be due to the high mean level as well as high range of plasma CK found using this EMS protocol.

CHANGES IN TREADMILL AND OVERGROUND RUNNING BIOMECHANICS WHILE LISTENING TO IN-EAR MUSIC: A PILOT, GENDER-BASED STUDY

VENTURA, L.1, MARTINEZ, G.1, ROSSANIGO, R.1, MORRONE, M.1, MELONI, M.1, BOI, A.1, BERTULETTI, S.1, MELIS, F.2, BUSSU, F.2,3, CEREATTI, A.4, DERIU, F.1,5, MANCA, A.1

1 DEPARTMENT OF BIOMEDICAL SCIENCES, UNIVERSITY OF SASSARI; 2 AOU SASSARI, UOC OTORHINOLARYNGOLOGY; 3 DEPARTMENT OF MEDICINE, SURGERY AND PHARMACY, UNIVERSITY OF SASSARI;

4 Department of Electronics and Telecommunications, Politecnico Di Torino, Italy

5 AOU Sassari, Unit of Endocrinology, Nutritional and Metabolic Disorders

INTRODUCTION: Listening to music while running has been proven to have several physiological benefits, including increased endurance and lactate clearance, but also a negative effect, i.e., increased impact forces while running with moderate-to-loud in-ear music, which represent a potential risk factor for injury.

Aim of this study was to test if music listening at moderate-to-high volume may alter running biomechanics.

METHODS: Thirty-six fit, normal hearing volunteers (F:M=18:18; 23±2 years old) performed 400-meter running stints over 2 conditions (no-music; 85-dB music), at 2 velocities (8 and 10 km/h) and 2 settings (indoor, treadmill; outdoor, athletics track).

A wearable system including two magneto-inertial units attached on the feet and connected to 16-elements pressure insoles was employed to estimate the main spatial-temporal parameters of running.

RESULTS: Regarding the trials on the treadmill, compared to no-music, listening to 85-dB music resulted for both sexes in decreased stride duration at 8 km/h (-3.8%, p<0.0001) and 10 km/h (-3.2%; p<0.0001), decreased stance duration at 8 km/h (-9.4%, p<0.0001) and 10 km/h (-9.1%, p<0.0001), and increased stride rate at 8 km/h (+3.7%; p=0.001). Vertical displacement of the center of mass increased only in women at 10 km/h (+8.6%, p=0.041).

Regarding outdoor trials, compared to no-music, music listening resulted, only for women, in increased vertical displacement of the center of mass at 8 km/h (+7.4%, p=0.005). No significant changes were detected in the other spatial-temporal parameters.

CONCLUSION: Listening to moderate-to-loud in-ear music led to significant biomechanical variations in both sexes when running on the treadmill, with shorter and less frequent strides. Conversely, overground running biomechanics was only marginally influenced, and only in women.

Further analyses are needed to unveil the major determinants of the observed biomechanical pattern alteration when running on a treadmill. In particular, looking into the timing of the subcomponents of the stance phase (initial contact, loading response, mid-stance, push) and the related ground reaction forces would allow to infer on differences in running biomechanics related to the setting as well as to gender.

IMPLEMENTING THE CONCUSSION AWARENESS TRAINING TOOL FOR HIGH PERFORMANCE ATHLETES

BABUL, S., TAYLOR, T., TURCOTTE, K., BRUIN, S., KARMALI, K., WETHERELL, A., BLACK, A.

UNIVERSITY OF BRITISH COLUMBIA

INTRODUCTION: Education is an essential component of sport-concussion protocols to improve management and avoid negative consequences associated with participants continuing to play through concussion symptoms. Tailored messaging is an effective way to help change the beliefs of those involved in concussion management. Partnering within government and provincial and national stakeholders, the Concussion Awareness Training Tool (https://cattonline.com/) was developed, which contain a series of evidence-based online educational modules and resources for various audiences including sport, health care, violence, and workplace related concussions. In 2019, partnering with U SPORTS (Canadian university sports-governing body), a new concussion education module with tailored messaging specific to high performance athletes (CATT-A) was created. The aim of this study was to evaluate the implementation of CATT-A among U SPORTS universities in Canada.

METHODS: University administrators and athletic therapists/physiotherapists at all 56 U SPORTS affiliated institutions were provided a link to the CATT-A to share with their athletes including a post-course assessment. A convenience sample of athletes assessed the course on 6 domains using a 5-point Likert scale (i.e. overall assessment, learned something new,

usefulness, engagement, recommendation for other athletes, and likelihood of returning). Certificate completions and requests for mandatory tracking throughout the evaluation period was observed.

RESULTS: A total of 24/56 (42.9%) universities contacted, participated, mandated or shared the tool during the 2020-2021 season. Approximately 1292/5555 athletes who were provided the link to the module, completed the course. In total, 347 athletes completed all the questions in the post course assessment (39.2% male, 59.7% females, 1.2% undisclosed; median (range) age: 19 (17-33)). The majority of athletes rated the course as good or excellent (296/347, 85.30%). In total, 283/347 (81.56%) athletes felt they learned something new, 305/347 (87.90%) felt the course was useful, 226/347 (65.13%) agreed the course was engaging, 258/347 (74.35%) agreed they would recommend the course to other varsity athletes, and 211/347 (60.81%) planned on returning to access content if needed. To date, 21 Canadian U SPORTS universities have implemented the institution email certificate tracking system and there have been over 10,562 certificate completions from 47/56 (84%; median (range): 153 (1-898)) universities.

CONCLUSION: Implementation of the CATT-A in Canadian university high performance athletes was very successful, despite the challenges associated with COVID-19. The CATT-A provides freely accessible, engaging and informative concussion information customized for high performance athletes, with the functionality to track certificate completions as part of a concussion protocol. The tool will be promoted nationally and internationally.

THE POWERLIFTING COMMUNITY'S KNOWLEDGE AND UNDERSTANDING OF THE TRIAD

DOYLE-BAKER, P.

UNIVERSITY OF CALGARY

INTRODUCTION: The Female Athlete Triad (Triad) is characterized by three interrelated components: low energy availability (LEA), menstrual cycle (MC) dysfunction, and low bone mineral density (BMD). Clinical manifestations include eating disorders, amenorrhea (loss of MC), and osteopenia. In the literature, the underrepresentation of female athletes has become a concerning issue along with the limited focus on ethnicity, diversity, and inclusion in sport science research (Langan-Evans et al. 2021). Female athletes in weight-restricted sports, i.e., Powerlifting, are underrepresented and recent research suggests that many coaches of female athletes have little awareness of the Triad, specifically because of misconceptions surrounding symptoms (Mukherjee et al. 2016). Therefore, the large project research goals were to identify these literature gaps while focusing on the community of female powerlifters and their coaches.

METHODS: This studys purpose was to determine knowledge of the Triad in the powerlifting coach community through a Qualtrics survey accessible on desktop and or mobile devices through a bar code or URL code found on a poster. Posters were available at major competitions in Canada, Europe and South Africa. The Female-Athlete Triad prep participation evaluation survey (Panteo 2006) was employed in this cross-sectional design and eligible individuals had coached a least one female powerlifter between the age of 18-39 years.

RESULTS: A total of 48 coaches accessed the survey, 37 consented, and 19 (50%) complete all 31 questions. Most (90%) survey respondents were male (65%), under 32 (90%) years of age, had coached for a minimum of 2 years (range 1 to 5 plus years), and the majority coached female athletes 51%-75% of the time. Forty-three percent (17/22) stated they had heard of the triad and 85% (18/20) were able to correctly name all components. Most coaches had noticed disordered eating (14/20) , 57% (11/19) stated that they used prevention strategies for the triad, and yet coaches were unsure of the suggested intake of calcium for females. Confusion over terms associated with bone mineral density and menstrual dysfunction may have resulted in a number of no responses and may have contributed to some coaches misperceptions related to low body fat, leanness, menstrual irregularity, and bone health in female athletes.

CONCLUSION: In summary, there were no significant differences between gender and the ability of the coach to correctly name the 3 triad components, or correlation between coach gender, age, number of years of coaching, and coach knowledge of the triad components, respectively. Surprisingly these results agree with the 2016 study by Mukherjee and 2006 by Panteo and therefore misperceptions and knowledge gaps still persist in the coaching community, specifically powerlifting. More communication with the powerlifting coaches on nutrition, menstrual history, and bone health is warranted through coaching associations or organizations accessed by coaches.

INVESTIGATING THE EFFECTS OF REPETITIVE SOCCER HEADING ON COGNITIVE AND SENSORIMOTOR PERFORMANCES IN FEMALE SOCCER PLAYERS – A PROSPECTIVE APPROACH

KERN, J., GULDE, P., HERMSDÖRFER, J.

TECHNICAL UNIVERSITY OF MUNICH

INTRODUCTION: Soccer is unique in that players deliberately expose themselves to repetitive head impacts by heading the ball. Although females have been identified as being particularly vulnerable towards these types of head impacts [1], previous studies have mainly focused on male populations and, moreover, employed retrospective research designs. Therefore, our aim was to prospectively investigate the potentially adverse effects of heading on cognitive and sensorimotor performance in female soccer players.

METHODS: A total of 27 female soccer players (22.2 ± 4.2 years) and 15 female athletes participating in non-contact sports (23.2 ± 3.0) took part in the study. We used an extensive test battery to assess subjects' cognitive and sensorimotor skills at baseline as well as one and a half soccer seasons (39 matches) after the beginning of the study. Moreover, soccer players took part in an additional assessment after the end of the first soccer season. Throughout the whole period, soccer matches were video-recorded and footage analyzed to obtain players' individual number of headers, which was used

to divide them into high and low exposure groups. ANOVAs were used to assess differences in test performances between groups over time. Further, a potential association between heading exposure and cognitive or sensorimotor performance changes was assessed by means of correlation and multiple linear regression analyses.

RESULTS: While conducted ANOVAs showed no unequivocal evidence for negative consequences of soccer heading, we found statistically significant interaction and main effects pointing towards adverse effects of heading on some aspects of fine motor control ($p < 0.01$), which were, in part, confirmed by correlation and multiple linear regression results. The latter revealed that greater heading exposure was linked to negative changes in fine motor performance as assessed by writing tasks ($p = 0.02$ and $p < 0.01$) as well as negative alterations in postural control ($p < 0.01$). However, most performance changes were not related to the number of performed headers.

CONCLUSION: While our findings must be confirmed in larger-scale studies, they, in contrast to previous reports [2], suggest that a greater number of headers might be associated with sensorimotor performance changes. Moreover, the present results are the first to point towards a cumulative effect of soccer heading on both postural and fine motor control in female soccer players.

OP-SH11 Mindfulness

A SYSTEMATIC REVIEW OF SELF-COMPASSION CORRELATES IN COMPETITIVE SPORTS

MICHALCZYK, M., ZHANG, S.

UNIVERSITY OF DERBY

Background: Compassion refers to the sensitivity to suffering in self and others with a commitment to try to alleviate and prevent it. It is linked to one's emotions, motives and competencies to be supportive, kind, helpful and understanding. To date, researchers have considered various benefits in athletes by adopting a self-compassionate mind, such as adaptive psychophysiological responses to stress, greater mental well-being, and superior coping under challenging performance scenarios. However, barriers exist when incorporating compassion in competitive sport (e.g. fear of losing personal standards), and there is a lack of synthesis of what influences athletes' self-compassion (SC) and what SC can facilitate athletes in competitive sport. Therefore, we systematically gathered quantitative evidence about correlates of SC for an up-to-date review of SC in competitive sport.

Method: We identified 108 research articles via a systematic search of databases (Web of Science, n = 31; Scopus, n = 38; SPORTDiscus, n = 14; Psychinfo, n = 25). 24 duplicates were removed, whilst a further 39 studies were excluded based on abstract and title screening. The 48 remainings with full-text articles were further assessed for eligibility, of which 30 papers were removed based on the set exclusion criteria (i.e., qualitative research, n = 7; irrelevant population, n = 9; irrelevant context, n = 11, not passing the quality assessment, n = 3). We retained 18 published research for the final review, which involves 14 cross-sectional survey studies, 2 laboratory-based studies, and 3 longitudinal survey studies.

Results: Greater self-esteem (strong correlations), mindfulness (moderate to strong correlations), lower-level sense of inadequate self (strong correlations), fewer concerns over mistakes (moderate to strong correlations), and lower self-criticism (moderate to strong correlations) were key predictors of SC in competitive athletes. Reduced sport-specific stress and internalised shame, mitigated fear of failure, and enhanced self-regulation (all strong correlations) were key outcomes associated with SC in competitive sport. Furthermore, SC manifested indirect effects on decreased grit, enhanced self-regulation, superior goal progress, and more positive affect under various sport situations. It also underpinned the mindfulness-burnout and the mental toughness-menatal health relationships, as well as moderating (mitigating) negative effects of threat appraisal, masculinity, and sport-specific daily stress on various outcomes facilitative to competitive athletes.

Conclusion: SC is associated with a variety of facilitative psycho-behavioural factors in athletes and plays a vital role in competitive sport. Researchers and practitioners would do well to disseminate the benefits of SC to competitive athletes and deliver interventions to promote the use of compassion and overcome its related fears. Future research should establish more evidence on the performance effect.

EVALUATION OF SPORTS-SPECIFIC MINDFUL PROGRAM (SSMP) FOR ELITE ARCHERS

LO, K.K., TSE, M.Y., CHUNG, W.Y., LAW, P.S., SUN, F.

THE HONG KONG METROPOLITAN UNIVERSITY, THE EDUCATION UNIVERSITY OF HONG KONG, THE UNIVERSITY OF HONG KONG

Introduction

Mindfulness is trainable with a structured program and regular practice for better self-awareness, attentional control, and emotional regulation to improve athletic coping skills under stressful sports competitions [1]. The application of Mindfulness-Based Intervention (MBI) to elite sports performance has recently become very popular in precision sports and has a positive effect on shooting and dart throwing but no consistent findings in archery. This study aimed to evaluate the effectiveness of a newly developed Sports-Specific Mindful Program (SSMP) with eleven mindfulness-based intervention sessions and one sports-specific simulated competition session to enhance archers shooting performance, mindfulness levels, and flow states with decreasing anxiety levels.

Method

A wait-list control design was used in the study. The participants first waited for 12 weeks and received the 12 weeks of the Sports-Specific Mindful Program (SSMP). Informed consent and demographic information were gathered at baseline. Twelve participants from the Hong Kong Elite Archery Team completed shooting performance competitions [2], the computerized Five Facet Mindfulness Questionnaire (FFMQ) [3], the computerized Competition State Anxiety Inventory-2 Questionnaire (CSAI-2) [4], Short Dispositional Flow State (SDFS) [5] at baseline, pre-intervention (12th weeks), and post-intervention (24th weeks). Participants views of the SSMP programs acceptability were measured post-intervention. ANOVAs with repeated measures were used to compare the intervention effects across the time points (baseline, pre-intervention, and post-intervention). Bonferroni test as a post hoc test was used if significant differences were found between the time points.

Result

The repeated measure analysis showed that SSMP had a positive effect on shooting performance ($p<0.001$). Furthermore, there was a significant increase in mindfulness level in the total score of FFMQ ($p=0.016$), and flow state ($p=0.014$). On a ten-point Likert scale, the mean enjoyment of the Sports Specific Mindful Program (SSMP) was 7.9, and the mean mindfulness practice frequency was 3.1 times/week. The athletes' favorite SSMP sessions were the sports-specific simulate competitions, with the highest the average enjoyment of 8.3 in the session.

Conclusion

The positive evaluations suggest that Sports-Specific Mindful Program (SSMP), with the sports-specific simulated competition session, is an acceptable and feasible intervention to enhance shooting performance, mindfulness levels and flow states of archers. Future study is suggested to include more subjects and explore their experience on how they apply mindfulness to enhance their experience in sports performance.

THE PSYCHOLOGICAL STATE AND MENTAL HEALTH OF ELITE ADOLESCENT ATHLETES: THE MEDIATION EFFECT OF RESILIENCE

CHANG, K.T.1, WANG, C.H.1, YANG, C.T.1,2

1.NATIONAL CHENG KUNG UNIVERSITY 2.TAIPEI MEDICAL UNIVERSITY

The mental health of adolescent athletes is important for their performance and career growth as they experience both physical and psychological development. Research has shown that stable psychological state helps athletes maintain mental health during stressful situations. The Peace of Mind (PoM) Index is a measure of psychological well-being in Asian cultures. It encompasses a state of low arousal, happiness, harmony, and an overall feeling of peacefulness within oneself. High PoM individuals are characterized by a stable emotional state, which allows them to quickly readjust their psychological condition without experiencing significant fluctuations. Hence, psychological resilience, the ability to maintain psychological stability and return to normal during adverse situations, is believed to play a significant role in the relationship between psychological state and mental health. To clarify the role of the resilience, we hypothesize that PoM will affect the mental health of adolescent elite athletes via resilience. In this study, 31 male adolescent soccer players (mean age: 16.61 ± 0.84 years) were recruited. The psychological state, resilence, and mental health were measured with POM, Resilience Scale for Adults (RSA), and Becks Depression Inventory scale (BDI-II), respectively. Using the bootstrapping method (with 5000 times) of Process 4.2 SPSS macro by Hayes (2022), the findings of the simple mediation analysis indicated that the indirect effect of PoM on BDI-II through RSA was statistically significant and in a negative direction. The bootstrapping result also confirmed the Sobel test, showing that the indirect effect was significant with the 95% confidence interval not including zero [-5.11 - -0.07]. The results emphasize the vital role of resilience in maintaining a stable psycho-

logical state and low levels of depression among elite adolescent athletes. Specifically, elite adolescent athletes with high resilience are found to possess a more stable psychological state and exhibit lower levels of depression. Future research can explore intervention for enhancing psychological resilience, thus improving the mental well-being of adolescent athletes.

EFFECTS OF AN 8-WEEK OF BRIEF MINDFULNESS MEDITATION COMBINED WITH A RUNNING PROGRAM ON MINDFULNESS SKILLS AND WELL-BEING OF TRAINED RUNNERS

CARTON, A.1, BARBRY, A.2,3, BERNIER, M.5, OVIGNEUR, H.3, COQUART, J.2

1UNIV. ARTOIS, UNIV. LILLE, UNIV. LITTORAL CÔTE DOPALE, ULR 7369 - UREPSSS - UNITÉ DE RECHERCHE PLURIDISCIPLINAIRE SPORT SANTÉ SOCIÉTÉ, LIÉVIN, FRANCE. 2UNIV. LILLE, UNIV. ARTOIS, UNIV. LITTORAL CÔTE

INTRODUCTION

The influences of Mindfulness Meditations (MM) on mindfulness skills in athletes are recent.1,2 Moreover, these studies1,2 proposed long time of MM at a low physical activity intensity level.3 We proposed here to approach new perspectives of reflections on this subject by evaluating the influences of Brief Mindfulness Meditation (BMM) combined with a running program with high intensity on mindfulness skills and well-being in runners.

METHODS

Fifty-five trained athletes were randomized in a control group or a BMM group following the same running training program. The Mindfulness Inventory for Sport (MIS) was assessed at 3 different times: baseline (T0), 4 (T4) and 8 weeks (T8). It includes 3 subscales: (a) awareness; (b) acceptance and (c) refocusing. The Diagnofeel® measured the manifestations and regulations of well-being at T0 and T8. There was 10 subscales: manifestations (4): leisure activities, joy, social relations (SR) ; regulations (6) (AP, isolation, pleasures, taking distance, SR and problem solving). A 2-way repeated measures Analysis of Variance (ANOVA) was conducted for each subscale. A Bonferroni post-hoc test was realized when significant differences were noted.

RESULTS

No time*group interaction is observed on awareness and acceptance. However, according to refocusing, an increase is discerned only for BMM between T0 andT4 ($p = 0.036$), T4 andT8 ($p = 0.027$) and T0 and T8 ($p = 0.002$). Moreover, intergroup comparisons suggest that BMM group had a (better level of refocusing compared to control group only at T8 ($p = 0.016$).

For the well-being, an increase of SR (manifestation) is noted between T0 and T8 for the BMM group only ($p = 0.045$). Pleasure also increased for BMM group between T0 and T8 ($p = 0.042$) which had also a greater level of pleasure compared to control group at T8 ($p = 0.01$).

DISCUSSION

The most powerful results of this new program are on refocusing. When athletes faced with the intensity of physical effort, they were able to refocus their attention on the present moment and stay engage in the intensity of the effort. From the well-being, the increase of SR and pleasure for the BMM group could also be associated with the ability to refocus in the present moment and to restore their well-being. The implementation of a BMM program seems having an impact on the athlete's ability to refocus. These benefits also seem to extend beyond a sporting context.More studies with larger sample sizes could be conducted to confirm these results.

EFFECTIVENESS OF AN ONLINE ACCEPTANCE AND COMMITMENT THERAPY-BASED PROGRAMME IN REDUCING PERFECTIONISM IN FEMALE SOCCER PLAYERS

WATSON, D.R., HILL, A.P., MADIGAN, D.J., DONACHIE, T.C.

UNIVERSITY OF BOLTON

Introduction

Perfectionism contributes to a range of psychological and emotional difficulties in athletes (e.g., burnout and depressive symptoms). However, there are few studies that have examined approaches to reduce perfectionism and help athletes deal with these negative effects. In the current study, we did so by evaluating the effectiveness of a novel online Acceptance and Commitment Therapy (ACT)-based intervention in adult female soccer players.

Methods

Using a randomized control trial (RCT), eighty-one female soccer players (M age = 24.28 years, SD = 6.77) were randomly allocated to either an intervention group (n = 41) or a waitlist control group (n = 40). The intervention group had access to set of online ACT-based modules for 8-weeks. Participants completed measures of trait perfectionism, perfectionistic cognitions, and pre-competition emotions pre-intervention and post-intervention.

Results

A 2 (group) x 2 (time) ANOVA revealed significant interaction effects for trait perfectionism, perfectionistic cognitions, and pre-competition emotions. Following the intervention, the two groups displayed significant mean differences for trait perfectionism (perfectionistic strivings, personal standards, striving for perfection, self-orientated perfectionism, perfectionistic concerns, concerns over mistakes, negative reactions to imperfections, and socially-prescribed perfectionism), perfectionistic cognitions, and all pre-competition emotions (anxiety, dejection, anger, happiness, and excitement). Largest effects were for negative reactions to imperfections and perfectionistic cognitions. Furthermore, the number of hours spent on the modules and number of modules completed were significantly correlated with observed improvements.

Discussion

The findings suggest that online ACT-based interventions may be an effective and viable way to reduce perfectionism in female soccer players. Therefore, this approach should be considered by sport psychologists, coaches, and organisations to support perfectionistic athletes.

DOES HEART RATE VARIABILITY MEDIATE THE ASSOCIATION BETWEEN CHRONIC STRESS, CARDIORESPIRATORY FITNESS, AND WORKING MEMORY MAINTENANCE?

LOOSER, V.N., LUDYGA, S., GERBER, M.

UNIVERSITY OF BASEL

INTRODUCTION: Young adulthood is a demanding developmental stage during which individuals encounter numerous physical and psychosocial stressors (Malter Cohen, Tottenham, & Casey, 2013). High degrees of chronic stress elicit detrimental effects on various physical and mental health outcomes (Malter Cohen et al., 2013). For working memory in particular, the sensitivity to acute stress is well-known, whereas insights into the consequences of prolonged stress exposure are lacking. Empirical evidence supports the assumption that cardiorespiratory fitness has the potential to buffer potential harmful effects of chronic stress on working memory performance (Loprinzi & Frith, 2019). According to the Neurovisceral Integration Theory, shared neurophysiological areas are involved in cardiac autonomic control as well as the modulation of attentional and emotional regulatory processing (Forte, Favieri, & Casagrande, 2019). Therefore, heart rate-variability (HRV) might be a physiological correlate mediating the association between chronic stress, cardiorespiratory fitness, and working memory maintenance.

METHODS: The present study investigates the mediating role of resting heart rate-variability on the association between chronic stress, cardiorespiratory fitness, and working memory maintenance in young healthy adults. Working memory maintenance was assessed in N= 115 healthy adults (48% female) aged 18 to 35 years (M = 24.1, SD = 3.8) using a modified version of the Sternberg task with low (3 items) and high cognitive load (6 items). Additionally, maximal oxygen consumption (VO2max) was estimated using the Åstrand test. Resting HRV was recorded using electrocardiography and the LF/HF ratio was extracted for mediation analyses.

RESULTS: Path analysis revealed a significant association between cardiorespiratory fitness and accuracy on high cognitive load trials, but not on trials with low cognitive load. Levels of perceived chronic stress showed a trend for a positive association with working memory maintenance, independently of cognitive load. The pattern of results remained unchanged after introduction of HRV as a mediator.

CONCLUSION: Results indicate that cardiorespiratory fitness influences working memory maintenance during young adulthood. However, this association cannot be explained by vagal influences on memory processing driven by the autonomic nervous system.

EFFECT OF A THREE-MONTH PHYSICAL ACTIVITY INTERVENTION ON BALANCE, EXERCISE CAPACITY AND MAXIMAL LOWER LIMB STRENGTH IN PATIENTS WITH LOWER EXTREMITY ARTERY DISEASE – PRELIMINARY RESULTS.

GUILLERON, C.1,2, DURAND, S.2, KERN, L.3, DESMARRES, M.2,3, FAYOUX, M.2,3, MOREAU, A.2,3, NEVEUX-BRECHETEAU, C.3

1 : IFEPSA, FACULTÉS LIBRES DE L'OUEST (UCO), LES PONTS-DE-CÉ, 2 : LE MANS UNIVERSITÉ, MOVEMENT – INTERACTIONS – PERFORMANCE LABORATORY, UR 4334, LE MANS, 3 : CENTRE HOSPITALIER LE MANS, LE MANS

INTRODUCTION: Lower limb artery disease (LEAD) is characterized by lower limbs arteries atherosclerosis. This can lead to walking pain and exercise intolerance called intermittent claudication (IC). Cardiovascular diseases progression and gravity are associated to lower limb strength and balance impairment. However, these aspects were poorly observed in studies on LEAD with patients presenting IC. Additionally, we showed that the anatomical level of ischemia in lower limbs affects gait parameters (Guilleron et al., 2021). When supervised exercise therapy (SET) is implemented for these patients (most recommended treatment for IC), exercises are non-specific to the level of ischemia. Therefore, this study seeks to compare these parameters in patients presenting IC following either a global or a focalized SET.

METHODS: Pain onset (POWD) and maximal walking distance (MWD; using strandness treadmill testing), unipedal balance (time), one minute sit to stand test (OneSTST) and maximal isometric strength of tibialis anterior (TA), rectus femoralis, triceps surae and gluteus maximus were recorded in 18 patients (67+/- 6 years) presenting IC during initial, intermediate and final evaluations of a three-month SET (three times a week walking and muscular trainings). Patients were randomized into two groups according to muscular training: global or specific to the pain localization (calf, thigh or buttock).

RESULTS: Significant differences were found between initial and final evaluations for POWD (+107%, p=0,002), MWD (+49%, p=0,012), unipedal balance time (+59%, p=0,002), OneSTST (+13%, p=0,023) and force of TA in both groups (+19%, p=0,05). MWD (+64%, p=0,07), OneSTST (+10%, p=0.07) trend to be more improved in groups with localized muscular training.

CONCLUSION: Our results on POWD and MWD are consistent to previous study implemented SET for patients presenting IC (Schieber et al., 2020). We do not find significant effect on lower limb strength except for TA.

Our study reveals the effect of SET for patients presenting IC on balance and OneSTST. We observed improvements for unipedal balance and OneSTST, a marker for overall exercise capacity (Bohannon & Crouch, 2019). These improvements seem to be greater in patients performing localized muscular training.

A three-month SET allows patients to walk longer and longer without pain, combined to better balance and exercise capacity. This should improve their quality of life and reduce risk of falls. In addition, localized muscular training appears to be more efficient than global training, however, we need to include more patients to confirm this trend.

IMPACT OF TWO TYPES OF PHYSICAL EXERCISE PROGRAMS AND NUTRITIONAL COUNSELLING ON CARDIOVASCULAR RISK IN TYPE 2 DIABETES MELLITUS

REBOLLO-RAMOS, M., MARÍN-GALINDO, A., MONTES-DE-OCA-GARCÍA, A., GONZÁLEZ-MARISCAL, A., CABEZA-DE-VACA-ÁVILA, L., COSTILLA, M., PONCE-GONZÁLEZ, J.G., CASALS, C.

UNIVERSITY OF CADIZ

INTRODUCTION: The prevalence of type 2 diabetes mellitus (T2DM) and obesity are increasing rapidly worldwide and increasing the risk of cardiovascular diseases (1). Nutritional education and exercise programs are used to improve cardiovascular health (2). The aim is to study the effect of the type of exercise training and nutritional counselling on cardiovascular risk and the management of T2DM.

METHODS: The study is a controlled clinical trial of 12 weeks of intervention. This is the first batch of 62 adults with T2DM and obesity (37 men; 55.90±7.28 years old) randomized into 6 groups according to the nutritional counselling (Diet vs. NoDiet groups) and the physical exercise program which consisted of high-intensity interval training (HIIT) or moderate-intensity continuous training (MICT) or maintaining their inactive levels (INACT) as controls. Thus, participants were allocated into Diet+HIIT, Diet+MICT, Diet+INACT, NoDiet+HIIT, NoDiet+MICT, and NoDiet+INACT. Weight, body mass index, fat percentage, visceral fat, waist circumference (Wc), blood pressure, glycosylated haemoglobin (GhA1c), cholesterol and triglycerides were measured. Delta was calculated as differences between post and pre intervention. ANOVA test and DMS were applied with statistical significance set at $p<0.05$.

RESULTS: The cardiovascular risk significantly differed after the intervention program in the fat percentage (p=0.008), visceral fat (p=0.002), Wc (p=0.009) and GhA1c (p=0.049). There was a difference in the fat percentage between Diet+MICT and NoDiet+INACT (-2.153±0.779;p=0.008), Diet+MICT and MICT (-1.744±0.779;p=0.029), HIIT and Diet+INACT (2.167±0.934;p=0.024), Diet+INACT and INACT (-2.562±0.779;p=0.002).

Visceral fat was statistical significant in Diet+MICT and NoDiet+INACT (-0.992±0.447;p=0.031), HIIT and Diet+INACT (1.417±0.536;p=0.011), MICT and CONTROL+EDU (1.644±0.447;p=0.001), Diet+INACT and NoDiet+INACT (-1,826±0.448;p=0.000). The Wc difference between Diet+HIIT and NoDiet+INACT (-4.768±2.156;p=0.031), Diet+MICT and

NoDiet+INACT (-4.369±2.059; p=0.038), MICT and Diet+INACT (6,388±2.059;p=0.003), HIIT and NoDiet+INACT (-5.32±2.503; p=0.038). Data showed differences in the GhA1c between Diet+HIIT and MICT (-0.838±0.336;p=0.016), Diet+HIIT and NoDiet+INACT (-0.787±0.319;p=0.017), MICT and Diet+INACT (0.778±0.328;p=0.022), Diet+INACT and NoDiet+INACT (-0.727±0.311;p=0.024).

CONCLUSION: Both interventions of physical exercise and nutritional counselling improve cardiovascular markers of adiposity and GhA1c independent of each group. The nutritional intervention was more effective in the fat percentage and visceral fat decreases, even in the inactive groups. However, it is important that the GhA1c improves in the Diet+HIIT group with respect to other groups.

CURRENT IMPLEMENTATION AND BARRIERS TO USING BLOOD FLOW RESTRICTION TRAINING: INSIGHTS FROM A SURVEY OF ALLIED HEALTH PRACTITIONERS

SCOTT, B.R.1, MARSTON, K.J.1, OWENS, J.2, ROLNICK, N.3, PATTERSON, S.D.4

1 MURDOCH UNIVERSITY; 2 OWENS RECOVERY SCIENCE; 3 CUNY LEHMAN COLLEGE, 4 ST MARY'S UNIVERSITY

INTRODUCTION: Blood flow restriction (BFR) exercise improves muscular and cardiovascular fitness without high mechanical loads. As BFR training is most useful for individuals who cannot tolerate the mechanical demands of vigorous activity [1], research is needed to determine how this technique is implemented by allied health professionals working with such populations. Therefore, this survey-based study investigated how practitioners use BFR exercise for clinical or older populations, and the barriers preventing the prescription of BFR.

METHODS: An online survey was disseminated globally to allied health practitioners, with data from 397 responders included in analyses. Responders who had prescribed BFR exercise (n=308) completed questions about how they implement this technique. Those who had not prescribed BFR exercise (n=89) provided information on barriers to this technique, and a subset of these responders (n=22) completed a follow-up survey to investigate how these barriers could be alleviated.

RESULTS: Most practitioners prescribe BFR exercise for musculoskeletal rehabilitation (91.6%), with cuff pressure relative to arterial occlusion pressure (81.1%) and implemented with low-intensity resistance (96.8%) or aerobic exercise (42.9%). Most practitioners screen for contraindications (68.2%), though minor side-effects including muscle soreness (65.8%) are common. The main barriers to using BFR are lack of equipment (60.2%), insufficient education (55.7%) and safety concerns (31.8%). These could be partly alleviated by affordable and convenient training on safe applications and benefits of BFR (n=20).

CONCLUSION: Prescription of BFR for clinical and older cohorts mainly conforms with current guidelines [1], which is important considering the potentially increased risk for adverse events in these populations. Despite this, minor side-effects to BFR were reported with greater frequency than in previous surveys [2], likely because of the specific client demographic targeted in this research. To reduce the likelihood of BFR side-effects, practitioners should gradually implement BFR exercise by increasing cuff pressures and exercise volumes over time. Barriers prevent broader utility of BFR training, though some may be alleviated through well-developed BFR educational offerings to train practitioners. Accessible education is needed to train practitioners on safe applications of BFR.

OP-PN29 Caffeine

DO CAFFEINE AND MENSTRUAL CYCLE PHASE AFFECT PHYSICAL PERFORMANCE IN A 5-KM CYCLE TIME TRIAL IN WOMEN? PRELIMINARY DATA FROM A PARALLEL, DOUBLE-BLIND, PLACEBO-CONTROLLED CLINICAL TRIAL.

MENDES, G.L., OLIVEIRA, H.A., DOS REIS, A.S., NAKAMOTO, F.P., ALVARES, L.A., FERREIRA, R.E.S., DOS SANTOS QUARESMA, M.V.L.

CENTRO UNIVERSITÁRIO SÃO CAMILO

INTRODUCTION: Studies involving women are scarce, mostly due to the influence of the different menstrual cycle phases on several physical and physiological parameters. Caffeine (CAF) is one of the most studied ergogenic supplements and its effects on exercise performance in different menstrual cycle phases are limited to endurance exercises. The aim of this study is to verify the effect of CAF supplementation on exercise performance of women in different menstrual cycle phases.

METHODS: Inclusion criteria: physically active healthy women aged 18-35 years; normal menstrual cycle for at least 4 months; IMC 18.5-24.99 kg/m2. Exclusion criteria: diabetes mellitus (HbA1 ≥ 6,5%) or other diseases which affect men-

struation; women taking supplements; women using hormonal contraceptive methods; smokers; and women consuming > 30.0g of alcohol/day. Subjects were randomly (randomizer.org) assigned to one of the 2 groups: CAF supplementation (GCAF) or Placebo (GPLA) (allocation ratio 1:1). Laboratory visit 1: health and sociodemographic questionnaire, resting energy expenditure (REE) assessment (indirect calorimetry; K5, COSMED®), body composition assessment (bioelectrical impedance analysis; model 450®, Biodynamics), and cycle ergometer familiarization. Visit 2 (follicular or luteal phase): planned meal + 30-minute interval + CAF or PLA supplementation + 1-hour interval + 5-km cycling time trial. Visit 3: identical to visit 2 for a different menstrual cycle phase (follicular or luteal phase). Data were analyzed using Jamovi® 2.3. version. Repeated measures ANOVA with post-hoc Tukey test were performed. Data are described as mean and SD.

RESULTS: Subject characteristics (n = 12): BMI (kg/m2): GCAF 22.38 (3.53), GPLA 21.99 (1.46); body fat (%): GCAF 29.68 (4.71), GPLA: 25.1 (2.53). The test duration (min) in the follicular phase was 9.97 (1.46) for GPLA and 10.52 (0.85) for GCAF, with no difference between groups (p = 0.184; d = 0.44). Likewise, test duration (min) in the luteal phase was 8.66 (0.48) for GPLA and 9.73 (0.39) GCAF, with no difference between groups (p = 0.201; d = 2.46). Test duration did not differ between menstrual cycle phases in GPLA (p = 0.964) and GCAF (p = 0.635). Exercise-induced energy expenditure (ExEE) did not differ between groups: follicular phase, GCAF 98.13 (4.41) kcal; GPLA 104.7 (10.44) kcal (p = 0.241; d = 0.78); luteal phase, GCAF 102.5 (2.67) kcal; PLA 114.3 (3.32) kcal (p = 0.159; d = 4.06). ExEE did not differ between menstrual cycle phases in GPLA (p = 0.981) or GCAF (p = 0.406). Mean respiratory quotient (RQ) did not differ between groups in the follicular phase: GCAF 1.03 (0.06); GPLA 0.94 (0.03) (p = 0.593; d = 1.8) and in the luteal phase: GCAF 1.01 (0.03); GPLA: 0.92 (0.02) (p = 0.137; d = 2.93). There were no differences in RQ between the cycle phases in GPLA (p = 0.936) and GCAF (p = 0.939).

CONCLUSION: Our preliminary data suggest that caffeine may not be ergogenic in a 5-km cycling time trial, and that the menstrual cycle does not affect physical performance.

EFFECTS OF CAFFEINE ON SALIVA IMMUNOGLOBULIN A IN RESPONSE TO PROLONGED INTERMITTENT EXERCISE IN FEMALE TEAM-SPORT ATHLETES

DULSON, D.K., RUTHERFORD-MARKWICK, K., ALI, A.

NEWCASTLE UNIVERSITY

INTRODUCTION: Female team-sport athletes, like their male counterparts are often required to train and compete in the evening. Consuming caffeine for potential training and competition advantage later in the day has been shown to impact female athletes' subsequent sleep quality (1). Caffeine has also been shown to modulate a number of immune functions and transiently increase saliva immunoglobulin (Ig) A in male athletes following prolonged exercise (2). Yet to date, little to no work has been conducted on female athletes. As such, the aim of this study was to investigate the effect of caffeine on saliva IgA in response to prolonged intermittent exercise in female team-sport athletes

METHODS: In a double-blind repeated-measures crossover design, ten healthy eumenorrheic female team-sport athletes [mean (SD): 24 (4) years; body mass 59.7 (3.5) kg; VO2peak 50.0 (5.3) mL/kg/min], currently taking a monophasic oral contraceptive (OC) (30 ug Ethinyloestradiol and 150 ug Levonorgestrel) completed two experimental trials during days 5-8 and 18-22 of their OC cycle. Participants reported to the lab at 18:00 h, at which time an unstimulated pre-supplement saliva sample was taken. Participants then ingested 0 (placebo, PLA) or 6 mg/kg BM of caffeine (CAF) taken in the form of gelatin capsules and rested in the lab for 1 h before providing a pre-exercise saliva sample. Participants then began 90 min intermittent running on the treadmill, which consisted of six x 15 min blocks designed to simulate the activity patterns of a football match. Further saliva samples were obtained immediately after and 30 min after exercise cessation. Saliva IgA, alpha-amylase and cortisol were analysed using commercially available kits. Data were examined using a two-way ANOVA with repeated measures design. Any significant data were assessed post-hoc using paired samples t-tests, with Holm-Bonferroni adjustments. Statistical significance was accepted at $P < 0.05$.

RESULTS: There was a significant trial x time interaction ($p<0.05$) for saliva IgA concentration. Caffeine significantly reduced the concentration of saliva IgA compared to placebo 30min post-exercise [CAF: 40.8 (19.5) v PLA: 91.5 (66.6) mg/L, $p<0.05$). Saliva alpha-amylase concentration was elevated above pre-supplement values at 30min post-exercise [time effect $p<0.05$; pre-supplement: 898 (354) v 30min post-ex 1217 (589) U/mL]. Saliva cortisol concentration did not appear to be influenced by caffeine or exercise ($p>0.05$).

CONCLUSION: These findings suggest that caffeine ingestion prior to prolonged intermittent exercise in female team-sport athletes (taking monophasic oral contraceptives) decreases the concentration of saliva IgA 30 min into recovery. Given the drop in one of our front-line defence mechanisms and the published negative impact evening caffeine consumption can have on subsequent sleep quality, more research in this area is needed to better determine the possible illness risk this practice could pose.

PRE-EXERCISE SUPPLEMENTATION OF 5 MG/KG CAFFEINE INCREASES HEAT PRODUCTION AND CORE TEMPERATURE WITHOUT CHANGING EXERCISE TOLERANCE IN THE HEAT: A DOUBLE-BLIND, PLACEBO-CONTROLLED TRIAL

WALDRON, M., JOHN, K., PEEL, J., PAGE, J., KATHURIA, S., HEFFERNAN, S., AITKENHEAD, R., JEFFRIES, O.
SWANSEA UNIVERSITY, UNIVERSITY OF CANBERRA, NEWCASTLE UNIVERSITY

INTRODUCTION: Endurance exercise in the heat increases thermoregulatory and cardiometabolic strain compared to temperate conditions, thereby reducing exercise tolerance. Whilst caffeine supplementation is often reported to enhance endurance performance, its ergogenic properties are questionable during exercise in the heat, where caffeine may even exacerbate thermal strain. However, the results of studies on this topic are inconclusive and the reasons for potential adverse effects are unclear. It is possible that the control of exercise intensity is partly responsible for this. Therefore, we aimed to evaluate the effects of pre-exercise caffeine (5 mg/kg) on time to exhaustion (TTE) and thermo-physiological responses at an intensity equivalent to the gas exchange threshold (GET) in a hot environment.

METHODS: Following ethical approval, 12 recreationally active males consented to participate in the study. Participants performed fixed-intensity cycling at the GET in a controlled thermal chamber (35°C & 40% relative humidity) until exhaustion, 1-h after supplementing with caffeine (5 mg/kg) or a placebo. Supplements were double-blinded and trials were separated by 72-h. Exercising thermo-physiological measures included: pulmonary gas exchange, core and skin temperatures, whole body sweat rate, heart rate, perceived exertion and thermal sensation. Heat production and evaporative heat transfer were determined using partitional calorimetry. Post-ingestion venous blood was analysed for plasma caffeine concentrations. Two-way analyses of variance were used to determine the effect of condition (caffeine vs. placebo) and time (10% to 100% epochs) on all thermo-physiological responses, while paired t-tests were used to assess condition effects on TTE. Data are reported as mean±SD.

RESULTS: There was no difference in TTE between the conditions ($p = 0.251$; caffeine 28.5 ± 8.3-min vs. placebo 29.9 ± 8.8-min). The caffeine condition had a higher concentration of plasma caffeine relative to placebo ($p < 0.001$). Compared to placebo, there was an increased oxygen uptake ($p = 0.003$; 2,883 ± 219 mL/min vs. 2,678 ± 190 mL/min), heat production ($p = 0.004$; 396 ± 37 W vs. 366 ± 32 W), evaporative heat transfer ($p = 0.006$; 341 ± 73 W vs. 289 ± 42 W), yet lower estimated skin blood flow ($p < 0.001$; 4.5 ± 0.8 L/min vs. 5.1 ± 0.9 L/min), after caffeine ingestion. This resulted in a higher mean core temperature in the caffeine condition ($p = 0.013$; 38.09 ± 0.37°C vs. 37.87 ± 0.34°C).

CONCLUSION: There was no ergogenic effect of caffeine ingestion prior to endurance exercise in the heat, with caffeine increasing heat production and core temperature. Whilst caffeine increased the capacity for evaporative heat transfer, estimated skin blood flow was reduced. These combined results demonstrate that ingestion of caffeine negatively influenced thermoregulation in the heat when exercise was controlled at the GET. These findings question the use of caffeine supplementation for those performing endurance exercise in the heat.

CAFFEINE IMPROVES 30-MIN TIME TRIAL RUNNING PERFORMANCE AFTER ONE NIGHT OF SLEEP DEPRIVATION

MARTINEZ-GONZALEZ, B.1, MARCORA, S.M.2
UNIVERSITY OF BOLOGNA

INTRODUCTION: Caffeine is one of the most popular substances used by athletes from a wide variety of sporting disciplines due to its ergogenic effects [1]. The use of caffeine to increase wakefulness has been studied extensively [2]. The purpose of the study was to investigate the effects of caffeine on endurance performance after one night of sleep deprivation.

METHODS: Ten subjects visited our laboratory on three separate occasions: a preliminary visit to determine maximal oxygen consumption (VO2 max) and to familiarise with the protocol, equipment and scales used; and two experimental visits, in a randomised order, a pill containing 6 mg/kg of caffeine or placebo were given to the participants after a night of sleep deprivation. The Alpha Attenuation Test (AAT), the Psychomotor Vigilance Test (PVT), and the Stroop Test (ST) were administered to assess sleepiness, vigilance, and inhibitory control, respectively. Participants run for 30 minutes at a constant workload of 60% VO2 max (CWL) followed by a 30-minute time trial (TT). During the running bouts, cardiopulmonary responses, blood lactate (BLa), ratings of perceived exertion (RPE), and ratings of feelings (FS) were measured.

RESULTS: Compared to placebo, subjective sleepiness was lower in caffeine ($p = 0.011$). No differences were found in AAT ($p = 0.784$). Caffeine enhanced PVT performance (reaction time, $p = 0.001$; number of lapses, $p = 0.008$), and ST performance (incongruent stimuli: reaction time, $p = 0.008$; accuracy, $p = 0.022$). During CWL, RPE was lower in caffeine condition ($p = 0.034$). Caffeine increased minute ventilation (VE, $p = 0.009$) and tidal volume (VT, $p < 0.001$). Caffeine improved TT performance ($p = 0.008$) by 319 m (5.54%). Consequently, running speed was higher in caffeine ($p = 0.008$). At minute 10, RPE was lower in caffeine than in placebo ($p = 0.018$). Physiological parameters were greater in caffeine (heart rate, $p = 0.013$; BLa, $p = 0.005$; VO2, $p = 0.005$; VCO2, $p = 0.012$; VE, $p = 0.002$; VT, $p = 0.002$). No differences were found in FS neither during CWL ($p = 0.073$) nor during TT ($p = 0.112$).

CONCLUSION: Our results are in line with current findings [3] and provide further evidence that, after one night of sleep deprivation, caffeine can improve running performance. An enhancement in cognitive functions, such as vigilance and inhibitory control, followed by a reduction in RPE during exercise, might have allowed participants to sustain a higher speed during TT. As a result of that, increases in physiological parameters, such as heart rate, VO2, VCO2, VT, and BLa were observed. Caffeine supplementation could be an effective measure to counteract the negative effects associated with prolonged periods of wakefulness in both cognitive and running performance.

THE EFFECT OF CAFFEINE ON GUT CELL DAMAGE FOLLOWING EXERCISE IS INFLUENCED BY ADORA2A GENOTYPE BUT NOT CYP1A2 GENOTYPE.

DAVISON, G.1, CARSWELL, A.T.2, MARTINEZ-GONZALEZ, B.1, BARON, P.3

1. UNIVERSITY OF KENT, UK; 2. UNIVERSITY OF EAST ANGLIA, UK; 3. UNIVERSITÉ DU LITTORAL CÔTE DOPALE, FRANCE

INTRODUCTION: Endurance exercise may be associated with acute damage to intestinal epithelial cells (gut cells). The effect of caffeine supplementation, and whether this is influenced by common genetic polymorphisms, is not currently known. Therefore, the aim of this study was to determine the effects of acute caffeine ingestion on a marker of gut cell damage and whether this is influenced by two commonly occurring genetic (single nucleotide) polymorphisms (SNPs).

METHODS: Eighteen recreationally active adults volunteered in this double-blind, randomised crossover study. After an overnight fast, they ingested a capsule containing 3 mg/kg body mass caffeine or placebo 45 min prior to 20 min cycling at 70% maximal oxygen uptake. They rested for 5 min then completed a 15-min cycling performance time-trial. Cognitive function tests (psychomotor vigilance test, PVT) were performed at baseline (before capsule), during the first cycling bout, and 10 min after the time-trial. Venous blood samples were collected at baseline (after the PVT, before capsule), before the 20 min cycle and after the final PVT (~30 min post-time-trial). Results for physiological responses, time-trial performance and PVT performance have been published previously (Carswell et al., 2020, Eur J Appl Physiol, 120(7):1495-1508). Plasma intestinal fatty acid binding protein (iFABP), as a marker of 'gut cell' damage, was determined by ELISA (Bio-Techne, USA). Genomic DNA was extracted from whole blood samples and SNPs in ADORA2A (rs5751876) and CYP1A2 (rs762551) genes determined with rhAmp assays (Integrated DNA Tech, USA). Participants were categorised by ADORA2A gene as high sensitivity (TT homozygous) or low sensitivity (C allele carriers: CT heterozygous or CC homozygous); and by CYP1A2 gene as fast metabolisers (AA homozygous) or slow metabolisers (C allele carriers: AC or CC).

RESULTS: For iFABP, three-way mixed ANOVAs (repeated for treatment [i.e. caffeine vs placebo] and time, between for genotype) revealed significant main effects of treatment, time, and treatment × time interaction ($P < 0.05$), showing an influence of caffeine. Post hoc paired t-tests (Bonferroni corrected) revealed a significant mean increase (~85%, $P = 0.009$) following the time-trial. There was a trial x ADORA2A genotype interaction ($P = 0.021$), showing that the overall effect of trial was influenced by this genotype. However, there were no other significant main effects, 2-way or 3-way interactions (all $P > 0.05$) for either genotype. Further post hoc analysis revealed a significant post-time-trial increase in the ADORA2A TT group only (~109% increase $P = 0.020$, vs ~48% increase $P > 0.05$ in CT/CC) suggesting the mean increase seen with caffeine vs placebo was largely driven by 'high sensitivity' participants.

CONCLUSION: Acute damage to gut cells caused by endurance exercise may be exacerbated by caffeine, especially in sensitive individuals. The potential implications of this to gut/gastrointestinal responses to exercise requires further examination.

OP-SH21 Motivation

STUDENTS' NEEDS FRUSTRATION IN PHYSICAL EDUCATION CLASS AS PREDICTOR OF THEIR INTENTION TO BE PHYSICALLY ACTIVE

FRANCO, E., GONZÁLEZ-PEÑO, A., OCETE, C., COTERÓN, J.

UNIVERSIDAD PONTIFICIA COMILLAS

Introduction

Physical education (PE) setting has been pointed out as an ideal context to promote healthy lifestyles and adherence to physical activity. Under the lens of self-determination theory, recent studies have evidenced the effect that teachers and students' interactions might have on their behaviours through the satisfaction or frustration of the basic psychological needs (Aelterman et al., 2019). The needs of autonomy, competence, and relatedness can be frustrated when the teacher exercise power as an authority, ignore students' interests, or pressure them to perform the activities (Vansteenkiste et al., 2020), which could decrease students' intentions to be physically active in other contexts (Aibar et al., 2021). The objectives of the present study were to analyse the influence of BPN students' frustration on their intentions to be physically active.

Methods

The sample consisted of 294 Spanish PE students (164 male and 130 female) aged between 10 and 18 years old ($M = 12.88$; $SD = 1.61$). A validated questionnaire was administered, and a stepwise regression was performed.

Results

The analysis revealed that students' perceptions of both autonomy and competence frustration were inversely associated with their intention to be physically active (tautonomy = -3.06, $p < .01$; tcompetence = -2.54, $p < .05$). Relatedness frustration did not emerge as predictor of intention to be physically active ($t = .11$, $p > .05$).

Discussion

The results suggested that the frustration of BPN is related to the intention to practice physical activity in contexts other than the PE ones. When students perceived their autonomy and competence needs are being frustrated, they are unlikely to participate in physical activities outside the school, probably because they do not feel freedom to make decisions and to express one's own sentiments and opinions in PE classes, or do not feel capable to facing the proposed activities. This study highlights the important role that PE teachers could play in class by supporting BPN students needs of autonomy and competence.

SELF-CONTROLLING TASK DIFFICULTY DURING SELF-REGULATED PRACTICE BENEFITS PERFORMANCE AND MOTIVATION.

DUIVENVOORDEN, J., VAN DER KAMP, J., VAN HILVOORDE, I.

WINDESHEIM UNIVERSITY OF APPLIED SCIENCES

Introduction

Self-regulation skills allow children to actively engage in learning. As a result, learners who cyclically plan, monitor and evaluate practice, will experience increased motivation and self-efficacy. These effects may in turn enhance commitment and performance (Zimmerman, 2002). According to the challenge point framework (Guadagnoli & Lee, 2004), task difficulty should be attuned to skill level to facilitate learning. Self-regulation may be an effective way to adjust task difficulty. This study evaluates the effects of self-controlling and monitoring task difficulty in a classroom-based physical education (PE) setting.

Methods

In two practice sessions, 55 Students (Mage = 13) divided over three groups practiced a novel aiming task. All groups were informed that their practice goal was to increase the distance from which they could successfully hit a ball onto a target using a handpaddle. Children in the Goal-group (G) and monitoring-group (M) self-controlled task difficulty (i.e., distance to the target). The M-group additionally monitored task difficulty and score with a digital form. The regulated-group (R) also monitored task difficulty but adjusted task difficulty by a prescribed rule based on their preceding score. In a pretest, posttest and a 2-week retention test, performance, self-efficacy and motivation were examined. During practice, task difficulty was registered.

Results

Repeated measures ANOVA's showed that performance and self-efficacy increased for each group. Only for the R-group, motivation decreased during the experiment. A linear regression analysis identified task difficulty relative to pretest performance as a significant predictor for performance at the posttest and retention test.

Conclusion

Each group increased performance and self-efficacy during the experiment. The G- and M-group could self-control task difficulty, the M-group additionally monitored task difficulty and score to stimulate self-regulated learning. These protocols did not hinder performance or self-efficacy. In the R-group, motivation decreased during the experiment. This may have been caused by the absence of self-controlled practice. The linear regression confirmed that task difficulty is a predictor for learning. These findings support allowing children to self-control and monitor task difficulty during PE.

Key Words: inclusion, self-determination theory, circumplex approach

Introduction

Recently, an innovative approach has been developed to enhance understanding of the interactions between teachers and students in physical education (PE) through the analysis of teaching behaviours (circumplex approach; Aelterman et al. 2019). The model distinguishes four different dimensions according to the level of directiveness y teachers' need support behaviours: autonomy-supportive, structure, chaotic and controlling behaviours. On the other hand, in the field of education, many studies have focused on the barriers to the inclusion of students with disabilities in PE from the perspective of teachers, identifying a lack of training as one of the main limitations pointed out by these professionals (Barber, 2018). The present study aims to advance in this research line by investigating whether the display of these behaviours can be related to the self-efficacy to include students with disabilities in their lessons.

Methods

The sample consisted of 375 Spanish PE teachers (251 male and 124 female) aged between 23 and 60 years old (M= 40.58 and SD = 8.10). The participants taught either in Primary (60%) or Secondary Education (40%). A validated questionnaire was administered, and a stepwise regression was performed.

Results

The analysis revealed that only teaching behaviours oriented to foster structure in the class were associated with self-efficacy to include students with disabilities in their lessons ($t = 11.11$, $p. <. .01$). None of the rest of teaching behaviours emerged as predictors of self-efficacy to include students with disabilities (autonomy-supportive: $t =1.42$; chaotic: $t = -.78$; controlling: $t = -1.34$).

Discussion

Findings suggested that a structuring teaching style might be aligned with inclusive practices in PE. When teachers engage in structure teaching behaviours, they can make use of guiding practices by, for instance, suggesting individual progressions to help the students to complete the task, or clarifying strategies such as being transparent and clear when communicating expectations from the lesson. This study has some relevant implications such as the potential of the circumplex approach to better understand and improve the quality of inclusive settings in PE.

"DO WHAT I SAY, NOT WHAT I DO": PUPILS PERSONAL VALUES ARE INFLUENCED BY THEIR PHYSICAL EDUCATION TEACHERS' VALUES IN CONTEXT OF INTENSE EMOTIONAL STATES.

SCHWEIZER, T., MAUDUY, M., MARGAS, N.

UNIVERSITY OF LAUSANNE

Research point to the role of physical education (PE) teacher in teaching values. If teachers' values education is often integrated in physical education by using sport as a medium, still little is known about the possible direct effect of PE teachers' values on pupils' values. Because sport and PE are contexts of intense emotional states that can facilitate norm adherence (e.g., Swann & al., 2010), we propose that bodily commitment may enhance adherence to PE teachers' values, as attachment figures. Indeed, stressfull situations and intense emotions lead individuals to affiliate themselves with sources of security (e.g., Mikulincer et al., 2002).

The study involved 207 adolescents (Mage = 13.85; ± 0.83; 41.5% girls) distributed into a 2 (norm salience) x2 (bodily commitment) experimental design. Personal values of participants were initially assessed. Two weeks later, a PE teacher norm was made salient (healthy eating norm vs control norm) followed by a gymnastic task (strong vs weak bodily commitment) and measures of personal values, attitudes, emotional states and affiliation. Healthy eating behaviors of participants were collected one week later. Data were analyzed using contrast method for which 3 orthogonal contrasts were tested, namely (C1) norm salience condition effect, (C2) bodily commitment effect in the experimental norm salience condition and (C3) bodily commitment effect in the control norm salience condition. Mediating effects of threat and arousal states but also affiliation to the PE teacher were explored.

Bootstrap linear mixed models revealed that C1 (Estimate = 0.26, SE = 0.05, $p < .001$) and C2 (Estimate = 0.28, SE = 0.07, $p < .001$) positively and significantly predicted values of pupils at T1. Attitudes of participants at T1 were positively and significantly predicted by C1 (Estimate = 0.17, SE = 0.04, $p < .001$) and by C2 (Estimate = 0.12, SE = 0.06, $p < .05$). Multilevel longitudinal mediation models revealed significant indirect effects of C1 ($p = .03$) and C2 ($p = .01$) on behaviors via values at T1, and a significant indirect effect of C1 ($p = .01$) on behaviors ($p = .03$) via attitudes at T1. Finally, and concerning the underly-

ing processes, strong bodily commitment revealed significantly stronger affiliation to the PE teacher ($p < .001$) and most importantly, affiliation had a positive and significant effect on pupils' values ($p = .02$).

Highlighting the role of bodily commitment in the adherence to PE teachers' values gives new opportunities to stakeholders to orient pupils' values, but also warn about the values that are made salient during sport practice, intentionally or not.

IS-PN01 The power-duration relationship: physiological determinants and practical applications

HISTORICAL BASES FOR THE CRITICAL POWER (CP) CONCEPT

POOLE, D.

KANSAS STATE UNIVERSITY

The power or speed discriminating sustainable exercise from that leading to imminent exhaustion in a finite and predictable time (i.e., Critical Power, CP; Critical Speed, CS) has crafted human history. For instance, that CS for Homo Sapiens exceeds the trot-gallop transition speed for ungulate prey underpinned our species success in hunting and venturing out of Africa many millennia ago. Moreover, the performance of soldiers, labourers and elite athletes locomoting over land, in water and in flight, has been bounded by the CP (CS) and W (D) parameters. The Roman military genius Vegetius, required legionaries to march for several hours at the 'military step' (2.85 mph, 4.6 km·h-1) carrying 43.25 lb (19.6 kg) requiring a sustained metabolic rate between 1.4 and 1.7 L O2·min-1. The Roman's success as the World's supreme fighting force over centuries implies that the military step was not positioned far below CP (CS). A.V. Hill constructed hyperbolic speed-time curves from World records for runners, swimmers, rowers and cyclists - a strategy that fits current World records. Central to Hill (and Otto Meyerhoff) winning the 1922 Nobel prize was his demonstration that aerobic and anaerobic energy sources coordinated to power high-intensity muscle contractions and our present understanding of the power or speed-time relation is founded on that coordinated function. In 1965 Monod and Scherrer defined the CP of a muscle (or muscular group) as "the maximum rate (of work) that it can keep up for a very long time without fatigue". They extracted the two parameters, CP and a finite amount of work performable above CP ('energy store' component, later termed W). Subsequent experiments demonstrated that CP is determined by oxidative function and that W upon finite (mostly) anaerobic energy sources. In 1982 Whipp and colleagues utilized a simple 2-parameter hyperbolic fit to the Power-time relation: (P-CP)t =W' which may be transformed into its linear formulation: P = (W'/t) + CP. CP occurs at ~80% VO2 max in young, healthy individuals (higher in elite distance athletes) and, accepting determination imprecision, this represents the highest power (or, more correctly, metabolic rate) at which VO2 and blood [lactate] can be stabilized. Exercise just above CP induces a completely different metabolic response: VO2 rising inexorably to VO2 max and blood [lactate] increasing to exhaustion. CP therefore represents the upper boundary of the heavy and the lower boundary of the severe exercise intensity domain in which all power outputs lead to VO2 max: The tolerable duration of work being predicted from the P-t relation. As presented in this symposium, the highly conserved hyperbolic P-t relation, its mechanistic underpinnings, and tight coherence with systemic and muscle physiologic profiles support its pivotal role in defining muscular performance.

MECHANISTIC BASES OF THE POWER-DURATION RELATIONSHIP

VANHATALO, A.

UNIVERSITY OF EXETER

In this talk, new evidence concerning the physiological determinants of the power-duration relationship and the mechanisms of fatigue in the heavy and severe exercise intensity domains will be discussed. The critical power (CP) indicates the boundary between the heavy intensity domain, within which a physiological steady-state is attainable, and the severe domain, within which exercise is non-steady state and the pulmonary oxygen uptake (VO2) continues to rise until the VO2max is attained. The limited work capacity above the CP is quantified as the curvature constant of the power-duration relationship (W), which has been classically interpreted work that can be derived via 'anaerobic' metabolism. The power-duration parameters differ from any physiological indices of cardiovascular fitness in that they are based upon the measurement of mechanical work done and exercise tolerance rather than any single physiological index, such as blood lactate concentration or pulmonary gas exchange. Research into the physiological correlates of the CP and the W has improved our understanding of the mechanistic bases of severe-intensity exercise tolerance. CP has been shown to separate discrete exercise intensity domains which have distinct blood acid-base, muscle metabolic, neuromuscular, cardiovascular, and respiratory gas exchange profiles. CP is inversely proportional to the rate at which pulmonary O2 uptake rises at the onset of exercise, indicating a close relationship to mitochondrial respiratory capacity. The mechanistic bases

of the CP are inherently linked to those that govern the size of the W. During exercise above CP, the progressive loss of muscle homeostasis signals a stimulation of 'excess' VO2 (i.e., the so-called VO2 slow component), and thereby a loss of efficiency, which propels the VO2 on a trajectory towards VO2max. Positive correlation between the W and the amplitude of the VO2 slow component during severe exercise suggests that the W, defines the time frame for the development of the 'maximal' VO2 slow component. Interventions, such as high intensity interval training, which accelerate the VO2 kinetics at exercise onset and reduce the size of the slow component tend to increase the CP and reduce the size of the W. These changes are reflected as a rightward shift in the power-duration curve and improved exercise tolerance.

W MODELLING DURING INTERMITTENT EXERCISE: CURRENT LIMITATIONS AND FUTURE CHALLENGES OF PREDICTIVE MODELS

CAEN, K.

GHENT UNIVERSITY

As illustrated by the number of scientific publications and the demand coming from professional sports teams, the application of the critical power (CP) model to intermittent exercise has been sparking a lot of interest from both academia and cycling practice. One of the main reasons for this is because intermittent exercise strongly relates to many sports disciplines in which high-intensity efforts (i.e., performed above CP) are alternated with low-intensity intervals (i.e., performed below CP). Applying the traditional CP concept to this type of exercise provides a mathematical and physiological framework that can be employed to estimate both the depletion and the recovery of the so-called W: a fixed amount of energy that can be spent during exercise above CP and can be recovered during exercise below CP. Originally, the recovery of W was thought to occur linearly, just like its consumption, but the curvilinear character of the W recovery soon became clear. In 2012, Skiba et al. used this knowledge to develop a mathematical model to predict the balance in W (WBAL) at any time during intermittent exercise. In this model, W recovery is assumed to occur in a simple exponential way with the speed of the recovery being dependent on the recovery power output. The development of this model was innovative and promising as it could provide a better understanding of the physiological factors that limit interval exercise performance and therefore, could also enhance our ability to predict performance and prescribe exercise. Given the technological advances of data tracking, one potential application may be the real-time monitoring of athlete fatigue in endurance and team sports (e.g., to help athletes in setting an optimal pacing strategy during races or to assist coaches in the design of more individualized interval training). Over the past years, also other, often derivative, model forms have been proposed and tested in the literature. Still, the dynamic behavior of W during exercise is rather complex and W kinetics have shown to be highly variable between individuals, which makes it very challenging to capture within a single mathematical formula. In this context, recent studies have highlighted need for further model improvements, in particular to take better account of the specific modalities of the interval exercise and to incorporate individual characteristics. This also requires a better understanding of the physiological underpinnings of the W recovery. For these reasons, it is important to be aware of the limitations inherent to the existing models before applying them in practice. During this symposium, we will touch upon these limitations and discuss some of the future challenges in the domain of W modelling. Furthermore, we will also illustrate the practical use of predictive W models by examples of real-time monitoring of WBAL in cycling.

Oral presentations

OP-PN11 Cardiovascular Physiology II

ACUTE LOCAL AND SYSTEMIC RESPONSES TO A MODULATED EXERCISE STIMULUS USING BLOOD FLOW RESTRICTION.

JI, S.1, FRANZ, A.2,3, BEHRINGER, M.4, WAHL, P.1,5

1. GERMAN SPORTUNIVERSITY COLOGNE, 2. UNIVERSITY HOSPITAL BONN, 3. ATOS ORTHOPARC CLINIC COLOGNE, 4. GOETHE UNIVERSITY FRANKFURT, 5. THE GERMAN RESEARCH CENTRE OF ELITE SPORT

INTRODUCTION: Low-intensity (LI) exercise with blood flow restriction (BFR) has gained attention as an alternative to high-intensity training for enhancing physiological adaptations in both athletic populations and rehabilitation [1]. A specific feature of BFR is high metabolic perturbations elicited by relatively low-intensity exercise. However, the physiological mechanisms behind BFR-training are not fully understood and there is limited data on the acute changes that occur at the local and systemic level, especially regarding its similarities and differences to workload-matched high-intensity training. Thus, this randomized cross-over study aimed to compare cardiorespiratory demands and local and systemic metabolic perturbations during LI exercise with and without BFR, as well as high-intensity exercise.

METHODS: Ten healthy young males (26.9±4.6yrs) underwent three 20-min external workload-matched cycling trials. The cycling trials consisted of LI cycling (55%PPO), LI cycling with BFR (LI+BFR, 50% of individual arterial occlusion pressure), and high-intensity intermittent cycling (HI, 10x1min at 90%PPO interspersed with 1-min recovery at 20%PPO). Cardiorespiratory responses were measured using spirometry. To evaluate metabolic changes at a systemic (blood) and local (skeletal muscle interstitial fluid) level, a venous catheter and a microdialysis probe were inserted into an antecubital vein and vastus lateralis muscle, respectively.

RESULTS: No significant difference was found in oxygen uptake among the different exercise protocols ($p=.39$). Average heart rate, pulmonary ventilation, and ventilatory equivalent for CO2 were similar between LI+BFR and HI ($p>.67$) and

higher than LI (p<.01). LI+BFR and HI resulted in higher total energy expenditure compared to LI (p<.05), but a greater proportion of fat utilization was found for LI (p<.05). Venous pH decreased significantly during LI+BFR and HI (p<.05), but remined unchanged during LI (p>.95). Regardless of exercise protocols, blood and interstitial lactate concentration increased during exercise, with significant lower levels found in LI compared to the other protocols (p<.05). In LI+BFR, blood glucose level increased continuously up to 5 minutes post-exercise (post5), whereas no changes occurred in LI and HI, resulting in a significant difference at post5 between LI+BFR vs. LI and HI (p<.05). In contrast, LI+BFR showed a trend towards lower interstitial glucose levels compared to the other protocols.

CONCLUSION: Our results indicate that LI+BFR cycling elicits similar cardiorespiratory and metabolic demands as the workload-matched HI protocol. This highlights the effective nature of incorporating BFR in low-intensity exercise to increase energy demand and further modify the metabolic stress in different physiological systems. The potential alterations of glucose metabolism resulting from BFR exercise, both at the local and systemic level, need to be further investigated in terms of its impact on signaling pathways.

MAXIMAL OXYGEN UPTAKE IS NOT REDUCED DURING A MAXIMAL INCREMENTAL RUNNING PROTOCOL WITH MUSCLE BLOOD FLOW RESTRICTION

CHRYSSANTHOPOULOS, C.1, SKARAKI, V.1, CHEROUVEIM, E.D.1,2, MICHAILIDIS, A.R.1, PATAKIOUTIS, K.1, KARATZANOS, E.1, POULOS, S.1, MARIDAKI, M.2, VASSILAKOPOULOS, T.1, PHILIPPOU, A.1

NATIONAL & KAPODISTRIAN UNIVERSITY OF ATHENS

INTRODUCTION: Numerous studies have been conducted examining the chronic benefits of blood flow restriction (BFR) to muscle strength and hypertrophy, as well as to aerobic and anaerobic capacity and performance [1]. However, the acute effect of BFR on maximal oxygen uptake (VO2max) has not been studied particularly in running. The purpose of this study was to investigate the influence of BFR application during a maximal incremental running protocol on parameters determining endurance performance, i.e., on VO2max, velocity at VO2max, running economy, and anaerobic threshold (AT) [2].

METHODS: Fifteen male club-level runners (age: 35.7±10.1 yrs, height: 176.3±5.7 cm, body mass: 73.6±5.0 kg, mean±SD) performed an incremental running protocol (speed increment 1 km/h per 90 s, inclination 0%) to volitional fatigue twice, i.e., with (BFR) and without (C) BFR in a random order. The occlusion pressure applied for BFR was at 40% of the arterial occlusion pressure (AOP) and cuffs were placed at the upper third of both thighs. Diet and physical activity on the day before and the day of the measurements were controlled.

RESULTS: No difference (p= 0.097) was observed in VO2max between the two conditions (BFR: 49.7±4.9 Vs. C: 51.4±5.2 ml/kg/min), whereas time to exhaustion (BFR: 476.7±83.3 Vs. C: 607.5±80.0 s) and velocity at VO2max (BFR: 16.4±1.6 Vs. C: 17.5±1.9 km/h) were significantly lower ($p < 0.01$) with BFR. Oxygen uptake at four common to both conditions submaximal speeds (about 12-15 km/h), reflecting running economy, was not different ($p > 0.05$), while velocity at AT (BFR: 13.3±1.3 Vs. C: 14.0±1.8 km/h) was significantly higher ($p = 0.01$) in C. Maximal perceived rate of exertion (BFR: 17.3±1.2 Vs. C: 16.2±1.7) and maximal pain in a 10-point scale (BFR: 7.8±1.2 Vs. C: 5.5 ± 2.1) were significantly lower ($p < 0.05$) in C, while maximal heart rate was similar between conditions (BFR: 185±9 Vs. C: 187±11 b/min) ($p > 0.05$).

CONCLUSION: The application of BFR at 40% of the AOP during a maximal incremental running protocol reduces time to exhaustion, velocity at VO2max and AT, but does not affect VO2max in male club-level runners.

HEMODYNAMIC EFFECTS OF INTERMITTENT PNEUMATIC COMPRESSION IN SPORT

MAIA, F., NAKAMURA, F.Y., SILVA, G., MACHADO, M.V.B., RIBEIRO, J.

UNIVERSITY OF MAIA

INTRODUCTION: Over the recent years, the use of practical mechanical interventions for enhancing recovery in sports have found a wide adherence across athletic population [1, 2]. A rather new and poorly explored tool (highly appreciated by the athletes) is intermittent pneumatic compression (IPC) [1, 2]. In theory, IPC enhances blood flow through cyclic inflation and deflation pressure, promoting an acceleration in the recovery process [3]. Nevertheless, IPC physiological/hemodynamic effect remains unclear for athletic subjects, as they often differ from general population (e.g., body composition). The aim of this study was to assess the acute hemodynamic effects caused by a moderate vs high pressure IPC protocol across athletes of intermittent and continuous modalities.

METHODS: Twenty-two male athletes (age: 21.5±2.9yrs; height: 1.80±0.04m; weight: 70.7±2.65kg; week training hours: 9±2.7h) competing from local to international level (soccer and track-and-field) performed 2x 15-min protocols at moderate (80mmHg) and high (200mmHg) pressure in a randomized order (1-hour washout period). Peak systolic velocity, arterial diameter, end-diastolic pressure (ecodoppler on the common femoral artery) and heart rate (Polar H10), were measured pre, during (at the 8th min, with the cuffs deflated, fully and half inflated), and 2 min post each IPC protocol. A repeated ANOVA was performed to assess the variability between protocols and across time and phase of IPC cycle.

RESULTS: Both IPC protocols enhanced the peak systolic velocity: (F=55.9; p<0.001; ηp2=0,93) and end-diastolic pressure: (F=29.7; p<0.001; ηp2=0,87), but no effect was detected for arterial diameter (F=0.36; p=0.70 ηp2=0,03) and heart rate (F=1,51; p=0.25; ηp2=0,15). During the IPC cycle, the highest blood flow values were observed when the cuffs were fully deflated. The between protocol comparisons detected a higher peak systolic velocity (F=26,4; p< 0.01; ηp2=0,56) and end-diastolic pressure (F=26,2; p<0.01; ηp2=0,56) in high-pressure protocol compared to the moderate one.

CONCLUSION: This study demonstrated that during 15 min IPC protocols, athletes blood flow and venous return markers (end-diastolic pressure) are increased, especially if a high-pressure approach is used. This fact corroborates the theoretical IPC mechanism of action in athletes, suggesting that it may be considered a valuable tool. Nevertheless, longer duration protocols should probably be addresses to guarantee an augmented blood flow after the IPC application.

IMPACTS OF ENDURANCE VERSUS RESISTANCE TRAINING ON DIASTOLIC FUNCTION IN HUMANS

COLLIS, J.J., NAYLOR, L.H., MARSH, C.E., THOMAS, H.J., LESTER, L., MASLEN, B., GREEN, D.J.

UNIVERSITY OF WESTERN AUSTRALIA

INTRODUCTION: Cardiac adaptations in response to exercise are modality–specific; different exercise modalities induce specific phenotypic adaptations to cardiac structure. Few exercise training studies have assessed the impact of exercise modality on cardiac function. This study aimed to investigate physiological changes in left ventricular (LV) systolic and diastolic function following distinct modes of exercise training, in healthy participants.

METHODS: 64 individuals participated in a randomised cross-over design trial, involving 12-weeks of endurance [END] and resistance [RES] training, separated by a 12-week washout. Comprehensive transthoracic echocardiograms were performed to assess systolic function by both ejection fraction (EF) and 2D LV global longitudinal strain (GLS), and diastolic function by mitral valve early velocity (E), tissue Doppler velocity (e'), their ratio (E/e'), and left atrial volume indexed to body surface area (LAESVi).

RESULTS: Following exercise training, resting heart rate (HR) differed significantly between modes of training. Post END there was a significant decrease in resting HR (58±8.5 bpm to 55±6.4 bpm, P<0.001), but not post RES. LV mass increased significantly following both modes of training (RES: 137±41 g to 141±39 g, P=0.001; END: 143±39 g to 152±39 g, P<0.001), with no difference between modalities (P=0.422). Significant changes were observed when LV mass was adjusted for lean mass (DXA) following END (P<0.001). LV internal dimension in diastole (LVIDd), increased following END (47.0±4.2 mm to 48.2±3.8 mm, P<0.001) but not RES (46.5±4.2 mm to 46.8±4.2 mm, P=0.475).

Diastolic function, measured as E/e' significantly differed between modes (P=0.001); E/e' decreased following END (6.7±1.1 to 6.3±1.0, P=0.011) but not RES (6.5±1.3 to 6.6±1.3, P=0.157). This was associated with a different response between modes for E (P=0.012), but not e' (P=0.378). E decreased with END (92±15 cm/s to 88±13 cm/s, P=0.039) whilst e' did not change (13.9±1.7 cm/s to 14.1±2.1 cm/s, P=0.521). Neither E nor e' changed with RES. LAESVi increased significantly following END (26.0±4.5 mL/m2 to 28.1 ±6.0 mL/m2, P=0.019) but not RES (24.9±4.8 mL/m2 to 25.9±4.9 mL/m2, P=0.113). EF and GLS were not impacted significantly by either mode of training.

CONCLUSION: In the absence of gross functional changes in systolic function, endurance, but not resistance training, improved diastolic function and LV adjusted for lean mass. Since diastolic dysfunction is an early and integral event in the development of intrinsic myocardial disease, END may be an effective early mitigation strategy for cardiovascular disease prevention.

NON-INVASIVE ASSESSMENT OF THE PULMONARY AND SYSTEMIC VASCULAR DISTENSIBILITY AT EXERCISE IN SEDENTARY VS. ATHLETIC SUBJECTS

CARPENTIER, M.

UNIVERSITÉ LIBRE DE BRUXELLES - ULB

INTRODUCTION: Physical activity improves cardio-vascular health condition. However, it remains uncertain how much training affects the vascular distensibility (α) of the pulmonary circulation, in regard to the systemic vascular distensibility. This is of particular interest as the right ventricle (RV) function is under heavy stress during exercise (1) at high cardiac output (Q). We hypothesized that a more distensible circulation (after physical training) would smoothen the RV afterload during exercise. We therefore compared the RV and pulmonary circulation response at exercise among athletes and sedentary subjects, in contrast with the exercise systemic vascular response.

METHODS: 17 international professional football players (24±3 years) matched by age and body mass index with 17 sedentary volunteers, performed an incremental cyclo-ergometric exercise echocardiography for right ventricular (RV) and pulmonary circulation evaluation. Gas exchanges and systemic arterial blood pressure were measured continuously during exercise. Q was calculated from the left ventricular outflow tract flow velocity-time integral, mean pulmonary arterial pressure (PAPm) was calculated from the peak tricuspid regurgitation velocity and right atrial pressure. The coupling of

RV function to the pulmonary circulation was evaluated by the tricuspid annular plane systolic excursion (TAPSE) to systolic PAP (PAPs) ratio. Pulmonary and systemic vascular distensibility, αpulm and αsys, were determined from multi-point mPAP/atrial pressure vs Q relationships, from an established equation.

RESULTS: While athletes displayed smoothened chronotropic (p<0.001) and enhanced inotropic (p=0.006) responses to exercise as compared to sedentary subjects, the exercise-induced increase in PAPm or the decrease in TAPSE/PAPs did not differ between the two groups. However, αpulm was higher in athletes than in sedentary people (1.37±0.41 vs 0.88±0.42%/mmHg, p=0.002) and correlated with the TAPSE/PAPs ratio (football players: p=0.006, r=0.63, sedentary: p<0.001, r=0.79). αsys was correlated to αpulm (p<0.05, r=0.33) suggesting a global (systemic and pulmonary) vascular training adaptation. Indeed, even if αsys was not different between the two groups, it was positively correlated to cardio-respiratory fitness indexes such as the VO2peak (p=0.02, r=0.37) and the stroke volume at maximal common effort (p=0.02, r=0.37).

CONCLUSION: Similar exercise-induced mPAP and TAPSE/PAPs response was observable in athletes and sedentary subjects, suggesting a preserved RV function in both populations. However, athletes present a higher vascular pulmonary distensibility, αpulm associated with better preserved RV-arterial coupling. How much this smoothened RV afterload and coupling changes are advantageous during long or intense exercise remains to be defined. The advantageous vascular distensibility effect seems to affect the exercise-induced response of both circulations systemic and pulmonary in relation to the aerobic capacity.

OP-AP27 Power/Strength: Training and Testing

POST-ACTIVATION JUMP PERFORMANCE ENHANCEMENT IS DIMINISHED FOLLOWING A LOADED PLYOMETRIC EXERCISE RESULTING IN MINOR MUSCLE DAMAGE

LIMA, L.C.R., BARRETO, R.V., FONTANETTI, G., MANTOVANI, G.B., DENADAI, B.S., NOSAKA, K.

UNIVERSITY OF SÃO PAULO

INTRODUCTION: Post-activation performance enhancement (PAPE) refers to performance improvement in explosive movements following intense contractions of the muscles. PAPE is speculated to be associated with enhanced myosin head phosphorylation, increased muscle temperature, and other adaptations in the muscles. High-intensity eccentric contractions lead to exercise-induced muscle damage (EIMD), that predominantly affects type II muscle fibers, which have been shown to be associated with responsiveness to PAPE. The present study investigated the hypothesis that PAPE would be negatively affected by a bout of loaded plyometric exercise (PLYO) that induces muscle damage.

METHODS: Twenty-two healthy men with no prior experience with resistance training participated in the study. Following two familiarization sessions, the participants were confirmed to show PAPE, based on at least 4% increase in counter movement jump (CMJ) height (peak of 5 trials) following a pre-activation protocol consisting of 5 squats with a 5-RM load. Eleven participants were considered to be non-responders and excluded from further study. The final sample consisted of 11 PAPE responders (19.6±1.8 y, 69±9 kg, 176±8 cm). Maximal voluntary isometric contraction (MVC) torque of the knee extensors and quadriceps muscle soreness were assessed at baseline, 15 min, 24 and 48 h following PLYO consisting of 5 sets of 6 drop-jumps from a 52-cm box with a weight of 20% of individual body mass. Responsiveness to PAPE was assessed at baseline, 15 min, 24 and 48h following PLYO by CMJ height prior to and 4 min following the pre-activation protocol that had been shown to produce PAPE for the participants. Changes in MVC and muscle soreness were analyzed by one-way repeated measures ANOVAs. Changes in CMJ height from pre- to post-PLYO and over time were analyzed by mixed-model ANOVAs with Tukey's post hoc tests. Significance was set at p<0.05.

RESULTS: MVC decreased at 15 min following PLYO (-15.1±9.7%) but returned to the baseline by 24 h post-PLYO. Quadriceps muscle soreness developed at 48 h (21.0±20.3 mm) after PLYO. Baseline CMJ height was 30.5±5.2 cm and increased 7.6±3.8% after the pre-activation protocol, but no changes in CMJ height were observed following the pre-activation protocol at 15 min, 24 and 48 h following PLYO. However, CMJ values prior to pre-activation increased at 24 and 48 h (32.3±6.0 cm and 33.3±6.2 cm, respectively) following PLYO compared to pre-PLYO.

CONCLUSION: These results showed that PAPE disappeared at 15 min, 24 and 48 h after PLYO that induced acute strength loss and development of delayed-onset muscle soreness for healthy young men who showed responsiveness to PAPE before PLYO. It should be noted that CMJ height increased at 48 h post-PLYO without PAPE. PLYO induced minor muscle damage, which diminished PAPE, but produced a supercompensation-like effect at 24 and 48 h post-PLYO.

EFFECTS OF LOADING POSITIONS ON THE ACTIVATION OF TRUNK AND HIP MUSCLES DURING FLYWHEEL AND DUMBBELL SINGLE-LEG ROMANIAN DEADLIFT EXERCISES

MO, R.C.Y., NGAI, D.C.W., NG, C.C.M., SIN, K.H.S., LUK, J.T.C., HO, I.M.K.
TECHNOLOGICAL AND HIGHER EDUCATION INSTITUTE OF HONG KONG

INTRODUCTION: The SLRDL is a popular exercise widely used by strength coaches or therapists for performance enhancement and rehabilitative purposes. However, regarding the effect of loading position on trunk and hip muscle activation, it is not extensively studied before. The study compared the surface electromyographic (sEMG) activities of trunk and hip muscles during single-leg Romanian deadlift (SLRDL) exercises using flywheel and dumbbell with different loading positions.

METHODS: Twelve young male subjects with at least two years of strength training experience participated in this study. sEMG in the percentage of maximum voluntary isometric contraction of four SLRDL exercises (ipsilateral and contralateral loading position for dumbbell and flywheel) in a randomized order. sEMG amplitudes of superior gluteus maximus (SGM), inferior gluteus maximus (IGM), gluteus medius (GM), biceps femoris (BF), erector spinae (ES), external oblique (EO), and adductor longus (AL) were measured whereas one-way repeated measure ANOVA with Bonferroni adjustment (statistical significance at 0.05) and magnitude-based decision was performed.

RESULTS: Results demonstrated a very high level of SGM (105.4 to 168.6%) and BF (69.6 to 122.4%) muscle activities. A significant moderate increase of sEMG signals in GM, IGM, and ES (dominant side) and a large increase in SGM in flywheel SLRDL when the load shifted from ipsilateral to the contralateral side. No significant difference was observed between flywheel and dumbbell SLRDLs.

CONCLUSION: SLRDL using either a dumbbell or the flywheel device with contralateral loading placement can effectively enhance the activation of BF, SGM, IGM, GM, ES-D, and ES-ND for strengthening purposes. Meanwhile strength coaches may adopt dumbbell or flywheel SLRDLs with contralateral loading positions to simultaneously strengthen the hip extensors and trunk stabilizers effectively.

ACUTE EFFECTS OF DRY LAND RESISTANCE TRAINING ON SWIMMING PERFORMANCE IN MALE AND FEMALE SWIMMERS

ARSONIADIS, G., BOTONIS, P., BOGDANIS, G., TERZIS, G., TOUBEKIS, A.
NATIONAL AND KAPODISTRIAN UNIVERSITY OF ATHENS

INTRODUCTION: Competitive swimmers may apply dry-land maximum strength (MS) or strength endurance (SE) training prior to in-water swimming training [1]. MS or SE may affect performance and physiological response on a following swimming training in male swimmers [2,3], but no such information has been reported for female swimmers. The aim of the study was to examine the acute effect of MS and SE training sessions on performance, physiological and biomechanical variables during a subsequent maximum intensity swimming training session on male (M) and female (F) swimmers.

METHODS: Twenty-seven swimmers, 13 M (age: 17.8±3.1 years) and 14 F (age: 15.6±1.8 years) completed three experimental sessions: i) MS, 3 sets x 4 repetitions, load 90% of 1RM, 3 min rest between sets, ii) SE, 2 sets x 20 repetitions, load 55% of 1RM, 20 s between sets and iii) no dry-land training (CON). Twenty minutes following MS, SE and CON sessions swimmers participated in swimming training, consisting of 800-m warm-up and maximum efforts of 10-s tethered swimming, 4X50, and a 100-m front crawl. Force was measured during tethered swimming (TF), performance time, arm-stroke rate (SR), arm-stroke length (SL), arm-stroke index (SI), and arm-stroke efficiency (ηF) were measured during 4X50-m and 100-m. Blood lactate concentration [La-] was measured before and after each swimming effort and heart rate (HR) was recorded continuously. Shoulder isometric strength (ISO) and hand grip strength (HG) were measured before and after the dry-land and swimming training in all sessions.

RESULTS: Males swam faster than F swimmers in 4x50-m and 100-m following all sessions (P=0.01). Both M and F swam slower in the 4x50-m set following SE compared to MS and CON (M: 1.8±2.3%; F: 1.7±3.2%, P=0.01). However, 100-m time was no different between sessions in both M and F (P=0.34). ISO was decreased both in M and F after MS (M: 1.2±10.9%, F: 2.1±5.9%, P=0.01) and SE (M: 3.8±11.8%, F: 1.7±9.4%, P=0.01) compared to CON. HG and TF remained unchanged following all sessions in M and F (P=0.11). [La-] was not different between M and F in swimming 4x50 and 100-m (P=0.29) but was increased in both genders following SE compared to MS and CON sessions (P=0.01). HR was higher in F compared to M during 4x50 and 100-m in all sessions (P=0.01). During 4x50-m, M showed a higher SR and SI compared to F, while F showed a higher ηF compared to M in all sessions (P=0.01).

CONCLUSION: Dry-land SE session deteriorates repeated sprint performance time in both genders. SE or MS sessions are not altering biomechanical characteristics both in male and female swimmers during a subsequent maximum intensity swimming training.

OP-PN08 Hormonal Biology II

MENSTRUAL CYCLE PHASES AND PERFORMANCE IN ELITE WOMEN SOCCER PLAYERS

LISTA, M., IENO, C., PITTACCIO, F., DI LUIGI, L., SGRÒ, P.

UNIVERSITY OF ROME

INTRODUCTION: The impact of the menstrual cycle (MC) on performance is one of the most critical topics in female sports. Hormonal fluctuation and symptoms related to different MC phases can influence performance in women soccer players. Indeed, as reported in previous studies, this fluctuation seems to affect parameters related to internal and external load (1,2). To date, different studies tried to investigate this topic, but results are still unclear. The aim of the present study was to investigate the effect of different menstrual phases on distinct performance parameters in an elite women soccer player during standard weekly training in the Italian first division.

METHODS: Sixteen female soccer players (Age: 24.59 ± 4.11 yrs; Height: 1.66 ± 0.07 m; Weight: 59.50 ± 6,31 kg) were involved in the current study. Players were pooled according to the MC phases. Four different MC phases were identified: Early Follicular (EC: days 1-7), Late Follicular (LC: days 8-14), Early Luteal (EL: days 15-21) and Late Luteal (LL: days 22-28). Information about MC phases, recovery status, quality of sleep, stress, fatigue, and muscle soreness was recorded by adopting a morning survey. External load parameters were collected during trainings using GPS system (OHCOACH). At the end of each training, the rating of perceived exertion (RPE) was recorded. The players that who took part in four weekly training sessions were selected. Weekly Training was divided in four training sessions: Day 1 (Strength training), Day 2 (Aerobic training), Day 3 (Repeated Sprint Ability - RSA training), Day 4 (Speed Agility Quickness - SAQ training). Weekly training load was the same during the weeks of intervention. One-way ANOVA, followed by Bonferroni post-hoc, was performed to analyze differences between the four MC phases for all the parameters collected.

RESULTS: High Speed Running (HSR > 19.8 km/h) distance, Explosive Acceleration (EX ACC > 2.5 m/s²) and Explosive Deceleration (EX DEC > 2.5 m/s²) distance were significant highest ($p < 0.05$) in the late luteal phase.

CONCLUSION: A greater running intensity above 19.8 km/h combined with a greater number of EX ACC and EX DEC in the late luteal phase in female soccer players were evidenced by our results. As reported in previous studies, the distance covered above 19.8 km/h is highly correlated with the high-intensity, intermittent running test commonly performed to evaluate the RSA of soccer players (3). We can speculate that this variation in RSA performance was related to the high levels of progesterone and estradiol of the late luteal phase. This result highlights the important role of female sex steroid hormones as determinant of RSA performance of women soccer players in different phases of MC.

THE INFLUENCE OF MENSTRUAL CYCLE PHASE ON PHYSIOLOGICAL ENDURANCE PERFORMANCE-DETERMINING VARIABLES IN ENDURANCE - TRAINED ATHLETES

TAYLOR, M., OSBORNE, J., DE MARTIN TOPRANIN, V., ENGSETH, T., STRØM SOLLI, G., VALSDOTTIR, D., ANDERSSON, E., FLUGSTAD ØISTUEN, G., FLATBY, I., WELDE, B., MORSETH, B., HAUGEN, T.

SCHOOL OF SPORT SCIENCES, UIT, THE ARCTIC UNIVERSITY OF NORWAY, TROMSØ, NORWAY

INTRODUCTION: The main determinants of endurance performance are maximal oxygen uptake (VO 2 max), oxygen uptake (VO 2) at lactate threshold, anaerobic capacity, and work economy/efficiency . It is currently unknown if the fluctuating levels of estrogen (E) and progesterone (P) across the menstrual cycle (MC) influence these performance-determining variables. Accordingly, the primary aim of this study was to investigate the effect of MC phase on physiological performance-determining variables in endurance-trained athletes.

METHODS: Twenty - one eumenorrheic endurance - trained female athletes (mean ± standard deviation : 27 ± 9 years; 62 ± 6 kg; VO 2 max 53 . 8 ± 5. 6 mL ⋅ kg - 1 ⋅ min - 1) completed standardized fitness tests during three hormonally distinct phases of the MC : 1) the early follicular phase (EFP), within 1– 4 days after the onset of menstrual bleeding ; 2) the ovulatory phase (OP), within 36 h after a positive ovulation test result, and ; 3) mid-luteal phase (MLP), 7– 9 days after ovulation. MC phases were determined using calendar-based counting and at-home urinary ovulation tests, and retrospectively verified from fasted serum hormone analysis of E and P on each test day. Testing consisted of an incremental lactate profile and a VO 2 max test on a treadmill with 10.5% incline, and a 30 s all - out double-poling sprint test on a ski ergometer. VO 2 and blood lactate concentration ([La-]) were recorded during the sessions. Performance was determined as time to exhaustion (TTE) in the VO 2 max test. VO 2 at the lactate threshold was expressed as %VO 2 max at 4mmol⋅L-1 [La-] (VO 2 @4mmol) and running economy (R E) as VO 2 in mL⋅kg-1⋅km-1 at the individual speed closest to 80% of 4 mmol⋅L-1 [La-where RER was < 1.0. Participants completed one familiarization session and six MC phase-specific tests over two MCs. Data were analyzed using linear mixed- effect models in R.

RESULTS: A total of 98 test sessions were included in the analysis (EFP=36, OP=30, MLP=35). MC phase did not affect TTE (seconds, EFP=382 ± 67, OP=388 ± 82, MLP=372± 74, p =.16), VO 2 max (VO 2 in mL•kg -1 min -1 : EFP =54.2 ± 4.3, OP=54.4 ± 5.3, MLP=53.8± 5 .0, p =.53),VO 2 @4mmol(%,EFP= 86.3 ± 4.6 , OP= 85.4 ± 4.4 , ML P = 86.7 ± 4.6 , p = .36), average power output during the double-poling test (PO30s in W : EFP=187 ± 40W, OP=193 ± 40W, MLP= 184 ± 34W, p=.08) ,or RE (VO2 in ml•kg-1•km-1 : EFP =3 50 ±23, OP=34 6 ± 20, MLP =347 ± 17, p = . 40) . However, notable within - and between - participant differences across MC phases were observed in all outcome variables.

CONCLUSION: MC phase did not have a significant effect on the physiological variables most commonly used to assess and understand endurance performance. Specifically, TTE, VO 2 max , VO 2 @4mmol , PO 30s and RE did not differ on a group level between MC phases. However, , as within -and between-participant differences existed, it could be important to document MC phase when testing female athletes.

THE PREVALENCE OF MENSTRUAL DISTURBANCES IN FEMALE ENDURANCE ATHLETES: THE INFLUENCE OF PERFORMANCE LEVEL AND COMPARISON OF METHODOLOGIES

NOORDHOF, D.A.1, TAYLOR, M.2, DE MARTIN TOPRANIN, V.3, ENGSETH, T.P.2, SANDBAKK, Ø.1,2, OSBORNE, J.O.2

1> NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY, 2> UIT THE ARCTIC UNIVERSITY OF NORWAY, 3> NORD UNIVERSITY

INTRODUCTION: The prevalence of subtle menstrual disturbances (MD) in exercising women (50%) has been shown to be much higher than in sedentary women (4.2%) (1). However, it is unclear if the prevalence in female athletes is dependent on performance level. Therefore, the primary aim was to investigate the association between performance level and the prevalence of MD in endurance-trained women. A 3-step method, consisting of calendar-based counting, urinary ovulation testing, and serum hormone verification, has been suggested for the identification of subtle MD (2). However, a less invasive and time-consuming method, consisting of calendar-based counting and urinary ovulation testing (i.e., the 2-step method), would be preferable for sports practice. Therefore, the secondary aim was to investigate the degree of agreement between the 2-step and 3-step method for the detection of MD.

METHODS: In total, 238 unique menstrual cycles (MCs) of 66 menstruating endurance athletes were analyzed. Athletes were classified based on their average weekly training volume and performance metrics as tier 2/trained (n=24), tier 3/highly trained (n=36), or tier 4/elite (n=6) (3). MC status was initially determined using the 2-step method. MCs were classified as either normal, anovulatory, short luteal phase (i.e., a luteal phase <10 days)1 or oligomenorrheic (MC >35 days) (1). A subsample of 32 female athletes also provided a serum hormone sample 7-9 days after a positive ovulation test for 49 MCs, which was analyzed for an inadequate luteal phase (mid-luteal phase progesterone value <16 mmol•L-1) (1,4). The data from this subsample was used to compare the two methodologies. Logistic mixed model analysis was used to investigate the association between performance level and MD prevalence, while the degree of agreement between the two methodologies was evaluated using Cohen's kappa (κ).

RESULTS: Performance level was associated with the prevalence of MD, with tier 3 athletes being 21.6 (95%CI: 4.6, 101.3) times more likely to present a MD than tier 2 athletes (p=.002). No other differences were found between performance levels (p=.38-.58). An almost perfect agreement was found between the 2-step and 3-step method (κ=0.95), with the 3-step method identifying only one extra MC with a MD (13/49), when compared to the 2-step method (12/49).

CONCLUSION: Tier 3 athletes showed a significantly higher prevalence of MD than tier 2 athletes. The lack of significant differences between tier 2 and tier 3 vs. tier 4 athletes, might be related to the small number of elite athletes included. The almost perfect agreement between the 2-step and 3-step method indicates that practitioners will detect almost all disturbed MCs when their athletes use the more practically feasible 2-step method.

PREVALENCE AND PERCEIVED IMPACT OF HORMONAL CONTRACEPTIVE USE ON PERFORMANCE IN A GLOBAL POPULATION OF WOMEN'S RUGBY

BROWN, N., ROLDAN-REOYO, O., WILLIAMS, G.K.R., STODTER, A., MOORE, I.S., WILLIAMS, E.M.P.

SWANSEA UNVERSITY

INTRODUCTION: Research has highlighted hormonal contraceptives may impair performance in some sportswomen. With the increasing popularity and growth in participation of women's rugby, there is a need to understand the potential impact hormonal contraceptive use may have, which should be a priority to understanding both the health and performance of players. Therefore, this study aimed to determine the prevalence of hormonal contraceptive use in a global population of women's rugby, investigating reported associations with training and performance to inform future practice and support.

METHODS: A total of 1,598 participants from 62 countries (26 ± 6 years; 7.5±5.1 year's playing experience) completed an online survey. The survey captured information on hormonal contraceptive use including type, reason for use and symptoms experienced along with whether training and performance was perceived to be altered. Participant eligibility includ-

ed being ≥18 years and either actively playing women's rugby fifteens and/or sevens, or having done so in the past decade, at any level, in any country.

RESULTS: Six hundred and six participants reported the use of hormonal contraceptives from across 33 countries, with the combined oral contraceptive being the most used (44%). Almost half (43%) tracked symptoms related to hormonal contraceptives but did not relate it to training despite over 10% reporting performance is altered in rugby due to symptoms related to contraceptive use and 22% requiring use of medication to manage symptoms. In relation to rugby, 11% use contraceptives just to control or stop periods caused by the menstrual cycle. Only 3 participants reported not taking part in rugby whilst experiencing a withdraw bleed irrespective of playing level.

CONCLUSION: There is a need to recognise the use of hormonal contraceptives in women's rugby especially in relation to training and performance. Associated symptoms varied in severity, in some cases causing altered performance, use of medication for management or even not taking part. In a team sport it is important to understand the prevalence and effect of hormonal contraceptive use on individuals to effectively provide support, management and optimise team performance.

ON-FIELD METHODOLOGICAL APPROACH TO MONITOR THE MENSTRUAL CYCLE AND HORMONAL PHASES IN ELITE FEMALE ATHLETES

DUPUIT, M.

INSEP

INTRODUCTION: Currently, there are no guidelines for implementing the follow-up of menstrual status including the natural menstrual cycle (NC) or oral contraception (OC) in a sports setting. We aimed to provide a feasible, on-field methodological approach for monitoring NC and OC in female athletes.

METHODS: We developed a smartphone app with daily questionnaires to monitor both NC and OC phases in 19 elite female soccer players (23.7 ± 4.4 years) over 7 months. Adherence and compliance were evaluated. The NC and OC phases were based on calendar data in order to establish an individual menstrual profile for each athlete.

RESULTS: Initial questionnaire revealed that vast majority of female players (4 out of 5) presented a large interest in monitoring their menstrual status. The online monitoring yielded high athlete adherence (87.0 +/- 14.2%) with a slight decrease over the winter break and at the end of the championship, which necessitated adaptations to promote compliance. Monitoring identified the specific menstrual pattern of each athlete and highlighted large inter-individual variability.

CONCLUSION: This study assesses for the first time the interest of female player's in monitoring their menstrual status. It provides a new methodological approach as well as guidelines for optimizing on-field monitoring. It also anticipates some obstacles sport staffs may encounter when trying to implement such follow-up. It is essential to better understand the menstrual profile of athletes and determine its potential impacts on wellbeing and performance.

Invited symposia

IS-MH07 Physical activity for cognitive health across the lifespan: when, what and how?

PHYSICAL ACTIVITY EFFECTS ON COGNITIVE AND BRAIN HEALTH IN SCHOOL AGE CHILDREN

HILLMAN, C.

NORTHEASTERN UNIVERSITY

Physical activity (PA) can improve physical, mental, cognitive, and brain health throughout the lifespan. During childhood, the benefits of PA for cognitive and brain health have been increasingly studied, with evidence indicating enhanced executive function and improved academic performance, along with adaptations to underlying brain structure and function in specific regions and networks that support these aspects of cognition. Such findings are especially relevant given that there is a growing public health burden of unhealthy behaviors (e.g., physical inactivity, excessive energy intake) among children of industrialized nations. In recent years, children have become increasingly inactive, leading to concomitant increases in the prevalence of being overweight and unfit. Poor PA behaviors during childhood often track throughout life and have implications for the prevalence of several chronic diseases during adulthood. Particularly troubling is the absence of public health concern for the effect of physical inactivity on cognitive and brain health. It is curious that this has not emerged as a larger societal issue, given its clear relation to childhood obesity and other health disorders that have captured public attention.

Relative to cognitive and brain health, the literature has predominantly focused on preadolescent children, with a comparatively smaller body of evidence in preschool age and adolescent children. Such a contrast is even more striking relative to the use of neuroimaging tools to assess PA on brain health. To date, the vast majority of neuroimaging studies have investigated preadolescent children, using electroencephalography and functional magnetic resonance imaging, and found that PA and aerobic fitness benefit neural structures and networks that support executive function and memory, including the prefrontal cortex and hippocampus. Such findings have been linked to cognitive outcomes including aspects of executive function such as inhibition, working memory, and mental flexibility as well as other cognitive outcomes including relational memory and academic achievement.

Despite evidence that PA promotes cognitive and brain health during development, a growing number of schools have minimized PA opportunities across the school day. Accordingly, this generation of children have become increasingly inactive, contributing to public health and educational concerns. By dedicating time to active play, sports, physical education, and other forms of PA, children are best-positioned to thrive in both the physical and cognitive domains. Such discoveries are timely and important for public health concerns related to chronic disease prevention as a function of childhood inactivity and obesity. These findings link pervasive societal concerns with brain health and cognition, and have implications for the educational environment and the context of learning.

ADULTHOOD - LOOKING TO BOOST A COGNITIVE AND BRAIN RESERVE

BEN, R.

UNIVERSITY OF CANBERRA

During adulthood, healthy individuals typically report few cognitive complaints. As a result, the role of physical activity in cognitive health either receives little attention or finds very few relationships. This is likely also a result of the cognitive engagement many adults have through education, vocational, and social settings. There are however observations that physical activity during adulthood does impact later life. Physical activity for cognitive health during early and middle adulthood therefore focuses on general health, reducing the potential harm to brain structures and processes that are associated with several lifestyle-related diseases.

Outside of reducing harm through physical health, physical activity may play a crucial role in building a cognitive reserve, potentially improving cognitive performance, but importantly protecting against later-life declines. Taking advantage of physical activity benefits, such as increases in cerebral blood flow and neurotrophic factors, offers an opportunity to maximise neural plasticity. In this session optimising the dose characteristics of physical activity will be discussed.

Interventions that specifically attempt to take advantage of plasticity-supporting physical activity are those that ensure cognitive activity is in close temporal proximity. Sequentially- or concurrently-programming physical exercise with a cognitive intervention are gaining popularity, with most evidence currently in older adults. This session will provide an update on the latest evidence for concurrent training in healthy adulthood.

It is hypothesized that an increased availability of factors such as brain-derived neurotrophic factor during targeted cognitive interventions improve the gains that such training can provide. However, depending on the outcome, some propose that concurrent activity may also work through the combination of effortful behaviours impacting individuals capacity, or tolerance for work. This fatigue-linked pathway may also impact cognitive health when engaged over longer periods, or when individuals are asked to report subjective cognitive complaints. These potential pathways will also be discussed in terms of informing the when, what, and how of physical activity interventions for cognitive health.

PHYSICAL ACTIVITY FOR COGNITIVE HEALTH IN OLDER ADULTS

EKBLOM, M.

SWEDISH SCHOOL OF SPORT AND HEALTH SCIENCES

There is consistent evidence to suggest that being more fit in young adulthood is associated to having better cognitive function in both young and older adulthood. We also know that being aerobically high fit is associated with having executive abilities that make it easier to attain and sustain healthy habits. While such information may be interesting, it tells us very little on whether physical activity promotion among low fit inactive individuals might have a positive influence on their future cognitive health. In midlife, lack of time is a commonly perceived barrier towards physical activity. Still, as we retire, individuals who were inactive in midlife tend to stay inactive after retiring, despite now having more spare time at hand. When preaching that it is never too late, we need to take care not to shame those whose shoes we have not walked in. Remember, that although we have all equal human value, we have different opportunities, both genetically and in terms of socioeconomic circumstances.

When we compare the brain health of senior athletes to that of their less active peers, this is not helping anyone. That is why I prefer randomized controlled trials for the purpose of figuring out what type of exercise might work for whom. The Finnish Geriatric Intervention Study to Prevent Cognitive Impairment and Disability evaluated whether a 2-year multicomponent intervention with exercise, cognitive training, diet and vascular risk monitoring could slow down the cognitive decline in an at-risk population. They show that such intervention actually can have small effects on the trajectories of cognitive decline, but we are still not close to understanding what the active component is. Large scale exercise RCTs using advanced neuroimaging to investigate neurophysiological mechanisms are under way, but these are very expensive. Major breakthroughs in plasma biomarkers of neurodegenerative disease progression have been exposed recently. Such new techniques should be exploited in future RCTs by researchers who want to investigate if support to increased physical activity can really change the cognitive trajectories of physically inactive individuals who want to spare their brain health. This presentation will explore our current understanding of how and physical activity affects cognitive health in older adults and suggest new avenues of exploration.

THE ROLE OF POSTURE IN REDISTRIBUTING THE RELATIVE CONTRIBUTION OF THE LOWER-LIMB JOINTS TO TOTAL LIMB MECHANICAL POWER DURING UNEVEN RUNNING

AMINIAGHDAM, S., NICHOLSON, G.

LEEDS BECKETT UNIVERSITY

INTRODUCTION: Proactive or reactive responses to gait perturbation paradigms allow insights into the biomechanical properties of human locomotion (1). This is deemed essential for the development of running-related injury management strategies (2). Despite ample studies on the biomechanics of human steady-state running, there is scarce research on the mechanical behaviour of lower-limb as a function of posture during perturbed running. Thus, this study aimed to characterize the redistribution of the relative contribution of the lower-limb joints (hip, knee and ankle) to total limb positive and negative mechanical powers as a result of changes in ground surface and trunk posture.

METHODS: Twelve recreational runners ran in the laboratory across even and uneven ground surfaces (10 cm anticipated drop-step) with three trunk angles from the vertical (self-selected, ~15°; anterior, ~25°; posterior, ~0°) while 3D kinematic and kinetic data were collected using a 3D motion capture-system and two embedded force-plates. Joint moment and power output were calculated for the ankle, knee, and hip. Two-way repeated measures ANOVAs ($\alpha = 0.05$) compared the relative contribution of the lower-limb joints to total limb negative and positive mechanical powers of an anticipated drop-step with that of level-step across trunk angle conditions.

RESULTS: Total limb negative and positive power increased in the drop-step (Step effect) with a proximodistal shift in the relative joint contribution to total limb negative power, which was more pronounced when leaning the trunk backward. Backward versus forward trunk lean (Posture effect) was associated with increased total limb negative power and decreased total limb positive power. Furthermore, there were increased relative contributions from the hip joint and decreased relative contributions from the knee joint to total limb positive power.

CONCLUSION: Insights from this study shed light on the mechanical behaviour of perturbed lower-limb as a function of trunk posture modifications. The accommodation of drop-steps, regardless of the running trunk posture, demands higher total limb negative and positive mechanical power. This involves a predominant relative contribution from the ankle to energy absorption or generation, which tends to be increased when the trunk is leaned backward. These findings provide implications for injury management, particularly, in the context of outdoor running, where accommodating changes in the substrate height is ubiquitous.

MECHANICAL PROPERTIES OF MODERN RUNNING SHOE FOAMS ARE HIGHLY VARIABLE AND CORRELATED WITH RUNNING ECONOMY IMPROVEMENTS

BURNS, G.T., JOUBERT, D.P., ZERNICKE, R.F., KOZLOFF, K.M.

UNIVERSITY OF MICHIGAN

INTRODUCTION: Recent advances in running shoe design have created a new footwear category—the so-called supershoe—that improves running economy (RE) and racing performance (1-4). One of the primary engineering developments that has facilitated these improvements was the introduction of novel polymer foams with higher resiliency (i.e., energy return) combined with lower material stiffness (i.e., more compliant or softer). While many running shoe manufacturers have released so-called super shoes, only the Nike VaporFly (NVF) has had the material properties of its novel foam characterized (1). Moreover, the RE enhancement afforded by shoes of these other manufacturers is highly variable (4). Finally, no data exist describing the spatial variation of shoe properties (i.e., heel to forefoot) , which may provide insight into the personalized benefits of shoe properties across different types of runners.

METHODS: The material properties of 9 models of racing shoes from 7 manufacturers (Nike, Asics, Adidas, Brooks, New Balance, Saucony, Hoka) were characterized, with 3 sizes of left and right shoes examined. An MTS MiniBionix 858 was used for uniaxial load-deformation assessment, delivering 350 and 500 kPa via a 20cm2 cylindrical stamp at a contact of 10 ms, simulating a heel strike impact transient from a 70 kg and 100 kg individual, respectively (5). Energy input, output, and material stiffness (MS) were assessed in 3 regions (heel, midfoot, forefoot). Material properties of the shoes were compared against a previous assessment of RE in each model (except for Adidas) (4). Multiple linear regression models were used to assess the influence of model, location, size, and load on the energy return and material stiffness of the shoes.

RESULTS: The energy returned (ER) from load impact varied across shoes by model, loading location, and their interactions ($p < 0.001$), but not by absolute load. ER values from the heel varied from 71.6% (Hoka Rocket X) to 84.4% (Nike Alphafly and Adidas Adios Pro 2). MS varied by model, loading location, and their interactions ($p<0.001$), as well as absolute load, indicating a degree of non-linearity in the elastic properties. MS in the heel ranged from 43.0 kN/m (Nike Alphafly) to 86.3

kN/m (Asics Hyperspeed). Previously measured RE in each shoe in a population of 12 runners (4) was inversely associated with ER (r = -0.91) and was positively associated with MS (r=0.91), with the most economical shoe (Nike Alphafly) being the most compliant and most resilient.

CONCLUSION: Significant heterogeneity exists in the mechanical properties of modern racing shoe foams, both across models and within shoes. Shoes with the highest ER and lowest MS are associated with the greatest improvements in running economy. Moreover, several shoes demonstrated large regional differences in these properties that may affect how runners respond to individual footwear design.

INCREASING LOAD CARRYING OR RUNNING SPEED DIFFERENTIALLY AFFECT THE MAGNITUDE, VARIABILITY AND COORDINATION PATTERNS OF MUSCLE FORCES

VAN WAERBEKE, C.1, WILLY, R.W.2, JACQUES, A.1, BERTON, E.1, PAQUETTE, M.R.3, RAO, G.1

1 AIX MARSEILLE UNIV, CNRS, ISM, MARSEILLE 2 DIVISION OF PHYSICAL THERAPY & HEALTH SCIENCES, UNIVERSITY OF MONTANA, MISSOULA, MT 59812 3 COLLEGE OF HEALTH SCIENCES, UNIVERSITY OF MEMPHIS

INTRODUCTION: Military training and ultra-endurance races require running with loads and/or at varying speeds (1). These situations lead to an increased stress on the musculoskeletal system and are therefore associated with an increased risk of injury (2-3). The aim of this study was to analyze the effects of load carriage or speed variations on inter- and intra-individual muscle force amplitudes, variability, and coordination patterns during running.

METHODS: Nine healthy participants ran on an instrumentalized treadmill with an empty weight vest at two velocities (2.6 m/s and 3.3 m/s) or while carrying three different loads (4.5, 9.1, 13.6 kg) at 2.6 m/s while kinematics and kinetics were synchronously recorded. A musculoskeletal model was used to estimate the forces of the major lower limb muscles. Muscle force amplitudes and variability, as well as coordination patterns, were compared at the group and at the individual levels using respectively statistical parametric mapping (4-5) and covariance matrices combined with multidimensional scaling (6).

RESULTS: Increasing the speed or the load during running increased most of the muscle force amplitudes ($p<0.01$, up to 185% of BW increase). Muscle force amplitudes and variabilities were more affected by changes in running speed than by changes in load carriage. During the propulsion phase, increasing the load increased muscle force variabilities around the ankle joint (change in standard deviation up to 5% of body weight (BW), $p<0.05$) while increasing the speed decreased variability for almost all the muscle forces (up to 10% of BW, $p<0.05$). A specific and individual muscle force coordination pattern signature was also shown for each runner ($p<0.05$). Furthermore, each runner significantly adapted his pattern in response to the perturbation associated with each experimental condition ($p<0.05$).

CONCLUSION: Muscle force amplitudes, variability, and coordination patterns during running were differentially affected depending on the perturbation (weighted vest or speed increase). These differences allow the runners to explore and develop new coordination patterns that could broaden the internal distribution of constraints. Therefore, from a training/clinical approach, due to a more progressive mechanical load on the lower limb muscles relative to an increased speed, running with a weighted vest at slow speed may be preferred in the early stages of training for novice runners (e.g., military cadets, novice trail runners) or to ensure a safer progression back to training after an injury.

COMPARISON OF PASSIVE AND ACTIVE MECHANICAL WORK IN HUMAN RUNNING AT DIFFERENT STEP FREQUENCIES

MESQUITA, R.M., IVANISKI MELLO, A., WILLEMS, P.A., DEWOLF, A.H.

UCLOUVAIN

INTRODUCTION: During steady-state running, if the foot is not skidding and wind speed is negligeable, the negative work done to (i) move centre of mass of the body (CoM) relative to the surroundings (Wext) and (ii) move the limbs relative to the CoM (Wint) is equal to the positive work done over a step (1). Instead, when considering joint work performed on rigid segments, there is a discrepancy between positive and negative work, resulting in a net-positive difference (2). It has been suggested that the discrepancy between the total amount of work done (Wtot= Wext+Wint) and the joint work reflects the passive 'soft tissue' work, done by the deformation of 'softer' parts of the body. Because muscles must actively offset any

net dissipation, soft tissue deformations may induce a deviation from the spring-like behaviour of the limb during stance, and in turn of lower-limb stiffness (3). The purpose of the present study is to estimate and compare the passive and active work contributions done during human running with different imposed step frequencies (SF). This modification in SF results in an adjustment of the lower-limb stiffness. We hypothesise that the amount work done by the soft tissues (ST) is greater at low SF and at fast running speeds, due to greater impacts on the ground, and that the offset between positive and negative active work is reduced when the lower-limb stiffness increases, with a higher SF.

METHODS: Eight recreational male runners ran on a treadmill at 5 different speeds and 5 different step frequencies from 2 to 3.6 steps s-1. The lower-limb segment motion and the ground reaction forces were recorded. The increments of Wtot+/- were calculated as the respective sum of Wext+/- and Wint+/- as in (4). Wj was calculated with inverse dynamics (5) and the same limb joints were summed to account for energy transfer. ST+/- were computed as the respective differences between Wtot+/- and Wj+/-.

RESULTS: Our results confirm our hypothesis: ST+ and ST- increase with speed and decrease with frequency. Accordingly, as the spring stiffness increases with increasing SF, the discrepancy between active positive and negative work decreases.

CONCLUSION: Optimal SF has been a topic of discussion in the literature. Elite runners have been reported to increase (6), decrease (7) or not show significant differences (8) compared to recreational runners. A deviation of the preferred SF adapts the amount of dissipative tissue work. This modification has key implications on running mechanics and performance and should be taken into account in such debate. Future studies should investigate ST modifications in conditions where net muscular work is uneven.

INTRODUCTION: Stride- and step-segmented running parameters provide valuable information in the study of the running biomechanics and performance [1]. However, segmentation requires accurate identification of initial and final foot contact events (IC and FC). Inertial sensors (IMUs) are the most effective solution for in-field running analysis. Although the morphology of the inertial signals exhibits great changes with running speed, most of the methods proposed for IC and FC detection are tested only on specific paces, limiting applicability to in-field use. In this work, a comparative evaluation among state-of-the-art IMU-based methods for the estimation of IC and FC was performed on a wide range of running speeds. In addition, a novel speed-adaptive method was proposed.

METHODS: Three datasets were used: 1) 11 amateurs running on treadmill and track at 8-10 km/h; 2) 10 amateurs running on treadmill at 14 km/h; 3) 9 athletes performing sprints on track at 20-32 km/h. All the runners were instrumented with two IMUs (fs=200Hz for dataset 2, 100Hz for 1 and 3) attached on the shoelaces. Eight methods [2-9] based on peak detection were implemented and a novel method based on dynamic time-warping (DTW) was proposed [10]. DTW was used to calculate the similarity between each analyzed running cycle and 20 templates, i.e., mid-swing to mid-swing inertial signals from all the datasets labeled and confirmed by a gold standard (stereophotogrammetric system or instrumented pressure insoles). IC and FC of an analyzed running cycle were derived from the gold standard events of its most similar template. Friedman test with Bonferroni correction was used to investigate the errors obtained with each method varying running speed.

RESULTS: Errors obtained with [2-9] highly varied across different datasets (RMSE on IC within 13-25 ms for dataset 1, 26-54 ms for dataset 2 and 22-83 ms for dataset 3; RMSE on FC within 21-90 ms for dataset 1, 20-66 ms for dataset 2 and 44-94 ms for dataset 3), reaching significant differences with [2-7] ($P<0.05$). The overall best performance was achieved with the proposed method (RMSE below 33 ms for IC and 49 ms for FC), followed by [2] (RMSE below 40 ms for IC and 59 ms for FC). A significant decrease of errors on contact and flight time at 8-10 km/h was found with the proposed method than with [2] ($P<0.05$).

CONCLUSION: This study highlighted that state-of-the-art methods for the estimation of IC and FC during running are speed-dependent. The proposed DTW-based method is the most suitable for the events identification at 8-32 km/h, encompassing the speeds used by the slowest and fastest runners, and thus for the outdoor running analysis. However, its accuracy relies on the number and morphology of the templates.

OP-PN09 Energy Metabolism II

THE INFLUENCE OF BIOLOGICAL SEX ON OXYGEN UPTAKE KINETICS DURING MODERATE AND HEAVY INTENSITY EXERCISE

ANSDELL, P., BERNERT, L., HUME, E., SOLLEIRO PONS, M., HUGHES, L., WILLIAMS, Z., BURNLEY, M.

NORTHUMBRIA UNIVERSITY

INTRODUCTION: The rate at which oxidative ATP provision can meet the energy demand of exercise is a determinant of contractile dysfunction [1]. Evidence suggests that females experience less contractile dysfunction than males for the same duration and intensity of exercise [2], however whether this is caused by bioenergetic differences or contractile properties is unknown. Therefore, this study compared the pulmonary oxygen uptake (VO2) kinetics during moderate and heavy intensity exercise in males and females.

METHODS: Sixteen healthy adults (8 of each sex, 27 ± 5 years) completed three experimental visits. First, an incremental exercise test (+25 W every 5 minutes) was performed to identify lactate threshold (LT), then an incremental exercise test (25 W.min-1) to exhaustion to identify VO2peak and power at VO2peak (Pmax). Visits two and three involved three six-minute cycling bouts at 80% of LT (moderate intensity), interspersed with six minutes of unloaded pedaling, and one 30-minute bout at a work rate 30% between LT and Pmax (heavy intensity).

Data from the final two visits were filtered and linearly interpolated (1s intervals), then pooled to form a dataset of six moderate and two heavy intensity transitions. The first 20 s of each transition was removed. Thereafter, three minutes of pre-transition data and six (moderate) or two (heavy) minutes of post-transition data were fit with a mono-exponential curve to obtain the parameters of the phase II kinetics. The VO2 slow component was also quantified for the heavy intensity bouts.

RESULTS: Absolute VO2peak was greater in males (3.47 ± 0.58 vs 2.49 ± 0.44 L.min-1, p=0.002), however relative values were not statistically different (46.2 ± 6.6 vs 40.5 ± 6.7 ml.kg-1.min-1, p=0.111). Males achieved greater power outputs at VO2peak and LT (p≤0.023), meaning power outputs for subsequent bouts were 30% greater compared to females.

The primary amplitude of the moderate intensity transition was not different between male and females (24 ± 3 vs 24 ± 5 %VO2peak, p=0.949). The time constant was also not different (27.9 ± 7.5 vs 24.8 ± 6.6s, p=0.385). Similarly, in the heavy intensity domain, neither the primary amplitude (43 ± 5 vs 38 ± 7 %VO2peak, p=0.179) or time constant (28.8 ± 7.9 vs 27.2 ± 7.1s, p=0.633) were different. Likewise, the amplitude of the VO2 slow component was not different between sexes (12 ± 7 vs 11 ± 3 %VO2peak).

CONCLUSION: No sex differences were observed in the VO2 response to exercise in the moderate or heavy intensity domains, implying there was no sex difference in the bioenergetic stress experienced. Combined with evidence of no hormonal effect [3] on these parameters, this suggests females should not be excluded from studies of cardiopulmonary responses to exercise. Data from near infrared spectroscopy will also be shared.

FAT OXIDATION IS POSITIVELY ASSOCIATED WITH RUNNING PERFORMANCE AFTER STRENUOUS CYCLING IN YOUNG TRIATHLETES

KELLER, S., WAHL, P.

GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: Endurance performance can be predicted by maximal oxygen uptake (VO2peak), sustainable percentage of VO2peak, and energy cost of movement (C) (1). However, during prolonged exercise, the ability to maintain these physiological attributes, i.e., durability, has recently been shown to characterize elite performance, e.g., in cycling (2). Mainly, two metabolic mechanisms are discussed to adversely affect durability: an increase in C, e.g., due to reduced neuromuscular efficiency, and/or increased reliance on fat oxidation (FO) due to gradual glycogen depletion during prolonged exercise. Since the prediction of prefatigued cycling performance has recently been improved by considering FO (3) and in triathlon, running always occurs after cycling, this study investigated C and substrate metabolism in triathletes before and after strenuous cycling to determine their relevance to prefatigued running performance.

METHODS: Fifteen young squad triathletes (16 ± 1 yrs; 60.8 ± 5.5 mL·min-1·kg-1) completed a combined cycling and running incremental protocol. After three 5-min running stages on a treadmill (2.8 + 0.4 m·s-1, 30 s rest), athletes performed a 15-s sprint test, followed by a 20-min recovery phase, and a 3-min incremental test to exhaustion (~1.5 W·kg-1 + 20 W) on a cycling ergometer. Following an 8-min rest, another 5-min incremental test to exhaustion (2.8 + 0.4 m·s-1, 30 s rest) was performed on the treadmill. C, carbohydrate oxidation (CHO), and FO were estimated from spirometric data via indi-

rect calorimetry and compared in the first three running stages under fresh (before) and prefatigued (after cycling) conditions using rmANOVA. Associations between VO2peak, C, and CHO/FO and time to exhaustion (tlim) in the exhaustive incremental running test, were examined by correlation and stepwise regression analysis.

RESULTS: In contrast to unaltered C (4.59 ± 0.34 and 4.53 ± 0.36 J· kg-1·m-1, p = 0.12), mean CHO (2.82 ± 0.45 and 2.07 ± 0.37 g·min-1, p < 0.001) decreased, while FO (0.14 ± 0.13 and 0.41 ± 0.18 g·min-1, p < 0.001) increased from fresh to prefatigued running. Besides VO2peak (r = 0.59, p = 0.02), tlim (1610 ± 176 s) correlated with the change in FO (ΔFO) from fresh to prefatigued running (r = 0.49, p = 0.06). Regression analysis identified VO2peak, C, and ΔFO as the most informative model for tlim (adj. R2 = 0.59, p = 0.01).

CONCLUSION: In young triathletes, CHO significantly decreased and FO increased during running after strenuous cycling compared to before, while C remained constant. Due to the correlation between ΔFO and tlim and higher accuracy when ΔFO was added to the model for tlim, substrate metabolism should be considered for predicting prefatigued running performance in triathlon. In addition, the positive association between ΔFO and tlim suggests that high FO rates may be beneficial for performance and should thus be improved, e.g., by training with low glycogen availability.

METABOLIC PROFILE IN BADMINTON MATCH PLAY

EDEL, A., FREIS, N., KAUFMANN, S., HOOS, O., WIEWELHOVE, T., FERRAUTI, A.

RUHR UNIVERSITY BOCHUM

INTRODUCTION: The intermittent nature of badminton suggests high involvement of anaerobic energy supply [2]. However, recent research showed that energy supply of match play might be predominantly aerobic [1]. To clarify the physiological requirements in badminton the present study aimed to analyse the metabolic profile using two different calculation models based on PCr-La-O2 method.

METHODS: 7 internationally ranked badminton players (5 males: age 21.2 ± 2.3 y, height 184 ± 7 cm, body mass 77.4 ± 9.8 kg; 2 females: age 18.5 ± 0.7 y, height 172 ± 11 cm, body mass 67.5 ± 9.1 kg) performed two sets of 15 min match play under training conditions. Rally and rest times, oxygen uptake (VO2), RER, and blood lactate concentrations (La) were obtained. Net metabolic cost (Etot) and percentage contribution to aerobic (Eaer), anaerobic alactic (Epcr), and lactic (Ela) energy supply were calculated by indirect calorimetry from VO2 and RER during exercise, fast component of postexercise oxygen kinetics (EPOC) and net La. The continuous model (con) considered replenishment of anaerobic energy stores only at the end of exercise. The intermittent model (int) accounted for replenishment of creatine phosphate (PCr) during the match by applying the EPOC model to each resting phase. Repeated measures ANOVA was used to compare the models.

RESULTS: On average 91 ± 11 rallies with mean duration of 7.1 ± 0.7 s and 12.3 ± 1.9 s rest in between were observed. Mean VO2, RER and La were 36.0 ± 5.3 ml·min-1·kg-1, 0.89 ± 0.05, and 2.2 ± 1.1 mmol·l-1. Etot was 675 ± 98 J·kg-1·min-1. Comparison between models revealed significant differences for Eaer and Epcr (con: Eaer 97% ± 1%, Epcr 3 ± 1%; int: Eaer 56% ± 9%, Epcr 43 ± 9%). Ela remained below 1% for both models. No differences could be observed between the sets or male and female players.

CONCLUSION: The study showed that selection of the underlying calculation model is crucial for the results. Consistent with a previous study, continuous model suggests that badminton is predominantly aerobic [1]. In contrast, the intermittent model revealed a considerably higher proportion of anaerobic alactic energy supply, while aerobic capacity is needed to replenish PCr stores during rest. This would be in line with general findings for metabolic profile in intermittent exercises [2]. However, since La dynamics cannot be reflected seamlessly by punctual measurements, the lactic content might be underestimated in both models.

ALL IN ONE TESTING OF ĊLAMAX AND V̇O2MAX: MODELLING ĊLAMAX OUT OF POST LACTATE VALUES AFTER A RAMP TEST – A CASE STUDY

VENZKE, J., SCHÄFER, R., SUTTMEYER, J., DMITRIEVA, A., REUTER, Y., PLATEN, P.

RUHR-UNIVERSITY BOCHUM

INTRODUCTION: Lactate concentrations during a graded exercise test are commonly used as indicator for endurance performance. Mader (2003) implemented a theoretical framework of human energy metabolism using mathematical equations which was further developed as a computer simulation. For a determination of the physiological responses of

exercise two key parameters are needed: the maximal glycolytic (ċLamax) and oxidative (V̇O2max) flux rates. As the maximum rate of lactate formation increases, the maximum lactate values post-exercise increase as well. For endurance athletes the ċLamax is considered as an important variable as they usually have high percentages of type 1 fibers, which usually contain low concentrations of anaerobic enzymes. Based on the simulation, Heck et al. (2022) proposed that ċLamax can be inferred from post lactate values after a V̇O2max-ramp test. We aimed to validate this approach to determine ċLamax via an exponential function.

METHODS: Recreational cyclists and triathletes (n=3) with a weekly training volume above 6h were recruited. A 15s sprint test to measure ċLamax followed by a ramp test until exhaustion to measure V̇O2max with a break of 45min between both test was completed. Testing was conducted on a Cyclus 2 ergometer on subject's own bike. Blood Lactate concentration was measured before and each minute after the respective test. Gas exchange was measured in the ramp test via the MetaMax 3B-system. ċLamax was calculated by using the formula: ċLamax = 0.18+0.00996*exp(0.241*maximal post lactate value). This formula based on assumed values for an average cyclist. One step further, we individualized this formula based on our measures. In the simulation, PCr-values for exhaustion were set at 1, 3 and 5 mmol per kg muscle mass (kgm), respectively. Descriptive statistics were used for comparing the experimental versus simulation-derived version.

RESULTS: Determination of ċLamax in the sprint test was higher [0.56 mmol/l/s (0.54-0.57)] compared to the calculation based on the post-exercise lactate values after the ramp test [0.47 mmol/l/s (0.33-0.66)]. The absolute difference showed a 30% difference from the measured value (0.17 mmol/l/s). With individualized formulas and different exhaustion criteria based on PCr, results also differed from measured values (1mmol/kgm: 0.37 mmol/l/s (0.24-0.53)]; 3mmol/kgm: 0.92 mmol/l/s (0.44-1.54); 5mmol/kgm: 2.85 mmol/l/s (1.33-4.83)].

CONCLUSION: Preliminary results show a high incongruent relationship between estimated and measured values. A fixed criterion for exhaustion based on the PCr-value does not seem to useful and should also be individualized. These results suggest that it might not be possible to calculate ċLamax after a V̇O2max-ramp test yet and should further be examined. For a more accurate assumption if the formula can be used, should be adjusted or if the criterion of exhaustion should be fixed or adjusted on an individual basis, a greater sample size is required.

MIR-29 FAMILY PLAYS A RELEVANT ROLE IN ENDURANCE PERFORMANCE THROUGH THE UPREGULATION OF EXERCISE-ASSOCIATED ENERGY MOLECULAR PATHWAYS

PINTO-HERNÁNDEZ, P., FERNANDEZ-SANJURJO, M., TOMAS-ZAPICO, C., CARAVIA, X.M., LOPEZ-OTIN, C., FERNANDEZ-GARCIA, B., IGLESIAS-GUTIERREZ, E.

UNIVERSITY OF OVIEDO

INTRODUCTION: Endurance exercise has been widely reported to have numerous beneficial effects on the oxidative capacity of skeletal muscle, mainly mediated by an increase in the number and size of mitochondria via PGC1α 1. This increase is largely related to improved exercise capacity and maximal oxygen uptake (VO2max) 2. In recent years, the miR-29 family has been reported to play a key role in both the modulation of mitochondrial homeostasis, targeting PGC1α, and glucose and fatty acids metabolism, two of the main substrates used during exercise 3,4. The aim of this study was to assess the role of the miR-29a/b1 cluster in endurance capacity through the regulation of energy metabolism pathways

METHODS: 14-week-old male mice deficient in the miR-29a/b1 cluster (KO; n=8) and their corresponding wild-type controls (WT; n=8) were used. After 2 weeks of adaptation, maximal endurance capacity was assessed using an incremental test on a treadmill, where blood glucose and lactate levels were monitored each 3 minutes. Animals were sacrificed 48 h after the test and skeletal muscle samples (quadriceps and soleus) were collected. The expression of miR-29a-3p, miR-29b-3p, and miR-29c-3p and several genes involved in glucose and fatty acid metabolism were measured by qPCR: Pgc1α, Glut1, Glut4, Ampk, Pfkm1, Acadvl, Acadm, Slc27a1, and Slc27a4

RESULTS: KO mice showed a significantly lower maximal endurance capacity. Accumulation of blood lactate during the test was observed in WT but not in KO animals, where this parameter remained low and stable. No expression of miR-29a-3p was confirmed in the KO group, showing also a significantly lower miR-29b-3p expression (Qua, p = 0.0001; Sol, p = 0.0001). Interestingly, as for miR-29c-3p, it was significantly reduced only in the soleus (p=0.012) but not in the quadriceps of KO mice (p=0.949). Unexpectedly, no differences in Pgc1α expression were observed between the two groups in either tissue. However, in relation to the expression of genes related with energy metabolism, both quadriceps and soleus showed an increase in Glut4 and Acadvl, while no changes were detected in Slc27a1 and Acadm. A muscle-type specific response was observed for Pfkm1, which was overexpressed in quadriceps, and Glut1, Ampk, and Slc27a4, in soleus.

CONCLUSION: The miR-29 family plays an important role in endurance capacity through the upregulation of the metabolism of the most important substrates for energy production via oxidative phosphorylation in skeletal muscle, in a muscle-specific manner. This response may be due to the specific downregulation of the other cluster member, miR-29c-3p, in soleus.

IS-MH05 The power of water: Hydrotherapy for the prevention and treatment of cardiovascular disease

H2-GO! THE PHYSIOLOGY AND CLINICAL IMPACTS OF WATER-BASED EXERCISE IN THE UPRIGHT POSTURE IN HUMANS

GREEN, D.

THE UNIVERSITY OF WESTERN AUSTRALIA

Results of a randomised controlled 6 month intervention comparing water and land based walking in older adults: This talk will summarise our novel findings regarding the acute effects of water immersion on systemic haemodynamics, and in particular the impacts on blood flow and shear stress through cerebral and peripheral arteries in vivo. These findings, including the impacts of exercise in the water on physiological outcome measures, led us to undertake a comprehensive randomised controlled superiority trial of the impacts of 6 months of supervised centre-based exercise at matched intensity, performed in either waist-to-chest deep euthermic water, or on land, versus a usual care control group. Outcomes included cognition, cardiopulmonary fitness, body composition (DXA), blood pressure, blood lipids, peripheral endothelial function (FMD) and cerebrovascular function assessed using transcranial Doppler ultrasound responses to autoregulation, neurovascular coupling and CO2 exposure. Our findings will encourage further investigation and potential uptake of this novel and safe interventional strategy, particularly in older less active individuals at risk of falls and musculoskeletal injury.

JUST ADD HOT WATER: TURNING UP THE HEAT ON CARDIOVASCULAR DISEASE

COTTER, J.

UNIVERSITY OF OTAGO

Many people find traditional exercise programmes a challenge due to medical conditions or physical limitations. Examples include those awaiting hip and knee joint replacement surgery, and those with peripheral arterial disease: both limited by pain and poor mobility. As a consequence of their immobility, fitness, mobility, cardiovascular status and quality of life can deteriorate, and risk of surgical complications increases, as these patient populations often proceed to surgical interventions beyond initial conservative management. Alternative cardiovascular therapies are needed for such clinical populations.

Recent work from our group and others has shown that regular heat exposure can be protective against cardiovascular disease. Heat induces transient cardiovascular and metabolic responses that are not unlike those occurring during a bout of exercise, including elevated core temperature, reduction in blood pressure and increased peripheral blood flow. The addition of individualised, non-weight-bearing, mild resistance exercise is important for increasing glucose uptake, neural activation, blood flow and muscle growth. This talk will focus on the role of heat therapy via hot-water immersion with mild resistance exercise in patients who find traditional exercise difficult. The intended outcomes of this program are to improve strength and functional capacity and reduce cardiovascular risk and associated cardiovascular pathology, and to improve quality of life.

MAKE A SPLASH - AQUATIC ACTIVITY AS AN OPTIMAL THERAPEUTIC EXERCISE STRATEGY FOR STROKE SURVIVORS

LUCAS, S.

UNIVERSITY OF BIRMINGHAM

Regular exercise is a recommended strategy to improve physical function, fitness and quality of life after stroke, and to prevent subsequent strokes. However, current exercise guidelines for stroke survivors are the same as the general population, which do not account for the reduced physical capacity of stroke survivors to exercise due to their stroke-acquired disability. Moreover, stroke-related loss of function and reduced physical fitness and muscle strength mean that traditional exercise approaches such as moderate intensity jogging are not realistic for many stroke survivors living in the community with permanent disability. Therefore, alternative approaches that are accessible to all stroke survivors are needed to allow these patients to access the health benefits of exercise.

Immersion in water applies an external environmental pressure on the body that helps return blood to the heart and improve blood circulation through blood vessels. This movement of blood through the vessels releases key compounds linked with better vascular function. Consequently, water-based exercise has great potential to enhance the benefits of exercise on vascular health; benefits that span from lowering resting blood pressure to improving brain blood vessel function, both of which are key risk factors for stroke. This talk will present findings from our work investigating the effectiveness of aquatic treadmill exercise to improve vascular health and physical function in stroke survivors.

EFFECT OF REPEATED SPRINT TRAINING IN HYPOXIA ON THE REDOX BALANCE IN WELL TRAINED ATHLETES

CHAMBION-DIAZ, M., FAISS, R., LÉGER, B., PIALOUX, V., MILLET, G.P.
CLAUDE BERNARD UNIVERSITY LYON 1

INTRODUCTION: Elite athletes use altitude or hypoxic training in the belief that it will enhance their ability to compete successfully at the international level. Beyond traditional "live high-train high" or "live high-train low" models, simulated altitude training modalities using hypoxia intermittently as an additional stressor have been widely investigated. The repetition of short 'all-out' sprints with incomplete recoveries in hypoxia - the so-called repeated sprint training in hypoxia model- has seen unprecedented scientific interest after the seminal study published by our group in 2013. Hypoxic exercise was however also shown to increase the oxidative stress through overproduction of reactive oxygen species. There is hence only scarce knowledge on the impact of RSH on the oxidative stress and antioxidant systems. Besides the significant molecular and systemic adaptations already reported after RSH, this work focused specifically on the effect of RSH on oxidative stress and antioxidant response. A potential positive effect of RSH compared to repeated sprint training in normoxia on the redox balance was hypothesized.

METHODS: 50 male well-trained road cyclists and mountain-bikers volunteered in the study. They were matched into two different intervention conditions (hypoxia; RSH vs normoxia, RSN) and tested twice near seal-level (before, pre-, and after, post-, a 4-week training protocol) for the determination of repeated sprint ability, endurance performance and anaerobic capacity, muscular signaling pathways, oxidative stress and antioxidant status. Antioxidant enzymes activity (SOD; GPX; and catalase), NO metabolites (NOx), ferric reducing antioxidant power, MDA, nitrotyrosine, carbonyls were measured in plasma. Only biochemical data will be analysed and discussed here.

RESULTS: MDA and carbonyls increased in the RSN group ($p<0.05$) but not in the RSH group, after training at rest and also after the RSA test. Carbonyls were increased in both groups after the RSA test ($p<0.05$). Catalase increased after the RSH training intervention, after the RSA test ($p<0.05$), regardless of the hypoxia or normoxia group. SOD and nitrotyrosine were decreased ($p<0.05$) at rest and after RSA post training, regardless of the group. NOx decreased after RSA, both before and after the training intervention, regardless of the group ($p<0.05$).

CONCLUSION: Our results show that 4 weeks of RSH blunted the increase in oxidative stress markers (MDA, carbonyls) both at rest and in response to RSA test, when compared to the same training intervention in normoxia. Training down-regulates SOD activity maybe due to an overproduction of ROS . The decrease of NO, illustrated by the decrease of NOx and nitrotyrosine, in response to the RSA test could be explained by radical overproduction, with a concomitant eNOS inhibition caused by the ROS. Our results may lead to a paradigm shift with a better enzymatic adaptation in response to the oxidative stress after RSH and/or a different ROS production between RSH and RSN.

SEX DIFFERENCES IN PULMONARY LIMITATIONS DURING MAXIMAL-INTENSITY EXERCISE IN NORMOXIA AND HYPOXIA

RABERIN, A., MANFERDELLI, G., SCHORDERET, F., MILLET, G.P.
UNIVERSITÉ DE LAUSANNE: UNIVERSITE DE LAUSANNE

INTRODUCTION: Pulmonary system is generally not considered as limiting for endurance performance. However, in some specific population (endurance-trained athletes) or environmental condition (altitude), this system may not meet maximal exercise demand. In endurance-trained athletes, the excessive strain placed on the respiratory system (relative to its capacity) could lead to expiratory flow limitation (EFL) and exercise-induced hypoxemia (EIH). Moreover, because of smaller airways and lung size, women are suspected to be more prone to develop pulmonary limitations to endurance performance. These mechanisms may be exacerbated in hypoxia due to lower alveolar-to-arterial diffusion.

The aim of the present study was to investigate the impact of sex and aerobic fitness on pulmonary limitations at maximal intensity in normoxia and hypoxia.

METHODS: 50 young healthy participants were divided in four groups according to their sex and aerobic fitness; trained women (TW, n = 12, VO2max = 54.9 ± 3.9 ml.min-1.kg-1), control women (CW, n = 12, 45.4 ± 4.7 ml.min-1.kg-1), trained men (TM, n = 12, 68.9 ± 6.0 ml.min-1.kg-1) and control men (CM, n = 14, 54.3 ± 4.3 ml.min-1.kg-1). They performed two maximal incremental cycle tests in normoxia and hypoxia ($FiO2 = 0.14$) with gas exchanges measurements. Standardized spirometry tests were used. Pulmonary limitations were evaluated using the maximal flow volume loop and pulse O2 saturation monitoring.

RESULTS: EIH was more prevalent ($p = 0.012$) and contradictory EFL less common ($p = 0.022$) in women than men. EIH prevalence was different ($p = 0.014$) between groups (28% TW, 43% CW, 24% TM, and 5% CM). All EIH men but only 40% of EIH women exhibited EFL. The normoxia- to-hypoxia decrease in VO2max (%VO2max) was correlated to EIH severity only in TM ($r = -0.63$, $p = 0.028$). In normoxia, EFL was associated to higher slope ratio ($p = 0.029$), higher ventilation (VE) ($p < 0.001$), larger %VO2max ($p = 0.019$) and lower hypoxia-related VE increase ($p < 0.001$). In hypoxia, EFL was only associated to higher VE ($p < 0.001$).

CONCLUSION: Our results show sex differences in the pulmonary limitations to exercise in normoxia and hypoxia. The well-described relationship (in male athletes)1 between EIH severity and %VO2max is not present when women are considered. Although women are more hypoxemic than men in normoxia, they are less impacted by hypoxia. EFL seems always involved in EIH men. Individuals with EFL in normoxia are not able to increase their VE in hypoxia and hence exhibited a higher drop in VO2max. Overall, these results highlight that pulmonary limitations have different origins (e.g., mechanical constraints) and consequences in women compared to men that required specific investigations.

ACUTE RESPONSES OF THE INTER-EFFORT RECOVERY HYPOXIA ON PHYSIOLOGICAL, CARDIORESPIRATORY PARAMETERS AND MUSCLE OXYGENATION DURING HIGH-INTENSITY INTERVAL EXERCISE IN RUNNING.

NORBERTO, M.S.

UNIVERSITY OF SÃO PAULO

INTRODUCTION: Exposure to hypoxia associated with interval training (IT) improves physical performance [1], but contradictory responses to the addition of hypoxia have been demonstrated depending on the variation of the IT. Apparently, the main benefits of adding hypoxia to training on performance seem to be evidenced when the absolute intensity of the training is preserved [2]. Additionally, a greater FiO2 variation seems to be an important stimulus for adaptations resulting from hypoxia exposure [3]. The aim of this study was to investigate the acute responses of inter-effort recovery hypoxia on physiological, cardiorespiratory parameters, and muscle oxygenation during high-intensity IT of running.

METHODS: Twelve amateur runners performed three IT sessions randomly distributed, composed of ten 1-min efforts at 120% of VO2PEAK with 2 min recovery between each effort in three different conditions: efforts and recovery in normoxia (GNN; FiO2=20.5%), efforts and recovery in hypoxia (GHH; FiO2=13.5%), and efforts in normoxia with recovery in hypoxia (GNH; FiO2=13.5%). Oxygen consumption, respiratory exchange ratio (RER), and vastus lateralis muscle oxygenation were monitored. During recovery, subjective perceived exertion (RPE), blood lactate ([La-]), and arterial oxygen saturation (SpO2) were measured. For all variables, mean values during effort (E), recovery (R), and mean differences between E and R (Δ=E-R) were compared by the Friedman test with Durbin-Conover post hoc ($p<0.05$).

RESULTS: No differences were found between conditions for [La-]. GHH showed higher mean RPE during efforts ($p=0.002$) and a lower success rate (85.7±15%) of complete efforts than GNN (100%; $p=0.003$) and GNH (100%; $p=0.003$). The ΔFiO2 of GNH (5.4±0.1%) was higher than GNN (0.01%; $p<0.001$) and GHH (0.1%; $p<0.001$). The mean SpO2 in GNN (94.8±2.2%) during recovery was highest than GNH (87.7±2.4%; $p<0.001$) and GHH (79.2±7%). Surprisingly, GHN presented the highest mean VO2 during the efforts (43.8±2.4 ml/Kg/min) than GNN (41.6±5.3ml/Kg/min; $p<0.001$) and GHH (31.7±5 ml/Kg/min; $p<0.001$). During recovery, GNN showed higher VO2 than the other conditions ($p=0.002$). The highest ΔVO2 was in the GHN, followed by GNN and GHH ($p<0.001$). During efforts, the RER of GHN (0.86±0.03) was lower than GNN (0.97±0.08; $p=0.007$) and GHH (1.08±0.2; $p<0.001$). The deoxy-hemoglobin (HHb) during recovery was higher for GHH (31.4±10.3μM) when compared to GNN (23.3±8.4 μM; $p<0.001$) and GNH (27.6±8.9μM; $p<0.001$). GNN also showed lower ΔHHb when compared to the other conditions ($p>0.025$).

CONCLUSION: It can be concluded that the inter-effort recovery hypoxia does not affect RPE nor limit performance but promotes increases in the aerobic contribution (i.e., VO2) during efforts of high-intensity exercise. Furthermore, the responses of RER suggest that HH is prone to buffering action during efforts, differently from HN, demonstrating the potential use of the aerobic pathway.

EFFECT OF HYPOXIA ON AEROBIC VS ANAEROBIC ENERGY EXPENDITURE DURING HIGH INTENSITY INTERVAL EXERCISE

ALMADHOUN, S., RAZAVIASFALI, M., TOWNSEND, N.

HAMAD BIN KHALIFA UNIVERSITY, QATAR

INTRODUCTION: Exercise in hypoxia decreases VO2max and markers of the maximum metabolic steady state (MMSS). Consequently, a given absolute exercise intensity in normoxia equates to an elevated relative intensity in hypoxia. Thus, exercise at given absolute workrate in hypoxia is characterized by a shift towards greater anaerobic energy contribution compared with normoxia. Few studies normalize relative intensity to MMSS nor select the magnitude of hypoxia based on known prediction equations. The purpose of this study was to examine the impact of hypoxia on aerobic, glycolytic and alactic energy expenditure (EE) during high intensity interval exercise (HIIE) at matched relative, and absolute intensity.

METHODS: Eleven active adults (M=6; F=5) completed a ramp-step incremental test on a cycle ergometer to determine the gas exchange threshold (GET) and respiratory compensation point (RCP). Normoxic MMSS was determined from RCP corrected for mean response time and hypoxic MMSS was estimated using a prediction equation. Thereafter, a HIIE session (5 or 6x3min intervals) was performed in three conditions: i) heavy domain normoxia (NORM-H: 12%MMSS), and iii) severe domain normoxia (NORM-S:12%>MMSS). Thus, NORM-H and HYPO were matched for absolute intensity, while HYPO and NORM-S were matched for relative intensity. Total work was matched for all conditions (147±49kJ). Aerobic, glycolytic and alactic EE were determined via indirect calorimetry, delta lactate and the fast component of the VO2 recovery curve respectively.

RESULTS: Total EE was higher in NORM-S (1063±266kJ) compared to NORM-H (975±233kJ; P=0.01) but not HYPO (1016±229kJ; P=0.13). Efficiency was lower in NORM-S (14.9±6.9%) than NORM-H but not significantly (16.2±8.2%; P=0.07), and was similar to HYPO (15.5±7.3%). Aerobic EE was lower in HYPO (697±154kJ) compared to both NORM-H (752±178kJ;

P=0.007) and NORM-S (745±189kJ; P=0.047), whereas glycolytic EE was higher in both HYPO (196±59kJ) and NORM-S (199±46kJ), than NORM-H (99±32kJ; P<0.001). No significant differences were observed for alactic EE between conditions. Consequently, the % contribution to total EE from glycolysis was lowest for NORM-H (10.3±2.8%) compared to HYPO (19.3±3.8%; P<0.001), and NORM-S (19.0±3.0%; P<0.001), whilst the opposite was true for % aerobic contribution (NORM-H: 77.4±4.5%; HYPO: 68.7±2.5%; NORM-S: 70.2±4.0%; P<0.001).

CONCLUSION: When exercise was matched for absolute intensity, aerobic EE was reduced in hypoxia and this was compensated for by increased glycolytic EE. When matched for relative intensity, glycolytic EE in hypoxia was equivalent to normoxic HIIE i.e. conducted at a higher absolute workrate. Thus when relative intensity was normalized to MMSS, the anaerobic EE of HIIE in hypoxia 'mimics' that of normoxic exercise, but at a reduced absolute workrate. It is primarily glycolytic EE that was altered in hypoxia as opposed to alactic EE.

OP-MH23 Metabolic syndrome and diabetes I

AEROBIC EXERCISE IMPROVES FAT OXIDATION CAPACITY AND REDUCES INSULIN RESISTANCE LEVELS IN PATIENTS WITH TYPE 2 DIABETES MELLITUS: PRELIMINARY RESULTS OF THE EDUGUTION STUDY

MONTES-DE-OCA-GARCÍA, A., MARÍN-GALINDO, A., RAMÍREZ-JIMÉNEZ, M., CORRAL-PÉREZ, J., PÉREZ-BEY, A., REBOLLO-RAMOS, M., OPAZO-DÍAZ, E., CASALS, C., PONCE-GONZÁLEZ, J.

UNIVERSITY OF CADIZ

INTRODUCTION: The practice of physical exercise is essential in patients with type 2 diabetes mellitus (T2DM). However, it is currently unclear which type of exercise is the best therapeutic tool for T2DM management. Thus, the aim of this randomized controlled trial was to analyze the effect of an aerobic training program, moderate-intensity continuous training (MICT) vs. high-intensity interval training (HIIT), on glycemic control and the maximal fat oxidation capacity during exercise (MFO) in people with T2DM.

METHODS: A total of 27 adults (n=11 females; 54.5±8.9 years; Body Mass Index=34.2±5.6 kg/m2) with T2DM were randomized into three groups: HIIT (n=7), MICT (n=9), and control group (CG) (n=11). The 12-week training consisted of three sessions per week, HIIT included 10×1 intervals pedaling at 90% of peak power output, and MICT consisted of continuous pedaling at 10% above the first ventilatory threshold for 50 minutes. Before and after the intervention, fasting blood samples were taken and glucose, insulin, and glycosylated hemoglobin (HbA1c) were analyzed. The homeostatic model assessment for insulin resistance (HOMA-IR) was calculated. The MFO was determined by indirect calorimetry with a gas analyzer with 15W/3-min increments. Then, after a 5-min resting period, a maximal test with 1-minute steps (15W) was performed until exhaustion. To examine the effect of the intervention, a 3×2 mixed ANOVA with repeated measures was used.

RESULTS: No statistically significant differences were found between groups at the beginning of the intervention (p>0.05). After the intervention, a main effect of time was observed for basal insulin levels (F(1,24)=5,73; p=0.025; ηp2=0.19) and HOMA-IR (F(1,24)=4,75; p=0.039; ηp2=0.17). Moreover, a significant time x group interaction was observed for MFO (F(2,24)=8,69; p=0.001; ηp2=0.42). Specifically, after the intervention, significant differences (p=0.008) were observed between the MICT group (0.36±0.10) and the CG (0.23±0.08). In fact, significant improvements in MFO were observed in MICT group (0.29±0.07 vs. 0.36±0.10; p=0.003), while the CG decreased MFO (0.27±0.10 vs. 0.22±0.08; p=0.016). No significant effects were observed for blood glucose or HbA1c (p>0.05).

CONCLUSION: A 12-week aerobic exercise program is effective for improving MFO and insulin sensitivity in adults with T2DM. In fact, MICT appears to be superior to HIIT, although no significant differences were found. However, more studies are needed, since it seems that the benefits of HIIT and MICT are different depending on the adaptations that each training produces. Thus, HIIT could be more effective for improving cardiorespiratory fitness, although it depends on the HIIT protocol used, while for the improvement of glycemic parameters, both trainings are equally beneficial.

DOES TRAINABILITY DIFFER BETWEEN PATIENTS WITH TYPE 2 DIABETES AND OBESE CONTROLS?

BORCH, J., HANSEN, M., DAL, M., LANGE, K.K., HELGE, J.W., DELA, F.

UNIVERSITY OF COPENHAGEN

INTRODUCTION: Aerobic exercise improves insulin sensitivity, reduces glycated hemoglobin (HbA1c), and increases maximal oxygen uptake (VO2max) in patients with type 2 diabetes (T2D)(1). However, adaptations following training vary between individuals(2), and it has been suggested that patients with T2D have a less pronounced increase in VO2max in response to the same intervention. This study investigates changes in VO2max and its relation to glycemic control in T2D and obese controls (CON) following an aerobic training intervention.

METHODS: Seven patients with T2D (7 males, age: 49.1 ± 7.4 years, BMI: 33.5 ± 3.7 kg/m2, VO2max: 24.7 ± 3.7 ml/min/kg, HbA1c: 67.3 ± 23.6 mmol/mol, time since diagnosis: 3.2 ± 2.1 years) and 8 CON (7 males, ne female, age: 51.9 ± 8.0 years, BMI: 35.2 ± 4.0 kg/m2, VO2max: 27.3 ± 3.4 ml/min/kg, HbA1c: 36.9 ± 5.3 mmol/mol) completed a

training intervention (12 wks; two bike sessions and one rowing session of 45 minutes with intervals of 3-8 minutes at an intensity equivalent to 80 % of VO2max or heart rate reserve. All participants completed between 35 and 37 sessions). The study is ongoing and actively enrolling, and preliminary data are presented. Aerobic capacity was measured before and after intervention by the Breath-by-Breath mode (COSMED, Rome, Italy). HbA1c was measured and taken as an index of glycemic control. Hba1c and VO2max data were analyzed using paired t-tests, and two-way ANOVA with repeated measures for changes between groups. Correlation between VO2max and change in HbA1c was done by Pearson's correlation coefficient. Results are presented as mean ± SD.

RESULTS: VO2max increased to the same extent (p=0.0914) both T2D and CON (+7.2 ± 1.6 ml/min/kg (29 ± 4 %), p<0.00001; +4.5 ± 3.9 ml/min/kg (18 ± 15 %), p=0.0138, respectively). HbA1c decreased significantly in T2D group (–6.4 ± 8.1 mmol/mol, p=0.0403) but not in CON (+0.6 ± 4.4 mmol/mol, p=0.3511). The change in glycemic control in T2D did not correlate with the change in VO2max (Pearson's correlation coefficient, R2=0.00574).

CONCLUSION: 12 weeks of aerobic training improves VO2max in both T2D and CON with no difference between groups. While no difference in trainability was observed, the T2D had a relatively lower baseline VO2max, which may impact the outcome. T2D had a significant change in HbA1c after training. The change in VO2max did not correlate to the change in HbA1c in T2D. Changes in VO2max were very similar for all subjects with T2D, whereas the changes in HbA1c were scattered. The broad range of baseline HbA1c partly explains this. A larger population with the possibility to stratify on baseline HbA1c perhaps elicit a different outcome.

THE EFFECT OF ACUTE KETONE MONOESTER INGESTION ON MUSCLE OXYGENATION AND SYSTEMIC VASCULAR FUNCTION AT REST AND DURING INCREMENTAL CYCLING EXERCISE IN ADULTS WITH TYPE 2 DIABETES MELLITUS

PERISSIOU, M., FEKA, K., EDWARDS, C., JAMES, T.J., SAYNOR, Z.L., CORBETT, J., MAYES, H., SHUTE, J., CUMMINGS, M., BLACK, M.I., STRAIN, W.D., LITTLE, J., SHEPHERD, A.I.

UNIVERSITY OF PORTSMOUTH

INTRODUCTION: Type 2 diabetes mellitus (T2DM) is characterised by chronic hyperglycaemia and progressive insulin resistance, ultimately leading to systemic and microvascular dysfunction. Insulin regulates muscle microvascular perfusion and blunts skeletal muscle microvascular function at rest and during exercise in people with T2DM [1]. Acute exogenous ketone monoester (Kme) ingestion is associated with improved glucose tolerance and peripheral muscle oxygenation in healthy adults, but this has not been investigated in people with T2DM. This study examined the acute effects of Kme ingestion on peripheral muscle oxygenation and systemic vascular function in adults with T2DM at rest and during incremental cycling exercise.

METHODS: Thirteen adults with T2DM (age=66±9 y; mass=90.3±15.2 kg; HbA1c=54±7 mmol/mol) participated in this double-blind, placebo controlled, randomised crossover trial. Participants attended the laboratory on 2 separate occasions, ingesting upon arrival either a Kme drink (0.115 g/kg (R)-3-hydroxybutyl (R)-3-hydroxybutyrate) or placebo drink, matched for taste. At rest and throughout incremental cycling exercise peripheral muscle oxygenation [tissue saturation index (TSI%)] of the gastrocnemius medialis was assessed using near-infrared spectroscopy, systemic vascular resistance (SVRi) was measured by thoracic impedance cardiography and pulmonary gas exchange and ventilation were quantified using a metabolic cart.

RESULTS: Circulating [ßHB] was higher throughout the experimental protocol (mean diff. 1.38 mM; 95%CI: 0.85, 2.1; P=0.001) after Kme ingestion, compared to placebo. After Kme ingestion, TSI% was higher during moderate-intensity [mean diff 9.8%, (95%CI: 1.7, 13.1; P=0.019)] and peak (mean diff 13.8%, 95%CI: 5.6, 18.2; P=0.001) cycling exercise compared to placebo. SVRi was lower at rest [mean diff -705 dyn·s/cm5·m2 (95%CI: -1,336, -75; P=0.031)] and during moderate-intensity cycling exercise [mean dif. -916 dyn·s/cm5·m2 (95%CI: -1,526, -253; P=0.014)] in the Kme versus placebo condition. No differences were found between conditions for oxygen uptake ($\dot{V}O_2$) or ventilation ($\dot{V}_E$) during moderate-intensity exercise [$\dot{V}O_2$, mean diff 0.3 mL/kg/min, (95%CI: 0.1, 0.9; P=0.438)]; [$\dot{V}_E$, mean diff 1.9 L/min, (95%CI: -11.2, 15.1, P=0.766) and at peak exercise [$\dot{V}O_2$, mean diff 0.2 mL/kg/min, (95%CI: 0.1, 0.8; P=0.256)]; $\dot{V}_E$ mean diff 3.5 L/min (95%CI -9.6, 16.7, P=0.591)].

CONCLUSION: In people with T2DM, acute ingestion of Kme improves peripheral muscle oxygenation during incremental cycling exercise and lowers systemic vascular resistance at rest and during exercise, but does not influence oxygen consumption or ventilation.

INTRODUCTION: Physical activity is well accepted to improve mitochondrial content, however, the current knowledge of mitochondrial adaptations to regular exercise in patients with type 2 diabetes (T2D) is inadequate in skeletal muscles and even further limited in adipose tissue. This ongoing project aims to study the impact of aerobic exercise training on mitochondrial respiratory capacity and reactive oxygen species production in skeletal muscle and subcutaneous white adipose tissue (scWAT). This will be studied in untrained patients with T2D and controls matched for age, sex, BMI, and maximal oxygen consumption (VO2max). We hypothesize that the training intervention will increase mitochondrial respiratory function and decrease mitochondrial production of reactive oxygen species in both groups.

METHODS: 30 obese patients with (n = 15) and without (n = 15) T2D will be subjected to a 12-week aerobic training intervention consisting of 45 minutes supervised bike exercise (2 times/week) and 45 minutes supervised rowing exercise (1 time/week). Skeletal muscle (vastus lateralis) and scWAT biopsies will be obtained at baseline and after the intervention to assess mitochondrial respiratory capacity for complex I, complex I+II and the total electron transport respiratory capacity. Also, production of H2O2 during leak respiration will be measured. The mitochondrial functional analysis will be performed using high-resolution respirometry and fluorometry. Mitochondrial functional data will be analyzed using linear mixed models.

RESULTS: At the moment, 10 obese males with (n = 7. Mean ± SD: age = 49.1 ± 7.3 years, BMI = 34.9 ± 3.8 kg/m2, VO2max = 25.6 ± 3.6 ml/min/kg , HbA1c = 62.4 ± 14.8 mmol/mol, time since diagnosis = 3.2 ± 2.1 years) and without (n = 3. Mean ± SD: age = 47.2 ± 2.8 years, BMI = 35.2 ± 3.8 kg/m2, VO2max = 26.5 ± 4.2 ml/min/kg , HbA1c = 38.3 ± 4.9 mmol/mol) T2D have completed the study. At baseline, no differences in mitochondrial respiration or ROS production were present between the groups. When analyzing all participants, the intervention resulted in a 24.0 ± 3.8 % increase in VO2max (p-value = 0.004). The training intervention resulted in an overall increase in mitochondrial respiratory capacity in both skeletal muscle and scWAT in the participants with T2D (skeletal muscle: p-value = 0.0166, scWAT: p-value < 0.001). The training intervention had no effect on respiratory capacity in the control group. No effect of training was found on H2O2 production normalized to respiratory flux in either of the groups. Further analysis will clarify whether the increase in respiratory capacity is a result of increased mitochondrial content or increased respiratory capacity of each mitochondrion.

CONCLUSION: In patients with T2D, 12 weeks of aerobic training improved mitochondrial respiratory capacity in skeletal muscle and scWAT. Lack of changes in the control group may be due to the small sample size.

THE EFFECT OF REPEATED HOT WATER IMMERSIONS ON INSULIN SENSITIVITY, GLUCOSE TOLERANCE, EHSP70 AND INFLAMMATION IN INDIVIDUALS WITH TYPE 2 DIABETES MELLITUS: A PRE- POST-EXPERIMENTAL TRIAL

JAMES, T.J.1, CORBETT, J.1, SAYNOR, Z.L.1, TIPTON, M.1, PERISSIOU, M.1, SHUTE, J.2, CUMMINGS, M.3, ALLARD, S.3, BELCHER, H.1, PICCOLO, D.D.1, SHEPHERD, A.I.1

[1, 2] UNIVERSITY OF PORTSMOUTH. [3] QUEEN ALEXANDRA HOSPITAL

INTRODUCTION: Type 2 diabetes mellitus (T2DM) is characterised by chronic hyperglycaemia, insulin resistance and hyperinsulinemia. Previous research suggests that chronic passive heating using hot water immersion (HWI) has the potential to improve insulin sensitivity and improve glycaemic control in healthy individuals [1], but data are limited in individuals with T2DM.

METHODS: 14 individuals with T2DM participated in this pre- vs. post-intervention study, with outcome measures assessed in fasted and post-prandial states (2 hr post 75 g glucose ingestion). HWI consisted of 1 hr immersion in 40°C water to the clavicle, with body position adjusted to maintain rectal temperature between 38.5 and 39°C; this was repeated 8-10 times over a 14 day period. Outcome measures included, insulin sensitivity, plasma [glucose] and plasma [insulin] (fasted and post-prandial). Other fasted outcome measures included plasma extracellular heat shock protein 70 ([eHSP70]), [interleukin-6] ([IL-6]) and interleukin-10 ([IL-10]), resting metabolic rate (RMR) and substrate utilisation.

RESULTS: Fasted insulin sensitivity increased (p = 0.03, d = 0.64) and fasted plasma [insulin] decreased (p = 0.04, r = 0.56) post-HWI intervention. In contrast, fasting plasma [glucose] (p = 0.83, r = 0.06), fasting plasma [eHSP70] (p = 0.08, d = 0.54), fasting plasma [IL-6] (p = 0.55, r = 0.16), fasting plasma [IL-10] (p = 0.59, r = 0.14), post-prandial insulin sensitivity (p = 0.19, r = 0.38), post-prandial plasma [glucose] (p = 0.40, d = 0.23) and post-prandial plasma [insulin] (p = 0.47, r = 0.19) were not significantly different post intervention. RMR was significantly reduced following the HWI period (p < 0.05, d = 0.59), although carbohydrate (p = 0.43, r = 0.21) and fat oxidation (p = 0.99, d < 0.01) rates were unchanged.

CONCLUSION: This study shows that 8-10 HWI's improves insulin sensitivity and lowers plasma [insulin] in the fasted state in individuals with T2DM, but not when glucose tolerance is challenged. A reduced RMR suggest improved metabolic efficiency. Together, these results are clinically important and may have implications for health outcomes and well-being in this population. Future work should investigate longer-term use of HWI, in addition to safety trials and establishing the minimum beneficial HWI 'dose' in individuals with T2DM.

OP-PN19 Thermoregulation I

AN OVERVIEW OF ELITE ATHLETE PREPARATION, KNOWLEDGE/PERCEPTIONS AND REAL/PERCEIVED BARRIERS TO THE IMPLEMENTATION OF EVIDENCE INFORMED BEST PRACTICE FOR COMPETITION IN THE HEAT.

TAYLOR, L., GALAN-LOPEZ, N., RACINAIS, S., ISHAN, M., ADAMI, P., ALONSO, J., CARDINALE, M., GARRANDES, F., LANGE, G., MOUSSAY, S., BERMON, S., PITSILADIS, Y., ESH, C.

LOUGHBOROUGH UNIVERSITY

INTRODUCTION: At the 2015 IAAF Championships, in a manner not seen previously, elite athlete preparation for competition in the heat was explored. Increasing globalisation of sport and global temperatures mean elite sporting events are ever more likely to take place in extreme heat (e.g., Doha 2019 IAAF Championship, Tokyo 2020ne, etc.). Understanding elite athletes: (i) use of evidence informed best practice [i.e., heat acclimation/acclimatisation (HA)] to protect against heat induced health and performance decrements; (ii) knowledge/perceptions of exercise in the heat best practice; and (iii) the real/perceived barriers to implementing these, appears prudent. Therefore, this review aims to provide comprehensive insight into elite athlete preparation across three elite championships, regarding the above (i-iii).

METHODS: Review survey data from three recent major championships in the heat: i) Doha 2019 World Championships (DOHA); ii) Tokyo Olympics 2020ne (TOKYO) and iii) Muscat World Team Race-walking Championships 2022 (MUSCAT). Specifically assessing elite athlete preparation, knowledge, perceptions and barriers to the use of evidence informed best practice prior to competition in the heat. Comparisons between sex [male (MALE) vs. female (FEMALE)] and climate athletes live/train in [hot (HOT) vs. temperate/cold (TEMP)] are made where appropriate.

RESULTS: Across these championships there is an enduring disconnect between evidence and practice. HA strategies were used by ≤68% of athletes surveyed (MUSCAT: 57%, DOHA: 60% non-road race and 63% road race, TOKYO: 61% non-road-race and 68% road race). In the road race events at DOHA and MUSCAT those who HA prior to championships ranked higher than those who did not and were less likely to visit the medical tent. Athletes who live/train in HOT are more likely to HA. Limited knowledge of exercise in the heat best practice was exhibited at DOHA and MUSCAT; FEMALE exhibited significantly less knowledge at MUSCAT than MALE ($p \leq 0.024$). Access to facilities (including cost) were highlighted as the main barriers to implementing HA, particularly among those from TEMP, likely accounting for the lower uptake of HA in these athletes.

CONCLUSION: HA use prior to competition in hot conditions has increased since 2015 (15% vs up to 68% in the data from this review) but is not yet universal, despite clear benefits for health/performance (i.e., higher ranking and less medical tent visits by those who HA). Knowledge of best practice among athletes is limited and is lower in FEMALE. Significant barriers to the use of HA exist. Significant efforts from sport governing bodies are required to provide continuously updated educational material to athletes to reduce the gap between evidence-based and real-world practice translation (particularly in FEMALE). Access to facilities should be a priority for federations of athletes in TEMP. Assessment of elite athlete practice must continue prior to competition in the heat.

CONCURRENT VALIDITY OF THE CORE WEARABLE SENSOR WITH BODYCAP TEMPERATURE PILL TO ASSESS CORE BODY TEMPERATURE DURING AN ELITE WOMEN'S FIELD HOCKEY HEAT TRAINING CAMP

GOODS, P.S.R., MALONEY, P., MILLER, J., JENNINGS, D., FAHEY-GILMOUR, J., PEELING, P., GALNA, B.

MURDOCH UNIVERSITY

INTRODUCTION: Wearable temperature sensors offer the potential to overcome several limitations associated with current laboratory- and field-based methods for core temperature assessment. However, their ability to provide accurate data at elevated core temperatures (Tc) has been recently questioned in a laboratory setting. Therefore, this investigation aimed to determine the concurrent validity of a wearable temperature sensor (CORE) compared to a reference telemetric temperature pill (BodyCAP) in an ecologically valid setting during a team sport heat training camp prior to the 2020 Olympic Games.

METHODS: Female field hockey players (n=19) in the Australian national squad completed 4 sessions in hot conditions where their temperature was monitored via CORE and BodyCAP. Concurrent validity of the wearable CORE device was determined with reference to the ingested BodyCAP pill. Three bands for temperature error were defined as: low (±0.1°C), moderate (±0.3°C), and high (>0.3°C), based on previously established thresholds.

RESULTS: Lin's Concordance Correlation Coefficients determined there was 'poor' agreement between devices during all sessions. Mean bias demonstrated that CORE underestimated Tc in all sessions (-0.06°C to -0.34°C), with wide mean 95% confidence intervals (±0.35°C to ±0.56°C). Locally estimated scatterplot smoothing regression lines illustrated a non-linearity of error, with greater underestimation of Tc by the CORE device, as Tc increased. The two devices disagreed by

more than ±0.1°C for 78-84% of all data samples in each session, and by ±0.3°C for 41-60% of all data samples in each session.

CONCLUSION: Our findings do not support the use of the CORE device as a valid alternative to telemetric temperature pills for Tc assessment in elite female team sport athletes, particularly during exercise in hot conditions where elevated Tc are expected.

EFFECT OF A NOVEL 'CONDENSED' HEAT ACCLIMATION INTERVENTION ON THE THERMOPHYSIOLOGICAL RESPONSES TO EXERCISE-HEAT STRESS.

STEVENS, C.E.1, COSTELLO, J.T.1, TIPTON, M.J.1, YOUNG, J.S.2,3, LEE, B.J.4, WALKER, E.F.5, CORBETT, J.1
1 UNIVERSITY OF PORTSMOUTH, UK. 2 NATIONAL HORIZONS CENTRE, TEESSIDE, UK. 3 TEESSIDE UNIVERSITY, UK. 4 COVENTRY UNIVERSITY, UK. 5 DEFENCE SCIENCE AND TECHNOLOGY LABORATORY, UK.

INTRODUCTION: Heat acclimation (HA) induces phenotypic adaptations that decrease thermal strain and heat- illness risk and improve performance in the heat. Short duration HA interventions (≤5 daily heat exposures), although attractive to time-poor individuals, result in incomplete adaptations compared to longer interventions (≥7 daily heat exposures). This is possibly due to the lower total accumulated thermal exposure over the shorter timescale. The aim of this study was to compare the phenotypic adaptations to a 'traditional' 8-day intervention with those induced by a 2-day 'condensed' HA intervention matched for total 'thermal exposure'.

METHODS: Using a between-groups design, healthy males performed either: 1) traditional 8-day HA (n =10; V̇O2max=47.7±8.1 mL.min-1.kg-1) consisting of 1×75-minute HA session·day-1 for eight consecutive days, or; 2) condensed 2-day HA (n=10; V̇O2max=50.8±5.6 mL.min-1.kg-1) consisting of 4×75-minute HA sessions·day-1 for two consecutive days. HA sessions used the controlled hyperthermia approach (ambient conditions=45˚C, 20% RH; target rectal temperature [Trec]=38.5˚C) and thermophysiological responses to 60-minute exercise-heat stress test (HST) were assessed pre- and post-intervention (ambient conditions=40˚C, 50% RH). Two-way mixed model ANOVA was used to investigate the main effects of condition (traditional vs. condensed HA), time (pre vs. post intervention) and their interaction (condition×time) on indices of thermophysiological adaptation; between groups differences in resting plasma volume expansions were analysed by independent samples t-test. Significance was set at $p<0.05$. These data represent an interim analysis of the final study sample.

RESULTS: A significant main effect of time was observed for resting Trec (-0.22˚C; $F=21.81$, $p<0.001$), peak exercise Trec (-0.39˚C; $F=135.10$; $p<0.001$), mean exercise heart rate (-7 beats·min-1; $F=24.55$; $p<0.001$) and peak exercise heart rate (-8 beats·min-1; $F=12.21$, $p=0.03$). In each instance there were no significant main effects of condition, or their interaction. Likewise, plasma volume expansion was similar between groups (traditional +8.1±4.0% vs. condensed +9.0±7.7%, $p=0.74$). A significant main effect of time ($F=148.36$, $p<0.001$) and interaction ($F=5.75$, $p=0.03$) was evident for whole-body sweat rate (WBSR), which was increased by +0.33 L·hr-1 with traditional HA and +0.22 L·hr-1 with condensed HA; the main effect of condition was not significant ($F=0.767$; $p=0.39$).

CONCLUSION: Both HA programs induced hallmark adaptations to heat that evidence an improved ability to thermoregulate. The novel finding from this preliminary analysis is that, excluding WBSR, a novel condensed HA program is capable of inducing robust thermophysiological adaptations within 2 days in healthy young males that are not different from the changes achieved in 8 days where thermal exposure is matched.

THE EFFECTS OF A COMBINED ACTIVE AND PASSIVE HEAT ACCLIMATION PROTOCOL IN ENDURANCE TRAINED TRIATHLETES.

SNAPE, D., WAINWRIGHT, B., PARSONS, I.T., STACEY, M.J., WOODS, D.R., O'HARA, J.
LEEDS BECKETT UNIVERSITY

INTRODUCTION: To investigate the effects of a combined active and passive heat acclimation (HA) protocol on thermal and perceptual responses to heat stress after 4 and 7-days. In addition, the effects of 8-days HA and temperate exercise on self-paced cycling exercise in the heat.

METHODS: Twenty (15 men, 5 women) endurance-trained triathletes were randomised to 8-days HA (32 °C, 70% RH ; HOT; n =10) or temperate exercise intervention (20°C, 50% RH; TEMP; n =10). Active HA sessions (x5) involved cycling in the heat (maximum 90 minutes/day) to elicit a core body temperature of 38.5-39.3 °C. Passive HA sessions (x3) involved an initial 30-minute treadmill run in temperate conditions, followed immediately by hot water immersion (HWI; ≤40-min; 39.5 °C). Participants in the TEMP group completed 5-days temperate exercise training, involving cycling exercise (maximum 90 minutes/day). Sub-maximal cycling heat stress tests (45-minutes, 32 °C and 70% RH) were completed on the first (HST1), fifth (HST2) and seventh (HST3) day of HA. In contrast, the TEMP group completed HST's pre (HST1) and post-intervention (HST3). Physiological (rectal temperature [Tre], heart rate [HR], sweat rate) and perceptual (rating of perceived exertion, thermal sensation, and thermal comfort) responses were collected during HST's to evaluate heat adaptation responses. Venous blood was analysed pre- and post- HST1 and HST3 to evaluate changes in sympathetic activity (normetanephrine [NMET]) and fluid-regulatory stress (copeptin). 20-km cycling time-trials in the heat (32 °C and 70% RH) were performed pre and post 8-days of HA and following the temperate exercise intervention.

RESULTS: A lower resting and exercising; Tre (-0.25 °C, p = 0.001 and -0.25 °C, p = 0.001) and HR (-7 bpm-1, p = 0.003 and -10 bpm-1, p = 0.012) was evident after 4-days HA, with no further change after 7-days HA (HST1 vs HST3) in resting and exercising Tre (-0.04 °C, p >0.999 and -0.07 °C, p = 0.834) or HR (-2 bpm-1, p >0.999 and -2 bpm-1, p >0.999). Only

sweat loss increased (+23%, p = 0.020) from HST1 to HST3. Plasma volume increased (+9.6%, p = 0.025) after 7-days HA, and there was significant reductions in NMET (-40.4%, p = 0.001) and copeptin (-30.2%, p = 0.025) at the post-HST timepoint (HST1 vs HST3). There were no physiological or perceptual changes in the TEMP group (p > 0.05) post-intervention. There was no change in performance during the 20-km cycling TT in either group (p > 0.05).

CONCLUSION: In conclusion, 4-days combined active and passive HA was just as effective as 7-days HA for reducing physiological and perceptual strain. Though, 7-days HA was associated with significant reductions in surrogate markers of sympathetic activity and fluid-regulatory stress along with greater sweat loss and plasma volume expansion. However, 8-days of combined active and passive HA had no impact on self-paced performance in the heat.

EFFECT OF HEAT ACCLIMATION WHEN EXISTING TRAINING LOAD REMAINS CONSTANT – A PILOT STUDY WITHIN INTERNATIONAL TRIATHLETES

LEE, C.W.D., JAMES, C.A., LI, P.Y.C., SO, C.H.R.

HONG KONG SPORTS INSTITUTE

INTRODUCTION: The acute nature of the induction and decay of heat acclimation (HA) adaptations often necessitates that HA is conducted in the weeks immediately preceding a competition, potentially interfering with a planned training taper. Therefore, we investigated the effect of a mixed active and passive heat acclimation protocol, during the 3 weeks prior to the 2022 U23 Triathlon World Championships, when the planned external training load was maintained.

METHODS: Six international triathletes (3 male, 3 female) completed eight heat acclimation sessions (5 active: running/cycling, 3 passive: hot water immersion [HWI]), across two weeks. To maintain the external training load, outdoor high-intensity training sessions were supplemented by 30-50 min HWI, whilst low-intensity cycling/running sessions were relocated to be completed in a hot environment (thermostatically controlled chamber). HWI sessions were designed to achieve and subsequently maintain, a core temperature of 38.5°C. A standardized 30-min run was completed in the hot environment (35°C, 60%) on days 1, 5, and 8, whilst hematological monitoring was conducted on 6 out of 13 days. Body temperature was monitored throughout all sessions using gastrointestinal pills (BodyCap, France) and sweat concentration was measured in duplicate at the sites of the upper arm and upper back on days 1, 5, and 8.

RESULTS: Compared with Day 1, there were changes in exercising core temperature (Day 8: -0.27±0.45°C, p<0.05), finishing heart rate (Day 8: -26±21 b.min-1, p<0.03), and sweat sodium concentration (upper arm Day 5: -33%, p<0.02; upper back Day 5: -33%, p<0.01; Day 8: -27%, p=0.04). There was no statistical difference in plasma volume (Day 5: +2.6±10%; Day 8: +2.4±7.8%; both p>0.05) whilst sweat potassium concentration increased (upper arm Day 8: +39%, p=0.01; upper back Day 8: +61%, p<0.01). Throughout the training period, no trends were evident for increases in cortisol (C), testosterone (T), C:T ratio, urea, platelets (all Δ<20%), or white blood cell count (Δ<28%). Similarly, there were no changes in athlete perceptions of training demands, muscle soreness, sleep quality, or appetite (all p>0.05).

CONCLUSION: A mixed active and passive heat acclimation protocol, implemented without altering the existing training programme volume, reveals various markers of heat adaptation, with no apparent detrimental effects on athlete health or training stress markers.

OP-MH20 Respiratory disease

THE EFFECT OF ADDING COGNITIVE TRAINING TO PULMONARY REHABILITATION PROGRAM IN PATIENTS WITH CHRONIC OBSTRUCTIVE PULMONARY DISEASES: A RANDOMIZED CONTROLLED TRIAL

TRABELSI, Y.

SOUSSE FACULTY OF MEDICINE

INTRODUCTION: Cognitive training (CT) has positive effects on some general cognitive functioning and selected cognitive abilities in patients with mild cognitive impairments. However, the combined effect of the CT and pulmonary rehabilitation (PR) program on selective cognitive abilities in patients with chronic obstructive pulmonary diseases (COPD) has not been evaluated yet. The aim of our study was to investigate the effectiveness of CT added to PR in patients with COPD.

METHODS: Thirty-nine patients with COPD were assigned to an intervention group (n = 21, age = 65.3 ± 2.79) and a control group (n=18, age = 65.3 ±3.2). The intervention group underwent PR combined with CT (PR: 45 minutes + CT: 30 minutes) and the control group underwent only PR (PR: 45 minutes), 3 times per week during 3 months. Spirometry, 6-minute walking tests (6MWT) and cognitive performances [Montreal cognitive assessments (MOCA) and P300 test] were evaluated. Measures were taken at baseline and after 3-months of training programs.

RESULTS: We showed a significant improvement of the 6MWT parameters (six-minute walk test distance, peripheral oxygen saturation, dyspnea and heart rate) after the rehabilitation period in both groups (P< 0.001). Both groups showed a significant improvement (P< 0.001) in cognitive performance (score MOCA and P300 test) latency in three midlines electrodes. However, these improvements in cognitive performances (Latency of P300 at Fz, Cz, Pz and the score of MOCA) were greater in the group that combined PR and CT.

CONCLUSION: The use of CT added to PR is more effective in improving cognitive abilities than PR alone for patients with COPD. This may offer to clinician a complementary approach to improve cognitive abilities in patients with COPD. It may be also useful for clinicians to help design new rehabilitation therapies.

NUTRITIONAL STATUS, METABOLIC PROFILE, PRO/ANTI-OXIDANT STATUS AND GUT MICROBIOTA COMPOSITION AS MEDIATORS OF NEUROMUSCULAR FATIGABILITY IN COVID-19 PATIENTS SIX MONTHS AFTER ICU DISCHARGE

MARTIN, V., KENNOUCHE, D., MILLET, G.Y., GUIBERT, E., ROFFET, C., CHEVARIN, C., BARNICH, N., CHASSAING, B., CINQ FRAIS, C., COMBIS, M.S., PIALOUX, V., OTERO, Y.F., SIRVENT, P., CAZAUBIEL, M.

UNIVERSITÉ CLERMONT AUVERGNE / UNIVERSITÉ ST ETIENNE / PARIS UNIVERSITÉ / CHU TOULOUSE / VALBIOTIS

Peltier, S., Boisseau, N.

INTRODUCTION: It is well established that intensive care unit (ICU) stay alters neuromuscular function, potentially promoting long-term neuromuscular fatigability. The COVID-19 pandemic has strongly increased the number of patients admitted to ICU, especially frail people (i.e. with immunodeficiency or metabolic disorders). It has also been shown that SARS-CoV-2 infection exacerbates gastrointestinal disorders, affects appetite, alters gut microbiota, and promotes dysbiosis leading to inflammation. As these parameters are connected to muscle dysfunction, the aim of this study was to evaluate the potential implications of nutritional status, metabolic profile and gut microbiota composition on neuromuscular fatigability in post-COVID-19 patients six months after ICU discharge.

METHODS: 29 COVID-19 ICU patients (64 ± 11 years; duration of stay: 35 ± 17 days) were recruited 6 months post-ICU discharge. Knee extensors maximal voluntary contraction (MVC), voluntary activation (VA), quadriceps potentiated twitch force (Tw pot) were evaluated during a quadriceps intermittent fatigue test (%loss compared to rest). Neuromuscular parameters were correlated with perceived fatigue (FACIT-F version 4), body composition, metabolic profile, nutritional status (food questionnaires and blood parameters) and gut microbiota composition.

RESULTS: 79% of patients had overweight or obesity (46% and 23%, respectively); 30% had low-grade inflammation (CRPus >3mg/L), but no link was found between CRPus and neuromuscular properties. Perceived fatigue was not associated with any neuromuscular parameter. As expected, MVC and Tw pot were associated with weight and fat-free mass ($p < 0.05$). Fiber, vit D and zinc intakes were lower than the current recommendations. Although selenium intake was twice compared to the usual recommendations, plasma selenium was below the expected normal ranges and was associated with MVC, Tw pot and %loss Tw Pot ($r = 0.458$, 0.599 and -0.472, respectively; $p < 0.05$). Prealbumin was correlated with %loss Tw pot and %loss VA. Plasma 25-hydroxyvitamin D also was associated with %loss Tw pot. Plasma superoxide dismutase was associated with the number of contractions (i.e. local endurance performance), and plasma glutathion peroxidase with MVC and Tw Pot ($r = 0.617$, 0.574, and 0.824 respectively; $p < 0.05$). Porphyromonadaceae and Clostridiaceae were associated with the number of contractions and Bacteroidaceae with %loss Tw Pot ($r = 0.478$, 0.482, and 0.502 respectively; $p < 0.05$).

CONCLUSION: Six months post-ICU discharge, perceived fatigue and systemic inflammation were not related to neuromuscular fatigability in COVID-19 patients. Conversely, body composition, blood concentrations of selenium, pre-albumin and 25-hydroxyvitamin D, pro/anti-oxidant balance and different bacterial families were associated with neuromuscular properties. These preliminary results suggest that nutritional management may improve neuromuscular function recovery in COVID-19 ICU patients.

O2 SUPPLEMENTATION IMPROVES O2-UPTAKE KINETICS AND EXERCISE CAPACITY IN PATIENTS WITH PULMONARY VASCULAR DISEASE

KADOSH, S.1,2, REUVENY, R.1,2,4, BAIDATS, Y.1,2, JONES, A.M.3, WILKERSON, D.3, VELNER, A.2, SEGEL, M.J.1,2

1. TEL AVIV UNIVERSITY, TEL-AVIV, ISRAEL 2.PULMONARY INSTITUTE, SHEBA TEL HASHOMER MEDICAL CENTER, RAMAT GAN, ISRAEL 3.UNIVERSITY OF EXETER, EXETER, UK 4.UNIVERSITY OF HAIFA, HAIFA,ISRAEL

INTRODUCTION: Supplemental oxygen (O2) is commonly used to treat pulmonary vascular disease (PulmVD). The mechanisms by which O2 therapy confers benefits in patients with PulmVD during exercise remain unclear.The aim of this study was to understand the physiological mechanisms underlying the benefit of supplemental O2 in patients with PulmVD during exercise.

METHODS: Patients with PulmVD (Pulmonary Arterial Hypertension (PAH) or Chronic Thromboembolic Pulmonary Hypertension (CTEPH)) completed two symptom-limited ramp cardiopulmonary tests, and eight constant work-rate tests (CWRTs) at 80% of the work-rate (WR) at the gas exchange threshold (GET) (four repetitions for each condition). Patients performed the tests while breathing room air (RA, $FiO2 = 0.21$) or 30% oxygen ($FiO2 = 0.30$, a clinically relevant concentration of O2). Healthy individuals performed a maximal test only with $FiO2 = 0.21$, and CWRTs with both conditions ($FiO2 = 0.21$ and 0.30). O2-uptake (VO2) kinetics were calculated from the CWRT results using mono-exponential modelling. Results in the two test conditions (FiO2 0.21 and 0.30) were compared by repeated-measure statistics (Wilcoxon test).

RESULTS: Ten patients (age 54 ± 17 yrs; 8 females), with a diagnosis of pre-capillary pulmonary hypertension (8 PAH, 2 CTEPH) and 11 healthy individuals (age 51 ± 17 yrs; 5 females) participated. Peak WR and peak VO2 increased significantly from 76±26 watts and 15.4±3 ml/kg/min with RA to 85±26 watts and 17.4±5 ml/kg/min with $FiO2 = 0.30$ ($p=0.011$ and $p=0.015$, respectively). VO2 at the AT increased from 640±120 ml/min with RA to 764±180 ml/min with $FiO2 = 0.30$ ($p=0.012$). Compared with RA, the peak VO2/HR was higher with $FiO2 = 0.30$ (7.4 ml/min vs. 8.4 ml/min, $p=0.008$). In CWRTs, the time constants (tau) of phase II of VO2 kinetics were significantly faster in PulmVD patients while breathing with

FiO2= 0.30 (36±4 sec) compared to RA (43±6 sec; p=0.009). Plateau end tidal CO2 (ETCO2), ventilation (VE) and ventilatory equivalent for O2 (VE/ VO2) were calculated as the average of the last 60 sec of four CWRTs. ETCO2 increased from 28 mmHg with RA to 30 mmHg with FiO2= 0.30; VE decreased from 31 L/min with RA to 28 L/min with FiO2= 0.30, and VE/ VO2 decreased from 37±4 L/min with RD to 35±4 L/min with FiO2= 0.30 (p=0.01, p=0.02, p=0.011 respectively); In healthy individuals there was no improvement in VO2 kinetics with FiO2= 0.30 in contrast to RA (tau 34±5 sec vs. 35±6 sec, respectively, p=0.916).

CONCLUSION: Oxygen supplementation (30%) in PulmVD patients leads to significant increases in peak work-rate and peak VO2, and accelerates VO2 kinetics, presumably by increasing pulmonary blood flow in pulmonary capillaries and reducing pulmonary vascular resistance, thus increasing cardiac output and muscular oxygen delivery. Ventilatory efficiency also seems to improve with FiO2= 0.30.

THE INFLUENCE OF SEX AND BMI ON PULMONARY FUNCTION TRAJECTORIES IN YOUTH WITH CYSTIC FIBROSIS

MCNARRY, M.A., ASPINALL, S., WHITE, M.G.E., WALDRON, M., MACKINTOSH, K.A.

SWANSEA UNIVERSITY

INTRODUCTION: Cystic Fibrosis (CF), the most common genetic disorder in Caucasian populations, is characterised by nutritional deficiency and frequent respiratory infections, with the foremost cause of morbidity and mortality remaining respiratory failure. There have been significant advances in the treatment and management of CF but, despite this, females with CF continue to have worse outcomes, including a poorer disease experience and shorter life expectancy, even when controlling for modulator therapy. This survival disadvantage is especially striking as it is in direct contrast to the superior survival associated with female sex in the general population. Whilst much research has focused on the role of sex hormones during puberty, this sex disparity is likely multi-factorial, with nutritional status believed to play an important role. Indeed, puberty is also associated with significant changes in nutritional status but, despite recognition that malnutrition and low body mass index (BMI) are associated with a poorer pulmonary function and increased risk of mortality, little is known regarding the influence of BMI trajectory on pulmonary function.

METHODS: This retrospective, longitudinal analysis used CF Trust registry data up to 2015 of those aged 6 – 17 years. Linear mixed models analysed the effect of sex and BMI percentile (BMIp) on percentage predicted forced expiratory volume in one second (ppFEV1) across time, with random effects for age using an autoregressive heterogeneous covariance matrix. The initial compact model used linear terms for age, BMI and their interaction with sex. This model was subsequently extended by progressively adding quadratic or cubic terms for age, BMI, and their interaction. Categorical differences in ppFEV1 in response to BMIp were explored in an independent model in which pairwise comparisons were adjusted using Tukey-Kramer.

RESULTS: The analysis involved 15,755 values of FEV1 and BMIp from 4,137 CF patients in the United Kingdom. According to the compact model, ppFEV1 declined with age, with a faster decline in girls (-2.3±0.1 vs. -1.75± 0.1%). In the full model, for every percentage change in BMIp, girls demonstrated a significant decrease in ppFEV1 that was not evident for boys. According to the categorical model, significant declines in ppFEV1 for every BMIp <50th (P<0.001) were evident in girls, compared to only <25th percentile for boys. Irrespective of sex, achieving a BMIp >75th percentile was associated with the most favourable ppFEV1 over time, with lower declines in ppFEV1 between the ages of 7-14 years.

CONCLUSION: This study shows that ppFEV1 declines from around puberty, with the rate of change influenced by BMIp, especially <50th percentile. Furthermore, the declines in ppFEV1 are influenced by sex, with females' ppFEV1 influenced by BMIp to a greater extent than their male counterparts. This highlights that BMI represents a key, sex-specific, intervention target to help ameliorate the sex disparity in CF-related outcomes.

OP-SH12 Psychology in team sports

STRESS AND PERFECTIONISM AMONG MALE AND FEMALE AGE-SPECIFIC NATIONAL TEAM PLAYERS IN FOOTBALL, HANDBALL, AND ICE-HOCKEY

SÆTHER, S.A., MEHUS, I., ASPVIK, N.P.

NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY

Introduction. Junior elite age-specific national players are expected to be future senior elite players. These expectations come with pressure both from the player him/herself and from significant others in their development environment. This study investigated how national team players (male and female) in football, handball, and ice-hockey in Norway experienced stressors (global score) (SG) and how the two perfectionism dimensions evaluative concerns (EC) and personal strivings (PS), as well as playing time (club), and an overload injury impact on SG. We also controlled for gender, age, sport, and playing level of the players. Methods. The sample in this study was 274 male and female (45,6% female and 54,4% male) (players selected to an age-specific national team of U16-U19, (M=16.23, SD=1.06). Cronbach´s alpha was calculated to test the scale reliability of the factors; SG (□=.88), EC (□=.76), PS (□=.79). A linear regression analysis was conducted with SG as the dependent variable. Results. The regression model explained 19% of the variance in SG and turned out statistically significant (p<.001). EC (p<.01) and overload injury (p<.05) had a significant positive association with

SG, while playing time had a significant negative (p<.01) association on SG. Women scored significant (p<.01) higher on SG. There was no significant difference in PS, age, sport, and playing level on SG. Discussion. To be evaluated, both by yourself and others, is a natural part of being in a talent development environment. However, if a player has (or develops) evaluative concerns one needs to be aware that this might increase their level of overall stress. Finding PS not to be associated with SG is interesting. One might expect that players scoring higher on personal strivings also would score higher on stress. One explanation of our findings could be the sample of national team players, where all players naturally are striving for being a better athlete. Another explanation could be that being evaluated (of others) is more stressful than your own strivings. Furthermore, it is important that talented athlete`s significant others (i.e., coaches, parents) are aware that both reduced playing time and experiencing overload injury increases a player's level of stress.

EXPERTISE AND TRAINING OF ANTICIPATION IN GOALKEEPING

HUESMANN, K., SCHORER, J., BÜSCH, D., LOFFING, F.

UNIVERSITY OF OLDENBURG

Goalkeepers across sports frequently experience high spatio-temporal pressure and have to anticipate the action of their opponents to prevent them from scoring a goal. The aim of the present study was to summarize the current state of research on expertise and training of an-ticipation in goalkeeping through two systematic reviews and provide a detailed basis for the development of diagnosis and training of anticipation in youth and adult goalkeepers.

For the review on expertise in anticipation, the search term (anticipat* AND (expert* OR skill*) AND goalkeep*) was entered into the databases Web of Science, PubMed, Scopus and SURF. Primary studies from all years published in the English or German language that compared anticipatory performance in at least two differently skilled groups of goalkeepers were included in the study. For the review on training of anticipation, the search term (anticipat* AND train* AND (handball OR soccer OR football OR field hockey OR water polo OR lacrosse)) was entered into the aforementioned databases. Here, primary studies from all years published in the English or German language that investigated training of anticipation in a goalkeeping task were included in the review.

For expertise, N = 24 studies (179 total hits; n = 13 soccer, n = 10 handball, n = 1 field hockey) were identified. A total of n = 18 studies revealed that skilled goalkeepers show superior anticipatory performance compared to less-skilled goalkeepers. For training, N = 12 (492 hits; n = 6 soccer, n = 3 handball, n = 3 field hockey) studies were identified. Training interventions differed greatly regarding type of intervention, ranging from implicit over guided discovery to explicit approaches, as well as training duration and frequency. Notably, the research area on anticipation in sports appears quite atheoretical, that is, studies are not developed and findings are not interpreted with regard to an underlying theory but rather based on earlier findings in the field.

The results provide important insights into anticipatory performance in varying skill levels and reveal the effectiveness of different training methods. The development of theories on, for instance, expertise and training of anticipation as well as the implementation and testing of existing theories might prove fruitful for future research in the field. Further, particularly the lack of diversity in research regarding sports and tasks as well as the sparsity of research on potential differences in expertise and training effectiveness between youth and adult athletes should foster future research to ultimately gain a thorough understanding on expertise and training of anticipation that provides both research and practice with conclusive evidence for developing and maintaining anticipatory skill from youth to adult (elite) sports.

INFLUENCE OF SOCIAL IDENTITY ON EMOTIONS AND GROUP DYNAMICS IN TWO WOMENS TEAM SPORTS

GERAT, P.

UNIVERSITY OF BURGUNDY

28th Annual ECSS Congress Paris/France, July 4-7 2022

Influence of social identity on emotions and group dynamics in two womens team sports

Gérat, P. & Campo M.

University of Burgundy

Introduction : Emotions are a widely studied topic in the field of sport psychology. In particular, the IZOF model (Hanin, 2000) and the Cognitive Relational Motivational Theory (Lazarus, 2000) have contributed to a better understanding of emotional phenomenon in competitive situations. To go further, some authors have pointed out the need to take more into account the social dimension of emotions, notably by mobilizing Haslam's social identity approach (Rees et al., 2015). Another limitation of the study of emotions is the lack of consideration of their intrinsic lability due to the constant evolution of the relationship between the individual and his environment (Cerin et al., 2000).

Purpose : This study aimed to investigate the dynamic relationship between individual emotions, team-referent emotions and perception of group dynamics through the self-categorization prism (personal or social identity). To approach the dynamic aspect of these relationships, we used the Mouse Paradigm developed by Vallacher, Nowak & Kaufman (1994) which allow us to continuously access to the emotional experience of the participant.

Method : A pre-match questionnaire composed of a measure of cohesion, two measures of identification was administered to ten female volleyball players and six female rugby players, all playing at a national level. After the match, a self-confrontation interview using the mouse paradigm was used to collect their dynamic evaluation of their emotions, the emotions of their group and the group dynamics of their team.

Results : Linear mixed-effects models showed that: a) individual and group emotions were correlated and that this relationship was moderated by the identity level, b) emotions (both individual and team-referent) were correlated with the perception of group dynamics.

Conclusion : These results confirmed Campo et al. (2019) study, and highlight the need to consider identity levels to understand emotions in sport, as well as their per-competition variability.

PERSONS WITH MULTIPLE SCLEROSIS CHANGE THEIR HABITUAL PHYSICAL ACTIVITY OUTSIDE EXERCISE SESSIONS AS A BEHAVIOURAL COMPENSATION TO EXERCISE: A PILOT STUDY.

NIESTE, I.1,2, SPAAS, J.1,3, FRANSSEN, W.M.A.1, SAVELBERG, H.H.C.M.2, VAN ASCH, P.4, EIJNDE, B.O.1

1. HASSELT UNIVERSITY, 2. MAASTRICHT UNIVERSITY, 3. GHENT UNIVERSITY, 4. MOVE TO SPORT FOUNDATION

INTRODUCTION: To date, exercise is a cornerstone in Multiple Sclerosis (MS) rehabilitation. However, recent systematic reviews indicate that objective physical activity (PA) levels of Persons with MS (PwMS) do not increase following an exercise intervention, while they self-report a higher exercise participation. This suggests that PwMS change their habitual PA outside exercise sessions (i.e. non-exercise PA) as a behavioural compensation to exercise, which might blunt the exercise effects. This pilot study aimed to explore non-exercise PA changes of PwMS and healthy controls (HC) when they participate in a structured exercise intervention, and how non-exercise PA changes interact with the exercise effects.

METHODS: Twenty nine mildly-disabled PwMS and 26 HC completed a 10-month home-based, running exercise program. Exercise adherence was tracked with sports watches. Primary outcomes were non-exercise PA (low- and moderate-to-vigorous intensity PA; LIPA and MVPA) and sedentary behaviour (SB; total SB and uninterrupted SB), which were monitored by accelerometry (activPAL3™) for 7 consecutive days at baseline (T1), after 5 (T2) and 10 (T3) months of exercise training. PA and SB were averaged over all days with an exercise session (EX days) and over all days without exercise session (NONEX days). Secondary outcomes included exercise effects on MS symptoms and physical function.

RESULTS: Exercise adherence was similar between groups (92.4±13.1% p=0.234). PwMS decreased their non-exercise MVPA significantly from T1 to T2 (-1.6±0.5% of waking time/day) and from T1 to T3 (-1.3±0.4% of waking time/day), with no difference between EX and NONEX days (group×time interaction effect p=0.017). These non-exercise MVPA reductions approximately matched the exercise duration at T2 and T3 (T2: -105 VS. 114±9min/week and T3: -84 VS. 105±9min respectively). Non-exercise MVPA did not change in HC. PwMS also significantly increased their uninterrupted SB on NONEX days compared to EX days (+0.7±0.3h, group×EX day interaction effect p=0.003), while HC did not. Non-exercise PA changes were not associated with demographics, baseline secondary outcomes nor exercise duration. Secondary outcomes improved similarly in both groups and were not associated with non-exercise PA changes.

CONCLUSION: In line with our hypothesis, PwMS changed their habitual PA outside exercise sessions. This was not seen in HC. Explanatory factors should be explored in future research, but based on the current findings it could be hypothesised that that is due to the specificity principle. Hence, future exercise interventions for PwMS should also include intervention components to target habitual non-exercise MVPA and uninterrupted SB. Although exercise effects were not impacted, the present findings in physically fit PwMS (on average >100% of their predicted cardiorespiratory fitness at baseline) with no to mild disability warrant further research in more disabled and/or deconditioned PwMS.

BENEFITS OF INDIVIDUALIZED TRAINING IN FATIGUED PATIENTS WITH MULTIPLE SCLEROSIS

ROYER, N.1, MIRA, J.1, LEPETIT, N.1, FAYOLLE, E.1, CAMDESSANCHÉ, J.P.2, MILLET, G.Y.1

1 UNIV LYON, UJM-SAINT-ETIENNE, INTER-UNIVERSITY LABORATORY OF HUMAN MOVEMENT BIOLOGY, EA 7424, F-42023, SAINT-ETIENNE, FRANCE; 2 DEPARTMENT OF NEUROLOGY, UNIVERSITY HOSPITAL OF SAINT-ETIENNE, FRANCE

INTRODUCTION: Chronic fatigue is the most common and debilitating symptom in people with multiple sclerosis (PwMS). Recently, physical activity has proven to alleviate chronic fatigue and to improve muscular, cardiorespiratory, and cognitive functions. However, the effects of exercise may vary between PwMS, as MS is a heterogeneous disease and does not affect each individual in the same way. Tailoring the training intervention to the potential fatigue causes (e.g. reduced

muscle strength, deteriorated cardio-respiratory capacity, sleep disorders) could optimize the beneficial effects of training on fatigue. The objective of this study was to compare the effectiveness of an individualized (IND) vs a traditional (TRAD) exercise intervention in reducing chronic fatigue and improving quality of life of PwMS.

METHODS: Twenty-nine PwMS with high chronic fatigue (score of ≥ 4 on the Fatigue Severity Scale and a score of ≥ 38 on the Modified Fatigue Impact Scale) were randomly assigned to 12 weeks of either a TRAD or IND exercise intervention. TRAD comprised aerobic and resistance exercises according to the guidelines for PwMS. IND specifically addressed the deficits or areas for improvement identified in the initial lab visits (loss of muscle strength, cardiorespiratory deconditioning or sleep disorders). Participants visited the laboratory before and after training for the following assessments: patient reported outcomes (fatigue, quality of life, sleep and depression questionnaires), incremental cycling test (maximal oxygen uptake (VO2max), maximal power output (Pmax)), and cycling fatigue test (maximal voluntary contraction (MVC), rating of perceived exertion (RPE)).

RESULTS: IND induced a significant greater increase in VO2max (+21.0 ± 13.9 vs 6.8 ± 11.5%) and Pmax (19.4 ± 11.8% vs 3.4 ± 6.6%) than TRAD. A greater reduction in RPE at a given submaximal intensity was also observed in IND compared to TRAD (-30.3 ± 18.9 vs -12.1% ± 20.4%, $p<0.001$) whereas MVC increased similarly in both groups. Despite a greater improvement of depression in IND vs TRAD (-41.0 ± 23.4 vs -30.5 ± 45.4%, $p<0.001$), the improvements in fatigue, sleep and quality of life were not different between groups ($p>0.05$).

CONCLUSION: Tailored physical activity appears more efficient than traditional exercise interventions to increase some objective (VO2max, Pmax) or subjective (depression, RPE at a given submaximal intensity) parameters in fatigued PwMS. However, MVC and other subjective parameters (fatigue, quality of life, sleep quality, level of physical activity) improved similarly after the two training interventions. Tailored training could be advised to health practitioners in order to optimize rehabilitation for PwMS.

EFFECTS OF A TAILORED EXERCISE TRAINING PROGRAM IN PATIENTS WITH AMYOTROPHIC LATERAL SCLEROSIS

FERRI, A., LANFRANCONI, F.

VICTORIA UNIVERSITY

INTRODUCTION: Amyotrophic Lateral Sclerosis (ALS) is a neurodegenerative disease characterised by the progressive loss of motor neurons, which leads to a reduction in muscle strength and physical function. Although "Exercise as Medicine" is accepted for many diseases, the role of exercise in individuals with ALS is still debated. However, evidence supporting a beneficial role for moderate-intensity exercise in these patients is emerging. The aim of this study was to evaluate the effects of a combined, moderate-intensity, aerobic and strength training program on strength and physical function in individuals with ALS.

METHODS: Twelve individuals with ALS were randomly assigned to either a training (3 times a week for 12 weeks; TRAIN, n=6) or a control (continued their usual standard of care; CTRL, n=6) group. At the end of the usual standard of care period, 4 participants in the CTRL performed the 12 weeks of training and these results are presented in TRAIN. The strength of both the lower- and upper-limb muscles were evaluated during a 1-Repetition Maximum (1RM) test on the leg press, leg extension, biceps curl, vertical chest press before and after 12 weeks. A handgrip maximal isometric test was also performed to evaluate the strength of the muscles of both hands. Participants performed the "Timed Up and Go" test (TUG) and the "6 min walking test" (6MWT)". The ALS Functional Rating Scale revisited (ALSFRS-R) was also measured.

RESULTS: There were 2 drop-outs in TRAIN and 1 in CTRL. The adherence to training was 84±2%, and the satisfaction regarding the training program, measured with the Visual Analog Scale, was 9.6±0.1 (out of 10). In TRAIN, the 1RM during leg press and leg extension increased significantly by 42±9% (from 98±17 kg to 139±22 kg, $p=0.01$) and by 46±13% (from 31±5 kg to 43±6 kg, $p=0.01$), respectively. In CTRL, the same parameters did not change significantly during the 12 weeks. There were no significant changes for the 1RM vertical chest press in both groups. For the biceps curl, we detected a significant difference between the changes in percentage for the two groups: the 1RM values increased by 20±6% in TRAIN while decreased by 36±17% in CTRL ($p= 0.003$). The maximal isometric strength during handgrip decreased significantly in CTRL by 11±3% (from 32±8 kg to 29±8 kg, $p=0.004$), while in TRAIN the value was maintained. The increase in strength of the leg muscles in TRAIN translated in a tendency toward a significant improved 6MWT performance from 461±57 m to 484±55 m (+6%, $p=0.09$), while in the CTRL there was not difference in the 6MWT (-2%, $p=0.86$). The TUG did not change in both the TRAIN and CTRL groups.

CONCLUSION: This study showed that individuals with ALS who trained for 12 weeks presented an improvement in lower- and upper-limb strength. Even if preliminary, these results support the beneficial role of tailored moderate-intensity exercise training in counteracting the muscle disuse in individuals with ALS.

RESULTS OF THE PHYSICAL ACTIVITY AND CAROTID ATHEROSCLEROTIC PLAQUE HEMORRHAGE STUDY

MURA, M., RIVOIRE, E., JOSSET, L., WEISS-GAYET, M., DEHINA-KHENNICHE, L., THOMAS, A., DELLA-SCHIVA, N., ARSICOT, M., CHAZAUD, B., LONG, A., MILLON, A., PIALOUX, V.

UNIVERSITÉ CLAUDE BERNARD LYON1

INTRODUCTION: Carotid atherosclerotic plaques can remain silent until their rupture triggers an ischemic stroke. Intraplaque hemorrhage (IPH) and intercurrent inflammatory processes cause plaque instability. IPH is the factor that better predicts plaque rupture. Benefits of endarterectomy surgery remains controversial in patients asymptomatic of ischemic stroke. In previous cross-sectional study, we demonstrated that patients with moderate physical activity (PA) had lower

rates of IPH and pro-inflammatory monocytes. We hypothesized that an individualized home-based PA intervention can reduce IPH and modulate inflammation, as well as monocyte phenotype in asymptomatic patients with a non-endarterectomized carotid atherosclerotic plaque.

METHODS: Fifty-seven patients, asymptomatic of ischemic events for more than 6 months and present a carotid stenosis >50%, had been included in this study. At inclusion and after 6 months, IPH was measured with a high-resolution MRI, the inflammation state was determined by the monocytes phenotype, physical fitness was evaluated with the 6minutes walking test (6MWT) and finally, sedentary behavior and PA levels were assessed by questionnaire. Patients were randomly allocated to the control or to the PA intervention group. In the PA group, patients should reach daily goals of steps of 7000, measured by a connected watch. Daily steps goal was re-evaluated twice a month, in order to encourage patients to increase their walking habits. Patients in the control group receive their usual care during the protocol.

RESULTS: Fifty-two patients finished the study, 26 where randomized in each group. At inclusion, blood test, frequency of comorbidities, associated treatments and risk factors were equivalents between groups. The PA group had higher daily step count compared to the control group throughout the 6 months intervention (between +50% and +78%). The 6MWT was significantly improved in the PA group compared to the control group (respectively +6% vs - 0 %, $p<0.05$). BMI decreased in the PA group (-4.3%, $p<0.05$) while it remained stable in the control group. IPH was significantly reduced in the PA group while it remained stable in the control group (respectively -43% vs +3%, $p \leq 0.05$). Thus, MRI seems a reliable tool to measure IHP variations du to PA. Moreover, the PA intervention stabilized the rates of classical pro-inflammatory monocytes, while it increased in the control group (+29%, $p<0.05$), according to the progression of the disease.

CONCLUSION: This study reports for the first time, that in asymptomatic stroke patients with carotid atherosclerotic plaque, an individualized home-based PA intervention reduces BMI and IPH measured by MRI, stabilizes monocyte phenotype, and increases 6MWT. It is therefore possible to implement an efficient home-based individualized PA intervention using connected devices for patients presenting with asymptomatic carotid atherosclerotic plaque and such additional treatment should be considered in these patients.

NEUROPHYSIOLOGICAL CORRELATES OF COGNITIVE-MOTOR DUAL-TASKING IN EARLY PARKINSONS DISEASE DURING A BALANCE TASK

PESKAR, M., MANGANOTTI, P., MARUSIC, U.

SCIENCE AND RESEARCH CENTRE KOPER; TECHNISCHE UNIVERSITÄT BERLIN; TRIESTE UNIVERSITY HOSPITAL - ASUGI; ALMA MATER EUROPAEA – ECM

Parkinsons Disease (PD) has been linked to changes in the waveforms of event-related potentials (ERPs), specifically the P3 component (Tokic et al., 2016). However, little is known about how cortical markers of information processing are modulated in the early disease stage and by concurrent demands posed on the motor system. Therefore, this study aimed to better understand the cortical signature associated with cognitive processing in early PD and to investigate how a balance task might affect it.

We present preliminary results of an ongoing clinical trial in which 9 healthy participants ($M = 67.1$ yrs; $SD = 4.0$; 6 women) and 9 early-stage on-medication PD patients ($M = 61.7$ yrs; $SD = 5.8$; 4 women) performed a cognitive-motor dual-task (DT) paradigm while behavioral and electroencephalography (EEG) data were recorded. The motor task consisted of balancing while standing in a semi-tandem stance (ST-Balance) on a force plate which computed the center of pressure path length (PL). The cognitive task encompassed the color-word Stroop stimuli while silent counting of a specific word-ink color combination occurrences had to be performed in a seated position (ST-Stroop). The DT combined simultaneous performance of the balancing and Stroop counts. ERPs locked to the stimuli onset were computed and the P3 mean amplitudes were extracted from the POz electrode across three consecutive 100 ms long time windows between 300-600 ms post-stimulus. A mixed within-between design was used for the analyses (2 [task: ST vs DT] x 2 [Stroop: attend vs ignore] x 2 [group: healthy vs patients). The significance level was kept at $\alpha = .05$.

Healthy participants were older than the patients, $t(16) = 2.29$, $p = .036$. For the PL, we observed the interaction between task and group ($p = .042$), and Bonferroni corrected simple effects showed healthy participants performing worse in an ST ($M = 53.3$; $SD = 14.7$) compared to the patients ($M = 35.2$; $SD = 8.4$; $p < .01$), but not in the DT (healthy: $M = 49.0$, $SD = 16.8$; patients: $M = 37.2$, $SD = 9.7$, $p = .086$). A main effect of the factor Stroop demonstrated the attended stimuli evoked greater P3 amplitude ($M = 2.0$; $SD = 1.7$) compared to the to-be ignored stimuli ($M = .44$; $SD = 1.8$) across the whole 300-600 ms time window ($p \leq .001$). No other effects were significant.

Worsening of the PL behavioral results in healthy participants could be attributed to the general age difference between the groups or a lesser degree of attention focusing on the balancing task in the healthy. The ERPs show no indication of PD-related modulation of cortical potentials. Beyond the significance levels, however, considerable differences were observed in the ERP waveforms between the groups following a visual inspection. We aim to address these speculations upon recruitment of an adequately powered sample size.

INFLUENCE OF BIOLOGICAL SEX ON BLOOD PRESSURE AND ENDURANCE PERFORMANCE DETERMINANTS AFTER ACUTE NITRATE SUPPLEMENTATION

ROWLAND, S.N.1, DA BOIT, M.2, JAMES, L.J.1, O'DONNELL, E.1, BAILEY, S.J.1

1. LOUGHBOROUGH UNIVERSITY, LOUGHBOROUGH, UK; 2. DE MONTFORT UNIVERSITY, LEICESTER, UK

INTRODUCTION: Dietary nitrate (NO3-) supplementation has been reported to lower systolic blood pressure (SBP) and improve athletic performance in males, but a paucity of research has investigated these effects in females. Typically NO3- supplementation is more effective at lowering SBP when SBP is higher, and improving exercise performance in individuals with a more glycolytic phenotype. Compared to females, males typically present with an elevated SBP and glycolytic phenotype, with females taking oral contraceptive pills (OC) commonly exhibiting higher SBP compared with females with a menstrual cycle (MC). Therefore, this study tested the hypothesis that NO3- supplementation would lower SBP and improve determinants of endurance performance to a greater extent in males and OC compared with MC.

METHODS: Recreationally active males (n = 22) and females (n = 25) ingested 140 mL of concentrated NO3rich (BR; 13 mmol NO3-) or NO3depleted (PL) beetroot juice. Baseline brachial and aortic SBP were assessed with these measures repeated 2.5 h following BR and PL ingestion, and a ramp incremental cycling test was subsequently completed. Menstruating females (MC, n = 13) were assessed between days 1-4 of the early follicular phase and combined, monophasic oral contraceptive pill users (OC, n = 12) were assessed between days 17-21 of active pill consumption. All experimental trials were administered in a double-blind, repeated-measures, cross-over experimental design. Data were analysed using independent-measures ANOVAs and independent- and paired-samples t-tests. Values are presented as means ± SD with statistical significance accepted as P≤0.05.

RESULTS: There was a main effect for supplement for brachial (P=0.046) and aortic (P=0.002) SBP, but no main effects for group or group x supplement interactions (P>0.05). Brachial SBP was lowered following BR compared to PL in OC (Δ -3 ± 3 mmHg; P=0.002), but not MC (Δ -2 ± 9 mmHg; P>0.05) or males (Δ -2 ± 6 mmHg; P>0.05). Aortic SBP was reduced after BR compared to PL in OC (Δ -4 ± 4 mmHg; P=0.005), MC (Δ -4 ± 6 mmHg; P=0.026) and males (Δ -2 ± 6 mmHg; P=0.042). There was no main effect for supplement for peak aerobic power (PAP), VO2peak, exercise economy (VO2-work rate slope) or gas exchange threshold (GET) (all P>0.05); however, there was a main effect for group, with all parameters higher in males than females (all P≤0.05), and no differences between MC and OC (all P>0.05).

CONCLUSION: Acute NO3- supplementation lowered central SBP in all groups, only lowered peripheral SBP in OC, but did not alter physiological determinants of endurance performance or PAP during the ramp exercise test in any group. Compared to males, females exhibited lower PAP, VO2peak and GET, but better exercise economy.

NITRATE-RICH WHOLE FOOD AS A NOVEL NUTRITIONAL STRATEGY TO REDUCE ORAL DISEASE RISK

BURLEIGH, M.1, DANIELI, A., SIMPSON, A.1, MUI, E.1, EASTON, C.1

1 UNIVERSITY OF THE WEST OF SCOTLAND, GLASGOW, SCOTLAND

INTRODUCTION: Athletes are at higher risk of oral disease. High carbohydrate diets, exercise induced dehydration and transient perturbations to immune function can increase risk in this group. Nitrate (NO3-) is an ergogenic aid which is now being considered as an oral health prebiotic. Our previous work has shown that ingesting NO3- in the form of concentrated beetroot shots attenuates the expected reduction in salivary-pH following carbohydrate supplements and exercise-induced dehydration[1], indicating that NO3- can be considered as a novel nutritional strategy to reduce the risk of developing acidity related oral health conditions. It is currently unknown if NO3- rich whole vegetables will have a similar protective effect. The aim is to determine responses to a single dose of NO3- in the form of whole vegetables and assess whether high NO3- vegetables can offset oral acidity following repeated sugar mouth rinses.

METHODS: Twelve healthy adults (6 male, 31 ± 8 years, stature 177 ± 7cm and body mass 79 ± 15.4kg) completed a randomised cross over study comprising of two experimental trials. After baseline measurements, participants rinsed their mouth with 10% unflavoured dextrose solution for at least 1 min 30 min prior to consuming either high NO3-salad (HN) (120g or ~4,2mmol/L) or low NO3-salad (LN) (negligible NO3- content). Further dextrose rinsing was carried out immediately after salad consumption, and at 90- and 160-min. Unstimulated saliva samples were collected at each timepoint for analysis of NO3-, nitrite (NO2-), pH, lactate, glucose, and ammonia. Blood pressure was recorded, and venous blood collected at 150 min post vegetable consumption. Values are reported as mean ± SD. A two-way repeated measures ANOVA with Tukey's correction was used to detect differences.

RESULTS: As expected, plasma and salivary nitrite (NO2-) and NO3- increased from baseline in the HN condition and were higher in HN than LN (all P<0.001). Systolic blood pressure significantly decreased in the HN condition (P<0.001). Diastolic blood pressure reduced in females only (P 0.007). Sugar rinsing caused the pH to drop in both conditions (all P <0.05), but pH was higher in the HN trial than LN (all P <0.001). Lactate and glucose were higher in the LN trial than the HN at 100 and 160 min (both P <0.001). Ammonia was greater post vegetables ingestion in HN compared to LN and stayed elevated for the whole trial duration (AUC, P < 0.034).

CONCLUSION: Ingesting NO3- in whole vegetable form attenuates oral acidity following repeated sugar exposure. NO3-rich salads could be considered by athletes as a novel nutritional strategy to reduce the risk of developing acidity related oral health conditions.

EFFECTS OF DIETARY NITRATE ON MITOCHONDRIAL EFFICIENCY AND EXERCISE CAPACITY IN ELDERLY INDIVIDUALS AND PATIENTS WITH TYPE 2 DIABETES

FLENSTED-JENSEN, M., SCHMÜCKER, M., INGERSEN, A., RØDER, J., LARSEN, S.

UNIVERSITY OF COPENHAGEN

INTRODUCTION: Several studies have shown that dietary nitrate can increase exercise capacity and reduce whole body oxygen uptake during submaximal exercise, yet the underlying mechanisms remain largely unknown. Some have suggested that nitrate may improve mitochondrial efficiency, by lowering proton leak, but studies are scarce and equivocal. Previous studies have primarily included young healthy participants, and thus the potential in various patient populations has yet to be fully explored. The aim of the current study was to examine the effects of dietary nitrate supplementation, in the form of beetroot juice, on exercise capacity and mitochondrial efficiency in patients with type 2 diabetes (T2D), elderly individuals and overweight individuals.

METHODS: 29 subjects (9 elderly individuals (OLD), 10 T2D patients (T2D) and 10 healthy overweight controls (CON)) took part in two similar experimental days, after ingesting either beetroot juice or placebo for three days prior to each experimental day, in randomized order. Experimental days included measurements of resting metabolic rate (RMR), blood pressure, blood samples, and a 45-minute cycling test at submaximal intensity (70% of VO2max). Muscle biopsies were obtained before and after the exercise test, and mitochondria were isolated from the muscle biopsies and examined for mitochondrial P/O ratio, leak respiration and respiratory capacity (MRC) by high-resolution Respirometry.

RESULTS: P/O ratio was unchanged in all groups after nitrate supplementation, and there was no difference in P/O ratio between groups at baseline. Likewise, leak respiration and MRC was unaffected by nitrate supplementation, with no differences between groups. Whole body oxygen uptake at rest and during exercise was unchanged, but tended to be lower in the OLD group during exercise.

CONCLUSION: The present study shows no effect of nitrate on mitochondrial efficiency and function, which is in line with most, but not all, existing studies. However, only very few human studies exist, and thus studies like this are important to clarify if nitrate does indeed have potential in modulating parameters of mitochondrial function. It is possible that the lack of an effect on exercise capacity could be attributed to the duration and intensity of the exercise test, as newer meta analyses have shown the largest effect sizes in short term high intensity tests. Since previous studies have primarily included young healthy participants, and have shown mixed results in terms of the ergogenic effects of nitrate, future studies are needed to clarify the effects in various patient populations that may suffer from exercise intolerance. These findings indicate that the ability of nitrate to enhance mitochondrial efficiency is unlikely, and therefore future studies should focus on alternative mechanisms of action that may seem more promising.

A DOUBLE-BLIND PLACEBO-CONTROLLED RANDOMISED CROSSOVER TRIAL TO EVALUATE BROWN FAT QUALITY, QUANTITY AND ACTIVATION WITH INORGANIC NITRATE SUPPLEMENTATION IN PEOPLE WITH TYPE 2 DIABETES MELLITUS

NEAL, R., SADANANTHAN, S.A., VELAN, S., COSTELLO, J., EGLIN, C., SAYNOR, Z., PERRISSIOU, M., SHUTE, J., BAILEY, S., CUMMINGS, M., PRICE, H., CORBETT, J., TOTMAN, J., SHEPHERD, A.

1 BOURNEMOUTH UNIVERSITY, 2 AGENCY FOR SCIENCE TECHNOLOGY AND RESEARCH, 3-5 UNIVERSITY OF PORTSMOUTH, 6 LOUGHBOROUGH UNIVERSITY, 7-8 NHS TRUST, 9 FATIMA COLLEGE OF HEALTH SCIENCES

INTRODUCTION: Identifying cost effective exercise/drug-alternative interventions for type 2 diabetes mellitus (T2DM) is imperative. Diets rich in dietary nitrate have cardiovascular benefits and have been shown to increase brown adipose tissue (BAT) expression by 'beiging' white adipose tissue in mice through a nitric oxide dependent process. Recent developments in the ability to non-invasively measure BAT quantity, quality and activation using magnetic resonance imaging (MRI) and infrared thermography (ITR) has opened the possibility to study the effects of nitrate on BAT in humans. This study hypothesises that nitrate can increase BAT activation in people with T2DM.

METHODS: A double-blind placebo-controlled randomised crossover experimental trial recruited 13 participants with T2DM (Age: 62±8 years; BMI: 29.1±3.1 kg·m-2) to examine the effect of beetroot juice supplementation (14-days) on BAT activation and quantity. Outcome measures for supraclavicular 1) fat quantity and quality, imaged by MRI (T2*, fat fraction), and 2) BAT activation, indicated by a relative change in skin temperature imaged with IRT (compared with sternum control), were taken pre- and post-cooling intervention (1 hour, 8.1±1.2°C water perfused jacket) and following placebo (140 ml·day-1, 0.1 mmol·L-1 inorganic nitrate) and experimental trial (140 ml·day-1, 12.4 mmol·L-1 inorganic nitrate) with a 7-day washout.

RESULTS: Supraclavicular fat quantity can be determined from MRI using proton density fat fractions (PDFF) in people with T2DM, in a representative example we have found a change in PDFF following this cooling protocol (i.e. 76.9% to 75.8%) and the impact of nitrate supplementation on BAT quantity will be established. Mean skin temperature was reduced in both conditions (nitrate -0.8±0.7°C, placebo -0.6±0.6°C, $p<0.05$) while relative skin temperature determined by IRT did not change after cooling following placebo (0.3±0.5°C) or nitrate (0.1±0.5°C) intervention ($p>0.05$).

CONCLUSION: Dietary nitrate supplementation does not increase brown fat activation. Possible explanations for the lack of effect include 1) an insufficient cooling protocol, 2) the IRT measurements of relative skin temperature may be insufficient

to elucidate potential changes in brown fat activation or, 3) that nitrate does not increase BAT in people with T2DM. However, MRI may be used to quantify BAT quantity and quality in this population following nitrate supplementation, with fat fraction being a superior biomarker for BAT and this may be associated with glucose metabolism and adiposity.

BEETROOT AND PARAXANTHINE BASED SUPPLEMENTS TO ENHANCE COGNITIVE PERFORMANCE: POSSIBLE APPLICATION IN SPORT?

CANNATARO, R., CIONE, E., CAROLEO, M.C., JAGER, R., INNOCENTI, B., VACCARO, M.G., BONILLA, D.A., ABREGO-GRANDIQUE, D.M.

UNIVERSITY OF CALABRIA

INTRODUCTION: Cognitive performance is also attracting growing interest in sports, particularly in activities that require a commitment from the point of view of concentration; it would be important to optimize this aspect.

METHODS: Here, we evaluate two possible supplements to improve cognitive performance: beetroot (BR) extract and paraxanthin (a modified form of caffeine). Both studies were operated in a double-blind, randomized, placebo-controlled, two-period crossover clinical trial; in the case of paraxanthin, the subjects underwent a caffeine washout of at least five days. In the first case, a sample of 44 subjects was administered three beetroot-based chewable tablets with an extract standardized in nitrates an hour and a half before being subjected to a battery of neuropsychological tests (RAVLT, Digit Span, SDMT, FAB, COWAT, STAI, and PRMQ). In the second, a sample of 39 subjects was administered three capsules containing 300mg of paraxanthin; after 30 minutes, they were subjected to a battery of neuropsychological tests.

RESULTS: Significant improvements with moderate effect size were found on memory consolidation in the short- and long-term only after BR supplementation via the Rey Auditory Verbal Learning Test (RAVLT) immediate (+20.69%) and delayed (+12.34%) recalls. Likewise, enhancement in both frontal lobe functions (+2.57%) and cognitive flexibility (+11.16%) were detected after BR-CT. There was no significant change ($p<0.05$) in verbal memory of short-term digits, working memory, and information processing speed. Mixed results were found on mood and anxiety through the Beck Depression Inventory-II (BDI-II) and the State-Trait Anxiety Inventory (STAI-Y1 & STAI-Y2); however, sequence and period effects were seen on STAI-Y2. In the paraxanthine group, only RAVLT delayed, and Digit Span showed a significant difference (+14,9% and +13,1% respectively); RAVLT immediate, even with $p=0.19$, showed an increase of 3,1%, the others tests did not show any appreciable change.

CONCLUSION: These two evaluations show how, even acutely, the cognitive ability of healthy subjects can be improved; BT supplementation appears to be more effective overall, but the timing of intake may also have affected the final effect; a subsequent study could be to combine the two principles to have a synergistic effect; it should be emphasized that no side effects have been recorded, not even in the long term (6-month follow-up). Therefore, the supplements are safe; new, exciting possibilities could open up in improving cognitive performance applied to sports.

EFFECTS OF BLOOD-FLOW RESTRICTED VERSUS CONVENTIONAL RESISTANCE TRAINING ON LOWER LIMB STRENGTH, FUNCTIONAL PERFORMANCE AND PAIN IN CLINICAL PATIENTS - A SYSTEMATIC REVIEW AND META-ANALYSIS

JØRGENSEN, S.L.1,2, KIERKEGAARD-BRØCHNER, S.1,2, BOHN, M.B.1, HØGSHOLDT, M.1, AAGAARD, P.4, MECHLENBURG, I.2,3

1 HORSENS REGIONAL HOSPITAL, 2 AARHUS UNIVERSITY, 3 AARHUS UNIVERSITY HOSPITAL, 4 UNIVERSITY OF SOUTHERN DENMARK

INTRODUCTION: Heavy-load resistance training (HL-RT) is usually deemed necessary to produce gains in muscle strength and mass. HL-RT can, however, be contraindicated in some patient populations. Emerging evidence on the use of low-load blood flow restricted exercise (BFR-RT), suggests it applied to increase muscle strength and mass as well as functional performance in patients. This systematic review aimed to compare the effect of HL-RT and BFR-RT on gains in muscle strength, muscle mass, functional performance, and patient-reported outcome.

PROSPERO ID (CRD42022337173).

METHODS: Systematic searches for published randomized controlled trials (RCT) were performed in Web of Science, Cochrane Central, Medline, Embase and SportDiscus. Two reviewers independently included studies comparing HL-RT and BFR-RT, extracted data, and assessed the risk of bias. Random effects meta-analyses were used to synthesize the results. Certainty of evidence was rated by the Grading of Recommendations Assessment and Evaluation approach. Outcome measures were isometric knee extensor strength, repetition maximum (RM) knee extensor strength, RM leg press strength, quadriceps cross-sectional area, sit-to-stand performance, patient reported pain and function. Prediction intervals were reported for all meta-analyses with three or more studies.

RESULTS: Seven RCTs comprising 293 participants (BFR-RT: n=147; HL-RT: n=146) were identified. BFR-RT and HL-RT showed similar gains in RM knee extension strength, RM leg press strength, quadriceps cross-sectional area, sit-to-stand perfor-

mance, and patient reported pain and function. However, there was a moderate effect favoring BFR-RT for evoking gains in isometric knee extensor strength. Certainty in the evidence was low to very low.

CONCLUSION: HL-RT and BFR-RT seems equally effective in producing gains in lower limb muscle strength, muscle mass, functional performance and patient-reported outcomes in young-to-old clinical patients, although greater gains in isometric knee extensor strength seem to occur with BFR-RT than conventional HL-RT. However, the certainty in the estimates was low to very low, and the results are likely to change with the inclusion of higher-quality trials.

THE EFFECTIVENESS OF HIGH-VELOCITY ELASTIC-BAND TRAINING IN REDUCING THE OCCURRENCE OF HAMSTRING INJURIES IN FOOTBALL PLAYERS

KAMANDULIS, S.1, CADEFAU, J.2, SNIECKUS, A.1, LUKONAITIENE, I.1, MICKEVICIUS, M.1, CONTE, D.1,3

1 LITHUANIAN SPORTS UNIVERSITY, KAUNAS, LITHUANIA; 2 INSTITUT NACIONAL D'EDUCACIÓ FÍSICA DE CATALUNYA, BARCELONA, SPAIN; 3 UNIVERSITY OF ROME "FORO ITALICO", ROME, ITALY

INTRODUCTION: Hamstring muscle injuries rates showed an increase in football players in recent years (Ekstrand et al. 2022). Significant portion of hamstring injuries occurs during high-velocity activities (Askling et al. 2012; Gronwald et al. 2022). However, current popular prevention strategies mainly target the development of maximal strength, which entails exercises performed at low velocity. We hypothesized that high-velocity elastic band training will reduce hamstring injury risk in football players.

METHODS: Male players from Lithuanian and Spanish semi-professional and professional teams (n = 608, age: 22.0 ± 5.0 years, playing experience: 14.8 ± 5.3 years) were recruited for this study. However, variations in methodology occurred due to disparities in the schedules of their respective championships as well as environmental factors. As a result, the analysis was conducted solely on data collected during the Lithuanian championship, which involved a total of 319 players from nine teams in the premier league and six teams in the 1st division. The players were assigned to either the intervention (INT) or control (CON) group for a five-week exercise period, followed by a ~4-month follow-up period where hamstring injuries and exposure time were recorded. In addition to regular football training, the INT group had 2–3 sessions per week of elastic-band training with low-load, high-velocity leg curls while lying prone; the CON group performed self-paced football-specific drills.

RESULTS: The INT group reported 8 hamstring injuries in 123 players (6.5%), whereas the CON group reported 18 injuries in 196 players (9.2%). Although the injuries rate was observed to be 29.2% lower in the group of individuals who underwent the intervention, the distribution of injuries between the INT and CON groups was not found to have a statistically significant difference (p>0.05).Moreover, no differences (P > 0.05, odds ratio [OR]= trivial-to-small) in distribution between the groups were found in hamstring injury characteristics (leg side, leg dominance, recurrence, typology and mechanism) except for the distribution of injuries that occurred during matches or training (P = 0.036; OR = 11.0, very large).

CONCLUSION: The high-velocity elastic-band training program did not effectively prevent

hamstring injuries in football players, despite showing some potential of including this exercise in injury prevention programs.

UNRAVELLING THE CHALLENGES OF REHABILITATION AND TREATMENT OF MUSCULOSKELETAL DISORDERS IN PROFESSIONAL BALLET DANCERS

BENOIT PIAU, J., BOLLING, C., MORIN, M., VERHAGEN, E.

UNIVERSITÉ DE SHERBROOKE

INTRODUCTION: Dancers are among the most injured athletes, which will cause repercussions on their physical and mental health, as well as their career (1,2). It is essential to establish strategies to prevent and manage these injuries. However, some challenges arise when preventing and treating injuries, as reported by dancers and health professionals (3). This study explored the experiences and challenges faced by the dancers and staff in a ballet company regarding the rehabilitation and treatment of injuries.

METHODS: We conducted twenty-two semi-structured interviews with dancers, members of the health team, the artistic staff, and administrative staff for this qualitative study. All participants were employed with the Dutch National Ballet. We audio-recorded and transcribed all interviews, and our analyses followed a thematic analysis.

RESULTS: According to dancers and other stakeholders, musculoskeletal disorders in dancers cannot be entirely prevented.

"How do you make ballet safe? Dont do ballet. Its not safe. Lets be realistic about it. It isnt safe, and making it safe, I think, impacts the art form."

The changes in repertoire during a season and the scheduling were among the challenges most often mentioned by participants.

"The changes in the repertoire. You just dont really have a choice. You just get in there. You wake up one day and then all of a sudden youre in a new ballet world."

However, it was noted that strength and conditioning programs designed by the health team to prepare the dancers for these changes in the repertoire were perceived as helpful in reducing the risk of musculoskeletal disorders.

"Yes, it is one of the reasons I go extra to the gym. To be able to have more strength in the role that I do. So that you wont get injured as quickly."

Other factors deemed important in a dancer's prevention and management of musculoskeletal disorders were communication with the health, artistic and administrative staff and the trust established between all stakeholders.

CONCLUSION: Considering the context around the current practices in preventing and managing musculoskeletal disorders in dancers is essential. By better understanding the context, programs will be more effectively targeted to the dancers' needs.

IS-BM01 Exercise and mental training as medicine for the brain

PREDISPOSITIONS AND EXERCISE-INDUCED PLASTICITY IN THE HUMAN BRAIN

TAUBERT, M.

UNIVERSITÄT MAGDEBURG

The human neocortex is essential for cognition, action and perception. Its complex morphology is tightly regulated by genetic factors, but is also malleable by environmental influences throughout the lifespan. Physical exercise (e.g., aerobic exercise or learning motor skills) is able to modulate cortical structure, with potential implications for healthy cognitive development and aging. However, recent studies highlight the fundamental role that more stable morphological features of the neocortex could play in predicting exercise effects on human behavior. The emerging view is that exercise effects on learning and cognition are mediated by predisposed traits and induced changes occurring at different levels of the neocortical architecture. This presentation will synthesize and integrate new knowledge in the field and consider its relevance to sports science and practice.

EXERCISE AND BRAIN HEALTH WITH A SPECIAL FOCUS ON GABAERGIC (INHIBITORY) PROCESSES

TAUBE, W.

UNIVERSITY OF FREIBURG

It is known that physical activity positively influences (cognitive) brain function not only in elderly but also young people; in both the short- and long-term. Furthermore, physical activity is a key factor to prevent neurodegenerative diseases. One aspect, which is commonly impaired in many neuro-pathologies but also in patients with motor control deficits, cognitive decline, insomnia or some types of depression is the cortical inhibitory system. Only very recently, it was discovered that sports activities have the potential to up- (e.g. balance training) or downregulate (e.g. strength training) the strength of the inhibitory circuits of the GABAergic system (i.e. cortical interneurons). The present talk will present evidence that physical activity strongly acts on the inhibitory system and that this impact may explain - at least partly - the positive influence of sports activities on pathologies that are known to go along with impaired (reduced) inhibitory capacity.

ENHANCING MENTAL TRAINING WITH NEUROFEEDBACK

WENDEROTH, N.

ETH ZURICH

Mental training is frequently applied in sports but also in neurorehabilitation to enhance performance or facilitate recovery. However, the effectiveness of mental training can widely vary between individuals, potentially because some mental

strategies do not optimally tap into the neurophysiological mechanisms that critically underpin performance or recovery. Here we can show that the neural specificity and effectiveness of mental training can be significantly enhanced by neurofeedback methods. Using the motor system and noradrenergic arousal control as examples, this presentation will show how neurofeedback can facilitate mental training and the acquisition of effective self-regulation strategies.

IS-AP03 A.I. IN SPORT AND EXERCISE SCIENCE: WE WERE SO PREOCCUPIED WITH WHETHER WE COULD, WE DIDN'T STOP TO THINK IF WE SHOULD

ARE WE DOOMED? THE FUTURE OF SPORT AND EXERCISE SCIENTISTS IN THE FOURTH INDUSTRIAL REVOLUTION

ABT, G.

THE UNIVERSITY OF HULL

Since the development of the personal computer in the 1970s, digital technology has largely played a complimentary role in our working lives. Yet Susskind and Susskind [1] argue that technology is increasingly substituting for professionals, such that tasks undertaken by robots or algorithms will eventually dominate. At the dawn of the fourth industrial revolution [2], it is appropriate that sport and exercise scientists consider how they adapt to this technological challenge. Although we may think our work is too complex or uncertain to be automated [1], tasks in other professions, like diagnosing skin cancers, are now being performed equally well by algorithms [3]. Likewise, in our profession, tasks once requiring specialised laboratory equipment and expertise are now performed with smartphones [4]. Although there is little evidence that technological change leads to net unemployment [5], our challenge is to consider which tasks will (or can) be automated, whether people will accept or want this automation [6], how we adapt [5], and how we create the optimal balance between human and machine [7]. We must also consider the ethical implications of devolving professional responsibility to decision algorithms [8], and by extension, to where liability rests following a negative outcome [9]. While we are all exposed to the implications of technological change, it is the next generation of sport and exercise scientists who will be most challenged by the exponential growth, capability, and scale of the fourth industrial revolution. As educators, we must help the next generation to develop the knowledge, skills, and resilience, to prepare, adapt, and rise to the technological challenge that confronts them [10].

MACHINE LEARNING FOR DUMMIES: SIMPLE METHODS TO IMPLEMENT ARTIFICIAL INTELLIGENCE ALGORITHMS INTO CONSUMER-BASED APPS

BALSALOBRE-FERNÁNDEZ, C.

AUTONOMOUS UNIVERSITY OF MADRID

Machine learning is often defined as a subfield of artificial intelligence (AI) devoted to methods that allow programs to 'learn' from data to automate and improve different types of tasks [1]. In sports and exercise research, some of the most frequent tasks that have been investigated are exercise recognition and training load analysis [2,3]: the former, to elaborate algorithms that could measure exercise performance or technique, the latter, to improve injury prevention strategies or even (try to) predict when/if they are going to occur [2]. Traditionally, creating AI to perform such tasks required advanced computing, coding, and data science skills, as well as computers with enough processing power to train the machine learning models that would perform those tasks. However, advances in smartphone and wearable technologies have not only improved the variables these devices can collect in a valid and reliable way [4]; some companies have also developed Software Development Kits (SDK), frameworks and apps for developers so they can train their own machine learning models in a simple, code-less way using personal computers. In this presentation, the free CreateML software (Apple Inc., USA) will be introduced, with an example of how to create an object-recognition model that automatically detects a weightlifting plate from a live video feed to measure barbell kinematics. This type of novel software simplifies the skills required to successfully implement AI in consumer-based products and can benefit the next generation of sport and

exercise scientists. Furthermore, it could help fight the 'black box' problem when dealing with sports technology, so rather than trusting undisclosed proprietary algorithms, sports scientists can have the power to build their own.

HUMAN VS MACHINE: WHO MAKES THE DECISION WHEN IT COMES TO ATHLETE MANAGEMENT?

CLUBB, J.

CHELSEA FOOTBALL CLUB

In the pursuit of high performance, there has been dramatic growth in the volume of data that sports science practitioners are expected to collect, manage, and disseminate [1]. Such data is thought to be a key enabler of decision making in elite athlete management [2]. It is unsurprising that the search for a competitive advantage has led teams and practitioners to seek out innovative approaches. Yet, such innovation is not without trepidation. Both athletes [3] and scientists [4] have expressed concerns that athlete monitoring has already gone too far, and that athletes are 'people, not just numbers' [3]. Despite this apprehension, complex data science methodologies continue to emerge. Solutions driven by artificial intelligence (AI) are now being employed across a multitude of applications in sports, including forecasting injury risk [5], providing individualised, 'precision strength training' [6], and developing sports technology solutions such as indoor navigation [7]. While practitioners have historically been encouraged to 'unpack the black box' with sports technology [8], this is becoming increasingly difficult in the face of unexplainable methodologies and proprietary algorithms. This landscape requires an urgent discussion of AI integration in the scientific management of athletes. How can practitioners critically appraise vendors, especially when the algorithm cannot be evaluated? How should system outputs be integrated into decision support systems? Who takes the blame if the system is wrong, or if the system was right but was not heeded by the human practitioner? How can academics and applied practitioners collaborate to produce evidence-based research in this area? Both ethically and operationally, the implication of devolving professional responsibility to a decision algorithm [9] is the foremost issue sport and exercise scientists face today.

OP-PN28 Ketogenic

KETO-ADAPTATION FOR TEAM SPORT ENERGETICS?

PRETORIUS, J., ENGELBRECHT, L., TERBLANCHE, E.

STELLENBOSCH UNIVERSITY

INTRODUCTION: Many believe that anaerobic carbohydrate metabolism is the main energy source for all high-intensity exercise. Yet, during intermittent sprints, typical of many team sports, ATP is in fact mainly derived from ATP-PCr and aerobic pathways (MacLarren & Morton, 2012). It is well documented that aerobic fat oxidation rates are enhanced on a ketogenic diet (KD). Yet, keto-adaptation in the ATP-PCr pathway has not been investigated.

METHODS: 15 Recreationally active participants (n=7 men, n=8 women; aged 25.1 ± 6.4 years) performed intermittent sprints (6 x 10 s with 2 min rest) and a graded maximal aerobic capacity test, both on a cycle ergometer, first at baseline

while they maintained their habitual diet (HD: 35% CHO, 45% fat, 20% protein) and at the end of a 6-week KD intervention (7% CHO, 66% fat, 28% protein). We used the fast component of VO2 off-kinetics to calculate ATP-PCr derived energy for the intermittent sprint test. During graded exercise tests, gas exchange- and blood lactate measures were obtained to determine various metabolic thresholds.

RESULTS: Both intermittent sprint mean power output (627,6 ± 167,83 to 629,1 ± 155,39 W; p = 0.858) and graded exercise peak power performance were preserved on KD (271.6 ± 60.19 to 272.7 ± 54.48 W; p = 0.772). ATP-PCr derived energy during intermittent sprints increased significantly on KD (+22.0 ± 43.15 Joule; p = 0.003). In the graded exercise test, absolute VO2max was maintained on KD (3133.5 ± 641.55 to 3179.6 ± 657.32 mL/min; p = 0.302) with significant increases in relative VO2max (+5.3 ± 5.66%; 40.5 ± 6.34 to 42.7 ± 7.14 mL/min/kg; p = 0.005) and power at aerobic threshold (+12.1 ± 12.77%; 190.5 ± 47.64 to 211.8 ± 51.86 W; p = 0.002) while peak blood lactate lowered significantly after KD (14.3 ± 3.14 to 8.1 ± 4.45 mmol/L; p = 0.005).

CONCLUSION: The most noteworthy finding of this study was the increase in ATP-PCr derived energy during intermittent sprints after the 6-week KD, presenting this energy pathway as a potentially novel site of keto-adaptation. Herewith, future research may investigate KD as a potential endogenous alternative or -addition to exogenous creatine supplementation, currently used as an ergogenic aid by many team sport players. Furthermore, higher power at aerobic threshold and lowered peak blood lactate with maintained peak power on KD during the graded exercise test, suggests that the 6-week keto-adaptation enhanced aerobic energy metabolism to reduce blood lactate accumulation during exercise. So, the maintained power output on KD in both the intermittent sprint- and maximal aerobic exercise tests, was underpinned by desirable metabolic keto-adaptations in the two key energy systems utilized during intermittent sprints (i.e., ATP-PCr and aerobic metabolism). These metabolic adaptations may suggest potential for keto-adaptation in team sport contexts.

EXOGENOUS KETONE SUPPLEMENTATION IMPAIRS 20-MINUTE TIME TRIAL PERFORMANCE IN TRAINED CYCLISTS

MCCARTHY, D.G.1, BONE, J.1, FONG, M.1, PINCKAERS, P.J.M.2, BOSTAD, W.1, RICHARDS, D.L.3, VAN LOON, L.J.C.2, GIBALA, M.J.1

1,3 MCMASTER UNIVERSITY, HAMILTON, ONTARIO, CANADA. 2 NUTRIM SCHOOL OF NUTRITION AND TRANSLATIONAL RESEARCH IN METABOLISM, MAASTRICHT UNIVERSITY, THE NETHERLANDS

INTRODUCTION: The effect of ketone monoester (KE) ingestion on exercise performance is equivocal. A KE supplementation strategy that increases blood [β-hydroxybutyrate] ([β-HB]) to ~1-3 mM has been suggested to be optimal for a potential performance benefit (doi:10.1113/JP273185). This can be achieved by ingesting ~0.3-0.4 g/kg body mass of KE, which reduces the potential for blood acidosis and gastrointestinal distress associated with higher doses. We examined the effect of acute ingestion of 0.35 g/kg KE on 20-min time trial (TT) performance in trained cyclists. We hypothesized that mean power output would be different after KE ingestion vs a flavour-matched placebo (PL). This TT test is strongly correlated with functional threshold power and has a day-to-day variability of ~1.4% using the same equipment and procedures in trained cyclists (doi:10.1123/ijspp.2018-0100).

METHODS: An a priori sample size estimation (G*Power) determined n=22 provided 80% power to detect a 2.0% difference (dz=0.63) in TT power output at alpha=0.05 with a 2-tailed paired t-test. A total of 23 trained cyclists (21 males, 2 females; peak oxygen uptake: 65±12 mL/kg/min; mean±SD, >5 h/wk cycling training) completed a familiarization session followed by two experimental trials. Diet was self-selected and replicated for 24 h before participants ingested either 0.35 g/kg body mass (27±4 g) of (R)-3-hydroxybutyl (R)-β-HB KE or a ketone-free PL 30 min before exercise in a randomized, triple-blind, crossover manner. Exercise involved a 15 min warm-up and 20-min TT on a cycle ergometer. Participants adjusted workload by changing cadence and/or simulated gear. The only feedback provided was elapsed time.

RESULTS: Mean TT power output was 2.4 [0.6 to 4.1]% (mean[95% CI]) lower after KE vs PL (255±54 vs 261±54 W; p<0.01; dz=0.60). There was no effect of trial order (p=0.44). An exploratory 2-way repeated-measures analysis of variance [(KE vs PL) * (power output each quarter of the TT)] indicated power output was lower after KE vs PL ingestion (main effect p<0.01) but no interaction effect (p=0.93). KE vs PL ingestion increased pre-exercise blood [β-HB] (2.0±0.6 vs 0.2±0.1 mM, p<0.0001). Blood pH was not different but [bicarbonate] was lower in KE vs PL (28.2±1.8 vs 29.9±1.9 mM, p<0.001), as was total CO2 (28.9±2.0 vs 30.5±2.0 mmHg, p=0.001). Median gastrointestinal symptom severity did not exceed 1 out of 10 in either trial. Continuous glucose monitoring revealed that blood [glucose] was lower after KE vs PL ingestion before exercise (4.1±0.7 vs 4.6±0.9 mM; p=0.048) but not different during the TT (KE: 4.5±0.7, PL: 4.9±0.9; p=0.12). Rating of perceived exertion on a 6-20 scale was not different between trials (17[16-18] for both; p=0.11).

CONCLUSION: Acute KE ingestion, which increased blood [β-HB] to within the range purported to be ergogenic, impaired 20-min TT performance in trained cyclists. The mechanistic basis for this effect remains to be elucidated.

A KETONE MONOESTER DRINK REDUCES POSTPRANDIAL GLYCAEMIA IN INDIVIDUALS WITH TYPE 2 DIABETES.

MONTEYNE, A.

UNIVERSITY OF EXETER

INTRODUCTION: Ketone monoester (KES) ingestion has been shown to reduce postprandial glycaemia in lean individuals and those with obesity. We sought to determine whether ingestion of KES would reduce postprandial glycaemia in individuals with Type II diabetes (T2D); a condition characterised by dysregulated glucose control.

METHODS: Ten individuals with T2D (m=5, f=5; age 59±5 y; BMI 32±3 kg·m-2; diagnosed 6±5 y; Hb1Ac 54±8 mM; not prescribed exogenous insulin or SGLT2 inhibitors) completed two trials, in a randomised, double-blind, placebo-controlled, crossover design. Participants consumed a KES drink [(R)-3-hydroxybutyl (R)-3-hydroxybutyrate; 0.5 g·kg-1 body weight] or a noncaloric taste-matched placebo (CON), 30 min before consuming a 475 kcal mixed meal tolerance test (MTT; 75 g carbohydrate, 18 g protein, 12 g fat) at t=0 min. Circulating ß-Hydroxybutyrate (ß-OHB), glucose, and insulin concentrations were subsequently measured over 4 hours. Data were analysed with two-way ANOVA and presented as means ± SD.

RESULTS: Plasma ß-OHB concentration remained at baseline during CON (0.3±0.0 mM), whereas it was increased to a steady-state of 3.0±1.0 mM (peak 4.3±1.2 mM at t=30) in KES (P<0.05). From values of 6.0±1.0 mM in CON, and 5.8±1.2 mM in KES at t=0 min, blood glucose concentration increased following MTT to a peak of 11.0±2.3 mM at t=75 min in CON, which was supressed in KES to a peak of 8.7±1.4 mM at t=60 min (P=0.0015), before decreasing to values of 5.9±1.6 mM and 6.5±1.9 mM in CON and KES, respectively, at t=240 min. Compared with CON, KES ingestion reduced glucose area under the curve by 31% (P=0.0286). From values of 29±17 mU/l in CON, and 45±21 mU/l in KES at t=0 min, serum insulin concentration increased following MTT to a similar extent in CON and KES, peaking at 108±46 and 108±63 mU at t=90 min, respectively, before decreasing to values of 50±25 and 68±30 mU/l, respectively, at t=240 min.

CONCLUSION: KES ingestion reduces postprandial glycaemia in T2D. The postprandial glucose excursion was lowered to near normoglycaemic values despite no apparent differences in insulin secretion, suggesting an improvement in peripheral insulin sensitivity, a reduction in hepatic glucose production and/or reduced gastric emptying.

EXOGENOUS KETOSIS ELEVATES CIRCULATING ERYTHROPOIETIN AND STIMULATES MUSCULAR ANGIOGENESIS DURING ENDURANCE TRAINING OVERLOAD

POFFÉ, C., ROBBERECHTS, R., VAN THIENEN, R., HESPEL, P.

KU LEUVEN

INTRODUCTION: De novo capillarization is a primary muscular adaptation to endurance exercise training and is crucial to improve performance (1,2). Excess training load, however, impedes such beneficial adaptations, yet we recently demonstrated that such downregulation may be counteracted by ketone ester ingestion (KE) post-exercise (3). From this perspective, we hypothesized that KE could increase pro-angiogenic factors and thereby stimulate muscular angiogenesis during a training-overload period.

METHODS: A randomized, double-blind trial was performed using eighteen young, fit males. Subjects performed a three-week endurance training-overload period involving 10 training sessions/week. Immediately after each training session and before sleep, subjects received either 25g of a ketone ester (KE, n = 9) or a control drink (CON, n = 9). Biopsies of m. vastus lateralis and venous blood samples were collected before and after the training-overload period to characterize the effect of KE on muscular angiogenesis. A two-way repeated measures analysis of variance (ANOVA) was performed to evaluate differences between both groups and over time.

RESULTS: The training period altered neither capillary contacts (CC, $p > 0.999$) nor capillary-to-fiber perimeter exchange index (CFPE, $p = 0.333$) in CON. In contrast, in KE, the training period increased CC and CFPE on average by 44% ($p = 0.005$) and 42% ($p < 0.001$), respectively. Furthermore, in KE, VEGF increased by 33% at the protein level ($p = 0.028$) and increased 2-fold at the mRNA level ($p = 0.007$). In contrast, VEGF mRNA and protein expression were unchanged in CON (both $p > 0.999$). eNOS mRNA expression increased twofold in response to training in KE ($p < 0.001$), but remained unaffected in CON ($p > 0.999$). Conversely, at the protein level, eNOS increased in both KE and CON by ~125% (main effect of time, $p = 0.001$). Serum erythropoietin concentration increased by 26% in KE ($p = 0.027$), but remained stable in CON ($p > 0.999$).

CONCLUSION: These data indicate that intermittent exogenous ketosis during endurance overload training stimulates muscular angiogenesis. This resulted from a direct stimulation of muscle angiogenesis, which may be at least partly due to stimulation of erythropoietin secretion and elevated VEGF activity, and/or an inhibition of the suppressive effect of overload training on the normal angiogenic response to training. This study provides novel evidence to support the potential of exogenous ketosis to benefit endurance training-induced muscular adaptation.

THE IMPACT OF DIET ON HUMAN VASCULAR RESPONSES TO MENTAL STRESS

BAYNHAM, R., RENDEIRO, C., VELDHUIJZEN VAN ZANTEN, J.

UNIVERSITY OF BIRMINGHAM

INTRODUCTION: Mental stress has been shown to induce cardiovascular events, likely due to the negative effect of stress on endothelial function. During stressful periods, individuals often change their behavior to be less physically active and worsen their diet, which can influence endothelial function. For example, fat consumption can impair endothelial function, whereas flavonoid-rich foods, have been shown to improve endothelial function. Yet, the impact of diet (fat or flavanol consumption) on endothelial function in the context of mental stress is unknown. Thus, we investigated the impact of a high-fat meal (Study 1) and cocoa flavanols (Study 2) on vascular responses to mental stress.

METHODS: A randomised, within-subject design was used in both studies.

Study 1: 21 healthy participants (11M) completed two sessions (order counterbalanced) and consumed either a high-fat meal (56.5g fat) or a low-fat meal (11.4g fat) 1.5 h prior to mental stress (8-min mental arithmetic task). Vasodilatory responses (forearm blood flow, FBF), blood pressure (BP) and cardiovascular activity (CV) were assessed pre-meal and post-meal during a pre-stress resting baseline and the stress task. Endothelial function (brachial artery flow-mediated dilatation, FMD) was assessed pre-meal and 30 and 90 min post-stress.

Study 2: 30 healthy males completed two sessions (order counterbalanced) and consumed either high-flavanol cocoa (150mg (-)-epicatechin) or low-flavanol cocoa (< 4mg (-)-epicatechin) 1.5 h prior to mental stress. FBF, BP and CV were assessed pre-cocoa and post-cocoa during a pre-stress resting baseline and the stress task. FMD was assessed pre-cocoa and 30 and 90 min post-stress.

RESULTS: In both studies, mental stress increased FBF, BP, and CV, and impaired FMD 30 min post-stress. Study 1 showed that FMD remained significantly impaired 90 min post-stress in the high-fat condition only, suggesting that fat intake attenuates the recovery of endothelial function following stress. Conversely, Study 2 showed that high-flavanol cocoa attenuated the decline in FMD 30 min post-stress and, improved vasodilatory responses at rest and during stress. No differences in stress task perceptions and performance were observed between interventions in both studies.

CONCLUSION: Fat consumption impaired the recovery of endothelial function following stress. Given the prevalence of maladaptive coping mechanisms, such as reduced physical activity and increased fat intake, during stress, these findings suggest that fat consumption during stressful periods can aggravate the impact of stress on the vasculature. Importantly, cocoa flavanols are effective at counteracting stress-induced endothelial dysfunction and improving blood flow during stress. Therefore, these findings have important implications for future dietary choices and, selecting flavanol-rich foods over high-fat foods, may be an important strategy to protect the vasculature during periods of stress.

OP-AP25 Team Sports: Load Monitoring

RELATIONSHIP BETWEEN INTERNAL AND EXTERNAL LOAD IN YOUNG ITALIAN HIGH-LEVEL SOCCER PLAYERS

MELIS, M., NIGRO, F., MARCORA, S.M.

ALMA MATER STUDIORUM UNIVERSITY OF BOLOGNA

INTRODUCTION: In top-level soccer, monitoring training loads has become a fundamental method for achieving top performance (1). In the present study, the relationships between external and internal training loads variables were investigated in high-level Italian youth soccer.

METHODS: 25 players from a soccer team participating in the Primavera 1 league, the most important youth soccer competition in Italy, were monitored via GPS during all training sessions held between November 2021 and May 2022 of the 2021/2022 competitive season. Total distance, distance at different speed, number of accelerations and decelerations, distance traveled in acceleration and in deceleration, distance at high metabolic effort, average metabolic power, energy cost, and session duration were collected as external load variables, while the perception of effort assessed by Fosters RPE scale method was used as internal load variable (2). For each repeated measure, a linear regression analysis was performed using the within-subjects correlation method (3). The statistical significance was set at an alpha level of 0.05.

RESULTS: Positive correlations were found for all the variables included, in a range between rho = 0,112 and rho =0,822. There were close to strong correlations for total distance and energy cost (rho = 0.691, rho = 0.698, respectively). There were moderate to strong correlation for distance traveled in acceleration and deceleration and distance at high metabolic effort (rho = 0.621, rho = 0.611, rho = 0.599, respectively), and moderate correlations for number of accelerations and decelerations, high speed distance and very high speed distance (rho = 0.437, rho = 0.505, rho = 0.426, rho = 0.300, respectively). Weak correlations were found for average metabolic power and distance covered in sprint (rho = 0.112, rho = 0.180, respectively).

CONCLUSION: According to the model presented by Jeffries et al. in 2021 (4), the manipulation of the training prescription based on the modulation of the external load variables is an effective method to obtain different responses in the internal load perceived by the athletes. Internal load can be better controlled by focusing on the training variables most correlated with the perception of effort. The results of this study show that total distance, energy cost, acceleration and deceleration distance, and high metabolic effort distance have the greatest effect on changing the perception of effort in high-level young Italian soccer players.

DIRECTION MATTERS WHEN DESIGNING FOOTBALL PRACTICE – INVESTIGATING THE REPRESENTATIVENESS OF POSSESSION GAMES VIA POSITIONAL DATA

DEUKER, A.1, BEHM, S.2, STAPMANNS, L.2, FAY, L.2, KLEMP, M.2, BRAUNSTEIN, B.3, VOGT, T.1, REIN, R.2
GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: In football, practitioners and sports scientists observe a growing involvement in possession games (PG) to encourage passing skills, interpersonal space exploration, and occupation tendencies (Menuchi et al., 2018). These training tasks are designed without goals so that goal-setting shifts from goal-scoring towards maintaining possession for as long as possible. Informed by the Ecological Dynamics framework, collective cooperative behaviour is shaped by the layout of the available affordance landscape (Pinder et al.,2011). So, to facilitate skill transfer from training to the actual game, the present study investigates the representativeness of interpersonal relations in PG practice in football (O Sullivan et al., 2021).

METHODS: 22 male football players (age: 23 ± 2.5 years, body height: 183 ± 8 cm, mass:77.2 ± 7.8 kg) participated in one formal game (FG) condition (FG11VS11), two on-goal (OG) practice games: 6 vs. 6 (OG6VS6) and 7 vs. 5 (OG7VS5) and two PG conditions, 6 vs. 6 (PG6VS6) and 7 vs. 5 (PG7VS5), which aimed players to maintain possession as long as possible. The teams performed 60 trials in a crossover study design. Players' positional data were computed using a global positioning system (10 Hz, Catapult ®) and processed to calculate measures of inter-team distance, dyadic distance, and distance to the nearest opponent. The resulting values were analysed via repeated-measures ANOVA using the statistical software R (version 4.2.2). Tukey test for pairwise comparison was used when the repeated-measures ANOVA was $\alpha \leq 0.05$.

RESULTS: Results from the repeated-measures ANOVA revealed significant differences between the played conditions for distance to the nearest opponent, $F(4, 50) = 48.14$, $p < 0.001$, $\eta 2 = 0.76$, dyadic distance, $F(4, 50) = 72.13$, $p < 0.001$, $\eta 2 = 0.85$, and inter-team distance, $F(4, 50) = 9.64$, $p < 0.001$, $\eta 2 = 0.44$. The pairwise comparisons between FG11VS11 and the other conditions reveal that FG11VS11 resulted in a significant higher distance to the nearest opponent compared to PG6VS6 ($p = 0.0116$) and significantly lower values compared to PG7VS5 ($p < 0.0001$). The inter-team distance also differed in the two PG conditions compared to the formal game condition: (PG6VS6 ($p = 0.0084$) and PG7VS5 ($p = 0.0004$). Furthermore, Dyadic distance in FG11VS11 was significantly higher across all practice conditions ($p < 0.01$).

CONCLUSION: The major findings indicate that concerning the spatiotemporal relation, the applied possession games differed significantly from the FG, while the OG conditions showed representativeness. Consequently, when simulating the interpersonal properties of football, the direction of play is crucial to facilitate kinematic representativeness. Future studies should extend the kinematic comparison between the formal game and practice tasks in football to facilitate skill transfer into the performance environment (Farrow et al., 2016).

EXTERNAL MATCH-PLAY LOADS IN ELITE FEMALE ASSISTANT SOCCER OFFICIALS

CARLING, C., GRUSON, B., PAVILLON, T., LEPRINCE, C., THIVILIER, F., PRAT, J.M., DOUDET, F.
FRENCH FOOTBALL FEDERATION

INTRODUCTION: In soccer, little research has examined the general physical demands of match-play in the contemporary elite female central referee [1] and to our knowledge, none exists in assistant referees (AR). Recent research [2] has shown that female central referees experience temporal deteriorations in physical performance across match-play. Once again however, no study has attempted to confirm whether similar declines occur in AR. This study aimed to 1) describe the overall external match loads in elite female AR during official matches, 2) compare performance across halves and whether decrements occur during the final 15-minute intervals of each match half.

METHODS: Altogether, 6 elite French AR (age 28.9±5.1) participated. Data were collected in 229 competitive matches over 3 consecutive seasons (2020/21-2022/23). The sample included domestic French female and male league (female D1, D2 and male D4) and cup matches and female international youth & senior matches. Global Positioning Systems (Catapult One, Catapult, Australia) were used to collect the data. Each participant wore the same device during the entire duration of the study. External load variables analysed for the match overall included: total distance covered (TD), distance >13km/h (D>13km/h) and >19km/h (D>19km/h), frequency of accelerations & decelerations (>3m/s/s) and maximal speed attained (MS, km/h). Percentage changes in TD & D>13km/h and D>19km/h were analysed across match halves and for the first 15-minute match interval versus the final 15-minute interval in each half (data analysed per minute of play to account for end-half injury time). Effect sizes (ES) are reported for differences in mean values (classified as small [0.2], moderate [0.6], large [1.2], very large [2.0] and extremely large [4.0]).

RESULTS: Overall match data were TD=5112.7±827.1m, D>13km/h1=732.0±334.8m, D>19km/h=104.0±80.9m, accelerations=36.0±21.8m, decelerations=52.1±31.5m and MS: 22.4±1.9km/h. 1st versus 2nd half changes for TD, D>13km/h1 and D>19km/h respectively were: -3.9%, +2.7% and -8.1% (ES: -0.3, +0.2 and -0.2 [all small]). Changes in TD, D>13km/h and D>19km/h for the first 15-minute match interval compared to the final 15-minute interval both in the 1st half and 2nd half respectively were: -8.7% (ES =-0.6, moderate], -25.6% (ES =-0.7, moderate] and -29.4 (ES= -0.5, small]) and -10.4% (ES =-0.9, moderate], -18.1% (ES =-0.5, small] and -27.0% (ES: -0.6 [moderate]).

CONCLUSION: This study has established the general physical match demands for elite French female assistant referees in national and international soccer match-play (total distance covered=~5KM of which ~14% run at speeds >13km/h and

~2% >19km/h). It also shows that small to moderate temporal declines in running performance occur across competition. While this result suggests a need for specific physical conditioning practices to counter fatigue, additional research is necessary to account for the effects of contextual factors.

MOVEMENT AND SUBJECTIVE TASK LOAD CHARACTERISTICS OF MATCH OFFICIALS DURING THE MEN'S AND WOMEN'S RUGBY LEAGUE WORLD CUP

TWIST, C., JOHNSON, E., ELLIOTT, D., HIGHTON, J.

LIVERPOOL JOHN MOORES UNIVERSITY; UNIVERSITY OF CHESTER; RUGBY FOOTBALL LEAGUE

INTRODUCTION: Rugby league match officials (i.e., a referee and two touch judges) must position themselves relative to the players' actions during a match to make appropriate decisions that enable regulation of the players' behaviour by administering the laws of the game. Influence of the official's role during matches (i.e., referee vs. touch judge) on the physical and subjective task loads remains to be elucidated. Likewise, whether an official's load is influenced when controlling men's or women's competition requires investigation. Therefore, the aims of this study were to examine the influence of the match official's role and whether they were officiating male or female players on their movement and subjective task loads during international match play.

METHODS: A total of 123 performances (referees: n = 39; touch judge: n = 84) from 28 match officials (male n = 25; female n = 3) were assessed during the Men's and Women's Rugby League World Cup. Movement and heart rate data were collected during matches using a 10 Hz global positioning system device and heart rate monitor, respectively. Individual subjective task load was quantified by each official after every match for six sub-scales (Mental, Physical, Temporal, Performance, Effort, Frustration) using the National Aeronautics and Space Administration Task Load Index (NASA-TLX).

RESULTS: Despite similar relative distances (78.7 ± 12.2 cf. 74.3 ± 12.2 m/min; P = 0.061), peak speeds (7.6 ± 1.6 cf. 7.6 ± 1.2 m/s; P = 0.904) and mean heart rate (146 ± 28 cf. 140 ± 21 bpm; P = 0.292), referees performed more accelerations (49 ± 14 cf. 42 ± 18; P = 0.032), decelerations (52 ± 18 cf. 41 ± 21; P = 0.009) and had higher perceived Mental (6.2 ± 2.2 cf. 5.4 ± 1.9, P = 0.03) and Physical (6.2 ± 1.6 cf. 5.1 ± 1.7; P < 0.001) loads during a match than touch judges. Conversely, touch judges (6.3 ± 3.4 m/min) performed more high-speed running in a match than referees (3.8 ± 2.1 m/min) (P < 0.001). High-speed running (6.4 ± 3.2 cf. 3.4 ± 2.3 m/min; P < 0.001), accelerations (49 ± 16 cf. 32 ± 14; P < 0.001), decelerations (50 ± 16 cf. 34 ± 19; P < 0.001), peak speed (7.8 ± 1.4 cf. 7.1 ± 1.0 m/s; P = 0.01), Mental (6.2 ± 1.8 cf. 4.5 ± 2.1; P < 0.001), Physical (6.2 ± 1.4 cf. 4.0 ± 1.5; P < 0.001) and Temporal (5.4 ± 1.8 cf. 3.7 ± 1.8; P < 0.001) perceived loads were higher in those officiating men's compared to women's matches.

CONCLUSION: An official's role during a rugby league match will influence the physical and perceived load that has implications for conditioning practices. Referees need to perform repeated multidirectional movements under high perceived mental and physical load, whereas touch judges require more high-speed running capability. Those officiating men's international rugby league matches also require greater high-speed running and sprint capability, the ability to perform repeated changes of direction and greater tolerance of perceived mental, physical and time pressure loads compared to those controlling the women's game.

(1) UNIVERSIDADE DA BEIRA INTERIOR, (2) LEN EUROPEAN SWIMMING LEAGUE

The most recent scientific evidence supports the importance of aquatic competence in reducing the risk of drowning, particularly in children (Campaniço, 2019). LEN has recently established the "Learning2Swim" sub-commission (L2TS) for the purpose of technical and scientific advice on the development of good practices for the massification of aquatic competence across all European member federations.

Data collection and dissemination actions is one important L2TS' strategic vector. This can allow the assessment of the impact of the measures carried out over time and promote the exchange of good practices. Thus, a comprehensive survey was developed to understand the general characteristics of governmental and/or federative swimming education programs, as well as the current qualification and professional license requirements for swimming teachers in Europe. 49 of the 52 member federations responded to the survey.

The results show evident asymmetries in the sports policy to promote the aquatic competence of populations. For example, in 61.2% of the countries there are government programs for learning to swim, generally aimed at basic education (ISCED 1; 87.2%). However, teaching swimming at school is mandatory in only 38.8% of countries (40.8% of which is optional), under different funding models. It was also found that the teaching of swimming varies greatly in terms of duration, frequency, student/teacher ratio and even average costs per class. In about half of European countries (51.1%) swimming

teachers are required to have a professional license, although prior professional training is very variable and does not always include continuing professional training (38.2%).

RESEARCH APPROACHES TO UNDERSTAND THE CORE DIMENSIONS OF AQUATIC LITERACY

DE MARTELAER, K., VAN DROOGENBROECK, L., SOONS, B., DE BLOCK, K., BUELENS, L., D'HONDT, E.

VRIJE UNIVERSITEIT BRUSSEL

Starting from the definition of physical literacy being the "integration of physical, psychological, social, and cognitive capabilities that help us live active, healthy, and fulfilling lifestyles", the translation into aquatic literacy (AL) is made. In the Aquatic Literacy for All Children (ALFAC) research project, three core dimensions will be integrated to analyze, compare, and stimulate the concept of AL among European elementary school children: (a) aquatic skills (both actual and perceived), (b) psycho-social features (autonomous motivation, enjoyment & engagement, confidence) and (c) a knowledge aspect (risk perception).

The present contribution provides an overview of the research approaches in the literature on swimming, water competence and AL, taking into account the three dimensions of this latter "new" concept. Specific attention will be given to those preparatory studies conducted at the Vrije Universiteit Brussel (VUB) during the last five years. Concerning the assessment of actual aquatic skills, an inter- and intra-rater reliability study of the Actual Aquatic Skills Test (AAST) will be presented (Mertens et al., 2022). Linking this to perceived aquatic skills, a study identifying the differences between young children's actual, self-perceived and parent-perceived aquatic skills (D'Hondt et al., 2021) is a nice illustration. In terms of the psychosocial dimension, we have some preliminary master thesis' data using a questionnaire to explore fun and fear aspects in relation to aquatic recreation. Finally, the knowledge dimension is covered by a study on the development and validation of tool for individual aquatic risk management among children aged 6 to 12 years (De Martelaer et al., 2022). This research overview offers a retrospective viewpoint and illustrates the challenges the recent ALFAC program has in the three dimensions of aquatic literacy.

PEDAGOGICAL DIAGNOSTICS IN SWIMMING: A NEED FOR COMPREHENSIVE EDUCATION

STAUB, I., FOKKEN, I., VOGT, T.

GERMAN SPORT UNIVERSITY COLOGNE

Researchers have been attempting to quantify learners aquatic skills since the 1970s (Erbaugh, 1978). The objectives were (i) the investigation of effects on different aquatic training methods, (ii) the evaluation of human physical adequacy in the water in general or (iii) the assessment of swimming and water safety competencies more specifically. More recently, the focus has been set on the comparison of perceived and actual water competence (i.e., Costa et al., 2020). Most of these assessments are, at least in part, based on diagnostics of basic aquatic skills, which form the foundation of a comprehensive aquatic education. Scientists require diagnostic procedures to be transferable into practical situations. Other than applying scientific diagnostics benefiting research, there is a need for an applicable every-day-approach supporting practitioners in their planning of swimming lessons. In that sense, particularly qualitative diagnostic procedures have been suggested to also match inclusive settings (Mertens et al., 2021).

The Assessment of Basic Aquatic Skills (ABAS; Vogt & Staub, 2020) has been designed as an easy-to-apply tool for the assessment of physical capabilities of learners in swimming. However, actual planning of individualised (swimming) lessons and adaptive teaching needs a pedagogical diagnostic of learners' prerequisites to begin with. For this purpose, the 19 ABAS tasks have been transferred to a diagnostic procedure in swimming to determine the learners' prerequisites. This procedure is structured in two stages: at first, an initial assessment dividing a group of learners up to four consecutive levels of swimming ability. Secondly, the learners' prerequisites are analysed by means of specific ABAS tasks according to the respective level. Based on the results of such pedagogical diagnostics, it will be possible to structure learning opportunities focussing different prerequisites and, thus, designing comprehensive swimming lessons that provide aquatic literacy for all children.

OP-BM13 Running II

HOW RUNNING SPEEDS AFFECT ANKLE AND KNEE MUSCLE FORCES AND THE METABOLIC COST?

GERUS, P., LEMINEUR, C.

UNIVERSITE COTE DAZUR

INTRODUCTION: Running economy plays a significant role in endurance running performance [1], depending on running speed and is influenced by several physiological, biomechanical and neuromuscular factors. The muscles are essential for supporting body weight, propelling the body forward, absorbing impact from the ground and contributing to the energy consumption during running. Running speed affects muscle forces through a combination of factors, including muscle activation, muscle length, and muscle contraction velocity. As running speed increases, the muscles must produce more force to maintain balance and propel the body forward. This study aimed to examine the effects of running speed on knee and ankle muscle forces and metabolic cost.

METHODS: Nine recreative athletes (5 females, 25±3yrs, 171.2±4.7 and 63.1±6.1kg) performed a series of five running trials during 6 min on a motorized instrumented treadmill (Bertec) at speeds of 1.75, 2, 2.5, 3 and 3.25 m/s. EMG data from 8 lower limb muscles, kinematic of the hip, knee and ankle joint and kinetic data were used into a two-joints EMG-driven model [2] to estimate the ankle and knee muscle forces. The metabolic cost was estimated by indirect calorimetry based on the expired gas. A one-way (speed) repeated measures ANOVA was performed to identify significant changes ($p<0.05$) for individual maximal muscle forces over the range of running speed. Simple and multiple linear regression models were used to analyze the relation between muscle forces and the metabolic cost of running (MCR).

RESULTS: The preferred running speed, at which the MCR was lower, ranged from 1.75 to 3 m/s. The averaged MCR was ranged from 4.0 to 4.5 J/kg/m. Among all the knee and ankle muscle forces, the maximal force is lower at speed of 1.75 m/s compared to 3 and 3.25 m/s except for the semi-membranous (SM), semi-tendinous (ST), vastus lateralis and vastus intermedius muscles. The maximal forces of plantarflexor muscles showed difference for intermediate running speed 2 and 2.5 m/s compared to 3.25 m/s. The simple and multiple linear regression models showed a positive correlation between MCR and the biceps femoris ($R^2=0.292$), rectus femoris (RF) and the tibialis anterior (TA) and negative correlation with the SM and ST. The combination of BF, RF and TA predicted over 51% of the variance in MCR.

CONCLUSION: As running speed increases, the ankle muscles and some knee muscles produced more force probably for the forward body propulsion. However, not all muscles were significantly affected by the running speed. The BF, RF and TA were the main contributor to MCR. In comparison, a previous modeling approach has shown that the quadriceps and plantarflexors are the major contributors to the acceleration of the body mass center during running [3]. Further analysis will be required to better understand the relation between muscle forces and MCR.

KNEE JOINT FORCES DURING SPORT LOCOMOTION: A COMPARISON OF LINEAR, TURNING AND CUTTING MOVEMENTS

STETTER, B.J.1, ARENSMANN, A.2, SELL, S.1, STEIN, T.1

1 KARLSRUHE INSTITUTE OF TECHNOLOGY, KARLSRUHE, GERMANY; 2 UNIVERSITY OF MÜNSTER, MÜNSTER, GERMANY

INTRODUCTION: Precise information about forces acting on the knee joint during sport activities is substantial for understanding injury mechanisms and developing training programs to reduce sports injuries or improve rehabilitation after injury [1]. Due to the difficulty of direct joint force measurement in living persons, musculoskeletal modeling approaches have been used to predict internal knee joint forces (KJF). Previous studies in this field have primarily focused on individual movements and no systematic comparison across multiple sport locomotion tasks has been realized. The purpose of this study was to investigate differences in three-dimensional (3D) KJF for typical linear, turning and cutting movements in sports.

METHODS: The OpenSim simulation software (Gait2392 model with 76 muscles in the lower extremities and torso) was used to determine 3D KJF of the right leg for 13 young (26.1 ± 2.9 years) and healthy male sports students for a variety of sport-specific movements, including walking, moderate running, fast running, sprint start and full-stop after sprinting as linear movements, walking 90° step turn, walking 90° spin turn, running 90° step turn and running 90° spin turn as turning movements, and 45° left-sided v-cut and 45° right-sided v-cut as cutting movements. Differences across movements were assessed using repeated measures ANOVAs for the body weight-normalized (BW) peak KJF and the area under the KJF curve during the stance phase.

RESULTS: Across all movements the peak vertical KJF and the area under the vertical KJF curve increased primary with movement velocity (e.g. peak vertical KJF walking = 3.71 ± 0.96 N/BW vs. peak vertical KJF fast running = 9.93 ± 1.51 N/BW). An increased anterior KJF (i.e. peak anterior KJF > 2.44 N/BW) was identified for sprint start and left-sided v-cut. In contrast, an increased posterior KJF (i.e. peak posterior KJF > 4.48 N/BW) was shown for full stop, running turns and right-sided v-cut. The medial KJF was significantly higher for the left-sided v-cut (e.g. area medial KJF left-sided v-cut = 163.30 ± 51.91 N/BW vs. area medial KJF sprint start = 6.36 ± 16.85 N/BW) than for all other movements.

CONCLUSION: The comprehensive comparison of KJF in this study helps to improve our understanding of biomechanical knee loads during sport-specific movements. The observed KJF are of similar magnitude as presented in earlier studies that focused on a limited number of movements (e.g. 12 N/BW peak vertical KJF during running at 5 m/s [2]). The findings of this study underline the diverse 3D loading characteristics of sport-specific movements. This should be taken into consideration when developing training programs in order to achieve optimal sports performance with minimal injury risk.

NO DIFFERENCE IN BASELINE RUNNING HIP ADDUCTION-ABDUCTION JOINT ANGLES BETWEEN RUNNERS WHO DEVELOPED ILIOTIBIAL BAND SYNDROME AND MATCHED NON-INJURED CONTROLS OVER A 1-YEAR PROSPECTIVE STUDY (SIP)

SANCHEZ-ALVARADO, A.1,2, FOHRMANN, D.3,4, HOENIG, T.5, ROLVIEN, T.5, STÜRZNICKEL, J.5,6, RAHLF, A.L.7, HOLLANDER, K.3

1. UNI. OF HAMBURG, 2. UNI. OF POTSDAM, 3. MSH MEDICAL SCHOOL HAMBURG, 4. GERMAN SPORTS UNIVERSITY COLOGNE, 5. AND 6. UNIVERSITY MEDICAL CENTER HAMBURG EPPENDORF, 7. EUROPA UNIVERSITÄT FLENSBURG

INTRODUCTION: The iliotibial band syndrome (ITBS) is accounted to be the second most common injury at the knee among runners [1]. Moreover, the individual running style is considered a biomechanical risk factor for running-related injuries (RRI), and the literature suggests conflicting evidence regarding the hip adduction angle as a risk factor for ITBS [2].

Still, most of the studies evaluate the differences at discrete time points (peak hip adduction angle) during the stance phase [2], limiting their interpretability throughout the continuous waveform of the kinematic data. Therefore, this study aimed to compare the continuous kinematic curves of the hip adduction-abduction joint angle of runners who later developed ITBS against matched control participants through Statistical Parametric Mapping (SPM).

METHODS: A total of 120 competitive runners and triathletes were followed up for one season (12 months). The RRIs were surveyed weekly via a smartphone app (athletemonitoring.com; FITSTATS Technologies, Inc., Canada). Participants were contacted if they reported an injury and then examined by experienced sports medicine physicians who made a precise diagnosis. Three-dimensional kinematic data were collected with 14 color cameras at 150 Hz (Qualisys AB, Sweden) and analyzed with markerless software (Theia Markerless, Canada), during baseline measurements, at the beginning of the season [3]. All athletes were free from any lower limb injury at least three months before the study's start. The current analysis is focused on those runners who later developed ITBS, compared to matched asymptomatic controls (no RRI reported, similar height, weight, and age). A set of 2-way ANOVA was used with the SPM1D package (version 0.4.18) on Python (Jupyter Notebook version 3.9.7) to compare the injured side against the ipsilateral leg of the matched controls.

RESULTS: Seven runners developed ITBS (37.1±8.3 years old, 172.4±5.8 cm height, 66.2±5.8 kg weight, 5 females/2 males, 4 on the right side) within the study period. They were matched with 7 asymptomatic runners (40.7±7.6 years old, 171.7±5.9 cm height, 67.6±6.7 kg weight, 5 females/2 males). Despite qualitative differences in the peak adduction angle during stance, the SPM1D ANOVA results showed no statistically significant differences ($p>.05$) between both groups at baseline measurement.

CONCLUSION: There were no statistically significant differences at baseline in the hip adduction-abduction angle while running between the runners who subsequently developed ITBS and their matched controls.

OLDER AND LESS ECONOMIC RUNNERS BENEFIT FROM A SOFTER MIDSOLE.

TRAMA, R., WANNOP, J.W., STEFANYSHYN, D.J.

HUMAN PERFORMANCE LABORATORY

INTRODUCTION: Running performance continues to increase thanks to better training programs and footwear. A key parameter of level and long-distance performance is running economy - the energy spent by a runner to move 1kg of their mass over 1km. With continuous improvements in footwear technology, the impact on average running economy is becoming smaller. However, opportunities may exist to continue to improve performance by better understanding runner

specificities as depicted by inter-individual responses (1). For instance, shoe cushioning can improve running economy on average (2); however, it is still unclear what population can benefit most from it. Thus, creating functional groups becomes necessary to better understand individual and group response to an intervention (1). The purpose of this study was to identify characteristics of the population based on their adaptation to a softer midsole, with a focus on how they compress the midsole while running, their running pattern, kinematics and kinetics.

METHODS: Twenty runners of various levels participated in the study and ran on an instrumented treadmill for two times 5 minutes at 85% of their speed at anaerobic threshold (determined before the study). They wore two prototype pairs of Adidas running shoes. The control shoe was composed of a full EVA midsole (HARD, 75.2 N·mm-1), while the second one was composed of a hollowed-out EVA midsole (SOFT, 56.4 N·mm-1). Six reflective markers were pinned to the lateral midsole of the left shoe to track midsole compression (3). Additional markers were placed at different locations on the participant's body and were tracked with a system of eight optoelectronic cameras to assess running kinematics. Ground reaction force data were collected with force plates embedded in the treadmill to assess running kinetics. A breath-by-breath metabolic analysis system was used to quantified gas exchanges and running economy. Two functional groups were formed, one group having better running economy with the SOFT footwear (IMPROVE, 11 runners), and one group having worse running economy (IMPAIR, 9 runners). One-way and two-way ANOVAs were used to assess differences between the two groups and interactions with the shoes.

RESULTS: The IMPROVE group was older (+5.5 years, $p=0.019$) and had a greater braking ratio (+0.37, $p=0.037$) than the IMPAIR group. The IMPROVE group had a worse running economy with the HARD shoe (+0.157 kcal·kg-1·km-1, $p=0.006$), and a greater midsole vertical compression with the SOFT shoe (+2.89 mm, $p<0.001$). No differences were found in running pattern, kinematic, or kinetic data.

CONCLUSION: Older participants with decreased running economy are more likely to benefit from softer shoes. This population was able to better compress the softer midsole and benefit from a reduced braking ratio to improve their running economy.

INFLUENCE OF DIFFERENT LONGITUDINAL BENDING STIFFNESS OF RUNNING "SUPER SHOES" ON BIOMECHANICS AND RUNNING ECONOMY.

RODRIGO-CARRANZA, V.1, HOOGKAMER, W.2, RODRÍGUEZ-BARBERO, S.1, SALINERO, J.J.1, GONZÁLEZ-RAVÉ, J.M.1, GONZÁLEZ-MOHÍNO, F.1

1 SPORT TRAINING LAB. UNIVERSITY OF CASTILLA-LA MANCHA, TOLEDO, SPAIN. 2 INTEGRATIVE LOCOMOTION LABORATORY, DEPARTMENT OF KINESIOLOGY, UNIVERSITY OF MASSACHUSETTS, AMHERST, MA, USA

INTRODUCTION: Running performance, particularly in long distance events such as the marathon, depends on an interplay of several physiological factors, including the metabolic cost of running (RE). Increasing shoe longitudinal bending stiffness (LBS) influenced RE and performance[1], being one of the main features of the new "Super Shoes". However, results on the effects of increasing LBS using flat carbon fiber plates or insoles are mixed. The main difference of the shoes conditions in these studies compared to "Super Shoes" is that "Super Shoes" have a curved plate instead of a flat plate and new more resilient and compliant foams. The purpose of this study was to evaluate the isolated effects of increased LBS by embedding a curved carbon fiber plate within a PEBA midsole of a "Super Shoe" on RE and biomechanics.

METHODS: Twenty-one male trained runners participated in this study. Subjects ran 4 x 4 min at 13 km·hr-1 with two experimental condition shoes models with curved carbon fiber plate in a "Super shoe" model with different LBS increments (Stiff: 35.5 N·mm -1 and Stiffest: 43.1 N·mm -1) and a control condition (without carbon fiber plate: 20.1 N·mm-1). We measured energy cost of running (W·kg-1), spatiotemporal and neuromuscular parameters in one visit.

RESULTS: There were significant differences between shoe conditions in RE measured as energy cost ($p<0.001$; $n2 = 0.374$). RE improved for the Stiff shoe condition (15.71 ± 0.95 W·kg-1; $p<0.001$; $n2=0.374$) compared to the control condition (16.13 ± 1.08 W·kg-1) and stiffest condition (16.03 ± 1.19 W·kg-1), without differences between stiffest and control conditions. Moreover, there were an increase of step length and flight time for both experimental conditions in comparison to control condition and an increase of leg stiffness in the Stiff condition in comparison to control condition, but without differences between Stiffest and control conditions.

CONCLUSION: Changes in LBS on "super shoes" influence RE in a "U-shaped" relationship, decreasing 2.56% energy cost of running (better RE) in the Stiff condition in comparison with the control, and 1.98% when comparing the Stiff condition with the Stiffest, similar to a previous study with flat plates[2]. However, the Stiff and Stiffest condition experienced similar spatiotemporal changes compared to the control condition (increases in step length and flight time) except for leg stiffness. Higher leg stiffness has been related to a better RE [3], thus, it seems that the "optimal" LBS condition caused changes in leg stiffness whereas when the increase in LBS is excessive (Stiffest condition) it did not.

OP-PN13 Hypoxia II

DIFFERENTIAL EFFECTS OF HYPOXIA AND HEAT ON RESTING AND EXERCISE-RELATED BLOOD OXIDATIVE STRESS

DEBEVEC, T., PIALOUX, V., SOTIRIDIS, A., CIUHA, U., MCDONNELL, A.C., MEKJAVIC, I.B., MILLET, G.P.
JOZEF STEFAN INSTITUTE

INTRODUCTION: While exercise is known to augment oxidative stress and alter antioxidant status, environmental stressors such as hypoxia (1) and/or heat (2) can also modulate redox balance. The present work sought to compare resting and exercise-related pro-antioxidant balance following acute exposure to both heat and hypoxia as well as after prolonged acclimatization protocols to both environmental factors.

METHODS: Within the framework of the X-Adapt project (3, 4), twenty-four healthy males underwent acute exercise testing under normoxic (NOR), hypoxic (13.5% FiO2; HYP), and hot (35 °C, 50% RH; HEAT) conditions in a randomized manner. Thereafter they underwent a 10-day acclimation protocol consisting of either 1) continuous normobaric hypoxic exposure combined with exercise training (N=12; FiO2=13.65±0.35%) or 2) daily 90-min controlled-hyperthermia exercise sessions (N=12; Tre=38.5°C). Venous blood plasma samples were obtained before and immediately after the acute exercise tests with further resting samples obtained following the prolonged acclimatization protocols. Several oxidative stress [advanced oxidation protein products (AOPP), malondialdehyde] and antioxidant status markers [ferric-reducing antioxidant power, superoxide dismutase (SOD), glutathione peroxidase, and catalase] along with uric acid (UA) and total nitrite and nitrate (NOx) were determined.

RESULTS: While acute exercise in HYP and HEAT increased AOPP ($P< 0.01$) and UA ($P< 0.05$), SOD was only reduced following HYP ($P< 0.05$). NOx ($P< 0.05$) and Catalase ($P< 0.05$) only increased following HYP and HEAT, respectively. Following prolonged acclimatization protocols, no significant between or Pre-Post differences were observed at rest in any of the measured markers.

CONCLUSION: These data suggest that hypoxia and heat differentially affect acute exercise-related oxidative stress modulation in healthy young males.

THE ISOLATED AND COMBINED EFFECTS OF ACUTE HYPOXIA, OVERNIGHT SLEEP DEPRIVATION, AND EXERCISE ON COGNITIVE AND PHYSIOLOGICAL FUNCTION

WILLIAMS, T.B., CORBETT, J., TIPTON, M.J., MCMORRIS, T., BADARIOTTI, J.I., MAYES, H.S., WHITE, D.K., CAUSER, A.J., CARVALHO, F.A., PARKER, M.O., THELWELL, R., ANDO, S., COSTELLO, J.T.
UNIVERSITY OF PORTSMOUTH

INTRODUCTION: It is well established that both acute hypoxia and total sleep deprivation may impair cognitive performance. However, few have considered whether there is a cumulative effect when both stressors are experienced in combination. In contrast, moderate intensity exercise has been shown to improve cognitive performance. Whilst a growing number of studies have examined the interaction between hypoxia, exercise and cognition, this relationship remains poorly understood. Furthermore, whether exercise improves cognitive performance after a period of sleep deprivation, or when hypoxia and sleep deprivation are experienced in combination, is currently unknown.

METHODS: Using a randomised, controlled, crossover design, this study examined the isolated and combined effects of acute hypoxia (60 mins at FIO2 0.12), one night of total sleep deprivation, and 40 minutes of moderate intensity (RPE 12) cycling exercise on cognitive performance. Twelve healthy male participants (mean [SD], age: 26 [4] years; height: 185 [7] cm; weight: 84 [12] kg; VO2max: 46 [9] mL.kg-1.min-1) completed a 7-task cognitive battery (ANAM: simple reaction time, logical relations, mathematical processing, Manikin test, n-back) at rest and during exercise in the following conditions: normoxia and hypoxia with a normal night of sleep; normoxia and hypoxia following one night of total sleep deprivation. Peripheral oxygen saturation (SpO2), cerebral oxygenation (measured via near-infrared spectroscopy at the prefrontal cortex), and breath by breath gas analysis were measured throughout.

RESULTS: As expected, SpO2 and cerebral oxygenation were reduced in hypoxia compared to normoxia, with lower values observed during exercise compared to rest. However, no further reductions were observed for either measurement when hypoxia and sleep deprivation were experienced in combination. Hypoxia experienced in isolation did not result in a reduction in performance for any of the cognitive tasks ($P > 0.05$), however, after one night of total sleep deprivation all tasks were impaired when performed at rest ($P = 0.001 – 0.027$). There was no further impairment when tasks were performed at rest during hypoxia and sleep deprivation in combination, than when completed after sleep deprivation alone.

When compared to rest in the same condition, cognitive performance during exercise was improved after total sleep deprivation in both normoxia and hypoxia (P = 0.001 – 0.047).

CONCLUSION: The principal novel findings of this study are as follows: 1) one night of total sleep deprivation reduces cognitive performance at rest across multiple cognitive domains; 2) there is no further reduction in cognitive performance when hypoxia (FIO2 0.12) and one night of total sleep deprivation are experienced in combination; and 3) sleep deprivation-induced decrements in cognitive performance are ameliorated by an acute bout of moderate intensity cycling exercise in both normoxia and hypoxia.

TIME COURSE OF RESTING AND EXERCISE-RELATED CARDIO-RESPIRATORY RESPONSES THROUGHOUT A THREE-DAY ALTITUDE EXPOSURE AT 3375 M

NARANG, B.J., MANFERDELLI, G., MILLET, G.P., DEBEVEC, T.

JOŽEF STEFAN INSTITUTE

INTRODUCTION: Multiple-day recreational trips to altitude are increasing in popularity. The reduced barometric pressure and physical activity requirements associated with these sojourns evoke a combined hypoxic and exercise stimulus, posing a significant physiological challenge. The aim of this work was to elucidate cardio-respiratory acclimatisation patterns at rest and during moderate-intensity exercise across three days at high altitude.

METHODS: Thirty-two healthy male participants (Mean ± SD; age, 21.9±3.2 yr; body mass index, 22.5±2.2 kg/m2; peak oxygen uptake, 49.9±9.4 ml/kg/min) underwent a three-day high-altitude sojourn at 3375 m. Upon arrival (A), and on each day (D1; D2; D3), participants performed a moderate-intensity exercise bout on a cycle ergometer, comprising a three-minute rest period followed by two minutes at 20 W and eight minutes at a moderate exercise intensity (20% below gas exchange threshold, adjusted for hypoxia-induced exercise capacity reductions). Outcome measures included oxygen uptake (VO2), ventilation (VE), capillary oxygen saturation (SpO2), heart rate (HR), stroke volume (SV), cardiac output (CO) and muscle oxygenation (TSI). Resting and exercising values were quantified as 60-s averages from the pre-exercise period, and the end of the moderate-intensity exercise bout, respectively.

RESULTS: At rest, SpO2 increased significantly from A to D3 (90.2±2.6% vs. 94.5±1.5%; p<0.001). VE increased from A to D1 (11.7±2.4 vs. 14.0±2.4 L/min; p<0.001), although no subsequent changes from D1 to D3 were observed. HR also initially increased (A vs. D1; 77±10 vs. 96±13 bpm; p<0.001), although a subsequent decrease from D1 to D3 (91±12 bpm; p=0.002) was apparent. Conversely, SV decreased from A to D1 (101±19 vs. 90±12 ml; p=0.016), after which it remained unchanged from D1 to D3 (90±15 ml; p>0.999). The opposing HR and SV effects largely washed out changes in resting CO.

The average moderate-intensity exercise workload was 88±28 W. VO2 was unchanged throughout the exposure (p=0.133). SpO2 increased significantly on each day from 84±4% at A to 89±3% on D3 (p<0.001). VE increased from A to D2 (46.5±10.7 vs. 54.3±11.3 L/min; p<0.001), and plateaued by D3 (54.2±12.1 L/min; p>0.999). HR increased from A to D1 (130±13 vs. 142±14 bpm; p<0.001), decreased to 137±12 bpm (p=0.007) in D2, then remained elevated relative to A. SV decreased from A to D1 (133±24 vs. 114±19 ml; p<0.001), then remained lower throughout the rest of the exposure. The time course of exercising CO data reflected changes in SV rather than HR. TSI did not significantly change throughout the exposure at rest or during exercise.

CONCLUSION: These data provide evidence of altitude acclimatisation, both at rest and during exercise, in the respiratory and the cardiovascular systems, but not skeletal muscle, during three days at 3375 m. The findings may inform acclimatisation strategies that consider the time course of pathophysiological risk at rest and during moderate exercise at altitude in healthy individuals.

MICRODOSES OF RECOMBINANT HUMAN ERYTHROPOIETIN AT ALTITUDE FURTHER ENHANCES HEMOGLOBIN MASS BUT NOT MAXIMAL OXYGEN CONSUMPTION (VO2MAX) COMPARED TO ALTITUDE OR ERYTHROPOIETIN TREATMENT ALONE.

BREENFELDT ANDERSEN, A., BONNE, T.C., BEJDER, J., OLSEN, N.V., HUERTAS, J.R., NORDSBORG, N.B.

AARHUS UNIVERSITY, UNIVERSITY OF COPENHAGEN, UNIVERSITY OF GRANADA.

INTRODUCTION: Here, we investigated if gradual levels of increased erythropoietic stress manifested in differences in total hemoglobin mass (tHb) by combing altitude exposure (ALT) with rhEpo treatment, thus providing an additional erythropoietic stimuli. From an anti-doping perspective, knowledge of the erythropoietic effect from combining ALT and microdoses of rhEpo is relevant as ALT has been suggested as a masking agent for rhEpo misuse. We hypothesized that microdoses of rhEpo at ALT would further increase tHb compared to ALT alone or rhEpo treatment at sea-level (SL).

METHODS: The study included two experimental arms separated by 2 months, each comprised of a 4-week baseline, a 4-week intervention at SL or ALT (2,320 m), and 4 weeks follow-up. Twenty-eight, healthy, low-altitude subjects (males: n=18, VO2max of 62±7 ml/min/kg; females: n=10, VO2max of 50±3 ml/min/kg) was included in the ALT arm and 14 (males: n=8, VO2max of 60±3 ml/min/kg; females: n=6, VO2max of 49±3 ml/min/kg) was included in the SL arm. Subjects were randomly assigned to intravenous injections of either epoetin β (20 IU/kg; n=10 at SL, n=11 at ALT) or saline (n=4 at SL, n=17 at ALT) every second day for 3 weeks. tHb and blood volumes was measured weekly using the carbon monoxide rebreathing method. VO2max was determined using an online breath-by-breath system and performed on a treadmill biweekly. A mixed linear model for repeated measurements was used with a level of significance of P<0.05.

RESULTS: An interaction effect (P<0.001) was evident in ALT for tHb when comparing the placebo (ALT-PLA) and rhEpo group (ALT-EPO). The peak increase (P<0.001) in tHb in ALT-EPO was 83±35g when compared to baseline, whereas the peak increase (P<0.05) in ALT-PLA was 35±10g two weeks after returning to SL. In the rhEpo group at SL (SL-EPO), tHb

increased (P<0.05) by 35±9g immediately following treatment. Comparing SL-EPO and ALT-EPO revealed an interaction effect (P<0.001) but no pairwise differences. No differences were evident between SL-EPO and ALT-PLA. Changes of red cell volume resembled those described for tHb with corresponding increases of 146±41ml (P<0.001) in SL-EPO, 310±90ml (P<0.001) in ALT-EPO, and 214±26ml (P<0.01) in ALT-PLA, respectively. When comparing VO2max in SL-EPO and ALT-EPO an interaction effect (P<0.001) was found, but only a significant change (+7%; P<0.05) was observed in SL-EPO following treatment despite a numerical increase (+5%; n.s.) in ALT-EPO. When comparing ALT-EPO and ALT-PLA no interaction effect was found

CONCLUSION: In summary, a microdose rhEpo treatment additively increase tHb when combined with ALT compared to ALT alone and the increase in tHb at SL following rhEpo was similar to that of ALT alone. However, no additive effect on VO2max in ALT-EPO was found despite a ~50g change in peak tHb increase compared to ALT. The discrepancy highlights that despite tHb is a main predictor of performance in a heterogenous group this does not translate per se into an increased performance.

ADDING WHOLE-BODY CRYOTHERAPY EXPOSURE TO LIVE HIGH-TRAIN LOW AND HIGH HYPOXIC TRAINING.

MIHAILOVIC, T.1,2,3, PIRLOT, T.1,2, GROSLAMBERT, A.1,2, MARIE, B.1,2, BOUZIGON, R.1,3, GUIRRONNET, S.4, BRUNET, E.4, BROCHERIE, F.6, MILLET, G.P.5, GIMENEZ, P.1,2

1. LABORATORY C3S UNIV FRANCHE COMTÉ; 2. LABCOM C3S/GROUPAMA/FDJ; 3. INSIDE THE ATHLETES 3.0; 4. FRENCH CYCLING FEDERATION, 5.ISSUL LAUSANNE, 6. INSEP PARIS

INTRODUCTION: "Live High- Train Low and High" (LHTLH) hypoxic training is described as a method consisting of chronic exposure to hypoxia with training at sea-level, and additional hypoxic training sessions per week [1]. This training model contributes to aerobic and anaerobic performance improvement [1]. Nevertheless, altitude exposure is a strong stressor for athletes associated with exacerbated fatigue [2]. Whole-Body Cryotherapy (WBC) which has been shown to improve recovery factors [3], could be an interesting complementary strategy to this training method. This study aimed to investigate the combined effect of LHTLH and WBC on performance improvement. We hypothesize that WBC would improve acclimation and recovery leading to a greater increase in performance.

METHODS: Thirteen well-trained cyclists (5 men and 8 women, 19.2 ± 4.4 yr, body fat mass 15.7 ± 5.5%) carried out 14 days of LHTLH composed of at least 14h.day-1 exposure to normobaric hypoxia (2800 m) and 6 repeated-sprint training sessions in hypoxia (RSH: 3 sets of 5 × 10-s all-out with 20-s of recovery, 3000 m). Cyclists were randomly assigned to two groups involving 9 recovery sessions (CTRL group: 5-min in sitting position at 20°C, n = 6; WBC group: 30-s at -25°C and 3-min at -55°C, n=7). Before (pre), immediately (post-1) and 3 weeks after (post-2) intervention, specific performance tests were performed: Repeated Sprint Ability (RSA), Wingate test, and maximal aerobic power (MAP). During intervention, physiological parameters were recorded to monitor the participants acclimation and recovery, including nocturnal blood oxygen saturation (SpO2).

RESULTS: Both groups tended to increase mean power output during RSA at post-2 compared to pre (CTRL: +4.6 %; WBC: +3.7%, p = 0.06). WBC group allowed reducing decrement scores at post-1 and post-2 (p < 0.05), while CTRL only at post-1 (p < 0.05). Wingate performance was not different at post-1 and post-2, but the mean heart rate was reduced for both groups at post-2 (CTRL: -5.9%, p < 0.05; WBC: -5.0%, p = 0.06). LHTLH induced an increase in MAP for both groups at post-1 and post-2 (CTRL: +5.9%, p < 0.05 and +5.2%, p < 0.05; WBC: +3.3%, p < 0.05 and +2.8%, p < 0.05), with a decrease in mean heart rate at post-2 during MAP test for WBC group (-8.1%, p < 0.05). Both groups showed a variation over time in SpO2 (p < 0.001), with a significant decrease during the LHTLH intervention. SpO2 was higher for the WBC group compared to the CTRL group during pre (96.7 ± 1.2% and 95.2 ± 0.9%, respectively, p < 0.01) and during LHTLH (92.6 ± 1.0% and 90.8 ± 1.3% respectively, < 0.01).

CONCLUSION: The results confirmed that LHTLH improves the physical capacities of athletes. Performance was not affected by WBC exposure. However, WBC could contribute to the acclimation of the participants and thus could prevent the appearance of excessive fatigue by limiting the decrease in SpO2.

APPORT OF THE IA TO IMPROVE BIKE PARAMETERS ON MUSCLE ACTIVITY AND POSITION IN ORDER TO OPTIMISE RIDER PERFORMANCE

ALGOURDIN, P.1,2, NUNEZ, N.1, OSTRE, B.1, JOLIFF, Y.1

1 UNIVERSITY OF TOULON MAPIEM 2 BEUCHAT INTERNATIONAL

INTRODUCTION: Different bike parameters can influence the position and activity of the muscles. These include saddle height, cadence and handlebar position [2,3]. The objective of this study is to carry out a multi-instrumented experimental design to determine the influence of bike settings on muscle activity. This is in order to optimise the cyclists position to increase performance.

METHODS: 6 non-professional cyclists performed tests on an instrumented test bench. Throughout the tests, the muscle activity of 7 muscles (Rectus Femoris, Vastus Medialis, Tibialis Anterior, Soleus, Biceps Femoris, Gastrocnemius Medialis) on the right leg were recorded using wireless EMG (Cometa MiniWave Inifinity) at a sampling rate of 2000Hz. The electrodes were placed according to SENIAM recommendations after the skin was prepared. The subjects were also fitted with inertial units (Cometa WaveTrack) on the pelvis, femur, tibia and foot [1]. The IMUs were calibrated using standing and lying down acquisition. In order to compare subjects with each other, MVC was measured with three 6s sprints with 3min breaks between each to avoid fatigue [4]. After a 10 min warm-up, 8 trials were performed following the order of the experimental design with adjustable factors: cadence (60 or 80 rpm), saddle position (crotch height*0.883 ±5%) and handlebar position. Each test was separated by a 2-minute break. Finally, a validation test was carried out and a final MVC to assess final fatigue. Heart rate was also recorded throughout the trials. The data collected for the EMGs was then filtered using a 4th order Butterworth filter with a cut-off frequency between 20 and 400Hz, rectification and a low pass frequency of 15Hz and then RMS on each cycle before being normalised using Matlab 2022 [5]. The IMU signals were filtered using a Kallman filter until the Euler angles were obtained [6]. Hexagons Lunar software was used to propose an optimised position to reduce energy consumption and thus increase performance.

RESULTS: The results of the experimental design indicate that some factors have a lot of influence such as saddle position and pedalling rate on the muscle activity recorded and therefore on the energy consumed by the cyclist. Indeed, we can see that between two extreme situations some muscles are more influenced : the biceps femoris goes from 31% activation to 8%. The position of the saddle has a very big influence on the heart rate (unlike the handlebars and the cadence). The heart rate increases from 120bpm to 140bpm in both extreme situations. A parameter configuration allowed us to obtain an optimal position for each rider

CONCLUSION: The results obtained have shown that the rider's position influence muscle activity and heart rate. Finally, an optimization model specific for each rider is propose to improved performance by optimising position for the cyclist and therefore muscle activity and energy consumption.

DEVELOPMENT OF A FORCE-ENDURANCE MODEL ABLE TO DESCRIBE THE MUSCLE FATIGABILITY IN THE SEVERE DOMAIN AND VALIDATION OF THE RACLET TEST.

BOWEN, M.1, SAMOZINO, P.1, VONDERSCHER, M.1, DUTYKH, D.2, MOREL, B.1

1 - LIBM, UNIV SAVOIE MONT-BLANC, EA 7424, CHAMBERY, FRANCE; 2- LAMA, UNIV SAVOIE MONT-BLANC, CNRS 5127, CHAMBERY, FRANCE

INTRODUCTION: Muscle fatigability corresponds to the decrease in the ability of muscles to generate force. The Critical Power (Pc) concept [1] predicts the point at which fatigue develops, in such a way that the required constant intensity will no longer be sustainable (W' reserve is emptied). During all-out tests the power plateau reached at the end of the test and the work done above this value have been numerically and conceptually related to Pc and W', respectively. These two mathematical models, characterizing similar phenomena but based on very different exercises (steady state versus all-out) have not been directly linked. Thus, the aims of this study were to i) develop an integrative model of exercise fatigability and ii) propose a submaximal test based on this model to determine critical intensity.

METHODS: From Mortons 3-parameters model [2] one can make the assumption that fatigability is proportional to the impulse accumulation above the critical force (Fc) so Fmax(t)=(-1/Tau)integral(F(t)-Fc)dt+Fi. Since the model can be applied to any exercises, a specific Ramp Above CriticaL Exhaustion Test (RACLET) was proposed. The test was designed so that the target intensity starts above the critical intensity and decrease below it, before exhaustion of W', so before exhaustion of the participant. It was tested for a cycling task with a 300s ramp test decreasing from 40% to 5% of initial force (Fi), where maximal capacities (Fmax) were assessed every 30s from 6-pedal-strokes sprints. Twenty participants realized 5 experimental sessions: 2 RACLET and 3 time to exhaustion (TTE). A custom friction regulated instrumented cyclo-ergometer was developed to measure crank torque and velocity. Each Fmax was used to adjust the model's parameters. The model's reliability and validity were tested by determination of individual parameters Fc & Tau by adjusting the model to Fmax and time data from RACLET and TTE tests.

RESULTS: The model's goodness of the fit on RACLET test experimental data was excellent (median adjusted R^2=0.95; RMSE=3.4%Fi). Mean±SD Fc &Tau were 29.6±7.2%Fi and 22.7±13.9s, respectively. Fc parameter in RACLET demonstrated good relative (ICC=0.9) and absolute reliability (SEM=4.5%). The comparison of Fc between RACLET and reference TTE method was acceptable (R^2=0.8, SEM=5.8%).

CONCLUSION: The proposed model fit very well with the experimental data obtained during the RACLET. The latter showed very good test-retest reliability. Moreover, the fitted parameters were very similar to those obtained with the gold standard method TTE. The present results show that it is possible to determine individual model parameters (Fi, Fc, and Tau) from experimental data obtained from the proposed RACLET. As this test does not lead to the participants exhaustion, it could be interesting for athletes monitoring tranings, or patients with pathologies that make it difficult to use traditional methods (TTE and all-out tests).

MUSCLE FASCICLE BEHAVIOR DURING SPRINT CYCLING: NEW INSIGHTS REGARDING THE GAIN IN MAXIMAL POWER IN STANDING COMPARED TO SEATED POSITION

DOREL, S.1, ROBIN, M.1,2, TALLIO, T.1, SACHET, I.1,3, NORDEZ, A.1,4

1 NANTES UNIVERSITÉ, MOVEMENT - INTERACTIONS - PERFORMANCE, UR 4334, NANTES, FRANCE; 2 TOTAL ENERGIES PRO CYCLING TEAM, FRANCE; 3 FRENCH CYCLING FEDERATION, FRANCE; 4 INSTITUT UNIVERSITAIRE DE FRANCE

INTRODUCTION: The standing position is mainly used during road-cycling sprints to increase the maximal power output capacity compared to the seating position. However, the adjustments in behavior of the lower limb muscles induced by this specific position remain unknown. This study analyzed the fascicle behavior during sprint cycling in elite cyclists in both seating and standing positions. The aims were i) to determine whether joint kinematics and both fascicle and muscle-tendon unit (MTU) lengths and shortening velocities of the vastus lateralis (VL) and the gastrocnemius medialis (GM) were modified between these two positions, ii) to relate their operating fascicle length during cycling to their own torque-length characteristic to investigate whether this would participate to explain the gain of power in standing position.

METHODS: Eleven elite cyclists (23.0 ± 3.7 yr; 178.8 ± 3.8 cm; 67.8 ± 3.0 kg) volunteered to participate in this study. The maximal torque-length relationships and optimal length (Lopt) of ankle plantar flexors and knee extensors were determined using series of single-joint maximal isometric contractions at 6 angles (1). Then, cyclists performed four 5-s sprints at 110 rpm on cycle ergometer: two in standing and two in seating position. Joint kinematic, fascicle-tendon behavior (using ultrasound imaging) and EMG activity of VL and GM were recorded throughout the session.

RESULTS: The maximal power output was higher in the standing position with a large inter-cyclist variability in this gain (mean: +15.8%; min: -0.4%; max: +37.8%). A more extended knee angle over the entire cycle (+5,1°) and a delayed and prolonged EMG activity of VL (up to 103.1±11.2° of crank angle in standing compared to 77.8±11.4°in seating position) were observed (P<0.01). In standing position, the VL MTU and fascicle shortened actively more compared to the seating position with an operating fascicle length shorter and near the plateau for maximal force production (117.4 % vs. 122.7 % of Lopt, respectively). GM fascicle operated close to Lopt (i.e. 95.7 % vs. 91.5 % of Lopt in seating and standing positions, respectively) with no significant difference between both positions.

CONCLUSION: The standing position induced adaptations resulting in changes in the fascicle behavior, particularly useful for the VL because it leads to a longer period of contraction around the optimal operating length configuration. Interestingly, this associated theoretical gain in force-generating capacity of VL seems, at least partially, participate to explain the gain of power in standing position. Despite the absence of clear difference in GM fascicle length between both positions, the slower MTU shortening velocity and greater lengthening of the tendinous tissues in standing position may participate to maintain the fascicle in favorable condition to transmit the power to the pedal when this muscle is maximally activated.

INTRODUCTION: The magnitude and rate at which a cyclist can apply pedal force to produce crank torque are important factors influencing power production (1). Implementation of appropriate training to improve peak force/torque and rate of force/torque development (RFD/RTD) are therefore critical to improve sprint cycling performance. While gym- and cycling-training have been shown to improve peak torque and peak power (2), little is known around the training-induced changes in cycling RTD. A cyclist's peak force/torque and RFD/RTD can be assessed using isometric protocols such as the isometric mid-thigh pull (IMTP) or during dynamic cycling (3). While research has shown a strong relationship between peak force/torque and RFD/RTD during the IMTP and sprint cycling (3), it is unclear if these measures change at the same rate following training. Therefore, the aims of the present study were to: (i) determine the extent that IMTP and sprint cycling measures change following a six-week resistance and sprint cycling training program; (ii) determine if the relative change in IMTP force and sprint cycling torque measures are associated. This would provide information to practitioners on whether the IMTP can be used to infer cycle-specific changes following a training intervention.

METHODS: Fourteen recreationally active individuals who were strength-trained and non-cyclists volunteered for this study. A single-group, longitudinal (pre-/post-test) study design was employed to determine the effects of a 6-week training program. Training consisted of supervised resistance (n=3) and sprint cycling (n=3) sessions per week. Pre- and post-testing involved IMTP force and sprint cycling power, cadence, and torque measurement.

RESULTS: Cycling results showed significantly higher absolute (10.7%) and relative peak power (10.5%), peak torque (11.7%), and RTD measures (27.9-56.7%) post-training (p<0.01). Significantly higher IMTP peak force (13.1%) and RFD measures (23.7-32.5%) were observed post-training (p<0.05). While strong-to-very strong relationships were observed between IMTP force and cycling torque measures pre- (r=0.57-0.84; p<0.05) and post-training (r=0.63-0.87; p<0.05), no relationship existed between relative changes in sprint cycling torque and IMTP force measures.

CONCLUSION: This study demonstrates the extent to which a six-week resistance and sprint cycling training program improves cycling power, torque, and IMTP force measures in strength-trained, non-cyclists. While there was transferability

between IMTP force and cycling torque pre- and post-training, the rate of change in these measures were not associated following training, and therefore, should not be treated as interchangeable for longitudinal monitoring.

REAL-WORLD CYCLING CADENCES: EFFECT ON ENERGY COST, JOINT MECHANICS, AND FATIGUE

DU PLESSIS, C.1,2,3, ANDREWS, M.2, KING, T.2, GIORGI, H.P.2, COCHRANE WILKIE, J.1,4, BLAZEVICH, A.J.1

INTRODUCTION: Within an individual pursuit event (IP; 3- to 4-km time trial) in track cycling, bicycles operate with a single, fixed gear, and riders are required to sustain high power outputs resulting in significant fatigue. Gearing selection will influence the muscles' shortening speeds, activation rates, and force production, impacting the energy cost and thus performance fatigue. Gear selection is therefore critical for IP performance and may be adjusted by a rider to achieve a small, 2-4 rpm (cadence) manipulation for a given power output. Over a large range (40-180 rpm), higher cadences are associated with a higher energy cost and fatigue, yet the effect of small changes in cadence in experienced cyclists during an IP is unknown. Our purpose was to test whether small changes in cadence (as a proxy for gearing) meaningfully impact a cyclist's oxygen uptake kinetics, joint-specific torque- and- power distributions, and performance fatigability.

METHODS: Thirteen highly trained male (10) and female (3) cyclists performed three 2-min cycling trials at their best IP power output on a stationary ergometer. Cadence was manipulated between the cycling trials, from the average cadence of their best IP (termed "preferred") to cadences 5 rpm above and below their preferred (PREF+5rpm and PREF-5rpm). Physiological stress (VO2 kinetics and blood lactate concentration) was monitored; joint-specific angular velocity, torque, and power were calculated through inverse dynamics; and performance fatigability was estimated as the mean power loss in a maximal 10-s sprint performed without pause after the 2-min cycling trials.

RESULTS: Greater performance fatigue was evoked by PREF+5rpm than both PREF and PREF-5rpm (8.8 vs 8.8 and 8.4 W·kg-1, respectively, $p=0.01$), and a trend towards an increase in peak VO2 and rate of VO2 rise were observed. PREF+5rpm was associated with an increase ($p<0.01$) in peak knee and hip angular velocities (extension and flexion). Changes in the average joint-specific torques and powers occurred mainly during the pedal upstroke where ankle dorsiflexion torque ($p=0.01$), hip flexion torque ($p=0.003$) and knee flexion power ($p=0.01$) increased in PREF+5rpm, possibly suggesting a concerted effort by the cyclists to increase leg flexion during the pedal upstroke phase. No significant relationship was found between level of performance fatigue and joint-specific mechanics.

CONCLUSION: This study demonstrated that a small increase in cadence (i.e., gear) may induce small but significant increases in performance fatigue and alter joint-specific mechanics in highly trained cyclists during the first 2 min of a simulated IP. Importantly, high inter-individual variations were observed, as particularly torque- and- power distributions varied across the joints for different individuals in response to cadence changes. This emphasises that practitioners should take an individualised approach to understand the effects of small (but practically relevant) changes in cadence on IP performance.

THE EFFECTS OF INCREASED MUSCLE VS. CORE TEMPERATURE ON NEUROMUSCULAR FUNCTION AFTER A HOT-WATER IMMERSION SESSION

RODRIGUES, P., ORSSATTO, L.B.R., TRAJANO, G.S., WHARTON, L., MINETT, G.M.

QUEENSLAND UNIVERSITY OF TECHNOLOGY

INTRODUCTION: Passive heating can increase skeletal muscle contractile function in humans (1). However, complexity exists when testing neuromuscular function after a passive heating intervention. While a passive increase in muscle temperature (Tmu) can enhance voluntary and evoked muscle contractile function (2), any parallel increase in core temperature (Tc) may impair neural drive transmission to the working muscles (3), masking the enhancement of muscle contractile responses resulting from increased Tmu. This study investigated the effects of a passive heating session on voluntary and evoked neuromuscular function, firstly with a concomitant increase in Tmu and Tc, and thereafter with increased Tmu but cooled Tc.

METHODS: Fifteen participants (24.9±5.6 yrs) performed neuromuscular assessments before, after, and 15-min after either 90-min of 42°C (hot) or 36°C (control) water immersion to the waist. Maximal voluntary contraction (MVC) torque, voluntary activation (VA), and rate of torque development (during the early phase [0-50 ms: RTDV50] and late phase [0-150 ms: RTDV150]) were assessed by isometric knee extension. The motor unit discharge rate (MUDR) of the vastus lateralis was assessed during submaximal contractions (20% of MVC). Resting evoked twitch was elicited on the femoral nerve for peak

torque, rate of torque development (RTDtwitch), half-relaxation time (HRT) and electromechanical delay (EMD) assessments.

RESULTS: After the hot-water immersion (Tc ↑1°C, Tmu ↑2.4°C), MVC torque and VA decreased (4.2% and 4.3%; P<.05) and RTDV50 increased (26.4%; P<.002). MUDR decreased, showing a time effect, after both water immersion conditions (36ºC and 42ºC) (7.7%; P<.001). Peak twitch torque and RTDtwitch did not change (P>.05) while EMD and HRT decreased (12.3% and 12.4%; P<.03). Fifteen min after the hot-water immersion (Tc at baseline, Tmu ↑1.4°C), MVC torque returned to baseline while VA remained lower (1.2%) and RTDV50 remained higher (27.9%). MUDR remained lower (7.7%). Peak twitch torque and RTDtwitch increased (13.4% and 21.8%; P<.02) and EMD and HRT remained lower (18.7% and 8.3%). No changes were observed for RTDV150 at any moment (P>.05).

CONCLUSION: After 90 min of 42ºC hot-water immersion session, increased Tc impaired MVC torque and VA, but the increased Tmu enhanced RTDV50, and evoked EMD and HRT. Fifteen min after the hot bath, a passive increase in Tmu improved all the evoked contraction assessments (peak twitch torque, RTDtwitch, EMD, and HRT) and the RTDV50, but did not change MVC torque or RTDV150. The MUDR required to attain the same relative torque (20% of MVC) decreased after and 15-min after the hot-water immersion, likely caused by lesser voluntary synaptic input needed due to increased muscle contractile function (4) after a passive increase in Tmu.

QUANTIFYING THE SPATIAL DISTRIBUTION OF INDIVIDUAL MUSCLE UNITS USING HIGH-DENSITY SURFACE EMG AND ULTRAFAST ULTRASOUND

ROHLÉN, R.1,2, CARBONARO, M.3, BOTTER, A.3, GRÖNLUND, C.2, ANTFOLK, C.1

1 LUND UNIVERSITY, LUND, SWEDEN; 2 UMEÅ UNIVERSITY, UMEÅ, SWEDEN; 3 POLITECNICO DI TORINO, TURIN, ITALY

INTRODUCTION: Resistance training is a well-known intervention to improve muscle strength (1), with motor unit (MU) adaptation playing an important role (2). Recently, MUs were tracked in humans before and after resistance training using high-density surface electromyography (HDsEMG), showing a correlation between maximal force increase and MUs' average discharge rate (3). Although these results demonstrate the relationship between an increase in strength and MU activity, only MU-level neural adaptation was considered. Indeed, neural and muscular information needs to be studied jointly to understand the exact adaptations of the MUs in response to resistance training (4).

Recently, a method based on ultrafast ultrasound was presented, providing estimates of MU territories in cross-section and the train of twitches evoked by the spinal motoneurons' discharges (5). In this study, as a proof-of-concept, we combined ultrafast ultrasound and HDsEMG to explore the spatial distribution of individual MUs.

METHODS: In a cross-sectional study, four participants performed low-force isometric contractions of the biceps brachii muscle while recording HDsEMG and ultrafast ultrasound signals from the biceps brachii muscle.

The HDsEMG signals were decomposed into individual MU discharge timings (6), and the ultrafast ultrasound signals were decomposed into many components, each having a spatial map and temporal signal (5). We matched each discharge timing of a MU with a component based on spike-triggered averaging of the component's temporal signal. Given a selected component, we applied a threshold to the spatial map and calculated the centroid and an equivalent diameter.

RESULTS: Out of 16 recordings from four subjects, we decomposed 82 MUs from HDsEMG. Given this, we found 32 matches between individual MU discharges and ultrasound components where the triggered twitches had a significant amplitude. The estimated territories were 4.6 ± 1.1 mm (ranging from 2.8 to 8.6 mm), in line with findings from previous research using scanning-EMG (7). Moreover, the components were located 12.7 ± 3.4 mm below the skin (ranging from 6.4 to 19.4 mm).

CONCLUSION: Our results show that using ultrafast ultrasound and HDsEMG in a strength training intervention, we should be able to quantify the relative contribution of the nervous system and skeletal muscle at the MU level. This information may provide the time course of both neural and hypertrophic adaptations to resistance training and elucidate the relative contributions of each to strength gain.

MUSCLE DESTABILIZATION AFTER A SPECIFIC PROCEDURE OF CONTRACTION AND PASSIVE MOTION QUANTIFIED BY MEASUREMENTS OF THE ADAPTIVE FORCE

DECH, S.1,2, SCHAEFER, L.V.1,2, BITTMANN, F.N.2

1UNIVERSITY OF POTSDAM , DPT. SPORTS AND HEALTH SCIENCES, HEALTH EDUCATION IN SPORTS 2UNIVERSITY OF POTSDAM , DPT. SPORTS AND HEALTH SCIENCES, REGULATIVE PHYSIOLOGY AND PREVENTION

INTRODUCTION: A special procedure whereby a muscle is contracted in a lengthened position and brought back passively in testing (middle) position (procedure CL) is thought to provoke a slack in extra- and intrafusal muscle fibers. This slack might influence sensitivity of muscle spindles to stretch. Thus, the stretch reflex was found to be considerably reduced [1]. The present study questioned if the Adaptive Force (AF) which depends on sensorimotor control is affected by the described procedure, too.

AF reflects the neuromuscular functionality to adapt adequately to external forces as a possible prerequisite of muscle and joint stability. A reduced AF could, therefore, be a risk factor for injuries [2].

METHODS: 19 biceps brachii muscles of 12 healthy subjects were examined. Maximal isometric AF (AFisomax) and maximal AF (AFmax) were measured by a handheld device during an examiner started manual muscle test (MMT) under different scenarios: regular, after CL, after CL with additional contraction in testing position (procedure CL-CT). Contractions were performed at ~25% of maximal voluntary isometric contraction (MVIC). All MMTs were executed twice in a defined order and statistically compared. MVIC was determined by pushing as strong as possible against examiner's resistance.

RESULTS: During regular MMTs, testing position was held isometrically until 99.7 ± 1.0% of the reached maximum force (AFisomax ≈ AFmax) reflecting muscle stability. In contrast, after CL the muscles started to lengthen at 53.0 ±22.5% of AFmax indicating muscle instability. After CL-CT isometric position could be held up to higher forces again (98.3 ± 5.5% of AFmax). The AFmax did not differ significantly between procedures and was similar to the maximal isometric pushing force (MVIC). However, the maximal isometric holding force (AFisomax) was significantly reduced after CL compared to the other scenarios (padjust<.001) .

CONCLUSION: The assumed slack of intrafusal muscle fibers might lead to the found significant reduction of the holding capacity of the biceps brachii muscle after CL. Under this circumstance, the muscle gives way considerably before its maximal strength capacity is reached. A muscle contraction at low intensity in the testing position possibly eliminates the slack and, therefore, the destabilizing effect immediately.

As the isometric AF is thought to rely on muscular tension and length control, the results fit to the explanatory approach of a reduced spindle sensitivity. The mechanical state of intrafusal muscle fibers together with the history of fusimotor activity need to be taken into account during muscle testing.

INFLUENCE OF MUSCLE LENGTH ON PRESYNAPTIC INHIBITION OF THE SOLEUS MUSCLE DURING PASSIVE LENGTHENING, SHORTENING AND STATIC MUSCLE ACTIONS

COLARD, J.1, JUBEAU, M.2, CROUZIER, M.3, DUCLAY, J.4, CATTAGNI, T.5

NANTES UNIVERSITY

INTRODUCTION: It is well documented that presynaptic inhibition (PSI) mechanisms are modulated by passive muscle actions, particularly during passive lengthening muscle actions. However, it is unknown if these modulations can be influenced by muscle length. This study aimed to determine whether variation in muscle length can affect the involvement of primary afferent depolarisation (PAD) and homosynaptic post-activation depression (HPAD) during passive lengthening, shortening and static muscle actions.

METHODS: Fifteen young healthy individuals participated in two experimental sessions. Percutaneous electrical stimulation of the posterior tibial nerve was used to evoke soleus compound action potential (M wave), and Hoffmann (H) reflex. Maximal H reflex (HMAX) and M wave (MMAX) were obtained from H-M recruitment curves. The efficacy of Ia-afferent-α-motoneuron transmission was analysed with the HMAX/MMAX ratio (%). PAD was evaluated with the D1 inhibition technique, including recordings of submaximal H reflexes with conditioning peroneal nerve stimulations (HCOND) and without conditioned stimulations (HTEST), i.e., HCOND/HTEST ratio reflecting the amplitude of PAD. HPAD was evaluated with stimuli at different time intervals, including recordings of submaximal H reflexes at interstimuli interval of 3 s and 6 s, i.e., 3 s/6 s ratio reflecting the amplitude of HPAD. HMAX/MMAX, HCOND/HTEST, and 3 s/6 s ratio were obtained at long, intermediate and short muscle lengths (which were verified by using ultrasound technique) during all passive muscle actions.

RESULTS: HMAX/MMAX ratio was significantly lower at long compared with intermediate (-10.1%) and short (-23.5%) muscle length regardless of the passive muscle action ($P < 0.001$). For HCOND/HTEST ratio a significant ($P < 0.05$) muscle length x passive muscle action interaction was found. For this parameter, the reduction at long muscle length reached -24.5% and -35.6% ($P < 0.001$) during lengthening, -11.1% and -18.3% during shortening ($P = 0.075$ and $P < 0.001$) and -10.7% and -17.9% ($P = 0.082$ and $P < 0.001$) during static passive muscle action compared with intermediate and short muscle lengths, respectively. This interaction shows that the increase of PAD activity at long muscle length is significantly further enhanced during passive lengthening muscle actions. 3 s/6 s ratio was lower at long compared with intermediate (-5.8%) and short (-12.3%) muscle lengths, regardless of the passive muscle action ($P < 0.01$ and $P < 0.001$).

CONCLUSION: This work highlights for the first time that PAD activity is enhanced when muscle length increases during passive muscle actions especially during passive lengthening muscle actions. These new results suggest that the additional Ia afferent discharge from increased muscle length might enhance PAD and HPAD activities. This increase in PSI activity could be involved in the lower efficacy of Ia-afferent-α-motoneuron transmission observed at long muscle lengths.

AEROBIC EXERCISE, INFLAMMATION, AND GLYCAEMIC CONTROL IN TYPE 2 DIABETES: A RANDOMISED CONTROLLED TRIAL

SABAG, A.1,2, READ, S.2, WAY, K.1,3, AHLENSTIEL, G.2, JOHNSON, N.1

1. THE UNIVERSITY OF SYDNEY, NSW, AUSTRALIA; 2. WESTERN SYDNEY UNIVERSITY, NSW, AUSTRALIA; 3. DEAKIN UNIVERSITY, VIC, AUSTRALIA

INTRODUCTION: Regular exercise improves hyperglycaemia in type 2 diabetes (T2D), however, the mechanism by which such improvements occur are not completely understood. Given the relationship between inflammation and hyperglycaemia, this study aimed to determine whether aerobic exercise-induced improvements in glycaemia are associated with improvements in inflammatory marker profiles.

METHODS: Twenty-eight inactive adults with obesity and T2D were randomised to 12 weeks of supervised moderate-intensity continuous training (MICT) (n=10) at 60% VO2peak for 45 min, 3 days/week; low-volume high-intensity interval training (HIIT) (n=11) at 90% VO2peak for 4 min, 3 days/week; or placebo control (n=7). Pearson correlation analyses were performed to determine the association between changes in circulating cytokines and glycated haemoglobin (HbA1c). Regression analyses were undertaken to determine whether the associations between Δcytokines and ΔHbA1c were independent of changes in adiposity.

RESULTS: There was a strong positive correlation between ΔHbA1c and interleukin 6 (IL-6) (r = 0.553). There were moderate positive associations between change in ΔHbA1c and Δtumour necrosis factor alpha (r = 0.459), Δinterferon gamma (r = 0.398), ΔIL-10 (r = 0.418), Δ interferon gamma-induced protein 10 (r = 0.390), and Δadipsin (r = 0.474). Participant age, sex, T2D duration and Δbody mass index accounted for 14% of the variance in ΔHbA1c. The addition of Δwaist circumference and Δintrahepatic lipid to the model increased the prediction of ΔHbA1c to 18%. Finally, the addition of Δcytokines associated with ΔHbA1c increased the prediction of ΔHbA1c to 54%.

CONCLUSION: Aerobic exercise-induced improvements in glycaemia are positively associated with changes in various inflammatory markers. These associations appear to be independent of changes in central adiposity and ectopic fat, however, further appropriately powered studies are required to confirm these preliminary findings.

THE EFFECT OF AEROBIC EXERCISE TRAINING ON INSULIN-STIMULATED FEMORAL ARTERY BLOOD FLOW IN PATIENTS WITH TYPE 2 DIABETES AND HEALTHY MATCHED CONTROLS

HANSEN, M., DAL, M.H., LANGE, K.K., BORCH, J., HELGE, J.W., DELA, F.

DEPARTMENT OF BIOMEDICAL SCIENCES

INTRODUCTION: In healthy people, insulin induces an increase in peripheral blood flow, which has been shown to contribute largely to glucose uptake in skeletal muscle, whereas the vascular effect in patients with type 2 diabetes (T2D) may be blunted(1). The majority of the studies investigating this during a glucose clamp have examined during euglycemic conditions (5 mmol/L). However, most T2D patients have higher habitual plasma glucose levels and may exhibit a normal response at this level(2). Exercise improves glucose homeostasis and insulin-stimulated blood flow, though few studies have investigated this effect in the conduit arteries(3,4).

In this ongoing study, we hypothesized that (1) aerobic exercise training improves insulin-stimulated blood flow in the femoral artery in patients with T2D and (2) there are no differences between T2D and healthy matched controls (CON) during isoglycemic conditions.

METHODS: 4 male patients with T2D (age 48.7±6.2 yrs, BMI 35.0±3.3 kg/m2, HbA1c 61±18 mmol/mol, T2D duration 2.0±1.2 yrs) and 5 controls (age 48.6±6.0 yrs, BMI 37.6±3.0 kg/m2, HbA1c 35±6 mmol/mol) completed a 12-wk aerobic exercise training intervention. We measured femoral artery blood flow (FBF) using ultrasound Doppler technique at baseline and the end of each step of a 2-step hyperinsulinemic (40 and 400 mU/m2/min) isoglycemic clamp. deltaFBF1 and deltaFBF2 represent the insulin-stimulated FBF from baseline to the two clamp steps. Data (mean±SD) were analysed by two-way ANOVA repeated measures.

RESULTS: We found no effect of the presence of T2D (P=0.80) or exercise training (P=0.14) on baseline FBF (391±61 to 535±178 ml/min in CON and 472±177 to 513±304 ml/min in T2D, before and after training, respectively). Neither did the presence of T2D (P=0.85) or exercise training (P=0.10) affect insulin-stimulated blood flow (deltaFBF1: +233±132 to -19±65 ml/min in CON and +45±42 to +147±148 ml/min in T2D; deltaFBF2: +369±127 to +179±149 ml/min in CON and +270±151 to +374±141 ml/min in T2D, before and after training, respectively).

CONCLUSION: Contrary to our hypothesis, insulin-stimulated blood flow did not increase in T2D or CON after 12 weeks of aerobic exercise training, but this may be due to the lack of statistical power at this stage. In accordance with our other hypothesis, there were no differences between the groups either at baseline or after the intervention.

COMPARISON OF A 12-WEEK EXERCISE PROTOCOL OF HIIT VS. MICT ON CARDIORESPIRATORY FITNESS AND GLYCOSYLATED HEMOGLOBIN IN TYPE 2 DIABETICS

ÁVILA-CABEZA-DE-VACA, L., GONZÁLEZ-MARISCAL, A., CORRAL-PÉREZ, J., MONTES-DE-OCA-GARCÍA, A., MARÍN-GALINDO, A., REBOLLO-RAMOS, M., OPAZO-DÍAZ, E., RAMIREZ-JIMENEZ, M., PONCE-GONZÁLEZ, J.G., CASALS, C.

UNIVERSIDAD DE CÁDIZ

INTRODUCTION: Cardiorespiratory fitness (CRF) is impaired in type 2 diabetes mellitus (T2DM). Moreover, the glycosylated haemoglobin (Hb1Ac) values have been considered an important marker in glucose control in T2DM (1). Aerobic exercise training improves both the CRF and values of Hb1A in T2DM (2), but it remains unclear if the type and intensity of the exercise may produce different benefits. Hence, the main aim of this study was to compared high intensity interval training (HIIT) vs. moderate intensity continuos training (MICT) on cardiorespiratory fitness and Hb1Ac. Indeed, a second aim was to analyse the relationship between changes with each training in CRF with Hb1A levels in type 2 diabetics.

METHODS: This preliminary analysis includes 46 type 2 diabetes participants (55.70 ± 6.97 years), who were randomized into 12 weeks of HIIT (n=15, 4 women), or MICT (n=20, 8 women) or control group (CG) (n=11, 5 women). Participants were tested on two consecutive days in fasting condition. On day 1, blood sampling was taken to determine the Hb1Ac. On the second day, body composition was evaluated by bioimpedance, and the maximum oxygen consumption (VO2max) was determined through an incremental test on a cycle ergometer (15W/1'). All measurments were performed before and after 12 weeks of intervention. Changes in study variables were tested for time (pre vs. post), group (HIIT, MICT, and CG), and time-by-group interactions using a mixed factorial ANOVA with Bonferroni post hoc comparisons. The significance level was set at a p value < 0.05. Pearsons correlation was used to observe if changes in VO2max correlated with larger changes in Hb1A.

RESULTS: The VO2max significantly increased in both intervention groups after the intervention (HIIT 22.43 to 26.16 ml/kg/min, p<0.001 / MICT 23.15 to 25.67 ml/kg/min, p<0.001), whereas CG remained unchanged (20.12 to 19.02 ml/kg/min). In addition to this, a time-by-group effect was found between HIIT, and MICT with CG (p<0.002). The Hb1Ac improved significantly in both intervention groups (HIIT 7.25% to 6.59%, p=0.003 / MICT 6.70% to 6.42%, p<0.001), but no differences were found in the GC group (7.04% to 6.97%).No significant correlation was found between the changes in relative VO2max and changes in Hb1Ac.

CONCLUSION: Both exercise interventions increases cardiorespiratory fitness and decreases glycosylated hemoglobin levels. The HIIT seems to be an time-efficient intervention compared to MICT that achieve similar results.

THE EFFECTS OF 10-DAYS OF MODERATE OVERNIGHT NORMOBARIC HYPOXIA ON THE GUT MICROBIOTA IN INDIVIDUALS WITH TYPE 2 DIABETES MELLITUS: A SINGLE-BLIND, RANDOMISED, SHAM-CONTROLLED TRIAL.

GOULD, A., CORBETT, J., JAMES, T., MAYES, H., NEAL, R., SHUTE, J., TIPTON, M., MASSEY, H., SAYNOR, Z., PERISSIOU, M., MONTGOMERY, H., STURGESS, C., MURRAY, A., GROCOTT, M., CUMMINGS, M., MCNARRY, M.

UNIVERISTY OF PORTSMOUTH

Dent, H., Robson, S., Shepherd, A.

INTRODUCTION: The gut microbiota has been linked to the pathogenesis and progression of insulin resistance and Type 2 diabetes mellitus (T2DM). Anaerobic fermentation of short chain fatty acids (SCFA), such as butyrate within the gut microbiota, can improve insulin sensitivity (Cui et al., 2022). These bacteria appear to be increased in individuals living at high altitude (Sturgess & Montgomery, 2021). Accordingly, we hypothesised that repeated exposure to a simulated hypoxic environment would increase the abundance of anaerobic bacteria responsible for SCFA fermentation in a with T2DM.

METHODS: 13 adults with T2DM completed this single-blind, randomised, balanced, sham-controlled, crossover study. Participants undertook 10 days of home-based overnight moderate normobaric hypoxia (fraction of inspired oxygen (FIO2)=~0.155) and a sham hypoxia intervention (FIO2=0.2093) using hypoxic 'pillow tents' (make) in a randomised order.

Stool samples were collected pre and post each intervention and stored at ≤-20 °C until analysis. Bacterial deoxyribonucleic acid (DNA) was extracted using the QIAamp PowerFecal Pro DNA kit and quantified by spectrophotometry. The 16S rRNA gene was targeted by polymerase chain reaction with primers 27F/1492R (27F = 5'-AGAGTTTGATCMTGGCTCAG-3'and 1492R = 5'-ACGGYTACCTTGTTACGACTT-3'). Sequencing libraries were prepared using the Oxford Nanopore Technologies LSK-114 Ligation Sequencing Kit and Nanopore EXP-NBD196 Native Barcoding Expansion 96 kit. Libraries were sequenced on R10.4.1 flow cells on a GridION X5 platform. Sequenced 16S rDNA sequences were compared against the SILVA database of known 16S rDNA sequences for taxonomic classification using Minimap2 and identification of operational taxonomic units was performed using QIIME2.

RESULTS: Alpha and beta diversity comparing hypoxia and sham control will be presented. Taxa responsible for butyrate production will be compared amongst conditions and functional potential will be assessed using PICRUSt2.

CONCLUSION: Hypoxia may elicit increases in butyrate producing taxa within the gut microbiota. This may improve insulin sensitivity and provide a cost-effective therapeutic intervention for people with T2DM.

THE EFFECTS OF 10 NIGHTS OF NORMOBARIC HYPOXIA ON GLUCOSE HOMEOSTASIS AND INFLAMMATION IN PEOPLE WITH TYPE 2 DIABETES MELLITUS. A SINGLE-BLIND, RANDOMISED, SHAM CONTROLLED TRIAL.

SHEPHERD, A., JAMES, T., GOULD, A., MAYES, H., NEAL, R., SHUTE, J., TIPTON, M., MASSEY, H., SAYNOR, Z., PERISSIOU, M., MONTGOMMERY, H., STURGESS, C., MURRAY, A., GROCOTT, M., CUMMINGS, M.

UNIVERSITY OF PORTSMOUTH

Young-Min, S., McNarry, M., Corbett, J.

INTRODUCTION: Type 2 diabetes mellitus (T2DM) is a metabolic disease where chronic hyperglycaemia leads to life shortening comorbid conditions. Preliminary studies in people with T2DM (Mackenzie et al., 2011) suggest that acute exposure to hypoxia can improve markers of metabolic function. The aim of this study was to examine the effect of repeated overnight hypoxic exposure on glycaemic control and inflammation in people with T2DM and to provide insight into the physiological mechanisms underpinning any beneficial effects.

METHODS: Thirteen people with T2DM completed this single-blind, randomised, balanced, sham-controlled, crossover design study. Participants were assessed pre and post 10-nights of sleeping at home in 'hypoxic tents' (fraction of inspired oxygen (FIO2)=0.155) and a normoxic sham tent: (FIO2=0.209) separated by ≥1 month washout. Outcome measures included fasted plasma [glucose] and peak plasma [glucose] and insulin sensitivity following a 2-h oral glucose tolerance test (OGTT; 75g sugar). [hypoxia-inducible factor 1-alpha] (HIF1α), [interleukin-6] (IL-6), [interleukin-10] (IL-10) and [extracellular heat shock protein 70] (eHSP70) were assessed. During sham and intervention periods overnight transcutaneous O2 saturation (SPO2) was continuously assessed, wrist-worn accelerometers measured sleep indices and continuous glucose monitors (CGMs) measured estimated glycated haemoglobin (HbA1c), glucose management indicator (GMI) and time in target range.

RESULTS: Hypoxia decreased overnight SpO2% compared to sham (p=0.01 r=0.89) but did not affect plasma [glucose] area under the curve (AUC; P=0.21, d=0.39); peak plasma [glucose] (P=0.70, d=0.12); fasting plasma [glucose] (P=0.65, d=0.13) or post-prandial insulin sensitivity (P=0.13, d=0.47) whilst fasting insulin sensitivity (P=0.10, d=0.49) trended towards significance. Hypoxia had no effect on 10-day [glucose] (P=0.42, r=0.24); estimated HbA1c (P=0.48, r=0.24), GMI (P=0.62, r=0.16) or time in target range (P=0.37, d=0.32) or sleep efficiency (P=0.65, r=0.15). Hypoxia had no effect on plasma [HIF1α] (P=0.48, r=0.20); [eHSP70] (P=0.79, d=0.08); [IL-6] (P=0.24, r=0.34); [IL-10] (P=0.48, r=0.20).

CONCLUSION: Repeated overnight exposure to moderate hypoxia does not improve glucose tolerance but small-moderate effect sizes for insulin sensitivity suggests hypoxia may have an effect and has clinically meaningful effects on HbA1c (mean difference 4.3 mmol•mol-1; Lind et al., 2008).

OP-PN20 Thermoregulation II

THE INFLUENCE OF CUP SIZE ON VOLUNTARY DRINKING IN RECREATIONAL RUNNERS.

DESBROW, B., COX, G.R., COFFEY, V.G., IRWIN, C.

GRIFFITH UNIVERSITY AND BOND UNIVERSITY

INTRODUCTION: Voluntary drinking during exercise has the potential to be moderated by access to, and acceptability of, the drinking environment. This study aimed to determine the impact of cup size on voluntary water consumption during recreational running.

METHODS: Eighty-five healthy individuals (24±5 y, 72±15 kg, 45 females) completed two trials (1-week apart) in mild conditions (~20oC, RH ~70%). Trials consisted of a self-paced 10 km run/walk (athletics track) with randomly-assigned access to either a small (240 mL) or large (375 mL) cup for self-administering water (18-22oC) at the end of each 2 km. Participants were assigned to 1 of 4 treatment groups (week 1/week 2) - small/small, small/large, large/small and large/large cups. Total fluid intake and measures of hydration status were collected before and throughout trials. Within-participant data for small/large and large/small treatments was explored via linear mixed-effects models using RStudio (Version 1.4) with the data transformed (√) as case residuals were non-normally distributed (Shapiro-Wilk test, $p<0.05$).

RESULTS: Pooled average fluid intakes across all treatments were 326±196 mL (small) and 377±215 mL (large). Mean differences (95% CI) between weeks for treatments were 73 (-75 to 221) mL (small/small), 68 (-38 to 173) mL (large/large), -26 (-155 to 102) mL (small/large), 35 (-96 to166) mL (large/small). The retained structure for mixed-effect model included 'cup size', and 'trial order' as fixed effects, and 'participant' as a random effect parameter. Average fluid intakes for these participants were 304±193 mL and 330±242 mL for the small and large cup trials, respectively. While an interaction between trial order and cup size was identified ($p=0.04$), planned comparisons (pairwise) indicated the typically small fluid intake shifts (all <30 mL increase from small to large) were not statistically significant, and well within the variability observed when cup size did not change.

CONCLUSION: Under mild environmental conditions, changing cup size appears to have little impact on voluntary drinking during self-paced running. The extent to which cup size variations may influence voluntary drinking when cups are pre-filled, under more thermoregulatory stressful conditions and/or during more rigorous exercise is yet to be elucidated.

EXERTIONAL HEAT STRESS INCREASES BIOMARKERS OF ACUTE KIDNEY INJURY AND IMMUNE FUNCTION

GIFFORD, R.E.1, LUCAS, S.J.E.1,2, WADLEY, A.1, ELSWORTHY, R.J.1, LUCAS, R.A.I.1

UNIVERSITY OF BIRMINGHAM

INTRODUCTION: Strenuous physical activity in the heat is associated with an increased risk of kidney dysfunction and acute kidney injury (AKI). AKI is also associated with heightened systemic inflammation. However, the relationship between exertional heat stress, inflammation and AKI remains unclear. This study aimed to investigate the effects of prolonged exertional heat stress on AKI biomarkers and the ingress and egress of lymphocytes from peripheral blood. We hypothesised that greater exertional heat stress levels would result in elevations in AKI biomarkers (Neutrophil gelatinase-associated lipocalin, NGAL; Insulin Like Growth Factor Binding Protein 7; IGFBP7) and a higher ingress and egress of lymphocytes.

METHODS: Ten healthy, endurance trained participants (4 females; mean ± SD, age 24 ± 3 years; mass 67.6 ±12.3 kg; height 172 ±10 cm; VO2peak 55 ±8 ml/kg/min) completed 90-min of cycling at 45% Wmax in both hot and temperate ambient conditions (HOT: 40 °C, 20% relative humidity (RH); TEMPERATE: 20 °C, 20% RH) to elicit two distinct levels of exertional heat stress. Rectal temperature (Tre), skin temperature (Tsk) and heart rate (HR) were monitored continuously during exercise. Urine and blood samples were obtained pre, immediately post, 1-h post and 4-h post (urine only) exercise. Urine was analysed for NGAL and IGFBP7. Whole blood was analysed for total lymphocytes (Horiba, Yumizen H500).

RESULTS: At baseline, Tre, Tsk, HR and lymphocyte concentrations did not differ between HOT and TEMPERATE conditions (all $P>0.05$). By design, HOT resulted in higher peak Tre (38.30 ±0.34 vs 37.79 ±0.25 °C, $P<0.01$), Tsk (36.35 ±1.45 vs 26.95 ± 1.27 °C, $P<0.01$) and HR (166 ±8 vs 125 ± 9 b/min, $P<0.01$), as compared to TEMPERATE. Total lymphocyte concentrations were higher in HOT compared to TEMPERATE conditions immediately post exercise (2.20 ±0.42, vs 1.74 ±0.39 cells/µL, $P<0.01$), with no difference 1-hour post exercise (1.60 ±0.32, vs 1.57 ±0.39 cells/µL, $P<0.01$). In HOT, there was a greater ingress at baseline to immediately post exercise (+0.59 ±0.28 vs +0.21 ±0.16 cells/µL, $P<0.01$) and egress at 1-h post exercise to immediately post exercise (-0.60 ±0.22 vs -0.17 ±0.16 cells/µL, $P<0.01$) of lymphocytes from peripheral blood, as compared to TEMPERATE. From baseline to immediately post exercise, there was an increase in NGAL (Δ; 2.65 ±1.47, $P<0.05$) and IGFBP7 (Δ; 18.53± 18.87, $P<0.05$) in HOT, but no difference (NGAL Δ: 2.57 ±1.58; $P>0.05$; IGFBP7 Δ: 7.49 ±6.48; $P>0.05$) in TEMPERATE conditions.

CONCLUSION: These data indicate that the higher level of exertional heat stress in the HOT condition caused a greater immune response, as indicated by a higher total lymphocyte concentration and higher ingress and egress of lymphocytes, which was associated with moderate perturbations in AKI biomarkers. Thus, signs of inflammation with AKI may result from exertional heat-induced kidney injury.

NEGATIVE EFFECT OF SLEEP RESTRICTION ON HEAT TOLERANCE TO EVEN MILD HYPERTHERMIA INDUCED BY PASSIVE EXPOSURE

TARDO-DINO, P.E., BEAUCHAMPS, V., GERMAIN, A., DUSSAULT, C., COLIN, P., LEPETIT, B., GUILLARD, M., GRUEL, A., BOURDON, S., AYOUNTS, H., CHARLOT, K., MALGOYRE, A., BOURRILHON, C.

FRENCH ARMY BIOMEDICAL RESEARCH INSTITUTE

INTRODUCTION: In a growing context of global warming, populations, in particular soldiers, are increasingly exposed to hot climate often exacerbated by sleep restriction. Both exposition, when cumulative, can challenge individual heat tolerance capacities. Sleep restriction was in particular shown to be involved in onset of exertional heat stroke. We here proposed to assess the effect of sleep restriction on heat tolerance to passive exposure, in particular through endothelial function, which was shown to be altered by sleep debt.

METHODS: 13 healthy subjects (military and/or sportsmen's) were monitored in a randomized cross-over design, after getting normal nights (NN) (>6h) and sleep restriction (SR) (<3h). In both conditions, the subjects were exposed in a climatic chamber to passive-induced hyperthermia by uncompensable stress (45°C; 70% RH; wind: 1,9 m.s-1) then compensable conditions (42°C; 50% RH; 1,6 m.s-1). Core and skin temperature (Tcore and Tsk), heart rate (HR), blood pressure and cutaneous vascular conductance (CVC) were monitored.

RESULTS: All subjects were kept euhydrated during the experiment. During heat exposure, sleep restriction induced higher elevation of Tcore (heat exposure p=0.001, interaction sleep restriction and heat exposure p=0,01) and Tsk (heat exposure p=0.001, interaction sleep restriction and heat exposure p=0,01). Regarding to cardiovascular function, we observed heat exposure induced higher elevation of HR (heat exposure p=0.001, interaction sleep restriction and heat exposure (p=0,01) after a night of sleep restriction. However, we observed on mean arterial blood pressure heat exposure (p=0.03) and sleep restriction (p=0.01) effect without interaction. This alteration of thermoregulatory response was associated with lower elevation of CVC after sleep restriction (p=0.01).

CONCLUSION: These results showed an alteration in thermoregulation capacities by sleep restriction. This alteration was associated with increased cardiovascular stress. In addition, during heat exposure, we observed a decrease in cutaneous vascular conductance which could havecontributed to less thermoregulatory efficiency. This higher heat strain, induced by sleep restriction may have arisen from impaired endothelial function. These first results highlight the relevance of conditioning known to alter endothelial function, like endurance training, in order to improve heat tolerance, even for mild hyperthermia, in young men with putative healthy endothelium function, .

THE EFFECTS OF HEAT-INDUCED HYPO-HYDRATION AND REHYDRATION ON BLOOD-BRAIN-BARRIER PERMEABILITY, CORTICOSPINAL AND PERIPHERAL EXCITABILITY.

UDDIN, N., SCOTT, J., NIXON, J., PATTERSON, S., KIDGELL, D., PEARCE, A., WALDRON, M., TALLENT, J.

ST MARY'S UNIVERSITY, TWICKENHAM, UK & UNIVERSITY OF ESSEX, COLCHESTER, UK

INTRODUCTION: Thermoregulatory sweating, coupled with inadequate fluid intake, leads to intracellular fluid losses from skeletal muscle and neural tissue. The effects of heat-induced hypo-hydration and rehydration on maximal strength and underlying neurophysiological mechanisms are not well understood. Therefore, this study aimed to investigate the corticospinal and peripheral responses to heat-induced hypo-hydration and rehydration.

METHODS: Twelve participants (29 ± 7 yrs, 86.4 ± 9.5 kg, 185 ± 12 cm) underwent a 3 h light-intensity exercise trial in 40°C, with i) rapid rehydration in 2 h (RHY2), ii) gradual rehydration across 24 h (RHY24) and iii) a euhydrated trial in ambient conditions (25°C; CON). Neuromuscular function and peripheral excitability were assessed by maximal voluntary contractions (MVC), potentiated twitch (QtwPot), maximum motor unit potential (MMax) and voluntary activation (VA). Corticospinal excitability was assessed by single-pulse TMS measures (at 10% MVC); motor evoked potential (MEP) amplitude, MEP/MMax ratio and cortical silent period (cSP). Neuronal and blood-brain-barrier integrity was assessed by serum Ubiquitin Carboxyl-terminal Hydrolase (UCH-L1) concentrations. All measures were obtained immediately pre, post, post-2 h and post-24 h (POST2 and POST24, respectively).

RESULTS: Mean body mass losses in RHY2 and RHY24 were both -4.6%, but 0.2% in CON. VA (91 ± 1% vs. 81 ± 2 %, $p = 0.037$) decreased post-exercise after RHY24 compared to CON, and increased at POST2 during RHY2 compared to CON (92 ± 1% vs. 85 ± 2 %, $p = 0.017$). MVC and MEP amplitude decreased across time for both dehydration trials ($p < 0.05$) and MEP returned to baseline at POST2 during RHY2, but not during RHY24 (2.6 ± 0.3 mV vs. 2.2 ± 0.3 mV, $p = 0.02$). MEP/MMax ratio decreased across time for all trials ($p = 0.009$) and returned to baseline at POST24, except during RHY24 (0.55 ± 0.05 vs. 0.43 ± 0.4, $p < 0.026$). A decrease in QtwPot (205 ± 13 Nm vs. 231 ± 18 Nm, $p = 0.045$), and increase in cSP (0.160 ± 0.006 ms vs. 0.146 ± 0.005 ms, $p = 0.011$) were only observed during CON post-exercise but returned to baseline at POST24. Serum UCH-L1 increased across time for all conditions ($p < 0.01$), but was not significantly different between conditions ($p > 0.05$).

CONCLUSION: Overall, maximal strength was impaired after heat-induced hypo-hydration and the neurophysiological mechanisms differed from that of light-intensity exercise in ambient conditions. Heat-induced hypo-hydration leads to a reduction in corticospinal excitability and VA, while exercise in a euhydrated state increases corticospinal inhibition and skeletal muscle impairment. In addition, low-intensity exercise (irrespective of hydration status) increases blood-brain-barrier permeability, resulting in an increase of UCH-L1 in the peripheral bloodstream.

ELITE ATHLETES WITH EARLY TENDINOPATHY - CLINICAL AND IMAGING FINDINGS

MEULENGRACHT, C., SEIDLER, M., SVENSSON, R.B., ZEIDAN, A., ØRNSVIG, K., BRUSHØJ, C., KRACHT, M.N., HJORTSHØJ, M.H., MAGNUSSON, S.P., BAHR, R., KJÆR, M., COUPPÉ, C.

BISPEBJERG HOSPITAL, COPENHAGEN

INTRODUCTION: Tendinopathy poses serious clinical and socio-economic problems, as the prevalence of tendon injuries is high. For affected individuals, the symptoms and reduction in performance often last for years and many never return to their previous performance leading to cessation of their sports career. Knowledge of how to treat chronic tendinopathy has advanced in recent years, but the disease progression and treatment of early tendinopathy is not well understood. The main purpose of this prospective observational study was to investigate possible changes in clinical and imaging (MRI and ultrasonography) outcomes over the course of 3 months in elite athletes presenting with symptoms of Achilles and patellar tendinopathy for <3 months.

METHODS: 65 elite adult athletes (24±5 years) with early Achilles or patellar tendinopathy (symptom duration <3 months) were examined at baseline and after 3 months. Patients were divided into groups based on duration of symptoms at the time of inclusion: 0-1 month (T1), 1-2 months (T2) or 2-3 months (T3). Recommendations on load management was the only intervention. We assessed the following clinical outcomes: Questionnaires (Victorian Institute of Sports Assessment (VISA)) and pain scores (0-10 numeric rating scale (NRS)), as well as ultrasonography (US) outcomes: thickness, echogenicity, and Doppler flow area. Also, dimensions (cross-sectional area (CSA), thickness and length) of the Achilles and patellar tendons were obtained by 3-Tesla MRI. A linear mixed effects model was used to analyze changes from baseline to 3 months in all outcome variables.

RESULTS: Tendinopathic Achilles and patellar tendons revealed no significant differences on clinical scores (VISA and NRS) or any imaging (US and MRI) variables between T1 (n=19), T2 (n=23) and T3 (n=23) at baseline or after 3 months, with one exception: Patellar tendons in T1 were larger than T2 and T3 at baseline ($p<0.05$). Elite athletes had clinically relevant improvements on the VISA (>14 points) and most NRS scores (>2 points) after 3 months. Tendinopathic Achilles and patellar tendons had a greater thickness, CSA and Doppler flow than the contralateral tendons at baseline that remained unchanged after 3 months.

CONCLUSION: These novel data suggest that symptoms of early tendinopathy in elite athletes improved clinically after 3 months, but morphology remained unchanged in both Achilles and patellar tendons. These data also suggest that tendon morphologic changes probably develop a long time before symptoms occur. Finally, based on previous results, recreational and elite athletes do not seem to differ in pain response or tendon dimensions.

ONE YEAR FOLLOW-UP IN ELITE ATHLETES WITH EARLY TENDINOPATHY - CLINICAL AND ULTRASONOGRAPHY FINDINGS

SEIDLER, M.1, SVENSSON, R.B.1, MEULENGRACHT, C.1, ØRNSVIG, K.1, BRUSHØJ, C.1,2, KRACHT, M.N.1, HJORTSHØJ, M.H.1,3, MAGNUSSON, S.P.1,3, BAHR, R.4, KJÆR, M.1, COUPPÉ, C.1,3

INSTITUTE OF SPORTS MEDICINE, INSTITUTE OF CLINICAL MEDICINE <1>, TEAM DENMARK <2>, NORWEGIAN SCHOOL OF SPORTS SCIENCES <4>

INTRODUCTION: Knowledge of how to treat chronic tendinopathy has advanced in recent years, but the understanding of the disease progression and treatment of early tendinopathy is limited. The primary aim of this prospective observational study was to investigate possible changes in clinical and ultrasonographic imaging outcomes over the course of 12 months in elite athletes presenting with Achilles and patellar tendinopathy within <3 months after symptom onset. The secondary aim was to assess the prognostic values of the baseline ultrasonography and clinical outcomes on the progression of these outcomes.

METHODS: Sixty-five elite adult athletes (24±5 yrs) with early Achilles or patellar tendinopathy (symptom duration <3 months) were examined at baseline and after 12 months. Recommendations on load management was the only intervention. We assessed the following clinical outcomes: Victorian Institute of Sports Assessment (VISA) questionnaires, pain (numerical rating scale 1-10 (NRS) scores), and ultrasonography outcomes: thickness, echogenicity, and Doppler flow area. A linear mixed effects model was used to analyze changes from baseline to 12 months in all outcome variables and also used to assess any potential association between baseline ultrasound findings and clinical outcomes on the changes in these parameters after 12 months, using a backward elimination process.

RESULTS: Elite athletes with early tendinopathy had clinically relevant improvements on VISA (>14 points) and most NRS (>2 points) pain scores after 1 year. Tendinopathic Achilles and patellar tendons had greater thickness than the contralateral tendon at baseline. Injured Achilles tendons demonstrated a trend towards reduced thickness after 12 months ($p<0.1$) while injured patellar tendons remained enlarged. Lower baseline Doppler flow was associated with greater reduction in thickness after 1 year ($p<0.05$), and longer initial symptom duration was associated with greater reduction in pain over 1 year ($p<0.05$). Higher baseline VISA scores also tended to be associated with greater increases in echo intensity (less hypoechogenic) ($p<0.1$).

CONCLUSION: These novel data suggest that symptoms of both early Achilles and patellar tendinopathy improved clinically in the long-term, but only patients with early Achilles tendinopathy showed trends towards improved morphology after 12 months. Patellar tendon thickness and echogenicity remained unchanged despite clinical improvement. Finally, lower baseline Doppler flow, longer symptom duration and better initial VISA scores tended to represent a better prognosis for tendinopathy morphology and symptoms in elite athletes.

EFFECTS OF PROTEIN SUPPLEMENTATION COMBINED WITH EARLY REHABILITATION ON MUSCLE VOLUME AND FUNCTION AFTER ACUTE MUSCLE STRAIN INJURIES

MERTZ, K.H., SORENSEN, H.H., LORENTZ, C., SVENSSON, R.B., KJAER, M., BAYER, M.
BISPEBJERG HOSPITAL

INTRODUCTION: Muscle strain injuries constitute a major problem in recreational and professional sports, causing substantial injury absence and greatly increasing the risk of re-injury (1). Despite extensive rehabilitation, muscle strain injuries typically induce a decrease in muscle volume and strength of the injured muscle (2), which might contribute to the high re-injury risk. We hypothesized that protein supplementation during early rehabilitation of acute muscle strain injuries would decrease the loss of muscle volume 3 months post injury.

METHODS: 51 sports active individuals with an acute muscle strain injury in the calf or hamstring musculature were randomized to whey protein supplementation (2x20 g daily, WHEY) or isocaloric placebo (maltodextrin, PLACEBO) during 3 months rehabilitation. Injuries were confirmed using ultrasound, and onset of rehabilitation was 2 days post injury. Total muscle volume was assessed using magnetic resonance imaging (MRi) acute and 3 months post injury. Eccentric muscle strength was measured post rehabilitation using isokinetic dynamometry at 60°/s.

RESULTS: 35 participants completed the intervention (18 PLACEBO, 17 WHEY). 2 participants were excluded, and 13 participants dropped out. The high drop-out rate was related to COVID lockdowns. Median eccentric strength deficit of the injured leg compared to the healthy after the rehabilitation period was -6,9% (Interquartile range (IQR): 9.0%), with no difference between groups (P = 0.51). Preliminary MRi results (n = 5 in each group) indicate larger decreases in muscle volume for PLACEBO compared to WHEY ([Median (IQR)]: -6.9% (-18.3 to +4.5) vs +3.0% (-2.3 to 8.2), P = 0.03). MRi analyses will be completed during spring 2023.

CONCLUSION: Preliminary findings indicate protective effects of protein supplementation on muscle volume after acute strain injuries. These findings will have great clinical relevance in securing optimal muscle mass and function upon return to sport after this type of injury.

IMPACT OF A 3-WEEKS SPECIFIC SPORT REHABILITATION CYCLE ON NEUROMOTOR CONTROL IN PROFESSIONAL SOCCER PLAYERS WITH LOWER LIMB INJURIES BEFORE RETURN-TO-PLAY.

MEMAIN, G., YIOU, E., CARLING, C., FOURCADE, P., BOUVET, J., MAILLE, P., TAMALET, B.
FRENCH FOOTBALL FEDERATION , CLAIREFONTAINE NATIONAL FOOTBALL CENTRE / , PARIS-SACLAY UNIVERSITY, ORSAY, FRANCE.

INTRODUCTION: During the last decade, professional soccer players (PSP) have been exposed to increased amount of stress on their musculoskeletal apparatus due to the greater volume and intensity of football demands1. Despite prevention strategies, the frequency and severity of injuries hasn't decreased2. As such, evaluating progression during rehabilitation and return-to-play (RTP) programmes3 and specifically neuromotor control is crucial in limiting the risks of re-injury4. This study aimed to investigated the effect of a 3-week specific sport rehabilitation (SSR) program on neuromotor control PSP with lower limb injuries.

METHODS: Altogether, 15-male PSP suffering from various unilateral lower limb injuries (chondropathy, muscle lesions, anterior crucial ligament rupture) and 22 uninjured PSP (UPSP) participated. All performed 3 unilateral countermovement jumps (CMJ) with each leg ; before and after a SSR program3 for injured participants and during a single session for healthy participants. Movement analyses included whole-body kinematics, kinetics and lower limb muscle activation. Main variables were: peaks of trunk flexion and lateroflexion, knee flexion, peak and mean of %maximal voluntary contraction of studied muscles, rate of force development (RFD), peak of vertical ground reaction force , reactive strength index modified, jump height and movement time. A limb symmetry index (LSI, % difference between injured and non-injured leg) and a deficit limb index (DLI, % difference between injured leg and dominant leg of healthy participants) were computed for each variable.

RESULTS: All CMJ variables significantly improved following the SSR program ($p<0.05$). Improvements ranged between +7% (RFD) and +26% (jump height). LSI applied to each CMJ variable almost reached 100% after SSR, indicating a quasi-equivalent performance level between healthy and injured leg. Despite the improvement, CMJ variables except eccentric

and early concentric RFD were lower in injured PSP than in healthy participants ($p<0.05$ to $p<0.001$). DI applied to each CMJ variable showed that CMJ performance remained lower in injured than in healthy participants.

CONCLUSION: The neuromotor control of injured PSP significantly improved following 3-week SSR program. However when CMJ variables were compared post SSR program to normative values in UPSP, it appeared that recovery was incomplete. These results suggest that a longer SSR program is necessary to ensure safe RTP, and that DLI seems to be more relevant than LSI for decision-making during RTP programs.

PLAYING WITH PAIN-THE EPIDEMIOLOGY OF HIP AND GROIN PAIN IN GAELIC GAMES PLAYERS

JORDAN, S., BLAKE, C., MCCARTHY-PERSSON, U., LODGE, C., FRENCH, H.

UNIVERSITY COLLEGE DUBLIN

INTRODUCTION: Large injury surveillance studies have suggested that hip and groin pain is prevalent in male Gaelic games players but no study has explored the epidemiology of hip and groin pain across all codes and levels of Gaelic games. The aim of this study was to examine the prevalence of hip and groin pain and Femoroacetabular Impingement Syndrome (FAIS) in male and female Gaelic games and to explore factors (age, gender, code, level, exposure) associated with hip and groin pain and FAIS.

METHODS: During the late 2019 and early 2020 season, a representative national sample of Gaelic games players were invited to complete a questionnaire in which they provided demographic information and reported on hip and groin pain that they have had within the last year, with specific questions pertaining to any FAIS diagnosis within the last year. Seven hundred and seventy-five (22.8±5.2 years) (n=438 males; n=337 females) Gaelic games players from all codes and multiple levels returned completed questionnaires. Logistic regression models were constructed after univariate analysis to identify factors associated with having hip and groin pain

RESULTS: Over half (54.8%) of players had at least one episode of hip and groin pain within the last year (annual prevalence) and 22.8% currently had hip and groin pain (point prevalence). Males were 1.4 (CI 1, 1.8) times more likely to report hip and groin pain than females ($p<0.05$) and players participating in additional sports/physical activity were 1.95 (CI 1.35, 2.79) times more likely to experience hip and groin pain throughout the year ($p<0.05$). Almost half (48.8%) of players with hip and groin pain continued to participate in training and games, 32.5% were sometimes unable to play while 18.7% were unable to participate. Although 40% of episodes lasted no longer than 3 weeks, there was a high rate of recurrent episodes of pain (33.5%). FAIS was reported in 1.8% of players and represented 3.3% of hip and groin pain diagnoses.

CONCLUSION: Hip and groin pain is prevalent in Gaelic Games but a large proportion of episodes appear minor, resolving within 3 weeks. The high proportion of players both continuing to play with pain and experiencing recurrent episodes of pain, needs to be addressed to prevent worsening and eventual time loss injuries. Gender and participation in additional sports/physical activity may be factors to consider in screening and prevention strategies for hip and groin pain. While FAIS has a low prevalence rate, the impact of this condition on players needs to be explored.

ASSOCIATIONS OF SEDENTARY BEHAVIOURS WITH DEPRESSIVE SYMPTOM AMONG CHINESE COLLEGE STUDENTS

ZHENG, J.X., TAN, T.C., ZHENG, K.F., LIU, Y.T., HUANG, T.

SHANGHAI JIAO TONG UNIVERSITY

Background: Mental disorders are the major causes of the global health-related burden, with depression being the primary contributor. Some epidemiological studies have started to recognize sedentary behaviour as an independent risk factor for depression. However, the associations of sedentary behaviours with depression symptom may vary by the type of sedentary behaviours. College students are a population at higher risk of being sedentary. Therefore, the objective of the study was to examine the associations of sedentary behaviours with depressive symptom among Chinese college students.

Methods: A total of 927 Chinese college students participated in this cross-sectional study. Different types of sedentary behaviours on weekdays and weekends were self-reported using questions based on the 24-hour movement behaviours questionnaire (24HMBQ). The participants were required to report the duration of engagement in three types of sedentary behaviors, including time spent on study (including taking courses, self-studying, etc.) and work, time on using electronic screen-based devices for entertainment (including watching TV/movies / short videos, video gaming, and using social media, etc.), and other sedentary behaviours (e.g., having meals, transportation). Depression symptoms were evaluated

using the Center of Epidemiologic Studies Depression Scale, 10-item version (CES-D-10). Linear regression modeling was used to assess the associations of sedentary behaviours with depression symptoms.

Results: After adjusting for potential confounders (i.e., sex, age, height, and weight), the duration of sedentary behaviours in studying or working on weekdays (B=0.158, p=0.006) and weekends (B=0.169, p=0.002) were positively associated with depressive symptom. The duration of sedentary behaviours on electronic screen-based devices for entertainment on weekends (B=0.195, p=0.017), other sedentary weekly behaviours (B=0.515, p=0.008), and other sedentary weekend behaviours (B=0.510, p=0.003) were positively associated with depressive symptom. There was no association between sedentary behaviours on electronic screen-based devices for entertainment on weekdays and depressive symptom.

Conclusions: The present study revealed that prolonged time on sedentary behaviours were positively associated with depressive symptom in college students. Interventions for improving mental health should consider reducing sedentary behaviours in college students.

ASSOCIATION OF EMOTION REGULATION AND DEPRESSIVE SYMPTOMS AMONG JAPANESE UNIVERSITY ATHLETES

KAWATA, Y.1,2,3, NAKAMURA, M.3, MUROFUSHI, Y.1,2, TSUNEYOSHI, O.1,2,3

1. JUNTENDO UNIVERSITY, 2. JUNTENDO UNIVERSITY, 3. JUNTENDO UNIVERSITY

INTRODUCTION: Depressive symptoms cause not only performance decline, but also the end of an athlete's career. To prevent such problems among athletes, the development of sufficient support systems to enhance their ability to cope with stress and maintain mental health is extremely important. Emotion regulation strategies have been emphasized as effective in coping with stress caused by these problems. "Emotion regulation" is defined as the regulation of thoughts or behaviors that influence emotions [1]. If emotion regulation is effective in preventing depressive symptoms, then emotion regulation can be proposed as a form of stress coping. Therefore, we examined emotion regulation associated with depressive symptoms in Japanese university athletes.

METHOD: Data were collected from 1054 Japanese university athletes (708 males and 346 females). We collected demographic data, emotion regulation (Emotion Regulation Questionnaire, ERQ [1]), and depressive symptoms (Self-Report Depression Scale, SDS [2]). The ERQ assesses two emotion-regulation strategies: reappraisal and suppression. We examined the relationship between demographic variables and SDS scores. Next, we conducted multiple logistic regression analysis by setting emotion regulation (reappraisal and suppression scores) as the independent variable and depressive symptoms (SDS items and total scores) as the dependent variables, including covariates.

RESULTS & DISCUSSION: Result showed that reappraisal had a significant negative effect on SDS total score (Odds Ratio [OR] = 0.25, 95%CI = 0.17–0.38, $p < .001$, Relative risk [RR] = 0.8), following symptoms of "Depressive affect," Crying spells," "Decreased appetite," "Confusion," "Psychomotor retardation," "Hopelessness," "Indecisiveness," "Personal devaluation," "Emptiness," and "Dissatisfaction." However, suppression had a significant positive effect on SDS total score (OR = 1.6, 95%CI = 1.07–2.43, $p < .05$, RR = 0.9), following symptoms of "Depressive affect," "Sleep disturbance," "Decreased libido," "Fatigue," "Hopelessness," and "Emptiness." This indicates that athletes who reappraise themselves to cope with stress have good mental health.

CONCLUSION: Thus, we concluded that emotion regulation associates with depressive symptoms in Japanese university athletes. Reappraisal may contribute to the maintenance of athletes' mental health.

EFFECTIVENESS OF A SHORT SPRINT TRAINING (SSIT) PROTOCOL IN WOMEN DIAGNOSED WITH MAJOR DEPRESSIVE DISORDER

BOULLOSA, D., RIBEIRO, J.A., VARGAS, K.F.M., OLIVEIRA-JUNIOR, S.A., SCHUCH, F.B., MÜLLER, P.T.

UNIVERSIDAD DE LEÓN

Purpose

High-intensity intermittent training has emerged as an option for treating major depressive disorder (MDD). However, short sprint training (sSIT) protocols were not tested yet for this purpose. The sSIT has been proven to induce the same metabolic effects, with the benefit of promoting lower fatigue than other HIIT protocols.

Methods

Eighteen adult (18-58 yrs) women diagnosed with moderate/severe MDD were randomly allocated into a sSIT group (n=9, BMI=28.3 kg/m2) and a control group (n=9, BMI=31 kg/m2). The sSIT group completed, over two weeks, six 10-min sessions in a periodized fashion which consisted of 3-12 "all out" sprints of 5 s interspersed with low-intensity recovery of ≥ 30

s. The week before and after the intervention, both groups were evaluated with the Hamilton Depression Rating Scale of 21-itens (HDRS-21), and for physical fitness (maximum aerobic power, body composition) and incidental physical activity.

Results

The sSIT group exhibited significant improvements for HDRS-21 scores (24.6±8.2 vs. 16.8±10.1, p<0.001), maximum aerobic power (140±15 vs. 155±15 W, p=0.016), % of body fatness (32.4±4.4 vs. 29.3±3.8%, p<0.001), and number of steps (13,626±11,309 vs. 16,643±15,371, p=0.009) after the training protocol when compared to the control group which did not exhibit any changes (p>0.05).

Conclusions

Two weeks of sSIT has demonstrated to reduce depressive symptoms, while improving aerobic fitness and body composition and increasing incidental physical activity.

ASSOCIATION AND CHANGES IN THE PHYSICAL AND MENTAL HEALTH OF ADOLESCENTS AT THE BEGINNING OF THE 21ST CENTURY

BIRGISSON, O., JOHANNSSON, E., HYSING, M., ERIKSEN, H.R., GESTSDOTTIR, S.

UNIVERSITY OF ICELAND

INTRODUCTION: Mental and physical health seems to have declined at the beginning of the 21st century. Therefore, the main aim of the present study was to compare mental and physical health at age 15 in two cohorts, one measured in 2003 and the other in 2015. Secondly, to estimate the association between mental and physical health in the two cohorts, and finally, to examine the association between level of fitness and mental health in each cohort.

METHODS: Data from 2003 (cohort born in 1988. N=443) and 2015 (cohort born in 1999. N=303) were analyzed. Mental health (body image, self-esteem, and symptoms of depression) and magnitude of exercise was assessed with self-reports. Physical health was measured objectively using body mass index and aerobic fitness that was estimated using maximal cycle ergometer test as an indirect measure of VO_2 max. Independent sample t-test was used to evaluate the differences between cohorts, linear regression to assess the relationship between mental health and aerobic fitness and ANOVA to see if level of fitness relates to mental health.

RESULTS: Participants measured in 2003 had lower depression scores (p=0.01, d=0.24), better self-esteem scores (p<0.01, d=0.62), and better fitness (p<0.01, d=0.99) compared to the participants in 2015. No differences were found in body image scores between cohorts. Aerobic fitness was associated with body image, depression, and self-esteem after adjusting for parents' education level, living conditions, sex, and BMI in both cohorts though not between fitness and self-esteem in 2003. Finally, in both cohorts, participants with low fitness level had significantly poorer body image, higher depression, and worse self-esteem than those with high fitness level.

CONCLUSIONS:

This study found that adolescents had poorer mental health and physical health at the beginning of the 21st century compared to a cohort assessed ten years earlier. Interventions to improve fitness specifically could benefit adolescents mental health, but further research is needed to understand the underlying factors and mechanisms.

EXAMINING MENTAL HEALTH OUTCOMES OF STUDENT-ATHLETE MINORITY SUB-POPULATIONS.

SULLIVAN, P.

BROCK UNIVERSITY

The mental health of university students is a significant concern, with research showing that they have higher levels of anxiety, depression, and psychological distress than the general population (Brown, 2018; Hunt & Eisenberg, 2010). Among university students, varsity athletes, who deal with the stresses of elite athletes as well as those of university students, may have even higher prevalence of mental health issues that non-athlete students (Sullivan et al., 2019; van Slingerland et al., 2018). The current study examined mental health outcomes of marginalized student-athletes relative demographic majorities. Specifically, racial and sexual orientation minorities, which have been linked to lower mental health in university students (Arday, 2018; Lipson et al., 2019) were examined among student-athletes. The database of the 2021 Canadian Campus Well-Being Survey, which includes the Kessler K-10 (Kessler et al., 2003) and Warwick Edinburgh Mental Well Being Scale (WEMWBS; Tennant et al., 2007) were analyzed for this study. The Kessler K-10 is a widely used measure of generalized psychological distress; the WEMWBS was developed as a valid measure of well-being in the general population. The responses of varsity athletes (N = 649) were examined for difference on these outcomes between heterosexual and minority sexual orientations and Caucasian and minority ethnicities. The sample included 1152 Caucasian student-athletes (949 heterosexual, 203 sexual minority) and 637 racial minority student-athletes (484 heterosexual, 153 sexual minority). Results of a factorial MANOVA revealed a significant interaction ($F(2, 624) = 7.25$, $p < .001$, $p\eta 2 = 0.02$) between race and sexual orientation on K10 and WEMWBS scores. Specifically, among Caucasian student athletes, minority sexual orientations showed significantly higher levels of psychological distress than heterosexual athletes whereas among racial minorities, there were no differences between sexual orientations. With respect to well-being, heterosexual Caucasians reported higher scores than sexual minority Caucasian student-athletes, whereas racial minority student-athletes who identified as heterosexual showed significantly lower scores than those who were sexual minority. These results suggest that the pattern of mental health outcome among student-athletes may be more nuanced than previously thought and there may be significant implications for mental health services delivered on campuses.

IMPACT OF SINGLE AND 7-DAY HANDGRIP AND SQUAT EXERCISE IN PREVENTING ENDOTHELIAL ISCHAEMIA-REPERFUSION INJURY IN PARTICIPANTS WITH INCREASED CARDIOVASCULAR RISK

SOMANI, Y.B., BOIDIN, M., PEGGEN, M.A.G., WANDERS, I., LOW, D.A., JONES, H., THIJSSEN, D.H.J.

LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: Exercise may provide immediate protection against endothelial ischaemia-reperfusion (IR) injury in young, healthy individuals (1). Whether these findings translate to older individuals with elevated cardiovascular disease (CVD) risk is unclear, which is especially relevant as exercise-induced protective pathways may be attenuated in the presence of CVD. Furthermore, it is unknown whether a greater volume of exercising muscle and/or short-term exercise provide additional protective effects against IR injury. The aim of this crossover study was to 1) compare two modes of acute exercise involving small (handgrip) and large (squats) muscle mass on vascular responses to IR-injury in older individuals with CVD risk factors, and 2) test whether 7 days of daily exercise modifies these responses.

METHODS: Fifteen participants (9 women, 58 ± 5 years, ≥ 2 CVD risk factors) visited the laboratory on 5 occasions. On visit 1 (control), brachial artery flow-mediated dilation (FMD) was measured before and after a temporary endothelial IR-injury induced in the upper arm (15-minutes ischemia, 15-minutes reperfusion). One week later, participants were randomized to perform dynamic unilateral handgrip (4x5 minutes bouts, 50% maximal voluntary contraction, 25 repetitions per min) or squat (4x5 minutes, bodyweight, 15 repetitions per min) exercises paced by a metronome prior to the IR-injury protocol. The exercises were continued at home for 1 week (daily) before participants returned to the laboratory and the IR-injury protocol was repeated. A two-week washout period took place between exercise modes. Data were analysed using general linear models.

RESULTS: When assessing the acute effect of exercise, there was a significant decline in FMD following IR-injury (P=0.02) and an IR injury*condition interaction effect (P=0.03). There was decline in FMD following IR-injury in the control condition (4.3 ± 2.1% to 2.9 ± 1.8%, P<.001) but not following handgrip (3.8 ± 1.6% to 3.4 ± 1.5%, P=0.33) or squat exercise (3.9 ± 1.8% to 4.0 ± 1.9%, P=0.75). Dose of exercise (1 vs. 7 daily exercise sessions) did not influence FMD responses after IR-injury to handgrip (1-week: 4.3 ± 1.9% to 4.7 ± 3.2%) or squats (1-week: 3.7 ± 2.1% to 4.7 ± 3.0%;(both, P>0.05).

CONCLUSION: We show that dynamic, small and large muscle mass exercise effectively attenuate IR-induced vascular injury in older individuals with CVD risk factors, whilst these effects remain similarly present following 7 days of continued exercise. This highlights the potency of exercise to provide immediate, remote protection against endothelial IR-injury in individuals with elevated CVD risk, which seems largely independent of the volume of exercise.

SEVEN DAYS OF SMALL OR LARGE MUSCLE MASS EXERCISE TRAINING IS NOT SUFFICIENT TO IMPROVE VASCULAR FUNCTION IN INDIVIDUALS WITH CARDIOVASCULAR RISK FACTORS

BOIDIN, M., SOMANI, Y.B., PEGGEN, M.A.G., WANDERS, I., LOW, D.A., JONES, H., THIJSSEN, D.H.J.

MANCHESTER METROPOLITAN UNIVERSITY

INTRODUCTION: Time course of change in flow-mediated dilation (FMD) in response to exercise training differs according to the individuals' characteristics such as cardiovascular health and age. Moreover, muscle mass seems to have a key role on arterial blood flow and shear stress. Small muscle mass such as handgrip causes minor changes in cardiac output, suggesting that increased blood flow during exercise is mainly attributed to vasodilation. Whist large muscle mass exercise such as squats increase blood pressure and cardiac output, suggesting that the increase in femoral blood flow might be responsible of the vasodilation. In clinical populations, early improvements in vascular function without impacting blood pressure may reveal important new insights into vascular biology. We used a within-subject, cross-over study to determine the impact of short-term large versus small muscle mass exercises on vascular function in older individuals with cardiovascular risk factors.

METHODS: Fifteen inactive participants (Females/males: 9/6, 58 ± 5 years, ≥ 2 cardiovascular risk factors) reported to the laboratory on four occasions to undergo blood pressure and vascular function measurements. Participants completed seven sessions over a one-week period, either handgrip (4x5/25 repetitions per minute/50% maximal voluntary contraction) or squat (4x5 minutes bodyweight, 15 repetitions/min) training in a randomized, balanced cross-over design with a two-week washout period between exercise conditions. Resting vascular function was assessed and analyzed with the expert-consensus guidelines for FMD protocol and statistical analyses were performed with general linear models.

RESULTS: There was no change in resting FMD following either exercise condition (time-effect: p=0.62, interaction-effect: p=0.20). Resting systolic (SBP) and diastolic (DBP) blood pressure did not change after both exercise training interventions (time-effect: p=0.52 and p=0.57, interaction-effect: p=0.95 and p=0.43, for SBP and DBP, respectively). Individual changes in FMD demonstrated a comparable pattern between both exercise modalities where nine and seven participants demonstrated an increase in FMD after seven days of exercise training in handgrip and squat groups, respectively. De-

spite this similarity at the group level, matching the individual changes to both types of training showed large variation between individuals, where no association were found between the two groups (R2=0.05, p=0.42).

CONCLUSION: Our results suggest that one week of exercise training is not enough to improve vascular function in individuals with cardiovascular risk factors. However, intra-individual variation in the adaptation of FMD was found. Since muscle mass involvement has a different impact on blood flow, further studies should focus on the short-term impact of whole-body aerobic exercise (e.g., cycling) on vascular function.

CARDIOVASCULAR PREHABILITATION IN PATIENTS AWAITING HEART TRANSPLANTATION - ADDRESSING CLINICAL NEEDS (PREHAB HTX)

REED, J.L., TULLOCH, H.E., ROSS, H., CHIRICO, D., TERADA, T., OH, P., CHIH, S.

UNIVERSITY OF OTTAWA HEART INSTITUTE

INTRODUCTION: Heart transplantation (HTx) is a life-saving treatment for patients with advanced heart failure (HF); however, considerable donor organ shortages limit its access. Patients with advanced HF awaiting HTx, in whom advanced age and co-morbid diseases are common, experience substantial declines in functional and exercise capacity, are frail, and suffer from poor mental health and quality of life (QoL). Cardiovascular rehabilitation (CR) programs are integral to managing HF. Such programs include health behaviour change and cardiovascular disease risk factor management (e.g., physical activity programming, nutritional counselling, stress management, and smoking cessation). Few studies have examined the effects of CR for patients with advanced HF awaiting HTx (prehabilitation [PREHAB]). The primary aim was to compare the effects of a 12-week PREHAB program and usual care (UC) in improving functional capacity (6-minute walk test) in adults listed for HTx. Secondary aims included comparing a 12-week PREHAB program and UC in improving exercise capacity (VO2peak), depression (Beck Depression Inventory-II, BDI-II), anxiety (Beck Anxiety Inventory, BAI), and QoL (Minnesota Living with Heart Failure Questionnaire, MLHFQ).

METHODS: An RCT was conducted at the Ottawa Heart Institute and Toronto General Hospital/Toronto Rehabilitation Institute in Canada. Participants were randomized to PREHAB or UC. The 12-week PREHAB program included thrice weekly high-intensity interval training (HIIT) sessions (2 x 8-minute interval training blocks of 30-seconds at 100% of peak power output [PPO] interspersed with 30-seconds active recovery at 50% of PPO, with 4 minutes of passive recovery between the blocks), a stress management course, and a nutrition workshop.

RESULTS: Trial recruitment began in October 2018 and closed, due to the COVID-19 pandemic, in December 2020. The target sample size was n=68. A total of 128 patients were screened for eligibility, 17 were recruited (age: 44±9 years, 71% male), and 4 were randomized (PREHAB=2, UC=2). Both patients completed the PREHAB program and 1 patient completed UC. Reasons for drop-out included: transplanted, medication and device contraindications, commitment and travel constraints, and lack of interest. The PREHAB program showed potential for improvements in functional capacity (baseline (B): 343±120, follow-up (F): 465 m), exercise capacity (B: 14.9±0.1, F: 15.8±0.4 mL/kg/min), depression (B: 11±5, F: 6±3 points), anxiety (B: 11±8, F: 10±0 points), and QoL (B: 41±33, F: 26±1 points).

CONCLUSION: Recruitment for and completion of a PREHAB program for patients listed for HTx proved challenging. Our target sample size was not achieved, and a high attrition rate was observed. Yet, improvements were seen among PREHAB participants across physical and mental health outcomes. Future research is encouraged to examine alternative PREHAB offerings (e.g., virtual based) which may be offered sooner following listing and address reported barriers.

ENHANCING FUNCTIONAL CAPACITY AND QUALITY OF LIFE WITH ECCENTRIC CYCLING IN HEART FAILURE PATIENTS: A RANDOMIZED CONTROLLED TRIAL

STAUBORG, L., MAIORANA, A., HAYNES, A., HILLIS, G.S., DEMBO, L., NOSAKA, K., GREEN, D.J., NAYLOR, L.N.

THE UNIVERSITY OF WESTERN AUSTRALIA

INTRODUCTION: Exercise training is recommended for comprehensive management of patients with heart failure and reduced ejection fraction (HFrEF). However, limited exercise capacity prevents many patients from gaining optimal benefits from training. Given that eccentric cycling is well tolerated in patients with HFrEF, and enables greater power output, we hypothesized that eccentric cycling training would result in superior functional outcomes than concentric cycling training when the interventions were matched for heart rate (HR).

METHODS: Thirty participants (7♀, 57±13 y; BMI 27±4 kg/m2) with HFrEF (ejection fraction 36±7%, New York Heart Association class II) were randomized in a 1:1 superiority clinical trial to undertake either eccentric cycling training (ET, n = 16) or concentric cycling training (CT, n = 14). Each intervention involved 2 weeks of familiarization period followed by 12 weeks of training at matched relative intensity (40-80% of HR reserve), twice weekly. The primary outcome was peak oxygen consumption (VO2peak), secondary outcomes included 6-minute walk, functional lower extremity strength and health-related quality of life (Minnesota Living with Heart Failure, MLHF).

RESULTS: Repeated measures ANOVA revealed a significant time effect for VO2peak (P<0.001) with comparable improvement in each group (ET: 16.5±4.5 to 18.0±5.1 ml/kg/min, P=0.019; CT 18.6±6.1 to 20.6±6.4 ml/kg/min, P=0.008). Similarly, main effects were evident in both groups for 6-min walk (P<0.001) (ET: 465±86 to 521±83 m, P<0.001; CT 495±87 to 523±109 m, P=0.041, 30s sit-to-stand (P<0.001) (ET: 11±2 to 14±3 repetitions, P<0.001; CT 13±3 to 14±2 repetitions, P=0.082) and timed up-and-go (P=0.003) (ET: 7.1±1.3 to 6.1±1.0 s, P=0.008; CT 7.4±1.5 to 7.1±1.4 s, P=0.138). MLHF score improved greater (P=0.045) for ET (29±22 to 21±17) than CT (28±18 to 27±17).

CONCLUSION: When matched for heart rate to control for cardiovascular burden, ET was well tolerated in HFrEF patients and conferred similar benefits in fitness and functional capacity as CT, with a superior effect on health-related quality of life and tolerability. Eccentric cycle training is a novel and efficacious approach for clinical benefit in highly compromised HFrEF patients, who represent a challenge in terms of exercise prescription.

SEX-RELATED PROTEOMIC DIFFERENCES OF THE ATHLETE'S HEART

BARTA, B.A., BOTTLIK, O., RUPPERT, M., SAYOUR, A.A., SCHILLING, O., MERKELY, B., RADOVITS, T., OLÁH, A.
SEMMELWEIS UNIVERSITY

INTRODUCTION: Regular physical activity results in characteristic structural and functional changes in the heart, which are collectively referred to as the athlete's heart. However, the extent of exercise-induced left ventricular (LV) hypertrophy and functional changes show significant differences between men and women, the molecular background of which is not fully elucidated. The aim of this study was to provide a proteomic characterization of long-term, intense exercise-induced LV myocardial hypertrophy in a rat model, with a focus on sex-related differences.

METHODS: Our rats were divided into trained (FEx) and control female (FCo) as well as trained (MEx) and control male (MCo) groups. In the trained groups, athlete's heart was induced by swimming for 12 weeks. Myocardial hypertrophy was confirmed by cardiac ultrasound and functional adaptation by pressure-volume analysis. Proteomic measurements based on liquid chromatography-coupled mass spectrometry were performed on proteins isolated from our left ventricular samples.

RESULTS: Echocardiography and post-mortem myocardial mass showed significant LV hypertrophy in both sexes, which was more pronounced in female animals (tibial length normalized LV muscle mass: + 17.4% MEx vs. MCo, + 31.0% FEx vs. FCo). LV contractility has increased to the same extent in both sexes. Relative expression of 3074 proteins were determined by proteomics. There was a significant change in expression of 229 proteins in males and 599 in females compared to the level of same-sex controls. Based on our gene ontological analysis, physiological LV remodeling in females is characterized by increased expression of proteins in cellular respiration and fatty acid oxidation, whereas in males, proteins that bind to the actin cytoskeleton is primarily increased.

CONCLUSION: Our data suggests that physiological LV hypertrophy resulting from regular, balanced exercise is associated with sex-specific changes in the myocardial proteome. Our results contribute to the understanding of the development of physiological myocardial hypertrophy.

OP-PN31 Brain

EFFECTS OF LACTATE PRODUCED DURING EXERCISE ON BDNF ACTIVATION THROUGH MCT2 AND GPR81 IN THE HIPPOCAMPUS

KIM, K., AHN, N., LIN, M., LEE, G., KIM, Y.
KEIMYUNG UNIVERSITY

INTRODUCTION: The possibility that lactate released from muscle during exercise has an effect on the improvement of brain function has been suggested. This study analyzed the effect of lactate produced in muscle by high-intensity exercise through MCT2 and GPR81 to reduce brain function deterioration and protein expression of dementia-related substances in hippocampus.

METHODS: To confirm whether lactate increases the expression of MCT2 and GPR81, 16 rats (Sprague Dawley) were divided into saline injection group (n = 8) and lactate injection group (n = 8) as the first experiment, and saline and lactate were intraperitoneally injected for 2 weeks, respectively. As a secondary experiment, sedentary (n=15), medium-intensity (MIIT) (n=15), and high-intensity interval training (HIIT) (n=15) were performed with C56BL/6 mice for 4 weeks, while saline (n=5), MCT2 blocker (n=5) and GPR81 antagonist (n=5) were divided into groups that were injected intraperitoneally. Measurement items were analyzed for blood concentrations of lactate, BDNF, and β-amyloid by ELISA, and protein expression patterns of molecular biological variables including BDNF, MCT2, and GPR81 in EDL muscle and brain hippocampus were analyzed by western blotting.

RESULTS: Levels of lactate and BDNF in the blood were significantly ($p<0.05$) higher in the lactate-injected group than in the saline-injected group in the first experimental rat. In the mouse of the 2nd experiment, the exercise group was higher than the sedentary group in all conditions, and the HIIT group showed the most significant increase. Rat lactate-injected group showed significantly ($p<0.05$) higher protein expressions of MCT2 in the EDL muscle than the saline injection group, and BDNF and MCT2 protein expressions in the hippocampus were significantly higher than the saline injection group ($p<0.05$). Lactate protein expression in hippocampus and EDL muscles after exercise training in mice was significantly

($p<0.05$) higher in the exercise group than in the sedentary group, and the highest in the HIIT group. The expression of BDNF, MCT2, and GPR81 in hippocampus and EDL muscles was not significantly different between the sedentary, MIIT and HIIT groups under all conditions of saline, MCT-2 blocker, and GPR81 antagonist injection.

CONCLUSION: Activation of BDNF expression in hippocampus by lactate was confirmed, and the role of MCT2 as a messenger was confirmed in this process. However, injection of MCT2 blocker and GPR81 antagonist could not confirm the effect of blocking the effect of lactate produced in muscle on hippocampus BDNF protein expression during exercise. In addition, lactate produced during 4 weeks of exercise including high-intensity interval training could not clearly confirm the activation of BDNF in the hippocampus and the action of MCT2 and GPR81. This work was supported by the National Research Foundation of Korea (NRF) grant funded by the Korea government (MSIT) (2020R1F1A1072018)

LACK OF BRAIN GLYCOGEN CAUSES COMPENSATORY LIPID METABOLISM IN MOUSE DURING EXERCISE.

OZEKI, K., NAKAMURA, K., HATA, T., HIRAGA, T., TORMA, F., MIYAZAKI, T., OKAMOTO, M., DURAN, J., GUINOVART, J., SOYA, H.

UNIVERSITY OF TSUKUBA

INTRODUCTION: As the demand for oxygen and energy increases during exercise, it is essential for animals to regulate their metabolism in response. Hence, the central nervous system must monitor not only the heart and skeletal muscle, but also organs involved in energy metabolism, such as the liver and adipose tissue, in an integrated manner to efficiently regulate the supply of energy substrates(organ circle linking). Our previous results implied that lactate broken down from brain glycogen plays a role in metabolic regulation in the hypothalamus during exercise, but the details remain unclear. Transgenic mice that lack brain glycogen (Gys1Nestin-KO mice) exhibit brain dysfunctions, such as reduced cognitive function and long-term potentiation(LTP; Duran et al., 2013). So, we hypothesize that a peripheral metabolic adaptation supported by the brain-liver-adipose tissue axis may be compensating for energy shortages in neurons. Thus, we examined the dynamics of carbohydrate and lipid metabolism during exercise in GysNestin-KO mice.

METHODS: Gys1Nestin-KO (CKO) and littermate control mice(Gys1[cond/rec]Cre[-/-]; CON) (male; 11-13 weeks old) were subjected to incremental treadmill running. Ventilation threshold(VT) was calculated based on respiratory gases using the V-slope method(Beaver et al., 1985), a criterium for moderate-intensity exercise. In a single bout of treadmill running, they performed light(CKO: 6 m/min; CON: 8 m/min) and high intensity(CKO: 15 m/min; CON: 20 m/min) exercise for 30 min. All running speeds were determined based on VT. Carbohydrate and lipid utilization was calculated from respiratory gases. After running, blood and tissue samples(brain, liver and muscle) were collected to measure blood glucose and lactate, plasma BHB, lactate and BHB in the hippocampus and hypothalamus, and other metabolites.

RESULTS: During incremental treadmill running, VT and maximal running speed were significantly lower in CKO than CON. In a single bout of high-intensity treadmill running, the blood lactate of both CKO and CON was higher than for light-intensity exercise and sedentary, indicating reasonable running speeds. Carbohydrate utilization in CKO was lower than in CON during high-intensity exercise, and lipid utilization in CKO tended to be higher. In addition, plasma BHB in CKO was higher than in CON.

CONCLUSION: As in our previous findings(Matsui et al., 2017), the relatively lower VT and maximal running speed found in CKO implies that brain glycogen contributes to exercise capacity, suggesting that a lack of brain glycogen leads not only to cognitive decline but also to reduced endurance. The crux here is that we found lipid-predominant metabolism and high plasma BHB in CKO, suggesting that a decrease in lactate utilization in neurons is compensated for by increased liver-derived lipid utilization. The close regulatory mechanisms among the brain-liver-adipose tissue axis(Uno et al., 2006) appears to be responsible for the coordination of the energetic balance between brain and brawn.

AEROBIC EXERCISE DELAYS ALZHEIMERS DISEASE BY REGULATING MITOCHONDRIAL PROTEOSTASIS IN THE CEREBRAL CORTEX AND HIPPOCAMPUS

FANG, G.

CHINA INSTITUTE OF SPORT SCIENCE

INTRODUCTION: Alzheimers disease (AD), a form of dementia, mostly occurs in elderly individuals. The specific clinical manifestations are progressive cognitive dysfunction and memory decline. The pathological characteristics are the appearance of senile plaques in the brain and the formation of neurofibrillary tangles. An increasing number of studies have shown that mitochondrial dysfunction is closely related to the occurrence and development of AD. In recent years, studies have found that mitochondrial proteostasis is disrupted in the brains of AD patients, leading to mitochondrial dysfunction, which manifests as dysfunction of the mitochondrial unfolded protein response (UPRmt), mitochondrial autophagy, and mitochondrial protein import. Moreover, it has been gradually confirmed that an appropriate amount of exercise can effectively delay and ameliorate neurodegenerative diseases, especially AD. Therefore, in this study, we explored the effect and mechanism of aerobic exercise in improving mitochondrial proteostasis and cognitive function in APP/PS1 mice, to provide a new research direction for studying the ability of exercise to prevent and treat AD.

METHODS: Male APP/PS1 mice were randomly divided into the normal group (NG, n = 20) and activation group (AG, n = 20). The AG was fed nicotinamide ribose (NR), a mitochondrial proteostasis activator, once daily for 13 weeks. The mice in each group were randomly divided into a quiet control group and exercise group (n=10 mice each), yielding the normal control group (CNG), normal exercise group (ENG), active control group (CAG), and active exercise group (EAG). After adaptive training, the mice in the exercise groups were trained on an aerobic treadmill for 12 weeks, and behavioral tests were

conducted in the 13th week. All mice were isolated the cerebral cortex and hippocampus, then Quantitative Real-time PCR and Western blot analysis were performed.

RESULTS: In the Morris water maze test, compared with CNG, the latency was significantly reduced and the number of platform crossings was significantly increased in the CAG and ENG respectively. Compared with ENG, the latency was significantly reduced and the number of platform crossings was significantly increased in the EAG. Compared with CAG, the latency was significantly reduced and the number of platform crossings was significantly increased in the EAG. Compared with CNG, the activity of UPRmt and the level of mitochondrial autophagy were significantly increased, while the level of mitochondrial protein import was significantly reduced in the CAG and ENG. Compared with CAG, the activity of UPRmt and the level of mitochondrial autophagy were significantly increased, while the level of mitochondrial protein import was significantly reduced in the EAG. Compared with ENG, the activity of UPRmt and the level of mitochondrial autophagy were significantly increased, while the level of mitochondrial protein import was significantly reduced in the EAG.

CONCLUSION: Aerobic exercise can enhance the activity of UPRmt and the level of mitochondrial autophagy, inhibit mitochondrial protein import in the cerebral cortex and hippocampus of APP/PS1 mice by regulating mitochondrial proteostasis, thus improve cognitive function and delay AD.

PERIPHERAL BLOOD TNF-ALPHA LEVELS IN CHILDREN WITH ATTENTION DEFICIT/ HYPERACTIVITY DISORDER: EVIDENCE FROM A META-ANALYSIS

ZHAO, F.1, QU, S.1, FANG, Q.1, YUN, Y.2, ZHAO, X.1

*1 : BEIJING SPORT UNIVERSITY 2:TIANJIN UNIVERSITY OF SPORT *:CORRESPONDING AUTHER*

INTRODUCTION: Studies have shown that inflammation is associated with the pathogenesis of attention deficit hyperactivity disorder (ADHD). Abnormal inflammatory cytokine levels have been reported in patients with ADHD, but the results are inconclusive. To assess the relationship between peripheral cytokine levels and ADHD, this systematic review was conducted, followed by a meta-analysis of random controlled trials evaluating peripheral cytokine levels in children with ADHD.

METHODS: This study was reported in strict accordance with the PRISMA guidelines. Through a systematic search of five databases, a total of 3549 potentially eligible articles were identified in the initial search. Finally, 11 studies with 1406 participants (ADHD group: n = 673, healthy group: n = 733) were included in the meta-analysis. The data extraction content is: (a) basic study information: title, author, year; (b) basic participants information: age, gender, sample size, medication; (c) elements of risk of bias assessment; (d) outcome measures: cytokine levels in ADHD and control groups. Publication bias was assessed by inverted funnel plots and statistical bias was assessed using Eggers method. Sensitivity analyses were performed to test the robustness of pooled results by removing trials at risk of assessment bias. Random-effects models were used to synthesize effect sizes for the included studies due to high heterogeneity of participants, participant sampling methods and other factors. The quantitative synthesis of data was performed using Review Manager software and the continuous variables were expressed as weighted mean differences (WMD), with each effect expressed as 95% confidence intervals (95%CI).

RESULTS: The levels of some inflammatory biomarkers in the peripheral blood of children with ADHD are abnormal, and there are statistically significant differences with healthy children. Conducted on 11 studies (totaling n = 1406 children), this meta-analysis on peripheral inflammation biomarker showed that TNF-alpha levels in ADHD children significantly declined 0.69 mg/l (95% CI: 0.36 to 1.02 mg/l, 8 studies, n = 890, effect sizes Z = 1.28, p = 0.02; I2 = 97%; p for heterogeneity < 0.01). However, no differences for IFN-γ (4 studies, n = 486, effect sizes Z = 1.05, p = 0.29; p for heterogeneity < 0.01) were observed.

CONCLUSION: The declined TNF-alpha levels may indicate a specific pattern of biomarkers in ADHD. TNF-alpha may have certain value in the early diagnosis of ADHD, and further large-sample studies and high-quality methodological studies are needed to determine whether the above indicators can be used as biomarkers for the diagnosis of ADHD.

MICROARRAY SCREENING IDENTIFIES DYSREGULATED MICRORNAS LINKED TO PHYSICAL FITNESS IN ANOREXIA NERVOSA.

FERNANDEZ-DEL-VALLE, M., TÉLLEZ, E., PAGADOR, A.V., MORÁN, E., TEJEDOR, P., VALLADARES, P., COBO, A., BAOS, S., OLMEDILLAS, H., SUAREZ, L., ITURRIAGA, T., LAMBERT, C., RAYA, J., IGLESIAS, E.

UNIVERSITY OF OVIEDO, HEALTH RESEARCH INSTITUTE OF THE PRINCIPALITY OF ASTURIAS

Santiago, C., Sanjurjo, M.F., Martinez, M.

INTRODUCTION: Anorexia nervosa (AN) is a mental illness characterized by low recovery rates (50%) and the highest mortality rate (5-7%) among all mental disorders. Scattered research in AN shows a biological imbalance, altered body composition, and poor muscular health [1] coinciding with the period of greatest risk of relapse (six months after hospitalization). In this context, circulating microRNAs (miRs) emerge as ultra-specific biomarkers that regulate multiple signalling pathways linked to different pathologies. However, miRs relevance and connection to physical fitness (PF) recovery in AN are poorly understood. Given the importance of returning to healthy PF as part of the healing process in AN [2], understanding these relationships is key to assist professionals in exercise prescription management. The objective of our study was two-fold, to identify 1) abnormally expressed miRs in AN compared to healthy controls (HC) and 2) their association with PF.

METHODS: Patients were recruited after hospitalization and HC were matched by age and sex. A total of 10 samples were collected (5 AN and 5 HC). After centrifugation, plasma was separated and stored at -80 ºC until later use. Total RNA was extracted using the miRNeasy Serum/Plasma Advanced Kit (Qiagen), and samples were profiled with ThermoFisher GeneChip miRNA 4.0 array. PF was assessed [body composition (anthropometry) and muscular strength (handgrip and half-squat strength test)]. To compare miR expression means, T-student was performed with a FDR correction. Moreover, Principal Component (PC) Analysis (PCA) was performed for miR expression to reduce dimensionality, identify the global relationship of miRs with PF measurements, and to define groups (AN and HC) based on it.

RESULTS: The expression levels of 7 miRs were significantly overexpressed in AN compared to HC (PDR<0.05, log2 FC≥9.35): miR-629-5p, miR-500a-3p, miR-502-3p, miR-505-5p, miR-18b-5p, and two 199 family members (miR-199a-3p and miR-199b-3p). PCA explained the 57% of the differences between groups. Moreover, PCA logistic regression showed a significant negative correlation of the model and waist circumference (WC) and waist-to-height ratio (WtHR) (p = 0.034). Regardless of the differences in muscle strength between groups, no significant associations were found regarding handgrip and half-squat strength with PCs. Uncovering, therefore, a relationship between body composition and miR expression in AN.

CONCLUSION: We have identified for the first time the miR profile in AN. Negative correlations of overexpressed miRs with WC and WtHR, highlight the importance of a combined assessment for disease staging. Future studies on miR profile validation and exploring its association with PF and mental health (with larger samples) are essential to uncover the clinical value of miRs as biomarkers in AN.

INFLUENCE OF AN EVALUATIVE AUDIENCE ON CONSCIOUS MOTOR PROCESSING AND PERFORMANCE DURING A STOP-SIGNAL SOCCER PENALTY SHOOTING TASK

SULLIVAN, R.1, UIGA, L.2, MASTERS, R.S.W.3, ANSON, G.1, NIEUWENHUYS, A.1

1 UNIVERSITY OF AUCKLAND; 2 MANCHESTER METROPOLITAN UNIVERSITY; 3 UNIVERSITY OF WAIKATO

Introduction

The Theory of Reinvestment predicts that pressure can negatively impact performance of perceptual-motor skills by experts, due to conscious reinvestment of explicit knowledge about how to perform the skills (i.e., 'conscious motor processing'). A recent systematic review confirmed that performance pressure generally leads to an increase in conscious motor processing, however, there was insufficient evidence to conclude that pressure-induced increases in conscious-motor processing are associated with negative impacts on performance.

Methods

The current study directly addressed this issue by investigating effects of pressure on conscious motor processing and performance in a soccer penalty shooting task. Fifteen experienced soccer players performed two different versions of the task ('Go-only' vs. 'Stop-and-Go'), which allowed for more, or less, conscious motor processing to occur. In both cases, pressure was manipulated by means of an evaluative audience (audience vs. no audience). Conscious motor processing was assessed with the Movement Specific Reinvestment Scale (MSRS) and by means of a skill-focused dual-task. Measures of performance included movement times and penalty shooting accuracy.

Results

Analyses indicate that penalty shooting accuracy was lower in the Stop-and-Go than in the Go-only task context (p = .01). Presence of an audience did not cause participants to experience an increase in competitive anxiety, nor did it result in significant effects on conscious motor processing or penalty shooting performance. Post-hoc exploratory analyses identified trait reinvestment as a significant covariate. High reinvestors had significantly higher state MSRS scores than low reinvestors (p = .01), they were more accurate in their skill-focused dual-task responses in the go-only compared to the stop-and-go task (p = .04) and, unlike low reinvestors, they showed faster reaction times (p = .01) and greater stopping success (i.e., improved response inhibition) in the presence of an audience compared to no audience (p = .04).

Discussion

Findings indicate that in general, presence of an audience had no significant effects on conscious motor processing or penalty shooting performance. Players who scored high on trait reinvestment, however, exhibited faster reaction times and greater stopping success in the presence of an audience, suggesting that increased monitoring pressure – while not causing significant increases in state anxiety – may facilitate inhibitory performance in those players who tend to go about their skill execution in a deliberate and self-conscious manner. Future studies are required to consider the influence of trait reinvestment in examining the effects of pressure on conscious motor processing and performance.

COMPARISON OF EXTERNAL LOAD AND LOAD DISTRIBUTION BETWEEN A RESERVE TEAM IN A ONE-GAME WEEK MICROCYCLE AND ITS FIRST TEAM IN A TWO-GAME WEEK MICROCYCLE WITHIN AN ELITE PROFESSIONAL SOCCER CLUB

CARPELS, T., KEMI, O.J.

UNIVERSITY OF GLASGOW

INTRODUCTION: To successfully transition from the academy to the first team, academy soccer players need to be prepared optimally to deal with superior demands on the senior level. While academy teams commonly carry out one-game week microcycles, competitive senior teams regularly carry out two-game week microcycles during congested fixture periods with games every 3-4 days. This study aimed to be the first one to quantify and compare weekly external load and load distribution between a reserve team (RES) in a one-game week microcycle and a first team (FT) in a two-game week microcycle within the same professional soccer club.

METHODS: Between 2017 and 2020, 36 one-game week microcycles of RES players and 64 two-game week microcycles of FT players were analyzed from the same professional soccer club that competed in the Scottish Premier League and the Union of European Football Associations (UEFA) Europa League. FT players were subcategorized into starters (FTS; ≥90 minutes game time) and non-starters (FTNS; ≤45 minutes game time). Data was collected using global positioning measurements for the following variables: duration (min), total distance (TD; m), total high-speed distance (THSD; >19.8 km/h; m), high-speed distance (HSD; 19.8-25.2 km/h; m), sprint distance (SD; >25.2 km/h; m), number of sprints (number of efforts >25 km/h, ≥0.1 s), number of high-speed efforts (HS efforts, number of efforts >20 km/h, ≥0.1s), meters per minute (m/min) and high-speed meters per minute (HS m/min). For each group (RES, FTS and FTNS), external load was quantified for each day of their typical microcycle, and as a cumulative weekly load. Inter-group differences in cumulative weekly load, weekly load patterns and intra-group day-to-day load variability were statistically analyzed. Training monotony (TM) was quantified to assess intra-group within-week load variation.

RESULTS: Overall, weekly loads between RES players in a one-game week microcycle and FTS in a two-game week microcycle were similar, apart from significant differences in duration (8%, $p<0.0001$), TD (21%, $p<0.0001$) and HS efforts (16%, $p<0.005$). FTNS had the lowest cumulative weekly load for all parameters observed. Weekly load patterns of RES players were significantly different from FTS and from FTNS ($p<0.05$). TM was highest for FTNS for all parameters observed, apart from number of sprints.

CONCLUSION: Academy graduates, progressing from a one-game-week microcycle to a two-game week microcycle, need to be prepared optimally to cope with the overall weekly loads and the lack of complete recovery between games FTS face. However, when young players become part of the FTNS group where weekly loads are consistently lower (impeding aerobic and neuromuscular performance capacity) and TM is higher (indicating a limited training load variation with no progressive overloads), coaches are urged to exploit all opportunities to adopt effective loading strategies within the limits of two-game week microcycles to ensure their continuous development.

THE PHYSICAL DEMANDS DURING TRANSITIONS IN ELITE SOCCER: ANALYSIS OF POSITIONAL DIFFERENCES, THE NOVEL CONCEPT OF CLUSTERS, AND IMPLICATIONS FOR TRAINING DESIGN.

BORTNIK, L., RHODES, D.

UNIVERSITY OF CENTRAL LANCASHIRE

INTRODUCTION: Transitional activities (TA's) and high-pressure actions in soccer match play represent specific high-intensity blocks and include a high technical-tactical context within. Given that limited number of studies exist on the physical demands during transitions, gaining more knowledge in this area, might equip practitioners with additional tools to effectively replicate high-intensity periods in training. Hence, this study investigated physical match demands across different playing positions during transitional activities and analysed repeated activities during transitions.

METHODS: Data was collected using 10 Hz GPS units from 10 official matches including 23 elite soccer players of the 1st Polish Division (Ekstraklasa) in season 2020-21. The following positions were investigated: center backs (n = 4), fullbacks (n = 5), central defensive midfielders (n = 2), central attacking midfielders (n = 2), central midfielders (n = 2), wingers (n = 5), and attackers (n = 3). Match data reflected distances covered per minute (m·min-1): total distance (TD), high-speed running distance (HSRD, > 19.8 km·h-1), sprint distance (SD, > 25.2 km·h-1), as well as the number of high-intensity accelerations and decelerations (A+D, > 3 m·s-2; n·min-1). Total absolute and relative high-speed running and sprint distances were also quantified. Metrics were observed in relation to 4 TAs commonly observed in football matches. Positive Transitions (PT), Negative Transitions (NT), Fast Attacks (FA) and High-Pressure Activities (HP). Clusters of transitional activities (CTA) included two or more transitional activities that occurred within a period shorter than 61 secs.

RESULTS: A univariate analysis of variance revealed position-specific differences and elevated physical outputs across all variables. Significant effects of position were found for all metrics during transitional play (large ESs; $p < .001$). Central attacking midfielders showed higher TD (m·min-1), fullbacks covered highest SD (m·min-1) and wingers had the highest A+D (n·min-1) ($p \leq 0.05$). Center backs showed lower physical outputs compared to other positions but achieved highest A+D (n·min-1) during defensive transitions ($p \leq 0.05$). Attackers reached higher physical metrics during high pressure activities ($p \leq 0.05$). Transitional activities recovery period was found to be 108.5 ± 26.2 s, CTA recovery period was 25.7 ± 3.6 s, while CTA peak duration reached 53.3 ± 18.2 s.

CONCLUSION: Physical metrics are increased when observing transitional play. This study shows that players are exposed to repeated short, intermittent high-velocity actions together during contextualized peak intensity periods (transitions) in football, emphasizing the need to move away from 90min averages. Findings could inform coaching practices

and training programme design in elite soccer to prepare players for their position-specific role during peak intensity periods and reduce their risk of injury.

YOGA DOES NOT ATTENUATE SPEED, AGILITY AND CHANGE OF DIRECTION DEFICIT IN PROFESSIONAL SOCCER PLAYERS

PEREIRA, A.A., MONTEIRO, L.F., MADEIRA, R.B., ABEL, M.G.

UNIVERSIDADE LUSÓFONA DE HUMANIDADES E TECNOLOGIAS

INTRODUCTION: Yoga is an alternative athletic training methodology that may have a positive impact on the recovery of football players due to the physical and psychological impact on restoration processes [1,2,3,4]. However, there is concern that Yoga may reduce football performance due to decreases in rate of force production and agility due to extensive static stretching aspects of Yoga [5]. Indeed, acceleration, deceleration, and change of direction (COD) are critical skills in football performance [6,7]. However, there is limited research evaluating the impact of Yoga on football skill-related performance. Therefore, the purpose of this study was to evaluate the effect of Yoga on football related skills. We hypothesized is that football players undergoing additional Yoga training would not impact speed, agility and change of direction abilities, and therefore may provide a viable strategy to facilitate recovery.

METHODS: A convenience sample of professional football players (N=21; senior levels under-23 and B; Age: 19±1.89 yr; Height: 182.5±6.02 cm; Body mass: 75.55±5.69 kg from the 1st Portuguese Football League voluntarily participated and were randomly placed into either the Experimental (EG; n=11) or Control (CG; n=12)) group. Participants completed a running velocity (5, 10 & 20 m distances) test and agility (Zigzag test) test using photoelectric cells, before and after 12 weeks of Yoga training. The EG performed (2) 60 min sessions of Yoga per week following football training that were guided by an experienced certified Yoga instructor. Yoga techniques were selected and ordered according to the objectives of the study: pránáyáma (breathing techniques), ásana (psychophysical techniques), yoganidrá (relaxation), samyama (concentration, meditation, etc.). The CG completed the standard football training program only. Mixed factor ANOVA were used to evaluate main and interaction (group x time) effects. Effect sizes (ES) were calculated using partial eta squared (ηp2). The level of significance was set at $p<0.05$.

RESULTS: Both groups demonstrated significant improvements from pre to posttest in all variables ($p<0.05$). However, there were no group by time interaction effects for 5m ($F(1,16) = 0.597$, $p = 0.451$; $\eta p2 = 0.036$, Power = 0.11), 10m ($F(1,16) = 0.186$, $p = 0.672$; $\eta p2 = 0.011$, Power = 0.07), 20m ($F(1,16) = 2.535$, $p = 0.131$; $\eta p2 = 0.137$, Power = 0.32), zig zag ($F(1,16) = 1.387$, $p = 0.256$; $\eta p2 = 0.080$, Power = 0.20), and COD ($F(1,16) = 0.357$, $p = 0.558$; $\eta p2 = 0.022$, Power = 0.087) outcomes indicating that Yoga did not attenuate these performance metrics.

CONCLUSION: In conclusion, Yoga did not have a deleterious impact on running velocity, agility and COD deficit in football players and may thus provide players with a viable option to facilitate physical and psychological recovery during training.

TRAINING LOAD AND MATURATION MONITORING IN YOUTH SOCCER: DOES UNDERSTANDING THE DATA IMPACT COACHING PRACTICE?

THOMPSON, N.G.1,2, HUGHES, J.D.3, DE STE CROIX, M.B.A.1, ROBERTS, W.M.4

1UNIVERSITY OF GLOUCESTERSHIRE 2UNIVERSITY OF NORTHAMPTON 3CARDIFF METROPOLITAN UNIVERSITY 4UNIVERSITY OF WAIKATO

INTRODUCTION: Training load and maturation monitoring is a practice widely used within professional soccer academies to aid player development and reduce growth-related injuries (1). While data can be used to inform coach decision-making on planning training, and retain and release decisions, the process can be ineffective in a fast-paced academy environment (2). Therefore, it is unclear how coaches interpret and deploy training load and maturation data as part of their coaching practice. Thus, the aim of this study was to explore how youth soccer coaches construct knowledge and resultingly, implement training load and maturation monitoring into their practice.

METHODS: Eleven experienced professional youth soccer coaches from a range of elite player performance plan (EPPP) (3) category clubs (1-3) were purposively sampled based on their coaching experience (>5 yrs working within an academy environment), coaching qualifications (> FA level 2), and were currently working in the youth development phase (YDP) within their club. Semi-structured interviews were conducted, and coding was carried out using NVivo, until data saturation was achieved (4). An inductive, reflexive, thematic analysis was used to identify themes from the interviews.

RESULTS: Three higher-order themes were identified (coach learning, club environment, and coach behaviour), which revealed that coaches' knowledge was constructed by learning through informal and formal sources. However, this was only reported within clubs that fostered a multi-disciplinary and social learning environment. Consequently, coaches' knowledge influenced the implementation and deployment of training load and maturation data into coaching practice. Category 2 and 3 status coaches (with the exception of clubs with significant funding) reported a lack of human resources, poor knowledge sharing, and limited communication between coaches/sports scientists as a barrier to using training load and maturation monitoring data.

CONCLUSION: Coaches and clubs of category 1 status fostered a multi-disciplinary, social learning environment that developed coaches' knowledge and use of training load and maturation monitoring as part of their practice. However, category 2 and 3 coaches reported a lack of human resources, knowledge sharing, poor communication of training load and maturation monitoring practices. Future research should aim to develop a coach learning framework for training load

and maturation monitoring, that can be used within resource-limited clubs, that are unable to facilitate a multi-disciplinary and social learning environment.

AUTOMATED IMU-BASED TRAINING LOAD MONITORING IN BEACH VOLLEYBALL

STROTKÖTTER, C.1, GROH, B.2, PRABHAKAR RAO, A.1, KAARTINEN, N.3, KERN, A.3, PFEIFFER, M.1

1. JOHANNES GUTENBERG UNIVERSITY MAINZ, 2. BEN'S CONSULTING & DATA ANALYTICS, 3. KAASA SOLUTION GMBH

INTRODUCTION: Optimizing training load management is of great importance in beach volleyball to elicit elite performance and avoid injuries. Due to the sandy ground surface and the structure of the game (3-contact rule, two persons per team), in addition to jumps, it is primarily short sprints, fast lateral movements, and dig movements with direct follow-up action that determine the degree of stress and load on the players [1]. Therefore, we developed a practical and cost-effective monitoring approach to automatically identify and quantify relevant events and ultimately enable an informed training load and recovery management.

METHODS: The developed system consists of an IMU-based event detection (ED) as well as action classification (AC). Kaasa Data Collector application was used to collect raw data from standardized training sessions (n=7, male German national level) using six channels of data (3D accelerometer + 3D gyroscope) from three synchronized sensors (Movesense IMU, left/right upper arm and chest strap, 104Hz each). Basic techniques (set, pass, service), jumps (jump service, attack, block) and defensive actions (defense, digs, sprints) were tagged in real time with hot buttons and reviewed by video.

ED: two-stage sliding window approach (0.5 sec); stage I: suprathreshold L2-normalized values of accelerations and angular velocities of the sensor on the hitting arm (right arm); stage II: suprathreshold upward rotations of the hitting arm and supporting arm.

AC: classification of eight specific actions (serves with and w/o jumping, reception, defense/digs, sets, attacks, and blocks with and w/o preliminary movement) using data of -1.5/+0.5 sec around automatically detected events. (a) Normalized feature vectors (statistical: min, max, mean, etc., specific: rotation during the event, etc.) were classified with Naive Bayes, kNN and C4.5 Decision Tree; CV / LOSO-CV was performed by open-source software ECST [2]. (b) raw data was classified using a sequential neural network model (Tensor flow light, 70% training, 15% test, 15% validation).

RESULTS: ED: 1481 automatically detected events (1040 TP / 441 FP; 1346 manually annotated actions); recall: 77.3% (306 FN) and precision: 70.2%; AC: accuracy (a) 75.4% to 94.7% and (b) 90.1%.

CONCLUSION: Traditional classification approaches as well as machine learning methods were used successfully to automatically detect and classify beach volleyball specific movements. Machine learning appears to be superior compared to traditional approaches. However, recall and precision of ED as well as accuracy of AC still need to be improved further to effectively support training load management and recovery of athletes.

RECOGNIZING KICKBOARD AND SKATEBOARDING BEHAVIORS USING WEARABLE ACTIVITY TRACKER DEVICES

TRIPETTE, J., ORIHARA, A., AUBERT-KATO, N., NAKAGATA, T., OHTA, Y.

OCHANOMIZU UNIVERSITY

INTRODUCTION: Contemporary wearable activity tracker devices and smartphones are able to predict various physical activity parameters. The estimation of daily energy expenditure often relies on data provided by the accelerometer, gyroscope and altimeter sensors. Software that accurately estimates energy expenditure commonly integrates a sequence of 2 algorithmic operations. The first operation consists in allocating data to some activity-specific classes. The second operation consists in intra-class regression procedures to make quantitative estimations of the energy expenditure. Many activity recognition algorithms have been proposed to classify a wide range of physical behaviors. Kickboard and skateboarding activities recently became popular among people with active commuting habits. These activities can sometimes make significant contributions to daily energy expenditure. The present study aims at developing a kickboard and skateboarding activity recognition algorithm for wearable activity tracker devices and smartphones.

METHODS: Ten subjects performed the 9 following activities: sitting, standing, walking on a flat surface, walking upstairs, walking down stairs, running, bicycle, kickboard and skateboarding. They wore 2 multi-sensor wearable devices, one at the wrist and one in the trouser back pocket, where activity trackers and smartphones are commonly put. Raw data from

the accelerometer, gyroscope and air pressure sensors were collected for each activity during 10 minutes at a sampling rate of 100 Hz. A 10-second sliding window analysis allowed extracting a total 211 data features in both the time and frequency domains. The reduced dataset was split into training and test samples using a subject-wise assignment method. Random forest classifiers were trained to recognize activities. The resulting activity recognition algorithms were evaluated on the test sample.

RESULTS: Models built with the back pocket sensor data predicted the activities with an average success of 84%. The "kickboard" and "skateboarding" activities had a sensitivity of 73 and 55% respectively with the large majority of the confusion occurring between these two behaviors. Grouping the two activities into one single "push-push-glide" activity class raised the performance to 88%, and the "push-push-glide" class showed a sensitivity of 98%. Models built with the wrist sensor data predicted the activities with a balanced average success of 86%. The "kickboard" and "skateboarding" activities had sensitivities of 95 and 92%, respectively. Models integrating two classification layers to allocate data to a "push-push-glide" activity class before making classifications for "kickboard" and "skateboarding" separately were 100% sensitive to these two behaviors.

CONCLUSION: Automatic recognition of kickboard and skateboarding activities using data collected by wearable activity trackers is feasible. Integrating this operation to activity tracker software would increase the accuracy of energy expenditure estimations.

STUDY ON THE FEASIBILITY OF BUILDING AN UNSUPERVISED LOCOMOTION CHARACTERISTICS VARIABLE-BASED ACWR PREDICTION AI MODEL

CHOI, S.H.1, JEON, J.H.1, SON, M.J.1, YOON, S.W.2, SONG, Y.G.3, BANG, J.4, LEE, Y.H.5

1JEIOS; 2SEOUL WOORICARD WOORI WON PRO VOLLEYBALL CLUB; 3PUKYONG NATIONAL UNIVERSITY; 4KOREA UNIVERSITY; 5SEOUL NATIONAL UNIVERSITY

INTRODUCTION: The acute:chronic workload ratio (ACWR) is an essential regulator of performance and injury risk in high-intensity team sports. However, this method requires at least 7 to 28 days of data accumulation, and the results are only reasonable if the data is measured at regular intervals. Therefore, this study aims to determine the feasibility of building AI modeling with locomotion characteristics and unsupervised learning variables to build an accurate ACWR prediction model.

METHODS: For 14 Korean professional volleyball players, an LPS sensor (Catapult ClearSky T6, Catapult Sports, Australia) was attached to their chest during the game and practice games, and the exercise load of explosive actions (left, and right turns, jumps, accelerations, and decelerations) was measured. In addition, locomotion characteristics were measured on the morning of the game with a MotionCore device (MotionCore, JEIOS, Korea). The locomotion characteristics consisted of unsupervised learning categories Motor Identity (aG, aa), Tele-signal (ID), and Entropy. Multiple regression analysis was conducted to predict the explosive volleyball action workload AL (Acute workload) and CL (Chronic workload) from the raw data. Then, based on the unsupervised learning variables comprising AL and CL, the measured data of volleyball players were considered 174 nodes, and k-means clustering was performed to identify the optimal clusters. An independent t-test was performed on the unsupervised learning variables characterizing the locomotion characteristics variables between the specified groups.

RESULTS: The explanatory power of the multiple regression model for predicting AL and CL based on explosive volleyball action of unsupervised learning variables of locomotion characteristics was $R^2 = 0.792$ ($adjR^2 = 0.765$) and $R^2 = 0.875$ ($adjR^2 = 0.856$), respectively. Afterward, k-means clustering analysis showed that both AL and CL formed two clusters. In the independent t-test results, the unsupervised learning variables of ALs locomotion characteristics were aG (t-test: -8.12, $p < .001$, ES: -1.27), aa (t-test: 6.61, $p < .001$, ES: 1.04), entropy (t-test: -9. 69, $p < .001$, ES: -1.52), and CL was significantly different from aG (t-test: -10.44, $p < .001$, ES: -1.66) and ID (t-test: 2.84, $p < .001$, ES: 0.45).

CONCLUSION: The ACWR component, AL, was characterized by differences between clusters in aG, a 3-axis acceleration feature, aa, a 3-axis gyroscope feature, and entropy, which indicates the difference in the amount of information between the left and right sides. CL showed that ID, the distance feature of the center of gravity during locomotion performance, differed between clusters (aG was also significant). These unsupervised variables exhibited different characteristics between the divided clusters, suggesting that unsupervised variable modeling approaches for ACWR prediction have the potential to build further, more detailed AI models.

RELIABILITY AND VALIDITY OF THE COUNTERMOVEMENT JUMP HEIGHT ON THE POLAR VANTAGE V2 SPORTS WATCH WITH HIGH PERFORMANCE FEMALE ARTISTIC GYMNASTS

HOFMANN, E.1, PROTTE, C.1,2, SCHÄRER, C.1

1 SWISS FEDERAL INSTITUTE OF SPORT MAGGLINGEN SFISM; 2 CENTER FOR KIDNEY, HYPERTENSION AND METABOLIC DISEASES HANNOVER

INTRODUCTION: Under controlled measurements regarding countermovement and peak power (PP), the jump height of the Countermovement Jump (CMJ) may be an appropriate parameter to evaluate neuromuscular fatigue. It is proven to indicate both acute as well as accumulated fatigue based on changes to baseline values (1, 2, 3). Polar Electro conceived the "Leg-Recovery-Test" on their Vantage V2 sports watch (V2) to track changes in jump heights and consequently generate statements about fatigue of the lower extremities. This study aimed to evaluate the validity and reliability of the described test in comparison with a force plate (FP), to make further assumptions about neuromuscular functions.

METHODS: Ten elite female artistic gymnasts (age: 17.2 ± 2.5 y) performed the "Leg-Recovery-Test" (three consecutive CMJs) three days in a row on a portable FP (CYCESS medical, SPSport, Österreich) wearing the V2. In the middle and at the end of the study period, two additional days of CMJ testing took place for validity calculations. Regression model of Hopkins was used along with the coefficient of determination (r2) to test the validity against the FP (4). Intra-class correlation coefficient (ICC) and coefficient of variation (CV) were calculated for intra-session and inter-session reliability as well as the standard error of measurement (SEM) for the latter one (2, 4, 5).

RESULTS: After applying the regression model on vertical jump heights of the V2, about 78% could be determined by the FP (r2 = .78; CV = 4.70%) (4). Inter-session reliability displayed high values within the V2: ICC = .82; CV = 4.8%; SEM = 1.95 cm and the FP: ICC = .88; CV = 3.9%; SEM = 1.62 cm. Reliability of single trials (intra-session) of the V2 was low to moderate: ICC = .58, CV = 8.7% (Day1); ICC = .68, CV= 6.9% (Day2) and ICC = .43, CV = 9.0% (Day3), but high to very high for the FP: ICC = .87, CV = 4.3% (Day1); ICC = .93, CV = 3.4% (Day2) and ICC = .86, CV = 4.1% (Day3).

CONCLUSION: In highly trained gymnasts the "Leg-Recovery-Test" demonstrated acceptable validity and reliability within the mean CMJ height of three consecutive jumps, but less within single trials. Compared to existing literature, CVs of the FP were within the expected values of < 4% (3) and means of V2 fell into expectations around 6% as well (6). Hence, assuming familiarity of execution of CMJ, the V2 can be partly considered as plausible tool for practicable daily use to assess changes in jump heights, that could be further investigated for relationships with neuromuscular fatigue.

REMOTE ASSESSMENT OF PELVIC KINEMATICS DURING SINGLE LEG SQUAT USING SMARTPHONE SENSORS: BETWEEN-DAY RELIABILITY AND IDENTIFICATION OF ACUTE CHANGES IN MOTOR PERFORMANCE

DEVECCHI, V., SAUNDERS, M., GALAIYA, S., SHAW, M., GALLINA, A.

UNIVERSITY OF BIRMINGHAM

INTRODUCTION: The biomechanical evaluation of pelvic movements during a single leg squat (SLS) often requires costly equipment which precludes its wider implementation out of the lab in real-world environments. To overcome such limitation, smartphone sensors could be a viable option to remotely measure pelvic movements, but their measure properties need to be tested before recommending their use in ecological settings. Hence, this study aimed to 1) assess the between-day reliability of pelvic kinematics measured remotely, when participants perform SLS at home using their own smartphones; and 2) identify changes in pelvic kinematics during an endurance task.

METHODS: A remote assessment was conducted on thirty-three healthy young adults on two separate days. Participants collected kinematic data using their personal smartphones positioned on their lumbosacral area. Pelvic orientation including tilt, obliquity and rotation, as well as acceleration signals along the three axes, were collected during three sets of seven SLS and an endurance task of twenty consecutive SLS. Time- and frequency-domain features related to pelvic orientation and balance/smoothness of movement were extracted. Between-day reliability was assessed using Intraclass Correlation Coefficient (ICC2,k), Standard Error of Measurement, and Minimal Detectable Change. Pelvic kinematics changes during the endurance task and between-day bias were assessed using T-tests.

RESULTS: Good to excellent reliability (ICC2,k ≥ 0.79) was found for measures of pelvic orientation and frequency features of the acceleration signals, with the latter showing a shift of the power spectrum to lower frequencies ($p<0.05$) on the second day suggesting better balance performance or smoother movements. During the fatiguing condition of the endurance task, participants exhibited an increase in contralateral pelvic drop and rotation ($p<0.05$), as well as a more irregular frequency content (i.e., spectral entropy, $p<0.05$).

CONCLUSION: The results of this study indicate that measures of pelvic kinematics and acceleration obtained remotely using participants' smartphones during SLS are reliable between days. Also, smartphone sensors can detect alterations in motor control like contralateral pelvic drop during an endurance task. These findings contribute to building evidence for the use of smartphones as a low-cost, objective assessment of movement strategies and to monitor exercise performance remotely.

LOCALIZATION AND TRAJECTORIES OF ATHLETES ON INDOOR ENVIRONMENTS

JUÁREZ, A.1, FORTES, S.1, BAENA, C.1, BAENA, E.1, COLIN, E.2, BARCO, R.1

1 DEPARTAMENTO DE INGENIERÍA DE COMUNICACIONES, UNIVERSIDAD DE MÁLAGA, SPAIN 2 EFREI RESEARCH LAB, EFREI, FRANCE

INTRODUCTION: The position, the velocity and the trajectory of the players have become essential data in order to assess the work load. These data are still not widely measured by current systems, especially at indoors and outside the high-competition. To address this, the present paper focuses on the athlete positioning for indoor sports, analyzing the capabilities of existing technologies.

With regard to the positioning and trajectory of athletes, systems are mainly based on vision or on wearables. Computer vision systems are expensive on hardware as well as on computation capabilities. For indoor positioning, there is not yet any universal GPS-like solution. Indeed, the presence of multi-paths, the importance of None Line-of-Sight (NLoS) visibility, the fading of signals due to the presence of obstacles, are all characteristics that make localization particularly complex.

Among wireless localization technologies, UltraWide Band (UWB) is well suited for high-accuracy applications and commercial products can reach centimeters in well controlled environments. UWB is a radio technology for short-range communications (less than 100 meters). This technology works in the frequency range between 3.1 and 10.6 GHz, with a large bandwidth and low power consumption. In indoor localization, UWB has a strong resistance against multi-paths. Nevertheless, this localization system has a high cost for high-scale deployments.

As a result, the proposed solutions are optimized for specific environments and scenarios of use with an accuracy that varies from a few tens of centimeters to a few meters. The aim of this paper is to review the classical techniques used for catching, in real-time, the position and the trajectory of the athlete on indoor sports, which means a reliable accuracy around tens of centimeters for a moving target (the athlete).

METHODS: Aspects addressed are the identification of the field's requirements and assessment of applicable localization technologies in terms of their capability to cope with such requirements. A complete wearable system for indoor localization based on UWB is defined, implemented and evaluated in a real-world scenario. Tests have been performed in a real environment, in the sports arena.

RESULTS: After processing the data, it has been obtained that the test subject has made the route it was obtained that the player completed the course with an average speed of 13 m/s and a and a maximum of 127m/s2.

CONCLUSION: After analyzing the main technologies and conditions associated to the implementation of positioning techniques for indoor sports, the present work developed a low-cost UWB-based indoor localization system. Its evaluation shows the capabilities of the approach to support players localization for its intended application. The low price and portability of this approach paves the way for future implementations affordable enough for use by modest professional teams and even amateurs, allowing for detailed monitoring and analysis of players and team performance.

HEART RATE MONITORING DURING GOLF PUTTING TO ESTIMATE MENTAL LOAD

GIELEN, J.

KU LEUVEN

INTRODUCTION: It is common knowledge that many factors, including physical activity and mental stress, elevate the heart rate from its resting baseline. Quantifying mental loads during training and competition gives coaches and athletes a tool to make informed decisions about the training process. Even though the physical load of golfing cannot be neglected, it is often referred to as a mental game. When the skill level between golf players is comparable, the mental toughness will be decisive. Moreover, the mental load is not a constant. In theory, all shots have an equal weight on the score, but missing or making certain shots makes a world of difference in the head of the player. This research investigates whether heart rate (variability) monitoring provides insights in the mental part of golfing.

METHODS: 7 youth golfing athletes (ages 14 – 17; 1 female) have participated in this study. Athletes have performed the test protocol multiple times, resulting in a total of 16 test measurements. The goal of the test is to score five consecutive putts from 3m distance to the hole. Ten different positions are marked in a circle around the hole. With each attempt, the athlete takes the shot from a different position to make sure that no two consecutive putts are the same. The exercise is self-paced, meaning that the golfers take as much time as they want to perform the shots and they only finish when scoring five consecutive times. The average duration of the exercise was 45 minutes. Throughout the exercise, a Zephyr Bioharness 3.0 is worn to continuously measure heart rate (variability) and accelerometer-based physical activity at 1 Hz. Video footage is used to label the putts as 'made' or 'missed' and add timestamps to these events. Unpaired t-testing of pre-shot heart rate (variability) was performed to identify differences between successful and failed putts.

RESULTS: Five out of seven athletes show significantly increased heart rate levels (on average +6.2 bpm) during their preparatory routine when the previous putt was a success. The heart rate levels did not change significantly when the previous putt was missed and they essentially start over again. The other two athletes did not show any changes in the heart rate levels, regardless of the putting results. Interestingly, these two athletes are labelled by the coaches as being the most 'stress-tolerant'. In the case that heart rate levels were elevated, the physical activity levels were not.

CONCLUSION: Our results show how heart rate monitoring in a specific golf context provides coaches with insights about the pre-shot mental load during putting. Additional data collection and analyses will be performed throughout February 2023 to June 2023.

CAN ACUTE LIGHT-INTENSITY EXERCISE REDUCE NEGATIVE MEMORIES?

NAKAMURA, M.1, KAWATA, Y.1,2,3, SHIBATA, N.4, OTA, T.1,2,3

1. JUNTENDO UNIVERSITY, 2. JUNTENDO UNIVERSITY, 3. JUNTENDO UNIVERSITY, 4. JUNTENDO UNIVERSITY TOKYO KOTO GERIATRIC MEDICAL CENTER

INTRODUCTION: Remembering unnecessary negative information can lead to depression and anxiety disorders [1]. Recent evidence suggests that exercise modulates memory function. Moreover, our research suggests that acute high-

intensity exercise may reduce negative memories. However, high-intensity exercise is a heavy physical and mental burden, and it is associated with injury risk. Thus, it is necessary to demonstrate whether negative memories can be reduced by a lower exercise intensity, which can be performed by anyone without burden. Therefore, we focused on light-intensity exercise, which is less burdensome, to examine whether acute light-intensity exercise reduced negative memories.

METHODS: Twenty-eight healthy adults (14 men, 14 women; M age = 21.89 years, SD = 1.93 years) completed a 20-min intervention (rest and light-intensity exercise conditions). The rest condition required the participants to sit quietly for 20 min with their eyes open. The light-intensity exercise condition required the participants to perform 20 min of cycling with a 30-35% heart rate reserve. In the memory task performed two days after the intervention, participants were required to recall the images (neutral and negative) that had been presented before each intervention. We determined emotional memory assessment as the hit rate and sensitivity index (d') based on the signal detection theory. We performed 2 (conditions: rest, light-intensity exercise) × 2 (valences: neutral, negative) repeated measures ANOVA separately for men and women.

RESULTS: The results revealed a significant main effect of valence for men and women and a higher hit rate for negative than for neutral images [men: $F(1, 13) = 30.49$, $p < .001$; women: $F(1, 13) = 17.08$, $p = .001$]. However, there were no significant main effects of condition [men: $F(1, 13) < 0.01$, $p > .05$; women: $F(1, 13) = 0.45$, $p = .51$] or interactions between condition and valence [men: $F(1, 13) = 2.28$, $p = .15$; women: $F(1, 13) = 0.08$, $p = .78$] for men and women. Furthermore, d' revealed a significant main effect of valence for men and women, and a higher sensitivity for negative than for neutral images [men: $F(1, 13) = 22.03$, $p < .001$; women: $F(1, 13) = 8.49$, $p = .01$]; however, there were no significant main effects of condition [men: $F(1, 13) = 0.45$, $p = .51$; women: $F(1, 13) = 0.90$, $p = .36$] or interactions between condition and valence [men: $F(1, 13) = 0.26$, $p = .62$; women: $F(1, 13) = 1.63$, $p = .22$] for men and women.

CONCLUSION: These findings suggest that negative information is more likely to be remembered and discriminated than neutral information. However, negative memories may not be reduced by acute light-intensity exercise.

IMPAIRED SLEEP QUALITY WAS RELATED TO MENTAL HEALTH DISORDER IN FEMALE LONG-DISTANCE RUNNERS

HIROMATSU, C., LIN, C., GOTO, K.

RITSUMEIKAN UNIVERSITY

Athletes have higher risk of sleep disturbances with impaired sleep quality than the general populations (Knufinke et al. 2018), even though sleep plays an important role in recovery (Vitale et al. 2009). It has also been reported that sleep deprivation is associated with facilitated negative mood status (Blumert et al. 2007) and iron deficiency (Neumann. et al. 2020). However, the relationship between sleep and psychological aspects or physiological indicators of iron status in female long-distance runners remains unclear.

PURPOSE: We evaluated the relationships between mental health and both sleep quality and serum ferritin level in female long-distance runners throughout a competition season.

METHODS: Seven-teen female college long-distance runners were evaluated serum ferritin level (an indicator of iron status). They also completed questionnaires related mental health and sleep 3 times (July, September and November) during 5 months. Mental health was evaluated using the Center for Epidemiological Studies Depression Scale (CES-D) and Depression, Anxiety and Stress Questionnaire (DASS-21). Sleep quality was evaluated by Pittsburgh Sleep Quality Index (PSQI). RESULTS: At all time points, PSQI scores were significantly correlated with CES-D scores ($P = 0.01$ in July, $P < 0.001$ in September, $P = 0.012$ in November), DASS anxiety scores ($P = 0.005$ in July, $P = 0.007$ in September, $P = 0.02$ in November) and DASS stress scores ($P = 0.003$ in July, $P = 0.002$ in September, $P = 0.006$ in November), indicating the relationships between lowered sleep quality and aggravated mental statuses. Serum ferritin levels significantly correlated with DASS anxiety scores ($P = 0.015$) and DASS stress scores ($P = 0.045$) in July, but the relation was not observed in September and November. Also, no significant relationship was found between PSQI scores and serum ferritin levels.

CONCLUSION: These findings suggest that impaired sleep quality is associated with the scores of depression, anxiety, and stress throughout a competition season in college female long-distance runners.

THE EFFECT OF A SUPERVISED 9-WEEK EXERCISE PROGRAM ON SELF-REPORTED DEPRESSION, ANXIETY, AND STRESS IN COLLEGE STUDENTS

SCHAERZ, S., ONTKEAN, N., PURKIS, N., ROBDRUP, D., AGUILAR RAMIREZ, D., QUESADA, R., GALLAGHER, D., VOGEL, C.
LETHBRIDGE COLLEGE

INTRODUCTION: The prevalence of depression, anxiety, and stress in college students is on the rise [1], underscoring the need for more mental health services and resources on college campuses [2]. Research has shown that exercise can protect against depression, anxiety, and stress [3]. Accordingly, our objective was to determine whether a 9-week exercise program protects against depression, anxiety, and stress in college students.

METHODS: Fifteen participants ([EXS] 8 females, age = 25.0±11.0 years, VO2max = 31.5±8.0 mL·kg-1·min-1) attended nine weeks of supervised exercise classes three times per week for 50 minutes, while sixteen acted as control participants ([CON] 5 females, age = 22.4±6.0 years, VO2max = 35.6±9.4 mL·kg-1·min-1). We measured pre- and post-intervention depression, anxiety, and stress using the 21-item Depression, Anxiety, and Stress Scale (DASS-21 [4]). We conducted a one-way between groups ANCOVA to compare post-intervention DASS-21 scores with sex and pre-intervention DASS-21 scores set as covariates in the analysis.

RESULTS: After adjusting for sex and pre-intervention DASS-21 scores, we found that post-intervention depression (EXS: 5.1±5.8, CON: 5.4±4.3, p = 0.413), anxiety (EXS: 4.3±3.4, CON: 3.9±3.0, p = 0.836), and stress scores (EXS: 5.7±4.3, CON: 6.3±4.0, p = 0.641) did not significantly differ between EXS and CON.

CONCLUSION: Contrary to similar research [5], we found that a 9-week exercise program did not significantly affect college students' depression, anxiety, and stress scores. Future exercise-based, intervention studies might consider targeted adjustments to exercise program parameters (e.g., duration, type, intensity), incorporating larger samples, and finding ways to promote program adherence.

DETERMINANTS OF RECOVERY BEHAVIOURS IN OLYMPIC SWIMMERS: A QUALITATIVE INVESTIGATION USING THE REASONED ACTION APPROACH

POIGNARD, M.1, BOSQUET, L.2, JONCHERAY, H.1, PLA, R.3, RUFFAULT, A.1,4
1 FRENCH INSTITUTE OF SPORT, INSEP, FRANCE ; 2 LABORATOIRE MOVE, FACULTÉ DES SCIENCES DU SPORT, UNIVERSITY OF POITIERS, FRANCE; 3 FRENCH SWIMMING FEDERATION; 4 UNIVERSITY OF LIÈGE, BELGIUM

Background

An adequate management of training and recovery allows swimmers to continuously achieve high performance and avoid illness and injuries. In the few weeks prior the Olympics Games, swimmers have a taper phase of training, during which recovery is one of the most important factors to reduce the cumulative training-induced fatigue and improve performance. Although swimmers' recovery behaviours have been recently described, the barriers and levers for their adoption have not been studied based on behaviour change theories. Using the reasoned action approach, we aimed to explore the sociocognitive determinants of swimmer's recovery behaviours.

Methods

Semi-structured interviews were conducted to explore the determinants of the adoption of recovery strategies. 14 French swimmers were interviewed among the 42 eligible swimmers who participated in the Summer Olympic Games in 2012, 2016, and/or 2021. The interviews were analysed using thematic analysis. The main themes and codes were first generated inductively and then mapped to the Reasoned Action Approach.

Results

Swimmers reported a daily use the bedrock of recovery (sleep, hydration, nutrition) and adopting various recovery routines. The number and variety of recovery techniques adopted were higher among swimmers who participated in Tokyo 2020. Despite negative attitudes (e.g. painful, unpleasant) reported towards the adoption of some recovery techniques, this does not prevent swimmers from considering that recovery is efficient and necessary to optimize subsequent training

or competition. The approval of swimmer's coaches was reported to be important and positively influencing the adoption of recovery strategies. Access to recovery equipment or resources was seen as both a barrier and an enabler as swimmers have access to a physiotherapist but had to adapt to their availability and get to their office. Swimmers describe that knowledge and perceived effectiveness of a recovery technique strongly influenced its adoption.

Discussion

Analysis of the semi-structured interviews provided insight into the specific determinants of swimmer's recovery behaviours. The present study could be of interest when designing theory and evidence-based behaviour change interventions to improve elite swimmers' adoption of recovery strategies. For example, targeted interventions for swimmers could include monitoring of swimmers recovery behaviours combined with feedbacks on performance self-efficacy or self-reported measures of perceptual recovery outcomes.

IMPACT OF PSYCHOLOGICAL PROCESSES ON MENTAL HEALTH SYMPTOMS IN COMPETITIVE ATHLETES: A CROSS-SECTIONAL STUDY BASED ON THE TRANSDIAGNOSTIC APPROACH

VALVERDE, S.1, HAMONNIERE, T.2, REGNAULD, C.3, KUENTZ, J.1, SOCQUET-DAGOREAU, C.1, CAUMEIL, B.1, RUFFAULT, A.1

1LABORATORY "SPORT, EXPERTISE, AND PERFORMANCE" , FRENCH INSTITUTE OF SPORT , FRANCE, 2RESEARCH UNIT CLIPSYD, UNIVERSITÉ PARIS NANTERRE, FRANCE, 3MEDICAL CENTER, INSEP, FRANCE

Introduction: Mental health disorders can impair performance and lead to injuries [1]. Transdiagnostic psychological processes are associated with the development of mental disorders [2]. The transdiagnostic approach of mental health posits that motivational, emotional, cognitive, meta-cognitive, and behavioral processes are common to several mental health disorders. In the general population as well as in competitive sports, women tend to show higher prevalence of mental health disorders [1]. The aim of the this study was twofold: (a) to evaluate the association of transdiagnostic psychological processes with mental health disorders in adult athletes practicing their sport at a competition level, and (b) to explore gender differences in mental health symptoms and transdiagnostic psychological processes.

Methods: A total of 159 competitive adult athletes aged between 18 and 40 years old (44% female; mean: 24.2 ± 4.88 years old) participated in this cross-sectional study. Participants were invited to fill in psychometric questionnaires to evaluate mental health symptoms, motivation to practice their sport, emotional competences, self-efficacy, ruminations, meta-cognitive beliefs, and impulsive and perfectionist behaviors. Correlational tests were performed to evaluate the association between mental health symptoms and transdiagnostic psychological processes, and mean group comparison tests were used to explore gender differences.

Results: Mental health symptoms were significantly and positively correlated with extrinsic regulations of motivation, ruminations, meta-cognitive beliefs, and impulsive and perfectionist behaviors; and significantly negatively correlated with emotional competences and self-efficacy. Female athletes showed significantly higher scores of mental health symptoms, ruminations, meta-cognitive beliefs, and impulsive and perfectionist behaviors; and significantly lower scores of emotional competences and self-efficacy.

Discussion: The results of the present study showed that transdiagnostic psychological processes were associated with mental health symptoms; and that female competitive athletes were more likely than males to experience mental health symptoms in addition to lower emotional, cognitive, meta-cognitive and behavioral processes. These results are in line with previous findings in clinical psychology, and allow investigating the risk mental health issues through psychological processes (including some specific measures to the context of sport). Further investigations may focus on the identification of the most relevant processes to estimate a risk of mental health disorder in competitive athletes.

ASSESSING AFFECTIVE RESPONSES IN STRETCHING EXERCISES

BASTOS, V., HENRIQUES, L., TEIXEIRA, D.S.

UNIVERSIDADE LUSÓFONA DE HUMANIDADES E TECNOLOGIAS

Introduction

Affective responses during exercise have been identified as a predictor of exercise adherence. However, research on core affect assessment has been mostly limited to aerobic and resistance exercises. Considering that stretching activities are also an important component in improving physical and psychological fitness, this quasi-experimental study was designed to 1) compare the affective responses during and immediately after stretching exercises in apparently healthy adults, and 2) verify the reliability and agreement of the affective responses assessment through a test-retest performed one week apart.

Methods

For that purpose, we applied and analyzed the Feeling Scale (FS) and Felt Arousal Scale (FAS) using Time (during and after stretching) x Intensity (light, moderate, and vigorous) x Stretched Muscle Group (quadriceps, hamstrings, glutes, latissimus dorsi, and triceps) with repeated measures analysis of variance (ANCOVA) in 34 participants (21 males; aged 32.8±8.6 years). Repeatability assessments of FS and FAS performed on different days were performed using a two-way mixed effects absolute agreement Intraclass Correlation Coefficients (ICC) and Bland-Altman plots.

Results

FS scores were higher following the stretching exercises, whereas FAS scores were lower, particularly in the vigorous intensity. The inter-day repeatability for FS and FAS measurements was generally good across muscle groups. ICC tended to be higher at vigorous intensities.

Discussion

An affective rebound effect could be verified in all stretched muscle groups and intensities but was particularly pronounced in stretches with vigorous intensity. This demonstrates the importance of the timing of core affect assessment in stretching activities, leaving suggestions that a measurement not conducted during the stretch could be reflecting the affective response of something other than the stretch itself. Regarding the test-retest results, the inter-day ICC at different intensities was, in general, moderate to good, with a tendency for higher reliability during vigorous-intensity stretching. Additionally, high variability in affective valence was identified between individuals, supporting an approach towards a more individualized intensity prescription of stretching exercises, in accordance with what the literature had previously indicated for aerobic and resistance training activities. Overall, the FS and the FAS applied during the execution of a static stretch represent a feasible and ecologically valid approach to measuring core affect. These results suggest that an adequate assessment of core affect in stretching activities should be performed during the exercise. Future studies should attempt to replicate these results with other types of stretches, with different muscle groups, and with more inexperienced participants.

COPING AND PAIN MANAGEMENT IN THE CONTEXT OF INJURY IN ELITE SPORTS

MACQUET, A.C.1, BONNET, R.1, TROUSSELARD, M.2,3

1LABORATOIRE SPORT, EXPERTISE ET PERFORMANCE EA 7370, INSEP 2INSTITUT DE RECHERCHE BIOMÉDICALE DES ARMÉES; DÉPARTEMENT DE NEUROSCIENCES ET SCIENCES COGNITIVES; UNITÉ DE NEUROPHYSIOLOGIE DU STRE

Pain is an unpleasant experience combining sensorial, cognitive and affective dimensions (e.g., O'Reilly, 2011). It is a stressor with which athletes have to cope. The IOC has underlined the need to address acute and chronic pain management in elite athletes (EAs, Hainline, et al., 2018). Experts have searched literature and best practices seeking a consensus on guidance for clinical practice and athlete management. They have highlighted the need for better understanding of acute pain management, including post-injury pain management. Athletes are known to have higher pain tolerance than the general population (e.g., Tesarz et al., 2012), suggesting that they may have a specific coping mechanism for dealing with pain. According to the transactional model of stress (Lazarus & Folkman, 1987), coping has two main functions: problem-focused and emotion-focused coping. This study aims to: (a) formalise the coping strategies used by EAs when they are managing acute pain due to injury, and (b) compare the frequencies of these coping strategies.

Semi-structured interviews were conducted individually with 12 EAs to ascertain their coping strategies while managing acute pain following a sport injury. Data were processed using the comparative method (Corbin & Strauss, 1990) and the transactional model of stress (Lazarus & Folkman, 1987). The results showed 14 pain management strategies relating to problem- or emotion-focused coping. Problem-focused strategies referred to: (a) modulating activity; (b) seeking instrumental support; (c) goal setting; (d) self-encouragement; (e) taking painkillers; and (f) reframing the perception of pain. Emotion-focused strategies referred to: (a) diverting attention; (b) acceptance; (c) relativizing pain; (d) repeating negative thoughts; (e) ignoring pain; (f) seeking emotional support; (g) hoping and praying; and (h) self-blame. The results highlighted that EAs reported greater use of problem-focussed (59% of occurrences of all strategies) than emotion-focussed strategies (41% of all strategies). EAs were shown to favour three strategies (49% of all strategies). Women and men reported problem-focussed and emotion-focussed coping strategies to a similar extent but the breakdown of emotion-focused coping strategies differed. Women more frequently reported strategies associated with "seeking emotional support" and "diverting attention" than men.

The results reinforce the transactional model of coping (Lazarus & Folkman, 1987). The variety of coping strategies suggests flexibility in coping with acute pain. The results highlight the multifaceted nature of pain management, going beyond the strategies elicited for coping with chronic pain in the general population (Rosenstiel & Keefe, 1983). This study demonstrates that exploring pain management strategies provides useful insights into ways to improve our understanding of pain management and clinical practice for athlete pain management.

ANALYSIS OF COMBINATORY EFFECTS OF SYSTEMATIC STRENGTH TRAINING WITH FREE WEIGHTS AND PROTEIN SUPPLEMENTATION ON STRENGTH GAIN AND BODY COMPOSITION IN POSTMENOPAUSAL WOMEN - A 12-WEEK RANDOMISED CONTR

DIEL, P., IOANNIDOU, P., DORO, Z., ISENMANN, E.

DEUTSCHE SPORTHOCHSCHULE KÖLN

INTRODUCTION: Menopause has a massive impact on the endocrine system of middle-aged women resulting in a loss of bone and muscle mass. Systematic strength training is an effective method to maintain or increase skeletal muscle mass. However, data on the effectiveness of strength training in postmenopausal women is limited. Preliminary data suggests that intensity and volume, plays a crucial role in this population. With respect to this the training recommendations of the World Health Organisation are not sufficient. To analysis which intensity and volume is suitable and whether the training result is affected by protein supplementation a four-arm randomised intervention study was conducted over 12 weeks.

METHODS: A total of 58 healthy postmenopausal women with no specific strength training experience (age: 58.2±5.6years, weight 69.1±9.6kg, height 166.5±6.5cm) successfully participated in the study. The initial examinations included hormone analyses (saliva samples), measurement of body composition (fat-free mass (FFM), skeletal muscle mass (SMM), fat mass (FM), as well as static grip strength and dynamic maximum strength in the squat and deadlift. After, the women were randomly assigned to either group A "training+protein (2.5g/kg FFM)", group B "only training"; group C "only protein (2.5g/kg FFM) or group D "control". Group A and B performed systematic strength training for the following 12 weeks with three training sessions and five exercises each. Groups C and D were prohibited from systematic training during the period. For statistical evaluation, all parameters were checked for normal distribution. Finally, FFM, FM and SMM had to be log-transformed. Then a 2x4 ANOVA was used with all parameters. In addition, the effect size of the changes (time*group) was calculated.

RESULTS: A time ($p<.005$) and a time*group ($p<.05$) difference was observed between groups A and B to control grip strength, deadlift and squat. Group A increased their grip strength by +4.7±2.4kg ($p<.001$; d:1.61), in the deadlift by +20.8±10.3kg ($p<.001$; d:1.59) and in the squat by +30.0±14.2kg ($p<.001$; d:1.63). Group B (training only) showed similar increases and improved in grip strength by +3.6±3.0kg ($p<.001$; d:1.41), in deadlift by +22.1±7.6kg ($p<.001$; 1.76) and in the squat by +32.5±12.0kg ($p<.001$; d:1.77). The protein group also showed a significant increase in the squat (+6.4±6.4kg; p:015; d:0.97). In body composition, a significant increase could only be observed in group A (+1.3±1.6kg; p:0.24; d:0.89) and a trend in group B (+1.3±2.6kg; p:.087; d:0.70). For SMM, a significant increase was observed in both training groups. Group A improved their SMM by +1.4±0.9kg ($p<.001$; d:1.38) and group B by 1.2±1.3kg (p:.004; d:1.09). In FM, both training groups also showed a significant reduction. Group A reduced their FM by -1.5±2.0kg (p:.019; d:0.75) and group B by -2.4±2.9kg ($p<.001$; d:0.93).

CONCLUSION: In conclusion, it was clearly shown that intensive strength training with free weights can promote both strength capacity and body composition in postmenopausal women and can be a preventive strategy against muscle atrophy. In addition, the effects show slight tendencies for additional protein intake to have an additive effect on muscle growth. However, in reducing FM, this can be inhibitory if consumed over-calorically.

DOES DIFFERENT-INTENSITY EXERCISE AFFECT THE REST-ACTIVITY RHYTHMS AMONG OLDER ADULTS?

YUE, C., JAEHEE, L., JAEHOON, S., KE, Z., TOMOHIRO, O.

UNIVERSITY OF TSUKUBA, JAPAN

INTRODUCTION: Sleep disturbances and poor rest-activity rhythms are common in older adults and might reduce the quality of life. Exercise interventions at night (e.g., close to or long before bedtime, scheduled or freely) might be a crucial factor affecting sleep quality and rhythms. However, previous studies show the inconsistency in discouraging evening exercise and abstaining for 3-4 hours before bedtime to prevent sleep disturbance, or evening exercises do not disrupt subsequent sleep and even improve subsequent sleep. Thereby, whether exercise affects circadian rhythms remains unknown, especially for exercise in different intensities. This study aims to explore the effect of exercise in the evening on rest-activity rhythms and sleep quality among older adults.

METHODS: This randomized controlled trial investigates the effects of a home-based aerobic exercise intervention with different intensities for 12 weeks in the evening on 54 older adults (71.8 ± 3.9 years; female = 46; BMI: 22.6 ± 3.3 kg/m²) with lower sleep quality (PSQI ≧ 6 pt). Participants were recruited from the local community in Tsukuba, Japan, and randomly allocated to a low-intensity exercise group (LG, 60-70 steps per minute), a moderate-intensity exercise group (MG, 110-120 steps per minute), or a control group (CG). Each intensity exercise group was performed for 30-min daily at home in the evening (between 18:00 to bedtime). Outcomes included: nonparametric approach actigraphy data of 24/7 (inter-daily stability, IS; intra-daily variability, IV; relative amplitude, RA; nocturnal activity, L5; daily activity, M10; L5 and M10 start times; the midpoint of L5 and M10 start times); actigraphy sleep variables, and self-reported sleep diary. Outcomes were assessed at baseline (pre), after 6 weeks (middle), and after 12 weeks (post) during the intervention.

RESULTS: For rest-activity rhythm results, there were no significant differences in the IS, IV, RA, L5, and M10. The MG showed a delay in L5 start time (23.8, 24.2, and 24.4 hours; P for trends = 0.002), and the midpoint of L5 and M10 start times (4.0, 4.4, and 4.6 hours; P for trends = 0.004) during the intervention. However, the LG and CG did not change during the intervention. For objective sleep results from actigraphy, the MG showed an increasing number of awakenings (P interaction = 0.035) in the post compared to the pre ($P < 0.05$). No significant changes were found in waketime but in shorter total sleep time (P interaction = 0.013) for both the LG and MG in the middle and post (all Ps < 0.05). For subject sleep results, no significant changes were found in PSQI and diary, including self-report quality for all groups.

CONCLUSION: Moderate-intensity exercise in the evening leads to delayed rest-activity rhythms among older adults with lower sleep quality and no subjective sleep quality decline. Thus, it is necessary to consider the timing and intensity of exercise when suggesting exercise therapy (i.e., combination with CBT-I) to older adults with sleep disorders.

ISOMETRIC TRAINING IMPAIRS CARDIAC SYMPATHOVAGAL BALANCE DESPITE ITS HYPOTENSIVE EFFECTS IN MIDDLE-AGE AND OLDER ADULTS

YAMAGATA, T., WAKIMOTO, T., YODA, T.

KAWASAKI UNIVERSITY OF MEDICAL WELFARE

INTRODUCTION: Isometric exercise training is a powerful non-pharmacological method to reduce resting blood pressure (BP); however, the mechanism of the hypotensive effect remains unclear. Although the shift in sympathovagal balance toward parasympathetic activity dominance is a potential factor that mediates the hypotensive effects, controversial results have been reported [1, 2]. The present study aimed to determine the effects of isometric exercise training on heart rate variability (HRV). It was hypothesized that isometric exercise training could augment parasympathetic nervous dominance in the resting position by lowering resting BP.

METHODS: Fourteen middle-age and older adults (mean [±SD] age, 68.5±8.8 years; male/female, n=6/8) were randomly assigned to a control (CON [n=6]) or isometric handgrip training (IHT [n=8]) group for 8 weeks. IHT involved 4 sets of 2 min isometric contraction consisting of 30% maximal isometric voluntary contraction using alternate hands, 3 times per week. BP and HRV were assessed with the subjects positioned supine before and after the intervention. HRV measurements included time domains (SDNN, RMSSD, pNN50, cardiac sympathetic index, cardiac vagal index) and frequency domains (ln LF, ln HF, normalized LF, normalized HF, and ln LF/HF ratio). Changes in BP and HRV following the intervention were compared between the CON and IHT groups using the Mann–Whitney U-test.

RESULTS: Mean BP was significantly reduced in the IHT group compared with the CON group (median difference, -8.4 mmHg; p=0.02). Changes in HRV were statistically significant in normalized LF (p=0.01), normalized HF (p=0.01), and ln LF/HF ratio (p=0.04) between the CON and IHT groups. Surprisingly, these changes in HRV indicated that isometric exercise training increased sympathetic and lowered parasympathetic nervous activity.

CONCLUSION: Contrary to the initial hypothesis, isometric exercise training induced a shift in sympathovagal balance toward sympathetic activity dominance despite its hypotensive effects. These data may implicate cardiac autonomic nervous system-independent mechanisms in contributing to lowering resting BP after isometric exercise training.

EFFECTS OF 8 WEEKS OF MULTICOMPONENT TRAINING ON FUNCTIONAL CAPACITY AND LIPIDIC AND HEMODYNAMIC PROFILE OF ACTIVE PRE-HYPERTENSIVE OLDER WOMEN AFTER THREE-MONTHS OF DETRAINING

LEITAO, L., FIGUEIRA, A., PEREIRA, A., FIGUEIREDO, T.

SUPERIOR SCHOOL OF EDUCATION OF POLYTECHNIC INSTITUTE OF SETUBAL

INTRODUCTION: Cardiovascular diseases have huge impact on the health and quality of life of older women. Exercise is a non-pharmacological method to prevent this type of diseases whether it is applied in the form of strength training, aerobic training or multicomponent training. Following some periods of exercise older women with pre-hypertension interrupt their training, which can range from less than one month to three months or more, depending on several factors such injuries or vacations. After detraining (DT) some older women return to practice. This retraining period can promote a faster return to the initial status before detraining, depending on the duration of this period. Our main goal was to evaluate the effects of eight weeks of multicomponent training in lipidic and hemodynamic profile and in functional capacity after three months of detraining in pre-hypertensive older women with the practice of nine months of multicomponent exercise before detraining.

METHODS: Nineteen pre-hypertensive older women (EG: n = 19, 67.4 ± 3.4 years) performed a nine-month multicomponent exercise program, followed by a three-month detraining period and an 8-week retraining period. Fifteen pre-hypertensive older women (CG: n = 15, 69.1 ± 2.1 years) maintained their daily routine. Functional capacity (FC) (Functional Fitness Battery Test), Total Cholesterol (TC), triglycerides (TG), blood pressure (BP) and resting heart rate (HRrest) were assessed before and after each training period.

RESULTS: After the first period of multicomponent training FC, TC, TG, HRrest and systolic blood pressure (SBP) improved ($p<0.05$). DT promoted declines in all variables compared to the end of training but when compared to baseline values only diastolic blood pressure (DBP) returned to the initial state ($p<0.05$). The retraining period improved BP and FC when compared to the end of DT (SBP: -8.7%; DBP: -5.1%; 30-second chair stand: 12.8%; 6-minute walk test: 16.5%; $p<0.05$) and end of the first training period (SBP: -5.2%; DBP: -3.6%; 30-second chair stand: 8.3%; 6-minute walk test: 11.5%; $p<0.05$). TC, TG and HRrest when compared to the end of DT also improved ($p<0.05$).

CONCLUSION: Eight weeks of retraining are enough to reverse the negative effects of DT in the lipidic and hemodynamic profile and FC. Moreover, it promoted greater benefits than the first training period which may mean that the benefits are quickly recovered with the return of exercise and that regular practice promotes quality of life and health in pre-hypertensive older women.

MINI-TRAMPOLINE AEROBIC TRAINING IMPROVES PULSE WAVE REFLECTION IN POSTMENOPAUSAL WOMEN

LEE, E., SON, J., PARK, S., HWANG, M.

INCHEON NATIONAL UNIVERSITY

INTRODUCTION: Arterial stiffness, an independent predictor of cardiovascular disease, drastically increases after menopause. Regular physical activity is an effective behavioral strategy to ameliorate arterial stiffness. Mini-trampoline exercise is known to improve cardiopulmonary and bone health. However, there is a lack of studies investigating the effects of mini-trampoline exercise on arterial stiffness in postmenopausal women. Therefore, the purpose of this study was to demonstrate the effects of mini-trampoline aerobic training on augmentation index (AIx) reflecting pulse wave reflection and pulse wave velocity (PWV) in postmenopausal women.

METHODS: Ten postmenopausal women (54±1 yrs) participated in this study and supervised mini-trampoline training was conducted for 40 minutes per day, 3 days per week for 10 weeks at a local community health promotion center.

The training intensity was set at 60% or more of the age-predicted maximum heart rate and participants' heart rate during training was monitored in real time using Polar heart rate monitors and Polar Team app. To evaluate arterial stiffness, AIx and carotid-femoral PWV were measured by SphygmoCor Xcel System.

RESULTS: AIx was significantly decreased after 10 weeks of mini-trampoline aerobic training (35±2.7 to 26±2.3%, P=0.002). However, there was no significant change in carotid-femoral PWV after the training (P=0.191).

CONCLUSION: To conclude, mini-trampoline aerobic training is an effective behavioral intervention to enhance pulse wave reflection, a measure of arterial stiffness, in postmenopausal women.

EFFECTS OF A 12 WEEK ONLINE PILATES BASED EXERCISE PROGRAM ON BALANCE AND CORE STRENGTH AND STABILITY IN OLDER ADULTS

GEREMIA, S., SAMPAIO, J., SOUSA, F., CARVALHO, J., PIZARRO A.

FACULTY OF SPORTS UNIVERSITY OF PORTO

INTRODUCTION: Aging is accompanied by a series of physiological alterations that lead to physical and cognitive decline, with multifactorial causes, but mainly due to loss of bone and muscle mass and dysfunctions of the neuromuscular system. Some studies have been carried out to evaluate the effects of the Pilates Method for delaying or minimizing these losses in the older population. This experimental study aimed to evaluate the effects of an online program of Mat Pilates exercises on strength and stability of the trunk muscles to minimize the natural decline in the balance in an older population.

METHODS: Twenty-four participants with a mean age of 76.4 (±5.8) were recruited to an online Pilates program, divided into two groups: fourteen participants in the intervention group and ten in the control group.

The intervention, which included exercises of the Pilates Method lasted 20 weeks, with 2 weekly sessions of 60 minutes of moderate intensity. Strength was assessed using the 1 minute sit-up test, trunk stability with the Core Muscle Strength & Stability test, for static balance we've used the single leg stance, and dynamic balance was measured with the timed up and Go (TUG) and TUG with congitive task.

RESULTS: Despite the initial dificulties, the elderly were able to use correctly the online tool to acess the class. At the end of the 40 sessions, the Pilates group demonstrated significant improvements in static (p=0.001) and dynamic balance with a cognitive task TUG-C (0.010) compared to the Control Group. The Pilates group also showed significant improvements in strength (p= 0.003) and trunk stability (p=0.014) between baseline and the end of the intervention.

CONCLUSION: The results demonstrated that online Mat Pilates can be used as an alternative training method for older adults, as it seems to promote positive effects on trunk strength and stability and, possibly, on cognitive function.

RELATIONSHIP BETWEEN SERUM IRISIN LEVELS, MARKERS OF SARCOPENIA, AND FATIGABILITY IN MEDICALLY STABLE OLDER FEMALES

JANDOVA, T.1, HOLA, V.1, POLANSKÁ, H.1, STEFFL, M.1, NARICI, M.V.2

1.CHARLES UNIVERSITY, FACULTY OF PHYSICAL EDUCATION AND SPORT, IC: 00216208 2. UNIVERSITY OF PADOVA, DEPARTMENT OF BIOMEDICAL SCIENCES

INTRODUCTION: Sarcopenia often leads to reduced functional performance (1) and the development of disability, with women often having a worse prognosis (2). Detecting early changes related to muscle loss before frank sarcopenia occurs is crucial, as the adverse effects can be reversed through increased physical activity (3). This cross-sectional study evaluated and explored associations between serum irisin levels, fatigability and sarcopenia-related parameters, including the novel ultrasound sarcopenic index (USI) in medically stable older females.

METHODS: Thirty medically stable older females (mean age 70.0 ± 3.8) participated in this cross-sectional study. Serum irisin concentration was measured by the enzyme-linked immunosorbent assay. Body composition - skeletal muscle mass (SMM) was measured by bioelectrical impedance (BIA) (InBody 720, Biospace Co., Ltd., Seoul, Korea). Lower body isometric strength and fatiguability by dynamometry (Humac NORM, CSMi, Stoughton, MA). USI was calculated using muscle architecture measured on the right vastus lateralis at 65% distal length (4) by ultrasound (Mindray M5). Functional capacity was tested by gait speed and chair stand test.

RESULTS: Statistically significant negative correlations were found between serum irisin level and age ($r = -0.513$, $p < 0.01$), fatigability index and age ($r = -0.370$, $p < 0.05$), and USI and fatigability index ($r = -0.571$, $p < 0.01$). A positive correlation was found between irisin and the fatigability index ($r = 0.40$, $p < 0.05$). No correlations were found for SMM, lower body strength, gait speed and chair stand test.

CONCLUSION: This cross-sectional study indicates that serum irisin levels are negatively associated with age and positively with fatigability. Moreover, the fatigability index is negatively associated with USI, which together might be used as novel non-invasive biomarkers of muscle function in older age regardless of sarcopenia diagnosis and, as such, might allow for early intervention.

ESTIMATE FOR POSSIBLE SARCOPENIA USING SEVERAL GRIP STRENGTHS AMONG COMMUNITY-DWELLING OLDER PEOPLE IN JAPAN

KOZAKAI, R., UEDA, T., SASAKI, H., IDE, K., HANAI, A., ODA, S., TAKADA, S., HONDA, R., OGAWA, H., ODAJIMA, M., AIUCHI, T., OKITA, K.

HOKUSHO UNIVERSITY

INTRODUCTION: Grip strength is widely known as the diagnostic measure of sarcopenia. Recently grip strength asymmetry has been the focus for predicting future functional limitations (Parker et al., 2021). Although maximal strength with the dominant hand is commonly used for such estimations, strength with the non-dominant hand may also provide meaningful information in later life. The Asian Working Group of Sarcopenia (AWGS2019) sets the definition of grip strength for possible sarcopenia, which can be interchanged with the chair stand test. However, previous studies reported that the agreement between the measurements was inconsistent. The accuracy of the indicators has still to be investigated. The purpose of the present study was to estimate properties in several indexes of grip strength along with possible sarcopenia diagnosis among community-dwelling older people in Japan.

METHODS: The subjects were 39 men and 45 women aged 60 years and over, who were randomly selected and who had completed measurements for identifying possible sarcopenia using AWGS2019 in the health checkup in 2017. Measurements included body size, grip strength, sit-and-reach, functional reach, chair stand in 30 sec (CS-30) and maximum walking speed. Individual attributes, health conditions and lifestyle were also checked using a questionnaire. Grip strength was estimated in 3 indices including average grip strength in both hands, maximum grip strength for the stronger hand, and that for the weaker hand using AWGS2019 definition. Grip strength asymmetry was calculated as grip strength for the stronger hand/that for the weaker hand ratio, and >10% was evaluated as asymmetry. The definition of chair stand using CS-30 was referenced in a previous study (Sawada et al., 2021). Cohen's coefficient of agreement in definitions between grip strength and CS-30 were calculated.

RESULTS: The prevalence of possible sarcopenia was 5 (6.0%) in average, 1 (1.2%) in the stronger hand, 7 (8.3%) in the weaker hand grip strength, and 7 (8.3%) in CS-30. Cohen's coefficient of agreement with CS-30 was 0.46 on average, 0.23 in the stronger hand, 0.69 in the weaker hand grip strength. The average asymmetry ratio was 1.23±0.20. The participants with asymmetry were 13 (33.3%) in men and 19 (42.2%) in women, and there was no significant difference between

men and women (Chi-square test, p=0.40). Possible sarcopenia estimated by the weaker hand grip strength was significantly more in the participants with asymmetry than those without (Fisher exact test, p=0.01).

CONCLUSION: The estimation by grip strength in the weaker hand had the highest agreement with CS-30 in possible sarcopenia definition. Our results suggest that estimating grip strength in each hand may provide more information about sarcopenia among community-dwelling older people.

ALTERATIONS IN PHYSICAL ACTIVITY AND SEDENTARY BEHAVIOURS MODERATE THE RELATIONSHIP BETWEEN DISEASE SEVERITY AND PHYSICAL FUNCTION IN RHEUMATOID ARTHRITIS

ALLEN, S.L., OBRIEN, C.M., ROWLANDS, A.V., VELDHUIJZEN VAN ZANTEN, J.C.S., METSIOS, G., KITAS, G., DUDA, J.L., GREIG, C.A., BREEN, L., FENTON, S.A.M.

UNIVERSITY OF BIRMINGHAM

INTRODUCTION: Rheumatoid Arthritis (RA) is a common autoimmune disease characterised by chronic systematic inflammation. RA is associated with a number of complications including an increase in cardiovascular disease (CVD) risk and a decline in physical function. Sedentary behaviour (SB) and physical activity may moderate the relationship between disease activity and severity, with physical function and CVD risk. Therefore, the aim of this study was to investigate the moderating role of SB and physical activity on the relationship between RA disease activity and severity, with CVD risk and physical function.

METHODS: People living with RA (n = 101) provided a fasted blood sample and underwent assessments of physical function. The Disease Activity Score 28-C-reactive protein (DAS28-CRP) was used to determine RA disease activity, and the Stanford Health Assessment Questionnaire (HAQ) was used to assess disease severity. Participants wore an Actigraph GT3X+ accelerometer on their right hip, and an ActivPAL on their right thigh for 7-days to assess physical activity and SB, respectively. Accelerometer data were analysed using the R package GGIR (version 2.0) to determine the M10 metric (i.e., acceleration/intensity above which a person's most active 10mins are accumulated). ActivPAL data were analysed using PAL analysis (PAL Technologies Ltd), to determine hours per day spent sedentary. CVD risk was determined by QRISK3, and 20m gait speed was used to assess physical function. Regression analyses examined associations between disease activity and severity with movement behaviours, and CVD risk and 20m gait speed. Moderation analyses were then conducted using Hayes Process Macro in SPSS.

RESULTS: Both disease activity and severity were significantly, negatively associated with M10 (DAS28-CRP, β = -.40; HAQ, β = -.32) and significantly positively associated with SB (DAS28-CRP, β = .27; HAQ, β = .23). No significant associations were identified between disease activity and severity scores with CVD outcomes. However, both disease activity and severity were significantly, positively associated with 20m gait speed (DAS28-CRP, β = .37; HAQ, β = .47). Moderation analysis revealed that a higher HAQ score was related to a slower 20m gait speed in patients engaging in ≥ 8 hours of SB, compared to < 8 hours of SB (unstandardised β = 4.1, P = 0.03). In addition, a higher HAQ score was associated with a lower 20m gait speed in patients with an M10 score ≥ 75mg (i.e., accumulation of 10-minutes of activity at an intensity similar to a slow walk), compared to < 75mg (i.e., did not accumulate 10-minutes of activity at an intensity similar to a slow walk) (unstandardised β = -5.4, P = 0.003).

CONCLUSION: Higher RA disease activity and severity are associated with lower M10 intensity and higher SB. Variability in these movement behaviours moderates the influence of disease severity on physical function.

EFFECTS OF NORWEGIAN HIIT AND CAFFEINE INTAKE ON COGNITIVE FUNCTION

MURATA, H.1, KOMOBUCHI, K.1, SAITO, A.1, TAKESHITA, M.1, TOMITA, A.1, SUZUKI, R.1, FUKUIE, M.2, HIRASAWA, A.1, KARASUYAMA, A.1, SHIBATA, S.1

1.KYORIN UNIVERSITY, 2.NATIONAL INSTITUTE OF ADVANCED INDUSTRIAL SCIENCE AND TECHNOLOGY

INTRODUCTION: High-intensity interval training (HIIT) or caffeine intake is reported to improve cognitive function. However, the effects of a combination of HIIT and caffeine intake on cognitive function are still unknown. The purpose of this study was to test our hypothesis that HIIT and caffeine intake would have a synergistic effect on cognitive function improvement.

METHODS: Eleven healthy adults (age: 21±1 years old, male/female: 8/3, height: 170.9±7.8 cm, weight: 63.0±12.4 kg) were recruited. The study was a double-blind, randomized, crossover design. The experiment consisted of three days. On the first day, maximal heart rate was measured by cardiopulmonary exercise testing and cognitive function tests were practiced. On the second and third days, a Norwegian HIIT was performed on a bicycle ergometer, which is a total of four sets of high-intensity exercise (90% of maximal heart rate for 4 min) and low-intensity exercise (30% of maximal heart rate for 3 min) with caffeine intake of 300mg or placebo. The cognitive function included a Stroop test (executive function) and reversal recitation of five-digit numbers (working memory). Emotional tests were performed with the Profile of Mood States 2nd Edition (POMS2). The autonomic activity was evaluated by HR variabilities using spectral analysis. These parameters were collected before and after HIIT. Two-way repeated ANOVA was used to analyze the effects of HIIT and caffeine intake on cognitive function, autonomic activity, and emotion.

RESULTS: Response time of the Stroop test shortened after HIIT ($p<0.05$) with a trend on the interaction between HIIT and caffeine intake (p=0.07). The number of wrong answers on the Stroop test was not affected by HIIT or caffeine intake. The duration to perform the five-digit number reversal shortened after HIIT ($p<0.05$), while it was not affected by caffeine intake (p=0.75). The total POMS2 score was not affected by either HIIT or caffeine intake. Among the items of POMS2, one item,

"Friendliness", showed an interaction effect between HIIT and caffeine intake ($p<0.05$). The high-frequency power of HR variability (index for ventral vagal activity) tended to be increased by caffeine intake ($p=0.085$) while it was not affected by HIIT. The ratio of low to high-frequency power of HR variability (index for sympathetic activity) tended to be increased by HIIT ($p=0.052$), while it was not affected by caffeine intake ($p=0.44$).

CONCLUSION: The combination of HIIT and caffeine intake may have synergistic effects on executive function. In addition, sympathetic domination was enhanced by HIIT, while ventral vagal activation was induced by caffeine intake in the present study, while friendliness emotion is affected by a combination of HIIT and caffeine intake. These changes in autonomic activity and emotion may be underlying mechanisms of acute changes in executive function.

DATA INFORMING GOVERNING BODY RESISTANCE TRAINING GUIDELINES EXHIBIT SEX BIAS: AN AUDIT BASED REVIEW

HAGSTROM, A., PANDIT, A., TRAN, T., LETTON, M., COWLEY, E., GIBBS, M., WEWEGE, M

UNIVERSITY OF NEW SOUTH WALES

INTRODUCTION: The objective of this review was to examine the ratio of female and male participants utilised in data informing consensus statements and position stands in the field of resistance training (RT). A second objective of this study was to examine the gender of the authors of these position statements.

METHODS: We conducted an 'Audit' style review. We accessed three databases: SPORTDiscus, MEDLINE, and Google Scholar utilising the following search terms: resistance or strength training AND consensus statements or position statements/stands. Eligibility criteria included consensus statements and position stands for RT in youth, adults, and older adults from the year 2000 onwards. Reference lists from each guideline were screened with the number of male and female participants extracted from each study. For each consensus statement we also attempted to identify the proportion of male and female authors.

RESULTS: We located eleven guidelines encompassing a total of 104,251,363 participants. Youth guidelines were comprised of 69% male participants. There were 287 studies that included both sexes, 205 male-only and 92 female-only studies. Adult guidelines were comprised of 70% male participants. There were 104 studies that included both sexes, 240 male-only and 44 female-only studies. Older adult guidelines were comprised of 54% female participants. There were 395 studies that included both sexes, 112 male-only and 83 female-only studies. There were 121 authors across these 11 statements, with 103 male (85%) and 16 female (13%) authors. One out of 11 first authors (9%) were female and 3 last authors were female (27%). Three out of 11 papers had zero female authors.

CONCLUSION: These results demonstrate an under-representation of females in data informing youth and adult RT guidelines. In comparison, we observed a similar representation of male and female data informing older adult guidelines. We also observed a large underrepresentation of female authors and females in senior authorship positions across these statements. It is imperative to ensure that data informing governing body guidelines and consensus statements are representative of the population that they aim to inform. If this is not possible, guidelines should clearly state when their data and recommendations are based primarily upon one sex.

HEALTH STATUS ASSESSMENT OF INDUSTRIAL WORKERS IN A MID-SIZE COMPANY: A NOVEL APPROACH IN WORKPLACE HEALTH PROMOTION

JAVANMARDI, S., RAPPELT, L., HEINKE, L., BAUMGART, C., FREIWALD, J.

UNIVERSITY OF WUPPERTAL

INTRODUCTION: Workplace health promotion is becoming essential to prevent absenteeism and negative economic impacts on manufacturers. Previous studies have focused on preventing of workplace accidents, predictable workloads, and hazardous working conditions (e.g., extreme heat or noise). However, potential health risks for industrial workers should be detected by appropriate screening procedures. This cross-sectional study examines whether different conditions influence the health status.

METHODS: A survey was used to assess the workplace characteristics of n = 373 workers in a mid-size metal-working company, thereof n = 64 (41.1 ± 11.6 years, BMI: 28.0 ± 4.1 kg/m²) operating in a forging (GF), n = 240 (40.5 ± 10.9 years, BMI:26.7 ± 4.5 kg/m²) in manufacturing (GM) and n = 69 (41.3 ± 10.9 years, BMI:26.9 ± 5.4 kg/m²) in a packaging environment (GP). The location of orthopedic complaints (neck, upper back, right/left shoulder, right/left elbow, right/left wrist, right/left hand, lower back, hip, right/left knee, foot) was documented based on the German Pain Questionnaire. Pain intensity, physical and psychological load were assessed using a visual analog scale (VAS: 0-100). The Global Physical Activity Questionnaire (GPAQ) and the Short Form Health Survey-36 (SF-36) were recorded to determine physical activity and physical and psychological domains.

Fishers exact test was applied to analyze the possible difference in the proportion of workers in the three environments reporting no pain and pain. The effect of the group on pain intensity was analyzed via a one-way ANOVA with post hoc Bonferroni correction.

RESULTS: Overall, 282 workers (75.6%) reported at least one orthopedic issue located in the neck n = 59 (15.8%), upper back n = 74 (19.8%), lower back n = 176 (47.1%), right shoulder n = 54 (14.5%), left shoulder n = 39 (10.5%), right elbow n = 30 (8.0%), left elbow n = 3 (.8%), right wrist n = 47 (12.6%), left wrist n = 33 (8.8%), right hand n = 6 (1.6%), left hand n = 4 (1.1%), hip n = 8 (2.1%), right knee n = 40 (10.7%), left knee n = 32 (8.6%) and foot n = 18 (4.8%). Fisher`s Exact Test revealed a statistically significant difference in the environments for the right elbow ($p < .01$). For the parameter pain-intensity (VAS), only the left shoulder showed a statistically significant effect ($F(2, 36) = 3.90$, $p = .029$, $\eta p^2 = .18$). Post hoc tests revealed a difference ($p = .046$) between GM (n = 22, 42.6 ± 24.8 au) and GP (n = 10, 68.9 ± 2.6 au). Other pain locations and intensities as well as GPAQ, SF-36, physical and psychological load showed no significant group effects.

CONCLUSION: There were no discrepancies or variations in the health status of the workers in the three industrial environments. Therefore, as no group differences were found, successful preventive and rehabilitative programs should focus on individual criteria (e.g., different workstations and working schedules).

PREVALENCE OF MARKERS ASSOCIATED WITH RED-S IN ELITE-LEVEL FEMALE FOOTBALL PLAYERS

DASA, M.S.1, ROSENVINGE, J.H.1, FRIBORG, O.1, PETTERSEN, G.1, TORSTVEIT, M.K.2, KRISTOFFERSEN, M.3, SAGEN, J.V.4, SUNDGOT-BORGEN, J.5

1. UIT - THE ARCTIC UNIVERSITY OF NORWAY, 2. UNIVERSITY OF AGDER, 3. WESTER NORWAY UNIVERSITY OF APPLIED SCIENCES, 4. UNIVERSITY OF BERGEN, 5. NORWEGIAN SCHOOL OF SPORTS SCIENCE,

INTRODUCTION: Relative Energy Deficiency in Sports (RED-S) is a syndrome which describes impairments of several bodily systems, which main etiology is low energy availability. RED-S may have severe consequences for both performance and health, and different markers are often used to assess the occurrence and severity of the phenomenon. Despite increasing awareness of the syndrome, few studies investigating direct measures of RED-S have been done in female football players. Therefore, the aim of this study was to investigate the prevalence of symptoms associated with RED-S in elite-level female football players

METHODS: 60 players (age 22.5 ± 3.7, height 169 ± 6.0 cm, weight 64.1 ± 6.3 kg, BMI 22.4 ± 1.7) from three different teams in the Norwegian premier (n =2) and first (n =1) division were included in the study. The clinical findings were scored dichotomous as positive (1 point) or negative (0 points) using cut off values from the literature, and point prevalence for each condition was also calculated (point prevalence = (number of cases)/(population size for assessment)) . The Criteria's included amenorrhea, RMR < 30.kcal FFM.kg-day, ≥ 4 on the EDE-Q 11, Thyroid stimulating hormone (TSH(, free triiodothyronine (ft3), Low density lipids (LDL), ferritin, time loss caused by sickness using the Oslo sport trauma research center questionnaire, bone mass density and previous history of stress fracture, giving a maximum score of 13.

RESULTS: Preliminary results show that the cumulative percentage distribution of RED-S points was 30% (0 points), 33% (1 point), 17% (2 points), 17% (3 points) and 3% (4 points), respectively. For the individual RED-S markers, the prevalence was generally low ranging between 0 and 22 %. However, the prevalence of RMR < 30. kcal FFM.kg-day was 42%. There was a significant difference in RED-S points between individuals with low and normal energy availability (EA) calculated by RMR ($P < 0.001$) with a mean score of 2.0 ± 1.0 and 0.8 ± 0.9, respectively.

CONCLUSION: The prevalence of symptoms described by the RED-S model were present in this cohort. Nevertheless, few players had high rates of accumulated RED-S points, supporting the notion that female football players may not be predisposed to development of RED-S, given the characteristics of the game. Further, the usage of RMR as a surrogate marker of LEA should be further explored, as it provides promising results.

TESTING AND EVALUATION OF AN ADAPTATION OF THE RAPID UPPER LIMB ASSESSMENT (RULA) BY A KINEMATIC ANALYSIS FOR OCCUPATIONAL HEALTH PRACTICE - AN EXEMPLARY APPLICATION IN THE FIELD OF DENTISTRY

MAURER-GRUBINGER, C., NOWARA, R., HOLZGREVE, F.1, GOLBACH, R., WANKE, E.M., ERBE, C., BRÜGGMANN, D., NIENHAUS, A., GRONEBERG, D.A., OHLENDORF, D.

GOETHE-UNIVERSITÄT FRANKFURT AM MAIN

INTRODUCTION: The Rapid Upper Limb Assessment (RULA) is used for the risk assessment of workplace-related activities. So far, the paper and pen method (RULA-PP) has been predominantly used for this purpose. In the present study, this method was compared with the MVN motion capture system (IMU) from Xsens (RULA-IMU). The aim of this study was, on the one hand, to work out the differences between these two measurement methods and, on the other to make recommendations for the future use

of the respective method on the basis of the available findings.

METHODS: For this purpose, 130 subjects from the dental profession were each photographed several times in pairs in lifelike working positions and simultaneously recorded with the IMU system. In order to compare both methods statistically, the weighted Cohens Kappa and the agreement chart (mosaic plot) were applied.

RESULTS: There were differences in the risk assessments in the Arm and Wrist Analysis A; assessment by RULA-PP (score of 3) was 1 point lower than with RULA-IMU (score of 4). The median of both overall risk assessment scores was 6, although RULA-IMU determined the assessment score to be more differentiated overall and was much more often 7 than when using RULA-PP. These results demonstrate a difference between the two measurement methods.

CONCLUSION: The new findings provide a form of key, especially for the evaluation of static movements, to be able to compare newly collected data by means of RULA-IMU with existing ergonomic data collected by means of RULA-PP. In

addition, the use of RULA-IMU can be recommended especially for assessing continuous motion sequences or motion sequences that are difficult for an observer to see, whereas RULA-PP appears to be sufficient for a general statement or initial findings as this method is less complex.

A 10-WEEK TRAMPOLINE EXERCISE PROGRAM ENHANCES CAROTID ARTERY COMPLIANCE IN POSTMENOPAUSAL WOMEN

SON, J., LEE, E., PARK, S., HWANG, M.
INCHEON NATIONAL UNIVERSITY

INTRODUCTION: With advancing age, postmenopausal women have a dramatically increased risk of cardiovascular disease. Carotid artery stiffness measures, including arterial compliance, distensibility, and stiffness, are non-invasive clinical indicators that can predict risk factors for atherosclerosis and cardiovascular disease. Regular aerobic exercise is recommended to maintain and promote cardiovascular health. Trampoline exercise is an effective aerobic exercise that consumes a lot of calories per unit time, improves balance and cardiorespiratory fitness, and strengthens the musculoskeletal system. However, research studies investigating the effect of trampoline exercise on carotid artery stiffness in postmenopausal women are difficult to find. Therefore, the purpose of this study was to evaluate the effect of 10 weeks of trampoline exercise on carotid artery stiffness in postmenopausal women.

METHODS: Ten postmenopausal women (47-61 years) voluntarily participated in this mini-trampoline exercise intervention study. Exercise intensity was set to moderate-high intensity corresponding to 65% or more of the age-predicted maximum heart rate. Participants performed mini-trampoline exercise with music for 40 minutes a day, 3 day a week, for a total of 10 weeks at a local public health center. To assess carotid artery stiffness, carotid artery compliance, distensibility, and stiffness index were measured and analyzed using an Aloka Prosound α7 ultrasound system and the FDA-approved Cardiovascular Suite software.

RESULTS: Ten weeks of trampoline exercise significantly improved carotid artery compliance in postmenopausal women (P=0.049). Although statistical significance was not obtained, distensibility (P=0.062) and stiffness index (P=0.052) also showed a strong tendency to improve after 10 weeks of trampoline exercise in postmenopausal women.

CONCLUSION: In conclusion, trampoline aerobic training is an effective behavioral intervention that can improve carotid artery compliance in postmenopausal women.

EFFECTS OF STEPPING EXERCISE WITH SINGLE-TOOTH SANDALS ON POSTERIOR TIBIAL ARTERY BLOOD FLOW AND SOLE SURFACE TEMPERATURE

NISHIWAKI, M., YAMAMOTO, M., OI, N., ODA, H., KUME, D.
OSAKA INSTITUTE OF TECHNOLOGY

INTRODUCTION: Single-tooth sandals under new development have special material and shape characteristics, and exercises with single-tooth sandals can increase pressing stimulus on the soles of the feet. Our recent findings indicate that exercise with single-tooth sandals has a positive effect on a suppressing decline in the medial longitudinal arch and an elevation in sole surface temperature. However, the influences of exercises with single-tooth sandals on blood flow are now unknown. This study thus aimed to examine the effects of exercise with single-tooth sandals on posterior tibial artery blood flow and sole surface temperature.

METHODS: Eighteen young adults (21.7 ± 0.2 years) participated in 20 min of stepping exercise on the spot. They randomly put on a regular normal sandal (N conditions) or a single-tooth sandal (Z conditions) on each left and right side. Before (Pre) and 0, 15, 30 min after (Post) the exercise, posterior tibial artery blood flow (diameter, velocity, and blood flow volume) and sole surface temperature were assessed by ultrasound imaging device and thermography, respectively.

RESULTS: No significant differences in baseline parameters were observed between N and Z conditions. After the exercise, posterior tibial artery blood flow (diameter, velocity, and blood flow volume) significantly increased in both conditions compared with Pre values. Although no significant differences were observed between two conditions, the blood flow changes and responses tended to be higher in Z conditions than in N conditions. The area under the curve of blood flow between Pre and Post 30 min was significantly higher in Z conditions than in N conditions (N conditions: 821.9 ± 106.5 arbitrary units, Z conditions: 1055.4 ± 139.5 arbitrary units). Central sole surface temperature in Z conditions also increased significantly after the exercise (Pre: 29.2 ± 1.7°C, Post 0: 30.1 ± 1.6°C), but did not in N condition (Pre: 29.2 ± 1.7°C, Post 0: 27.8 ± 1.7°C). The central sole surface temperature changes were significantly higher in Z conditions than in N conditions (N conditions: -4.7 ± 1.0%, Z conditions: 4.8 ± 1.1%). The sole area ratio of surface temperature above reference values was also significantly higher in Z conditions than in N conditions.

CONCLUSION: Therefore, our data indicate that exercise with single-tooth sandals elevates posterior tibial artery blood flow and sole surface temperature. These findings raise the possibility that exercise with single-tooth sandals has a positive effect on sensitivity to cold by improving foot blood circulation and increasing sole surface temperature.

SMOKING STIMULATES MUSCULAR MURF-1 AND PGC-1 ALPHA EXPRESSIONS ON CIGARETTE SMOKE-EXTRACT ADMINISTERED MURINE MODEL.

SAKAMOTO, M., YMAMOTO, T., ABE, S., NAKASHIMA, S., UEHARA, Y.
FACULTY OF SPORTS AND HEALTH SCIENCES, FUKUOKA UNIVERSITY

INTRODUCTION: Smoking is associated with increased risk of metabolic syndrome and type 2 diabetes, and one of the possible mechanisms might be caused by muscle atrophy. As a previous study supporting this, Petersen et al. has been reported that myostatin and MAFBx gene expressions of skeletal muscle are markedly elevated in smoker, furthermore aerobic exercise has been represented to affect the protein synthesis of skeletal muscle resulting in muscle hypertrophy by Konopka et al. Therefore, we hypothesized that the smoking reduces muscle protein synthesis and stimulate proteolysis in skeletal muscle.

METHODS: Fifteen 8-week-old male mice were divided into three groups (n = 5 in each group); control group, cigarette smoke-extract given (CS) group, and cigarette smoke-extract given with exercise (CSE) group. CS and CSE were administered cigarette smoke-extract once a week for 3 weeks, intraperitoneally. The mice of CSE group were allowed to voluntarily exercise in a running wheel. Three weeks after the exercise intervention, soleus (Sol), red-region of gastrocnemius (Gas) and extensor digitorum longus (EDL) of mice hind-limb muscles were removed and weighed. All muscle were extracted mRNA and measured P70S6 kinase (P70S6K), muscle ring-finger protein-1 (MuRF-1), E3 ubiquitin ligase Atrogin1, forkhead box protein O1 (Foxo1), and peroxisome proliferator-activated receptor gamma coactivator (PGC)-1 alpha expressions by reverse transcription real-time PCR.

RESULTS: One of the protein degradation-related gene, MuRF-1 mRNA expression of Sol and Gas was significantly elevated, and Foxo1, an upstream transcriptional regulatory gene of it, expressions were also markedly increased in CS group as compared with control group. On the other hand, P70S6K mRNA expressions of all muscle were not significantly changed in CS group. The elevated MuRF-1 and Foxo1 gene expressions of Sol were significantly reduced to control level by exercise intervention with the voluntarily exercise in a running wheel. Contrary to our expectations, PGC-1 alpha mRNA expressions of all muscles were significantly increased in CS group compared with control group.

CONCLUSION: An administration of cigarette smoke-extract might suppress muscle mass by stimulating muscle protein degradation via an activation of Foxo1 - MuRF-1 pathway. Cigarette smoke-extract may influence muscular mitochondrial function through upregulation of PGC-1 alpha, although reducing muscle mass.

EFFECTS OF MOTIVATIONAL MUSIC ON PERCEIVED EXERTION DURING AEROBIC EXERCISE

GALLAZZI, M., SIGNORI, C., VUKAJ, X., ANDRIOLO, G., GRIGNANI, L., FIGINI, A., CANTARELLI, D., BARATTI, M., GHIRARDI, P., BRUSEGHINI, P., ANNONI, I., BERTOZZI, F., CASTENETTO, M., GALVANI, C.
UNIVERSITÀ CATTOLICA DEL SACRO CUORE, MILAN (ITALY)

INTRODUCTION: Music is associated with improved physical performance in a wide range of activities. When music is used during physical activity, it can elicit positive emotions and distract athletes from unpleasant feelings associated with physical exertion and fatigue(1). Some evidence shows no effect of time of day on the rating of perceived exertion (RPE) during aerobic performances(2). The aim of this study was to test the influence of self-selected motivational music, and time of training on RPE during a cycling exercise at moderate and vigorous intensity.

METHODS: Forty-seven university students were recruited: 24 males and 23 females (age 22.6±2.4 yrs; BMI 21.9±2.7 kg/m2; V'O2max 39.3±7.6 mlO2/kg/min). All subjects performed four randomized training sessions at two different times of day, with and without self-selected motivational music(3): two sessions in the morning from 8:30 am to 9:30 am (MO+M; MO-M) and two sessions in the evening from 5:30 pm to 6:30 pm (EV+M; EV-M). Each training session included 6 min of cycling at constant load at 60% of V'O2max (MOD), interspersed by a 10-min break, and at 90% (VIG) of V'O2max, estimated from a submaximal direct test. At the end of each 6-min bout, CR10 Borg's scale(4) was administrated to rate fatigue.

RESULTS: RPE was significantly influenced by music, indeed it decreased during exercise performed with self-selected motivational music both at MOD (MO+M: 2.3±1.2; MO-M: 2.6±1.3; EV+M: 2.2±1.1; EV-M: 2.5±1.3; p=0.025) and VIG (MO+M: 6.1±2.0; MO-M: 6.8±1.9; EV+M: 6.5±2.1; EV-M: 6.7±2.0; p=0.001) intensity, regardless of gender. Conversely, time of day did not influence RPE neither at MOD nor at VIG intensity, in both gender.

CONCLUSION: This research, taking into account both the influence of music and of time of day, confirms previous findings of a positive effect of motivational music(5) and no influence of time of day(2) on RPE. Exercisers are advised to listen to self-selected motivational music while training, which would help them to feel less fatigue and maintain a better adherence to their physical activity program.

THE DEVELOPMENT AND ASSESSMENT OF A NOVEL COMBINED PHYSICAL AND COGNITIVE ASSESSMENT: THE FLANKER-Y

PUMPA, K.L.1,2, MASON, B.1, BALL, N.1, RATTRAY, B.1, PLOWMAN, J.1, MARTIN, K.1, MCKUNE, A.1, KILDUFF, L.3, WALDRON, M.3, MARA, J.1

1 UNIVERSITY OF CANBERRA RESEARCH INSTITUTE FOR SPORT AND EXERCISE; 2 UNIVERSITY COLLEGE DUBLIN; 3 SWANSEA UNIVERSITY.

INTRODUCTION: Sporting success intuitively relies on the combination of physical, mental, and cognitive performance. Strategies aimed at enhancing the preparation of team-sport athletes on the day of competition are integral to the optimisation of performance, yet acute physical strategies on game-day have been the focus of most research [1]. Whilst coaches and support staff may make assessments of on-field cognition, there are no readily available tools to assess the effectiveness of any strategies that may impact competition cognitive readiness. This study developed and assessed the implementation of a novel test that merged the cognitive requirements of an adapted Flanker task [2] with the reactive physical requirements of a Y-Agility test [3].

METHODS: Fifty-five (28 male, 27 female) physically active adults completed a computer-based modified Flanker task that included three different conditions (i.e., congruent, incongruent, switch), before completing our newly developed novel Flanker-Y task. The Flanker-Y task integrated the computer based Eriksen Flanker task (with an additional pre-planned task) with the reactive Y-Agility test. Timing gates were set up at 5 m in a straight line from the start (split 1), and 10 m at a 45-degree angle from split 1 (split 2). For this test, the computer task was presented on a 42-inch TV, with each condition displayed on the screen in response to the crossing of electronic timing gates at the 5 m mark. Participants completed 100 computer based Flanker tasks, before undertaking 12 combined Flanker-Y tasks at 30 second intervals.

RESULTS: In regards to the Flanker-Y, total time to complete the Flanker-Y task increased as the complexity of the task increased for both sexes ($p<0.001$, ES=0.46-2.97), with males faster than females across all conditions ($p<0.001$, ES=0.94). The difference in total time between conditions was mostly attributed to an increase in time to complete the second 10 m split ($p<0.001$, ES=0.29-11.08), while the time to complete the first 5 m split remained consistent between conditions ($p=0.923$, ES=0.00-0.11). The coefficient of variation (CV%) for split 1 were similar between conditions (3-4% for each condition, $p=0.086$), with the CV% for split 2 considerably worse (ranging from 8% for the pre-planned to 16% for the switch task, $p<0.001$).

CONCLUSION: The novel Flanker-Y task successfully demonstrated construct validity with varying degrees of reliability in physically active adults. Repeating this methodology in a homogenous, trained population is the next step to identify if reliability improves with training status. The application of this test is far reaching including the assessment of match-day strategies on competition cognitive readiness, as well as the ability to assess the impact of chronic training interventions and changes in cognitive capacity in a sporting context.

A QUALITATIVE ASSESSMENT OF TRUCK DRIVERS' NEEDS FOR PHYSICAL ACTIVITY PROMOTION

GAWLIK, A., HABERSTOCK, S., ZEPP, C.

GERMAN SPORT UNIVERSITY COLOGNE

Introduction

Due to the accessibility of employees, the workplace is an ideal setting for health promotion. To develop health promotion measures in the workplace, specific needs of this target group need to be taken into account. Especially for working target groups with unhealthy working conditions and difficult accessibility, such as truck drivers, the current state of research is limited. Due to the nature of a truck drivers` workplace, one of the most neglected health behaviour is physical activity. Thus, the aim of the present study was to qualitatively identify the individual needs in terms of capabilities, opportunities, and motivation of truck drivers in relation to increasing their physical activity behaviour. Based on identified needs specific measures and interventions to increase truck drivers' motivation for more physical activity at work can be developed.

Methods

A qualitative study with semi-structured interviews was performed with N = 19 truck drivers (M = 50.5 years, SD = 11.4 years; 89.5% male). The interview guide was based on the COM-B model to identify the needs of truck drivers in form of capabilities, opportunities and motivation regarding physical activity. The interviews were transcribed and coded by two independent investigators.

Results

In sum, the codes encompassed N = 395 statements from the participants. The developed code system contained a total number of 14 sub-categories related to the study aim of identifying the individual needs of truck drivers regarding a physical activity change in terms of capabilities, opportunities and motivation. Three additional sub-categories describe other individual needs of truck drivers related to other health behaviours (nutrition, recreation) or their thoughts about company external incentives for health promotion interventions. Quantitative results show that 11% of the truck drivers' suggestions referred to capabilities, 73% to opportunities, and 16% to motivation.

Discussion

The results represent a large number of identified needs that comply with the COM-B model and can be fundamental for the development of physical activity promoting intervention approaches for truck drivers. Possible approaches should include practical implications such as the linking of automatic motivation and psychological capabilities, which comprise

the combination of motivational techniques coupled with information in the psycho-education of truck drivers. To conclude, truck drivers have particularly high and various needs in terms of opportunities to improve their physical activity behaviour. However, the satisfaction of these needs is closely intertwined with the contentment of their motivational and capability needs, which were smaller in proportion but should not be neglected when targeting a holistic implementation of workplace physical activity programs for truck drivers.

THE EFFECT OF ACUTE COMBINED ORAL CONTRACEPTIVE ADMINISTRATION ON SUBSTRATE METABOLISM: A RANDOMISED-CONTROLLED TRIAL

MARTIN, D., PENNINGTON, K.

UNIVERSITY OF LINCOLN

INTRODUCTION: Combined oral contraceptives (COCs) are the most common hormonal contraceptive used by athletes and are and ingested daily, containing synthetic oestrogens (e.g., 17-α-ethinyl oestradiol) and progestins (e.g., levonorgestrel) which peak in the bloodstream ~60-90 minutes post-ingestion. To date, no research has considered how the acute pharmacokinetic profile of COCs affects physiological function related to sport and exercise. The aim of this study was to assess whether acute changes in synthetic hormone concentrations that occur with daily COC use affect substrate metabolism.

METHODS: Nine COC (30 micrograms ethinyl oestradiol, 150mg levonorgestrel) users completed a familiarisation including a lactate threshold (LT) and VO2max test, followed by two main trials. In the main trials, at 8.00 h after a 24h abstinence from COC consumption and an overnight fast, participants ingested their COC or a matched, lactose, placebo (PLA) in a double-blind, randomised and counter-balanced manner. Ninety minutes following COC or PLA ingestion, participants exercised on a treadmill at 60% and 90% LT for 6 minutes each, with respiratory exchange ratio (RER) measured in the final minute. Upon completion of exercise, participants ingested the pill corresponding to alternative condition to maintain contraceptive efficacy. Two-way repeated measures ANOVAs were used to assess the effects of condition (COC and PLA) and intensity (60% and 90% LT) with statistical significance set at $P < 0.05$ and Cohen's D used to calculate effect size.

RESULTS: There was a significant effect of exercise intensity ($P < 0.001$) and condition ($P < 0.01$) on RER, with no intensity x condition interaction effect ($P = 0.337$). RER at 60% LT was significantly ($P < 0.05$; $d = 0.47$) lower in COC (0.845 ± 0.049) compared to PLA (0.864 ± 0.035) and RER at 90% LT was significantly ($P < 0.05$, $D = 0.92$) lower in COC (0.904 ± 0.044) compared to PLA (0.933 ± 0.012).

CONCLUSION: The acute increase in circulating synthetic reproductive hormones shortly after COC ingestion resulted in lower RER values during exercise compared to a placebo, indicating differences in substrate utilisation. To the authors knowledge, this is the first study to show that the timing of COC ingestion can be manipulated to affect aspects of physiological function. Further work is needed to explore the potential applications of this novel concept to sporting populations. N.B. Data for 7 participants are pending (total n = 16) and cognitive function, subjective measures, performance measures (e.g., VO2max) and blood data are to be included in final work.

DESCRIPTION OF THE SEXHORMONAL VARIATIONS ON MENSTRUAL SYMPTOMS AND WELLNESS OF ELITE ATHLETES DURING THEIR MENSTRUAL CYCLE.

LAFITTE, A.

INSTITUT NATIONAL DU SPORT, DE LEXPERTISE ET DE LA PERFORMANCE

INTRODUCTION: The different phases of the menstrual cycle can be characterized by sex hormonal variations. Each of these variations can impact the athletes' wellness (i.e. fitness, mood, sleep quality). During their menstrual cycle, some women will develop premenstrual symptoms [1]. Studies have shown that a consistently higher level of progesterone in the luteal phase is associated with low levels of premenstrual fatigue [2]. Objective : to determine the sex hormonal profile of elite athletes (i.e. estradiol, progesterone and testosterone) and the impact of its variations on their wellness and menstrual symptoms, comparing athletes with a natural menstrual cycles (MC) or IUDs* and athletes on combined oral contraception (OC).

*abbreviation for intra-uterine device

METHODS: 27 elite athletes (12 skiers, 11 rowers, 4 cyclists) volunteered to participate in the study. There were 14 athletes on OC and 13 with a MC. For MC eumenorrheic athletes were included. Salivary samples were taken on average every 3/4 days for x cycles on average. In order to identify abnormal data, while still considering the atypical hormonal profiles of some athletes, we used the Z-scores-based methods [3]. Wellness data and different menstrual symptoms (i.e. soreness, headaches, increased fatigue) were collected. In order to model hormonal profiles, a mixed model with random effect on athletes was used.

RESULTS: In MC athletes, a significantly higher level of progesterone was observed in the luteal phase than in the follicular and menstrual phase (Wilcoxon test: p-value <0.001). There was also a significant difference in estradiol levels between

natural cycle and pill athletes (Wilcoxon test: p-value <0.001). There is a greater variation in testosterone for MC athletes than for OC athletes. In addition, for the MC athletes, the menstrual symptoms were significantly different across the cycle's phases (Kruskall-Wallis test: p-value <0.001). The number of symptoms observed, on the whole of the MC athletes, in the menstrual phase is more important than in the follicular phase and the luteal phase (13.03% in fol., 41.96% in lut. and 45% in menst., n=591). Premenstrual symptoms (i.e. increased fatigue, headaches, breast pain) were reduced in athletes taking hormonal contraceptives.

CONCLUSION: Through this study, we observed the variations of estradiol and progesterone according to the different phases of the cycle while testosterone seems to remain rather stable across the MC. The study of estradiol and testosterone through wellness and symptoms in high performance athletes is still very under researched. Understanding these variations will allow athletes and staff to optimize and adapt their training loads to improve performance.

DOES TIMING OF ORAL CONTRACEPTIVE PILL INTAKE AFFECT EXERCISE PERFORMANCE? A RANDOMIZED CROSSOVER CONTROLLED STUDY

BISGAARD, M.S., RINDOM, A., GJERLEVSEN, S., HANSEN, M.

AARHUS UNIVERSITY

INTRODUCTION: Use of combined oral contraceptives (OC) containing synthetic estradiol and progesterone is prevalent among female athletes. Proportions between 27 and 41% have been reported for different athlete populations in various European countries [1-3]. Research to date indicates a potential slightly reduced exercise performance in OC users compared to non-OC users [4]. However, the acute effect of OC pill intake on athletic performance has not been studied.

During OC use, endogenous sex hormones are downregulated to fairly constant low levels. However, serum concentrations of exogenous hormones from the OC pill peak between one and two hours after pill intake [5, 6]. Nevertheless, already after eight hours, the concentrations of exogenous hormones have declined to a more stable low level. Whether these fluctuations affect exercise performance remains undetermined.

We aimed to investigate a potential acute effect of OC pill intake on strength, power, and endurance performance in trained women.

METHODS: Trained women using monophasic 2nd generation OC pills were tested in a randomized cross-over controlled study. Participants completed a physical performance test protocol one hour after intake of the OC pill and 24 hours after intake of the OC pill. The physical tests included balance stand test, muscular endurance push-ups test, agility test, isometric handgrip strength, countermovement jump height, flexibility test and a maximal oxygen uptake bike test. In addition, a questionnaire about psychological wellbeing was completed before testing. Time of the day, energy intake and exercise preceding the tests was standardized and participants were familiarized with the tests beforehand.

RESULTS: Six out of thirty women have completed tests. Recruitment and testing is ongoing. Analysis of preliminary data showed that countermovement jump was numeric 3,8% higher and maximal oxygen uptake numeric 3.9% lower one hour after OC pill intake compared to 24 hours after OC pill intake. However, the preliminary data showed no significant difference in any of the physical tests between OC pill intake one hour before testing versus 24 hours before testing.

CONCLUSION: Preliminary data of only six participants showed no acute effects of OC pill intake on exercise performance.

In female elite athletes, a minor difference in performance related to OC intake will be of great importance during competition. Thus, this study will bring important knowledge to the female athlete.

RESTING HEART RATE FLUCTUATIONS DURING THE MENSTRUAL CYCLE IN COMPETITIVE FEMALE TRACK AND FIELD ATHLETES

BÜTHE, E., SIPPL, J., PLATEN, P.

RUHR-UNIVERSITÄT-BOCHUM

INTRODUCTION: Early morning resting heart rate (rHR) is an important parameter for athletes to monitor the state of recovery. There are several parameters that might influence rHR, among them the menstrual cycle. The menstrual cycle can be divided into different phases by its hormonal fluctuations of estrogen and progesterone. Some aspects relevant to athletic performance are that estrogen, which peaks in the late follicular phase prior to ovulation can increase endothelium-dependent vasodilatation, while progesterone can increase cardiac excitability. The purpose of this study was to

analyze the influence of the phase of the menstrual cycle on rHR in female elite athletes to gain more detailed knowledge on the interpretation of rHR in the context of load control and regeneration management.

METHODS: In this controlled monitoring study, rHR was assessed at different phases of the menstrual cycle in 9 eumenorrheic competitive female track and field athletes with a total of 22 tracked menstrual cycles. Subjects did not take any hormonal contraception. During the study period, the athletes measured their HR each morning after awakening and documented the value in a monitoring APP. rHR of the 22 cycles were averaged in either 1) five (5-phase-model) or 2) three (3-phase-model) different phases of the menstrual cycle, namely: 1) menstruation (M), late follicular phase (lateF), ovulation (O), early luteal phase (earlyL), late luteal phase (lateL)), and 2) follicular phase (F), ovulation (O), luteal phase (L). Phases of the menstrual cycle were determined by the ovularing©. One-way ANOVA was used for the comparison of mean rHR of the different phases. The significance level was set $\alpha \leq 0.05$.

RESULTS: The following rHR values were determined: 5-phase model: M: 57.0±6.2; lateF: 57.1±6.6; O: 57.4±6.2; earlyL: 57.6±6.5; lateL: 57.1±6.8 (1/min), p>0.05); 3-phase model (L: 57.0±6.2; O: 57.0±6.6; L: 57.5±6.3 (1/min, p>0.05). We could not detect any influence of the phase of the menstrual cycle on rHR in neither of the two models. Individual rHR profiles showed a high inter-individual variability.

CONCLUSION: Despite known influences of female sex hormones on the cardiovascular system, no menstrual cycle-related influences of the variation in the blood concentrations of estrogen and progesterone on early morning rHR in elite athletes were detected in this study. As vagal influence might be higher in endurance athletes and their rHR accordingly lower, a larger number of female athletes from different disciplines (e. g. endurance, sprint, power/strength disciplines) should be recruited in follow-up studies. In addition, heart rate measurements should be performed with identical technically equipment to ensure more accurate determination. This study was part of an investigation about the implementation of menstrual cycle tracking in the German athletics association. This project was funded with research funds from the Federal Institute for Sports Science based on a decision by the German Bundestag.

CLASSIFICATION OF ELITE FEMALE CYCLISTS SESSIONS AND THE IMPACT OF MENSTRUAL CYCLES

CARLIN, H., STORME, F., CHASSARD, T., DURMION, G., TOUSSAINT, J.F., ANTERO, J.

INSTITUT NATIONAL DU SPORT, DE LEXPERTISE ET DE LA PERFORMANCE

INTRODUCTION: The menstrual cycle of female athletes may impact training effort, particularly those in high intensity[1]. We aimed to i) classify the training sessions of elite female cyclists based on the power meter data of each session to ii) identify the effect of the menstrual cycle phases on the different types of training sessions.

METHODS: 13 elite cyclists volunteered to participate in the study. They declared the beginning and the end of their menstrual periods and the other phases of their cycle were determined relying on a prediction method[2]. Three phases make up the female hormonal cycle: the menstrual period is the first phase, followed by the follicular phase which ends with ovulation and begins the luteal phase where progesterone level is highest. Eight of the 13 cyclists met the criteria of a regular cycle between June 2017 and November 2022 . A total of 2,858 cycling sessions were then collected during this period of follow up. A principal component analysis (PCA) was implemented to determine the variables the most discriminants of the effort performed by the cyclists. 14 external load variables were then selected, (e.g., session distance, time, average speed and power, Coggan loads).Then a K-means Clustering was implemented to group similar cycling sessions together stablishing a classification of different types of training. A Wilcoxon test was performed to look for differences in effort between phases of the menstrual cycle.

RESULTS: Two groups of variables were distinguished in the PCA, one representing the training volume, the other the intensity. Four clusters were established: intensive effort (medium Volume, high Intensity), moderate effort (medium Volume, medium Intensity), long effort (high Volume, medium Intensity), and light effort (low Volume, low Intensity). We found a significant difference ($p = 0.005$) between the Intensity of the sessions, in the cluster of intensive effort, during the menstrual phase compared to the follicular. The Intensity indicator the cyclists displayed were 2 times higher during the follicular phase in comparison with the menstruation phase. No differences across the menstrual cycle phases were found in the clusters of moderate, long or light effort ($p > 0.05$).

CONCLUSION: The clustering of cycling sessions allows comparisons among similar training sessions. We showed greater training intensity during the follicular phase among the most intense training sessions, possibly suggesting an impact of the menstrual cycle on the most intense sessions among an elite of female athletes. These findings suggest that the hormonal phases of the menstrual cycle influence elite cyclists performance.

HORMONAL AND IMMUNOLOGICAL RESPONSE TO A COMBINED BIOPSYCHOSOCIAL STRESSOR AND RESISTANCE EXERCISE - A PILOT EXPERIMENT

RAIDL, P., METHLAGL, M., WESSNER, B., CSAPO, R.

UNIVERSITY OF VIENNA

INTRODUCTION: The notion that stress (both physical and psychosocial) has a negative impact on recovery and training adaptations is widely accepted, which is reflected by the recommendation to closely monitor stress as an indicator of an

athlete's state of recovery [1]. Nevertheless, currently, no experimental studies have been performed to directly test the effect of stress on exercise reactions. In this pilot study, we investigated the endocrine and immunological response to resistance exercise (RE) following the Maastricht Acute Stress Test (MAST) [2]. A Solomon 4-group design was used to differentiate between the effects of RE and the stress test.

METHODS: Eight healthy male participants (age = 20 - 35 yrs) were scheduled for a familiarization session and two tests separated by a two-week washout period. Two blocks of n = 4 randomly selected participants underwent the MAST or a non-stress-inducing sham version of the MAST prior to executing either an isokinetic leg press protocol (LP; 4 × 10 reps) or a sham version of the protocol (sLP). In the latter, participants had to perform the same LP protocol while generating only minimal force. The order of the two test days was assigned in a counterbalanced manner.

On both days, blood samples were taken at four timepoints (baseline, post-MAST, post-LP, and 30' post-LP) for analysis of serum cortisol, testosterone, and IL-6 .

All results are presented as change scores from baseline (mean ± SD) and standardized mean differences (SMD) as measure of effect size. Considering the small sample size and associated lack of statistical power, no inferential statistics were computed.

RESULTS: Baseline levels of cortisol, testosterone and IL-6 were similar between the testing days and groups.

Prior to exercise, the stress test had a large effect on cortisol levels (MAST: +3.3 ± 3.2 µg/dL compared to sham-MAST -1.7 ± 0.8 µg/dL; SMD = 2.3). After LP, no differences in blood cortisol were observed between the MAST conditions.

Testosterone levels were unaffected by either MAST condition but increased directly following the LP (+76 ± 45 ng/dL) but not the sLP (-27 ± 56 ng/dL) protocol (SMD = 2.2). Within the LP block, testosterone showed considerably higher increase (SMD = 3.6) after the MAST (+111 ± 22 ng/dL) than after the sham-MAST (+40 ± 27 ng/dL).

No meaningful changes for IL-6 were detected in either group.

CONCLUSION: In our sample, the MAST was effective in increasing blood cortisol levels, but the effect was outweighed by the subsequently performed resistance exercise. The LP protocol increased testosterone, with the effect being larger when the exercise was preceded by the MAST. While the generalizability of the present study is limited by the small sample size, we found promising results for a higher-powered follow-up, to better understand the interaction of stress and exercise adaptations.

SEX STEROID HORMONES IN YOUNG AND MASTER MALE ENDURANCE RUNNERS

SEDLIAK, M.1, CUPKA, M.1, ORESKÁ, L.1, BUZGÓ, G.1, CERNÁCKOVÁ, A.1, HAMAR, D.1, CVECKA, J.1, KERN, H.3, OKULIAROVÁ, M.2, ZEMAN, M.2

1 COMENIUS UNI IN BRATISLAVA, SLOVAKIA FACULTY OF PHYSICAL EDUCATION AND SPORTS, BRATISLAVA, SLOVAKIA 2 FACULTY OF NATURAL SCIENCES, 3 INSTITUTE FOR PHYSICAL MEDICINE, PHYSIK & RHEUMATHERAPIE, AUSTRIA

INTRODUCTION: Testosterone is one of the most potent naturally secreted androgenic-anabolic hormone in men. Ageing beyond 35 to 40 years is associated with a decline of 1% to 3% per year in circulating testosterone concentration (1.6% in total and 2% to 3% in bioavailable testosterone). Previous research showed that rather than decline in total testosterone concentrations, increases in sex hormone binding globulin (SHBG), albumin and decrease in free and bioavailable testosterone are of higher physiological importance in aging. We aimed to compared selected sex steroids hormone parameters in young and senior endurance runners and their untrained age counterparts.

METHODS: Four groups of young and sedentary men were compared: young endurance runners (YE, n=11, 28.2 ± 0.6 yrs, BMI 21.9 ± 0.4 kg.m-2), young sedentary (YS, n=11, 25.5 ± 0.7 yrs, BMI 27.8 ± 1.6 kg.m-2), master endurance runners (ME, n=10, 69.0 ± 1.0 yrs, BMI 24.4 ± 0.8 kg.m-2) and elderly sedentary (ES, n=10 71.1 ± 1.2 yrs, BMI 27.7 ± 0.8 kg.m-2). Young and master endurance runners done more than 300 min per week of running and competition from 10 km to marathon. Sedentary subjects were defined as individuals with no history of regular physical training and activity less than 150 minutes of moderate or 75 minutes of vigorous intensity per week. Early morning fasting sera were assayed for total oestradiol, testosterone, free testosterone and SHBG.

Data were controlled for normality and heterogeneity. Based on the results, parametric or non-parametric tests were calculated. All data are expressed as means ± SEM.

RESULTS: No significant differences were found in total testosterone between the groups (18.6 ± 1,2; 17.7 ± 2.3., 18.1 ± 1.2., 14.8 ± 1.2 nmol/L in YE, YS, ME and ES, respectively). Free testosterone was significantly higher in merged young vs. elderly groups regardless of training status and in sedentary compared to runners (both $p<0.05$). In addition, young runners had higher percentage of free testosterone compared to master runners (1.84 ± 0.01 and 1.57 ± 0.08 % in YE and ME, respectively). SHBG was higher in both YE and ME compared to their age-matched groups. SHGB levels in ME (53.3 ± 3.9 nmol/L) were significantly higher also compared to YE (36.9 ± 0.8 nmol/L, $p<0.05$). Oestradiol levels were significantly higher in YS compared to the other groups.

CONCLUSION: Neither aging nor training status affected the serum concentration of total testosterone. Free testosterone decreased with aging and endurance training did not significantly affect the decline. SHBG level increased with age as

expected, however, the serum levels were higher in both young and master athletes compared to their age-matched groups. Endurance running training may have some effects on bioavailability of testosterone in men regardless of age.

The study was partially supported by the INTERREG V-A Slovakia—Austria (CAA, ITMS2014 + 305041X157) and by the Slovak Research and Development Agency (grant no. APVV-21-0164).

GENDER DIFFERENCE IN GASTRIC EMPTYING RATE AND GASTROINTESTINAL SYMPTOMS AFTER ENDURANCE EXERCISE

LIN, C., ASANO, M., HAYASHI, N., GOTO, K.

RITSUMEIKAN UNIVERSITY

INTRODUCTION: Consumption of nutrition within the early few hours after exercise is recommend (1). Gastric emptying (GE) could affect exercise-induced changes in appetite and energy intake. GE has been shown to be delayed after high-intensity endurance exercise (>70% VO2max) (2). Although females presented delayed GE of both solid and liquid types of meals compared to males (3), little is known about gender difference in GE after endurance exercise. Therefore, the purpose of the present study was to compare the exercise-induced changes in gastric emptying and gastrointestinal symptoms between healthy males and females.

METHODS: Nine healthy males (22.2 ± 1.7 years; 173.5 ± 6.1 cm, 62.5 ± 9.4 kg) and eight healthy females (21.5 ± 3.1 years; 164.7 ± 3.3 cm, 57.3 ± 3.5 kg) were recruited. Participants initially evaluated maximal oxygen consumption (VO2max) by an incremental running test. Then, they conducted 60 min run on a treadmill at 70% of VO2max, followed by a 1-h rest period. Participants were allowed to consume 2 mL/kg BM of water in every 15 min during running. Female participants conducted the 60 min run during the first 10 days of the menstrual cycle. During the 1-h rest period, the gastric emptying rate was determined using 13C-sodium acetate breath test. Appetite and gastrointestinal symptoms (fullness, hunger, stomach distension, stomach pain, desire to eat, nausea) were measured using visual analogue scales before exercise, immediately, 30 min, and 60 min after exercise.

RESULTS: The appearance time of maximum 13C excretion (Tmax, an indication of GE rate) was 40.56 ± 12.4 min in males, and 49.38 ± 12.7 min in females, respectively. However, there was no significant difference between males and females (P = 0.167). No participants complained of GI symptoms before exercise. While the score of hunger increased during 1-h rest period (P = 0.012), it did not differ significantly between males and females (P = 0.146). Also, there was no significant difference in the score of fullness, stomach distension, stomach pain, desire to eat, and nausea.

CONCLUSION: During high-intensity exercise, GE is thought to be delayed mainly through the augmented sympathetic nervous system (4). However, in the present study, there was no significant difference in heart rate during exercise (P = 0.900), post-exercise blood lactate concentrations (P = 0.964) between males and females. In conclusion, there were no significant gender differences in gastric emptying rate and gastrointestinal symptoms after endurance exercise.

AEROBIC EXERCISE TRAINING IN OVERWEIGHT YOUNG ADULTS DOES NOT INDUCE WEIGHT LOSS BUT A REDUCTION IN RESTING METABOLIC RATE

KNAAN, T., ZIV-AV, E., DUBNOV-RAZ, G., MELANSON, E., GEPNER, Y.

TEL AVIV UNIVERSITY

INTRODUCTION: Exercise training intervention studies have shown that total daily energy expenditure (TDEE) increases less than expected, and consequently, less weight than predicted is lost. However, the physiological mechanisms for exercise-induced energy compensation remain unclear. This study aimed to identify changes in the metabolic efficiency that occur as a physiological adaptation to moderate exercise training.

METHODS: Using a clinical trial protocol, 16 overweight (body mass index: 28.1±2.1 kg/m2) men (n=8) and women (n=8) aged 38.9±3.7 years were enrolled in a 3-month exercise intervention. Exercise training was supervised at a moderate intensity (65%-75% HRmax) of 20 kcal/kg/week. Changes in resting metabolic rate (RMR) were evaluated by whole human room indirect calorimetry ("metabolic chamber"), and total TDEE was evaluated by double-labeled water. Body composition was assessed by multi-frequency bioelectrical impedance before and after the intervention

RESULTS: Mean adherence to exercise training was 95%, with a significant increase of TDEE by 194±304 kcal/day (p=0.03) and VO2max by 1.77±2.91 ml/min/kg (p=0.04). However, no change was observed for body weight, fat mass, or fat-free mass (0.1±2.1 kg, 0.4±1.7%, and 0.4±1.2 kg, respectively). Following the exercise intervention, RMR decreased significantly (p=0.02) by -70±102 kcal/day.

CONCLUSION: Compensatory mechanisms induced by chronic exercise at moderate intensity may be mediated, at least partly, by reducing RMR. This trial was registered at clinicaltrials.gov as NCT04460040.

THE EFFECTS OF REPEATED COLD WATER IMMERSION ON THE IMMUNE SYSTEM AND CARDIOVASCULAR FACTORS IN HEALTHY MALES: A PILOT STUDY

VERSTEEG, N., CLIJSEN, R., HOHENAUER, E.

UNIVERSITY OF APPLIED SCIENCES AND ARTS OF SOUTHERN SWITZERLAND

INTRODUCTION: In recent years, cold water swimming has received much attention due to its potential health benefits. Despite the growing interest and popularity, there is little evidence available that repeated cold water immersion (CWI) has positive effects on the immune system and cardiovascular health [1]. Therefore, this pilot study aimed to investigate the effects of a 3-week CWI intervention on inflammatory markers (blood cell counts of total leukocytes, neutrophils, basophils, eosinophils, monocytes, lymphocytes, thrombocytes) and cardiovascular factors (mean arterial pressure [MAP], heart rate [HR]) in healthy males.

METHODS: 12 healthy men (26.0±3.7 years, 171.0±7.5 cm, 74.9±8.0 kg), non-habituated to CWI, were randomly allocated to the CWI or control (CON) group. The CWI group underwent a 3-week CWI intervention (12 min at 7°C., 4x per week). The CON group was instructed to maintain their daily habits and were not allowed to perform any type of cold therapy. Blood cell counts (total leukocytes, neutrophils, basophils, eosinophils, monocytes, lymphocytes, thrombocytes) and cardiovascular factors (MAP, HR) were assessed at baseline and after the 3-week intervention period. Wilcoxon matched-pairs signed rank test was used to compare the before-and-after differences, with a significance level set at $p<0.05$.

RESULTS: Total leukocyte count decreased significantly ($p=0.031$) in CWI, with a median difference of -1.10 x 10^3/µL (95%CI: -2.80 to -0.20) while CON did not show a significant change ($p>0.05$). Leukocyte differential count revealed a significant decrease in neutrophils in CWI ($p=0.031$), with a median difference of -0.65 x 10^3/µL (95%CI: -2.20 to - 0.10) while no change was observed in CON ($p>0.05$). There were no significant differences in the counts of basophils, eosinophils, monocytes, lymphocytes or thrombocytes in either CWI or CON (all $p>0.05$). CWI showed a significant decrease in MAP ($p=0.031$), with a median difference of -12.00 mmHg (95%CI: -25.00 to -7.00). HR was significantly reduced ($p=0.031$) in CWI, with a median difference of -3.50 bpm (95%CI: -9.00 to -1.00). In contrast, CON did not show a significant change in either MAP or HR ($p>0.05$).

CONCLUSION: The preliminary results of this pilot study indicate that a 3-week CWI intervention may have a suppressive effect on the immune system in healthy males. However, the findings suggest potential beneficial effects on cardiovascular health. Further studies with larger sample sizes are needed to more thoroughly examine the effects of repeated CWI on health markers. Given the potential for sex differences in response to the intervention, future research should also explore the effects in a female population.

IDENTIFYING KEY PERFORMANCE INDICES THAT DISTINGUISH ELITE MIDFIELDERS FROM SUB-ELITE COUNTERPARTS IN PROFESSIONAL MENS FOOTBALL USING A MULTIPLE-MODEL MACHINE LEARNING APPROACH

PHATAK, A.1, JAMIL, M.2, MEHTA, S.1, HINRICHSEN, J.1, MEMMERT, D.1

1GERMAN SPORTS UNIVERSITY, 2UNIVERSITY OF SUFFOLK,

INTRODUCTION: Previous research has effectively employed multiple machine learning algorithms (MMLAs) to investigate Key Performance Indicators (KPIs) that differentiate elite football players from sub-elite ones in the top 5 European soccer leagues. These studies have focused primarily on goalkeepers [1]. The present study employs the same approach to investigate KPIs that distinguish elite and sub-elite midfielders.

METHODS: 272 distinct performance statistics were collected from the top five European football leagues for the seasons 2013-2018 using Opta sports data, a highly reliable source [2]. A total of 2600 midfielders, corresponding to 82527 unique match performances, were examined by dividing them into two groups: those who played in the Champions League (CL: 1) and those who did not (NCL: 0). This classification was similar to the previous studies performed on goalkeepers [1]. The performance statistics were pre-processed through scaling, normalization, and K-best feature selection, resulting in 20 features as input to the chosen models. Three Machine Learning classifiers - logistic regression (LR), XGBoost (XGB), and decision tree classifier (DT) - were used to analyse the chosen features. The imbalance in the data set was addressed by balancing "class weights" for each algorithm. A data science expert conducted hyperparameter optimization for the ten-fold cross-validation scores to optimize 'balanced accuracy'. Relative feature importance or odds ratios were reported to identify the top features that differentiated CL midfielders from NCL midfielders. All analysis was performed using python 3.10.0

RESULTS: XGBoost outperformed logistic regression and decision tree classifier across multiple model performance matrices. "Passes received," "Successful Passes Opposition half," "Touches open play opp box," and "Successful short passes" were the top four features (KPIs) across all models, with "Passes received" being the most influential. Odds ratios showed that an increase in these top features enhanced the likelihood of a midfielder being classified as CL. However, the odds

ratios were relatively high due to scaling and normalization, and a one-unit increase in KPIs does not directly translate to a literal unit increase in game-specific terms.

CONCLUSION: Successful short passing and the number of touches in the opponents penalty area were identified as features that distinguished elite from sub-elite midfielders. The findings suggest that successfully executing passes and involving oneself in attacking play are key distinguishing features of elite midfielders. However, the study had limitations such as the use of only one proxy measure of talent, and a lack of physical/psychological performance data and advanced performance metrics. Future research should aim to address these limitations and expand this area of research using a similar multiple-machine learning approach with a wider range of measures and proxy measures of talent.

RELATIONSHIP BETWEEN GAZE BEHAVIOUR AND DECISION MAKING DURING ON-FIELD SPORT SITUATIONS IN PROFESSIONAL VS YOUNG ELITE RUGBY LEAGUE PLAYERS.

ILLE, A., GARGAGLI, M.

UNIVERSITY TOULOUSE III - PAUL SABATIER

INTRODUCTION: This study was initiated by a rugby league coach who wanted to gain insight about the visual cues that expert players use to make decision in a specific 3 vs 2 game situation, in order to provide better guiding cues for perception and decision performance of young elite players. Our aim was to study gaze behaviour in relation with the quality of decision, during on-field offensive situation [1], and to compare between professional and young elite players.

METHODS: Four male professional and international rugby league players (mean age 30+/-1 years) and 4 male young players (mean age 17+/-1 years) from a national talent development program participated. All had normal vision. On a 10 x 10m delimited area, three attackers had to bring the ball over two defenders. The ball carrier, equipped with a wearable eye tracker (Tobii Pro Glasses 2), had to either run with the ball, or pass it to one of his teammates, depending on the situation. An experienced coach coded the relevance of the decision and the quality of the action performed. Eye tracking data was analysed by means of Tobii Pro Lab software. Seventeen areas of interest (AOI) were defined, representing the various locations of fixations in the visual scene. Repeated measures ANOVAs were performed on the relative duration of the fixations. The link between quality of decision and action performance was analysed by a chi-square test.

RESULTS: Only AOI had a significant main effect ($F_{16,96}=6.87$; $P<0.01$). The space between defenders was fixated for longer time than others areas. A significant interaction expertise level x AOI ($F_{16,96}=4.13$; $P<0.01$) showed that professional players and young elite players had different gaze patterns. Experts spent more time fixating the outsider defender and defenders' shoulders whereas younger elite players focused on the space between defenders and defenders' lower body. The quality of decision had no effect on fixation relative duration. The decision quality was linked to performance in professional players (chi-square1=9.77; $P<0.01$), whereas no significant link was found in young players (chi-square1=0.56; $P>0.05$).

CONCLUSION: Visual fixations on the space between defenders may represent a visual pivot or gaze anchor [2] allowing players to take information on surrounding areas. Both professional players and young elite players spent time fixating defenders' bodies, allowing them to anticipate the running direction and detecting deceptive movement [3]. Visual information pick-up was not clearly linked to decision quality in this explorative study. For professional players, a good choice always lead to a good performance, but not for young athletes: an issue of motor skill or of timing of decision making?

CHARACTERIZING THE PEAK KINEMATIC AND MECHANICAL MOST DEMANDING PERIODS IN ELITE FOOTBALL: COMPOSITION ANALYSIS OF EACH HALF AND MATCH DEMANDS

YOUSEFIAN, F.1,2, ZAFAR, A.3, FRANSSON, D.4, BRITO, J.2, TRAVASSOS, B.1,2

1 UNIVERSITY OF BEIRA INTERIOR; 2 PORTUGAL FOOTBALL SCHOOL, PORTUGUESE FOOTBALL FEDERATION; 3 UNIVERSITY OF WATERLOO; 4 UNIVERSITY OF GOTHENBURG

INTRODUCTION: A comprehensive understanding of the most intense periods (MIP) of elite football activity is critical to informing training design to ensure optimal preparation of athletes. The characterization and reporting of MIP demands in current studies [1,2] are limited in their application in performance monitoring and designing of training sessions. Therefore, the aim of this study was to characterize the 5-min peak kinematic (5'MIPk; running distance) and mechanical (5'MIPm; acceleration/deceleration) periods in elite football through describing the composition of the respective MIP in terms of the percentage magnitude, percentage duration, and number of efforts of the constituent performance variables.

METHODS: Global positioning system (GPS) data was collected during 45 matches of two teams in the Swedish first division (n=329 observations) across two seasons. The 5'MIPk periods were identified based on the maximal total distance covered concurrently at 15-19.8 km·h-1 (high-intensity running; HIR), 19.8-25.2 km·h-1 (high-speed running; HSR), and ≥25.2 km·h-1 (sprinting; SPR). The 5'MIPm were identified as the maximal average magnitude of concurrent high-intensity acceleration (ACC3; ≥3 m·s-2) and deceleration (DEC3; ≤ -3m·s-2) demands. The percentage of the total distance (MIPk) and average acceleration/deceleration (MIPm), percentage duration of the 5-min period, and the number of efforts for the performance variables and their respective constituent variables were analyzed between each half and the full match.

RESULTS: Linear mixed-effects models revealed small to moderate significant ($p\leq0.05$) decreases of 5-9% and 9-11% between halves for the magnitude, number of efforts, and duration of both 5'MIPk and 5'MIPm, respectively. Similarly, small

to moderate significant (p≤0.05) differences of 11-12%, 7-10%, and 5-10% between halves were observed for the magnitude, number of efforts, and duration of HIR, HSR, and DEC3, respectively. The percentage distance, percentage duration, and number of efforts composition of MIPk and constituent kinematic performance variables were small to very large significantly (p≤0.05) greater in the match 5'MIPk compared to 5'MIPm. Similarly, the high intensity mechanical constituent variables and MIPm were significantly (p≤0.05) greater in the match 5'MIPm compared to 5'MIPk.

CONCLUSION: Results of this study provide greater insight into the composition of peak kinematic and mechanical demands in elite football and demonstrate that MIPk and MIPm represent distinct periods of peak demands in each half and the full match. The detailed characterization of the respective MIP allows coaches to design bespoke training sessions targeting specific locomotor activities, and the design of MIP in standardized settings to assess individualized physiological response and fatigue development to the respective MIP based on match demands.

IMPACT OF WELLNESS INDICATORS IN THE RELATIONSHIP BETWEEN EXTERNAL AND INTERNAL LOAD IN FOOTBALL

CHASSARD, T., DORMION, G., DUPUIT, M., BLANQUET, L., MEIGNIE, A., HALLADJA, A., TOUSSAINT, J.F., ANTERO, J.

INSEP

INTRODUCTION: Understanding the relationship between external and internal load according to the wellness monitoring commonly used in elite sports can be of great interest in order to adapt and optimise the athletes' training sessions.

We aimed to determine whether the external load performed in a training session is below or above what is expected for an athlete considering a specific internal load, based on the athletes' individual profile, and then to identify the wellness parameters that may be associated with these variations.

METHODS: Training and wellness data from 15 elite female footballers (23.7 ± 4.4 years) was collected during a 7-month follow-up throughout the 2021-22 season.

Wellness data (i.e. sleep duration and quality, perceived fitness, wake up mood), were collected through a daily mobile app questionnaire.

Regarding the training data, the players wore GPS Catapult tracking devices which provide information on their displacements, speeds, accelerations and related metrics.

We chose to use Catapult Player Load, which is the sum of the acceleration across all axes of the internal tri-axial accelerometer during training session as our external load metrics, and Rating of Perceived Effort (RPE) as our internal load metrics [1,2]. A total of 1,419 training sessions containing both Player Load and RPE were collected. The internal-external load pairs were grouped by player and by RPE, to calculate the 15 and 85 percentiles of Player Load for each RPE category. The "expected zone" of external load was determined when the Player Load corresponded to the estimated within the 15 and 85 percentile values; "below the expected " when Player Load is below 15 percentile values and "above the expected" when Player Load is above 85 percentile values.

Thereafter we compared the wellness indicators of the specific days where the external load variable was not in the "expected" range, through a Mann-Whitney U test.

RESULTS: The internal training load is highly and significantly associated with the external load ($r = 0.65$; $p = 0.01$).

Considering the whole group, sleep duration is significantly higher (p-value = 0.011) when external load is above the expected for a specific RPE.

At individual level, sleep duration is significantly higher (p-value < 0.05) when external load is above the expected for 7 players. For other players the factors the most determinants for an external load above the expected is the sleep quality for 2 players, emotional feelings for 4 players and perceived physical condition for 4 player

CONCLUSION: We showed that RPE is an excellent measure of external load. Yet, variations on such correlation occurs. We showed that increased sleep duration is the wellness indicator that is mostly associated with an external load above the expected for a similar level of internal load, suggesting that increased time of sleep is associated with a lower perception of fatigue.

LEUKOCYTE TELOMERE LENGTH IN ELITE MALE SOCCER PLAYERS: EXERCISE INTENSITY ROLE STUDIED

SELLAMI, M.

QATAR UNIVERSITY

INTRODUCTION: Biological aging is associated with changes in the metabolic pathways. Leukocyte telomere length (LTL) is a predictive marker of biological aging; however, the underlying metabolic pathways remain largely unknown. The aim of this study was to investigate the metabolic alterations and identify the metabolic predictors of LTL in elite male soccer players.

METHODS: Levels of 837 blood metabolites and LTL were measured in 126 young elite male soccer players who tested negative for doping abuse at anti-doping laboratory in Italy. Multivariate analysis using orthogonal partial least squares (OPLS), univariate

linear models and enrichment analyses were conducted to identify metabolites and metabolic pathways associated with LTL. Generalized linear model followed by receiver operating characteristic (ROC) analysis were conducted to identify top metabolites predictive of LTL.

RESULTS: Sixty-seven metabolites and seven metabolic pathways showed significant associations with LTL. Among enriched pathways, lysophospholipids, benzoate metabolites, and glycine/serine/threonine metabolites were elevated with longer LTL. Conversely, monoacylglycerols, sphingolipid metabolites, long chain fatty acids and polyunsaturated fatty acids were enriched with shorter telomeres. ROC analysis revealed 8 metabolites that best predict LTL, including glutamine, N acetylglutamine, xanthine, beta-sitosterol, N2-acetyllysine, stearoyl-arachidonoyl-glycerol (18:0/20:4), N-acetylserine and 3-7-dimethylurate with AUC of 0.75

(0.64-0.87, p <0.0001).

CONCLUSION: This study characterized the metabolic activity in relation to telomere length in elite soccer players. Investigating the functional relevance of these associations could provide a better understanding of exercise physiology and pathophysiology of elite

athletes

THE CLOCK IS TICKING: EFFECTS OF SHOT-CLOCK RESET RULES CHANGES ON EUROLEAGUE BASKETBALL PERFORMANCE

PENG, S.H., LIU, Y.T.

NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: Rules in sport ensure players compete in fair conditions. In basketball, the shot clock reset rules limit the time during which the team that possesses the ball may attempt a field goal. Following recommendations from the International Federation of Basketball Association (FIBA), the EuroLeague adopted the shot clock reset rules changes in 2008 and 2014. This means the 14-second shot clock reset is implemented when certain defensive fouls are committed, or when certain offensive rebounds are collected. The shortening of the shot clock reset time has the potential to increase the number of ball possessions, reflected by the pace of the games. While the number of possessions is not recorded in the basketball box scores, an estimate is made possible from the box scores based on the equation proposed by (1). Thus, this study aims to examine the effects of the shot-clock reset rules changes on possession related team performances over the last 22 seasons for the EuroLeague.

METHODS: Data included 494 sets of box scores from the EuroLeague regular season 2000-01 to 2021-22. Each set of box scores was the averaged box scores of a team over a season. The data was divided into three periods: before the rule changes in 2008, between 2008 and 2014, and after the rule changes in 2014. The Field-goal Attempts (FGA), Free-throw Attempts (FTA), Turnovers (TOV), and Offensive Rebounds (OREB) from the box scores were used to calculate the number of ball possessions (POSS) in a game, and were also analyzed individually. One-way ANOVA was used to examine the effect of rule changes on the possession related variables.

RESULTS: FTA and TOV were reduced significantly over the 3 periods, (ps< .001). There was also a significant effect of the rule changes on FGA and OREB, and the post-hoc paired comparisons showed that a significant increase was only observed after the second change of the shot clock reset rule (p<.01). There was no significant effect of rule changes on POSS.

CONCLUSION: The overall number of possessions in a game did not change significantly over the two changes of the shot clock reset rules. The pace of the EuroLeague games was not affected by these rule changes. The effect of the rule changes mainly influenced the specific performance that contributed to the overall number of possessions. The reduction of FTA may have been the balance effect from the encouraged non-shooting defensive fouls as a result of the reduction of the shot clock reset time. Increased pressure from the defense, as well as the reduced shot clock reset time after offensive rebound, could have both contributed to the increase of FGA and OREB. The reduced TOV, although without direct evidence, we deduce could be the result of reduced deploy time.

CP-BM13 Jumping

THE DISCRETE VARIABLES DERIVED FROM THE FORCE-TIME CURVE CAN CLUSTER DIFFERENT LEVELS OF DROP JUMP PERFORMANCE RATHER THAN SPORT-SPECIFIC BACKGROUND

PANOUTSAKOPOULOS, V., CHALITSIOS, C., NIKODELIS, T., KOLLIAS, I.A.

ARISTOTLE UNIVERSITY OF THESSALONIKI

INTRODUCTION: Drop jumping (DJ) tests the effectiveness of the stretch-shortening cycle. Multivariate analysis methods, i.e. Principal Components Analysis (PCA), have been used to examine sport-specific differences in DJ that were evident due to different sporting background (1). Recently, cluster analysis revealed different patterns and dissimilarities for the force, power and vertical stiffness-time curves that identified the level of DJ performance across different sport-specific backgrounds (2). Thus, it is still unclear whether DJ performance parameters are unbundled to sports-specificity. This study aimed at investigating if the DJ discrete (0D) variables can reveal specific patterns that can cluster DJ performance.

METHODS: Data of DJ from 0.4m (n = 128) were used (2). A PCA with varimax rotation over the 0D variables (force output, F; rate of force development, RFD; power output, P; duration, T; vertical stiffness, K) was performed. The scores of the 0D variables in the resultant principal components were hierarchically clustered (Ward's method) to summarize the characteristics of the formed subgroups. The assessment of the derived clusters' quality was conducted by calculating the cophenetic correlation coefficient between the hierarchical cluster tree and the pairwise distances. The R v3.6.1 software (R Foundation for Statistical Computing, Vienna, Austria) was used.

RESULTS: PCA revealed three principal components (Kaiser criterion; eigenvalues > 1) that explained 87.0% of the total variance. The first rotated principal component accounted for 60.9% of the variance and was associated with the DJ kinetic characteristics (eigenvalue: 7.31), as it was mostly related to the force derived parameters (RFD, F, P, K). The second PCA dimension explained 17.6% (eigenvalue: 2.12) of the variance and was related to T. The third component represented the 8.5% (eigenvalue: 1.02) of total variance and had a strong association with the downward peak RFD and P, as well as with T for peak F. Hierarchical clustering (cophenetic correlation coefficient: 0.75) revealed three clusters: Cluster 1 with lower-than-average values for P, T, F and downward peak RFD, Cluster 2 with lower-than-average values for K, P, RFD and F, but the common variables considered in the partition for Cluster 2 had greater values than Cluster 1, and Cluster 3 with higher-than-average values for P, F, RFD, K and T.

CONCLUSION: Results suggest that F and P measures can identify distinct levels of DJ performance (1,2). This confirmed past research that found that clustering techniques applied on DJ force-time curve data relate distinct movement strategies with different functional performance outcomes (3). In conclusion, data reduction methods applied on DJ variables can be used to classify the level of performance regardless of the sport-specific background.

THE ACUTE EFFECTS OF ASSISTED AND RESISTED VARIABLE RESISTANCE BACK SQUATS ON COUNTERMOVEMENT JUMP PERFORMANCE

VAN ENIS, A.

UNIVERSITY OF DERBY

INTRODUCTION: Back squat warm-up activities using elastic band (EB) resistance in combination with free weight resistance (FWR) can improve subsequent countermovement jump (CMJ) performance [1], a phenomenon termed post-activation performance enhancement (PAPE). However, across the literature sub-maximal loads of 85% are commonly used, with limited research existing on the effect of lighter loads on acute performance enhancement under both FWR or EB (resisted [RES] or assisted [ASS]) conditions. The aim of the present study was to compare the effects of back squats at 50% 1-RM under two EB attachment sites (ASS and RES) and FWR alone after a task-specific comprehensive warm-up on subsequent CMJ performance.

METHODS: Twenty active males (age = 24.9±3.7 y, height = 1.7±5.7 m, mass = 83.4±12.6 kg) volunteered for the study and completed three separate experimental conditions (FWR, RES, ASS) separated by 48 h following a randomised crossover design. During each condition, participants first completed initial baseline CMJ tests (BL1) followed by a task-specific comprehensive warm-up that involved 5 min of cycling, two sets of 5 bodyweight squats, 5 continuous CMJs at 70% of perceived maximum, and finally, maximal CMJs every 30 s until 3 consecutive jumps were within 3% of jump height. Baseline 2 (BL2) CMJ tests were then completed and followed by 3 back squats following either the FWR, RES or ASS protocols at 50% 1-RM with 35% of the load generated by EBs during the RES and ASS conditions. CMJs were then performed 30 s, 4 min, 8 min and 12 min later.

RESULTS: Significant increases ($p<0.05$) in both jump height (4.6-18.8%) and peak power (5.3-10.8%) were observed across all timepoints when compared with BL1 measure in all conditions. In the ASS condition, significant increases in jump height

(4.6-11.8%) and peak power (6.5-2.0%) were observed at 30 s, 4 min, 8 min, and 12 min compared to BL2. In the RES condition, significant increases in jump height (7.1-1.2%) and peak power (2.3-5.4%) were observed at 30 s, 4 min, and 8 min, and in the FWR condition, significant increases in jump height (2.2-5.7%) and peak power (1-4.6%) were observed at 30 s and 4 min.

CONCLUSION: The implementation of back squats into a warm-up activity at 50% 1-RM increased jump performance when EBs were used during both the ASS and RES conditions, with the increase in jump height being greater than that observed in the FWR condition. The use of EB resistance speculatively reduces loading at the sticking point, potentially allowing for greater acceleration during the concentric phase as lower-limb joints extend at the point where more optimal muscle lengths are achieved [2].These data have important implications for warm-up design for strength and power activities.

EFFECTS OF HAMSTRINGS-TO-QUADRICEPS RATIO AND THE LOWER EXTREMITY PERFORMANCE DURING SINGLE-LEG DROP JUMP IN FEMALE BASKETBALL PLAYERS: A PILOT STUDY

HSIAO, H.W., TSENG, P.C., LEE, H.J.

NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: Lower limb injuries commonly occur in female basketball players due to basketball having a unilaterally dominant characteristic, which may lead to an imbalance in the strength and reaction of the lower limbs. In past studies, the effect of knee flexor and extensor strength differences in the lower limbs has been extensively discussed to the risk of injury. Additionally, lower limb strength and landing style significantly influence jumping performance. This may increase the incidence of non-contact injuries while landing and jumping. In contrast, the reactive strength index (RSI) is reliable for evaluating plyometric performance and examining both jump and landing capability. However, the relationships between the hamstrings-to-quadriceps (H/Q) ratio value and sports performance in both legs have yet to be thoroughly investigated. Therefore, this study aimed to examine the differences between single-leg drop jump (SLDJ) performance and H/Q ratio in female basketball players.

METHODS: This study included seven professional women basketball players (age 24.1±1.5 years; height = 1.7±0.5 m; weight = 67.3±8.5 kg) who performed three SLDJ tasks for each leg from a 30 cm height platform. A motion analysis system with six cameras (Motion analysis crop, 200Hz) and one force plate (Kistler, 9260AA6, 2400Hz) was used to collect the lower extremity kinetic and kinematic data during SLDJ. The joint angle, moment, and joint stiffness were processed by Visual 3D software (C-Motion, USA). The dominant sides of the Participants lower extremities in this study were decided according to their H/Q ratio from manual muscle testing (MMT), which was conducted using the handheld dynamometer. A paired t-test was used to compare the differences between SLDJ performance, lower extremities MMT, and biomechanical variables of the dominant and non-dominant sides.

RESULTS: There were significant differences between the H/Q ratio (62% vs. 43%, p=.021) on the dominant and non-dominant sides. The H/Q dominant sides performance was significantly better in jump high (p=.046) and RSI (p=.009) than the non-dominant side. Besides, the MMT showed that H/Q dominant sides hamstring strength was significantly higher (p=.035). In contrast, the quadriceps strength was significantly lower (p=.047) than the non-dominant side. Though the biomechanical variables during SLDJ have no significant difference in lower extremity angle and moment, the ankle and knee joint stiffness showed significantly greater in the H/Q dominant side.

CONCLUSION: Our present results indicate that asymmetry of the H/Q ratio and lower limb strength affect their jumping performance. The difference in strength, RSI, and joint stiffness between the H/Q dominant and non-dominant side in womens basketball players may be a potential risk of injury in the future. We suggest players require appropriate lower limb muscular strength, especially for knee flexors in H/Q non-dominant side, to elevate performance and avoid injuries.

COMPARISON OF MUSCLE ACTIVITY IN LOWER EXTREMITIES BETWEEN HIGH JUMPERS AND GENERAL ATHLETES DURING RUNNING SINGLE-LEG VERTICAL JUMP OVER DIFFERENT DISTANCES

HSU, T.M., HUANG, B.X., NAI, H.F., LIN, J.Z.

NATIONAL TAIWAN UNIVERSITY OF SPORT

INTRODUCTION: The running vertical jump is a common action on sports fields, and most running vertical jump applies single-foot takeoff [1]. With special training, horizontal kinetic energy can be effectively converted into vertical kinetic energy. The speed of the approach run affects jumping performance, which is affected by the running distance. Therefore, the ideal jumping performance requires a balance between the vertical jump and the speed of the approach run. However, the differences regarding muscles and the speed of the approach run between professional athletes of jumping events and general athletes have rarely been discussed. The aim in this study was to determine how different approach run lengths affect single-leg vertical jumps. The jumping performance and characteristics of lower limb muscle activation of professional and general athletes were observed.

METHODS: In this study, 23 junior college athletes divided into two groups: 11 athletes in the general group and 12 professional jumping-event athletes in the specialty group. The distance of the approach run was set to 1, 3, and 5 m from the force plate boundary. The participants were required to perform a vertical take-off with single-leg on the force plate after an approach run, and then land on both feet. Kinetic data were collected by Two Kistler force plates and seven Noraxon wireless EMG. The phase was divided into the pre-landing, landing, descending, and ascending. The statistical method used was two-way ANOVA, mixed design.

RESULTS: In the pre-landing phase, 100 ms before landing, the activation of ST in the specialty group with a 1 m approach run was significantly higher than that in the general group; the activation of VL, RF, ST, and TA in the specialty group with a 3 m approach run was significantly higher than that in the general group. We further compared the effects of different distances on muscle activation. The results indicate that the activation of VL, RF, and VM with the 3 m approach run in the specialty group was much higher than with the 1 m approach run.

CONCLUSION: We found that the rectus femoris and vastus medialis muscles with 1, 3, and 5 m approach runs were more activated than the hamstring tendons during the process of landing to take-off, which indicates that the main function of the quadriceps during the take-off process was to assist the knee joint to extend the knee and perform concentric contraction. In this study, different approach distances and groups were used to analyze the changes in the muscle activation of the lower limb during a single-leg vertical jump. We found that the degree of muscle activation in the specialty group was significantly higher than that in the general group for the different approach distances. Because vertical jump performance is closely related to the performance on the horizontal approach run, the results show that only those with a certain level of skill could achieve higher running vertical jump performance.

DOES THE LIMITATION OF THE FIRST METATARSAL-PHALANGEAL JOINT IMPACT VERTICAL JUMP PERFORMANCE?

GONTHIER, J., GILLET, C., LETENEUR, C., SIMONEAU-BUESSINGER, E.

LAMIH-UMR-CNRS-8201

INTRODUCTION: Athletes who participate in high-impact sports are at higher risk for acute and chronic forefoot injuries, including hallux rigidus (1). This alteration can result from repeated traumas and mechanical overloads especially in case of hyper flexion at the hallux. Hallux rigidus affects 10% of patients between the ages of 20-34 years and a incidence of 1 in 40 adults over the age of 50 (2) (3). The physiopathology of hallux rigidus corresponds to a degeneration of the 1st metatarsal-phalangeal (MTP) joint of the hallux and is characterised by a progressive decrease in the range of dorsiflexion at this joint. Hallux rigidus can involve a variety of therapeutic interventions, conservative or surgical The use of insoles is one of the conservative treatments. Such insoles (Morton's extension), thanks to a rigid element, consist of limiting the mobility of the 1st MTP joints. While this intervention is known to reduce pain in patients (4), its impact on the wearer's motion is unclear. The aim of this study was then to determine the biomechanical impact of limiting the 1st MTP joint during a jump task in healthy participants.

METHODS: All participants were sportive people (9 males and 3 females, age 27 ± 7.89 yrs, height 1.76 ± 0.56 m, body mass 71.3 ± 11.08 kg), free of neuromuscular disorders, and with no lower limb injuries in the past 6 months. The study was approved by a Research Ethics Board.

Participants had to perform counter movement jumps (CMJs) with and without insoles, in a random order, and with sport shoes provided by the experimenter.

A 10-high speed digital video camera system (Vicon) was used to record the 3-dimensional trajectories of retro-reflective markers placed on the athlete. It allowed to assess the position of the centre of gravity of the body and then to determine jump height. Force platforms (Kistler) embedded in the ground were used to assess the vertical impulse.

RESULTS: For the CMJ condition, there were no significant differences in jump height (41.46 ± 8.55 cm vs 41.38 ± 8.74 cm ; p=0.64) nor vertical impulse (183.30 ± 26.75 N.s vs 169.30 ± 61.52 N.s; p=0.18) with the insoles and without the insoles, respectively.

CONCLUSION: The main finding of this study was that the limitation of the first MTP joint did not induce any significant impact on the CMJ performance While this was true for healthy patients, it would be very interesting to investigate the impact of such rigid insoles in people suffering from hallux rigidus.

AGE-RELATED CHANGES IN THE KINEMATICS OF THE LOWER LIMBS DURING DOUBLE- AND SINGLE-LEG REBOUND JUMPS

HIOKI, Y.1, KASUGA, K.2, HAYASHI, R.2

1: HYOGO UNIVERSITY OF TEACHER EDUCATION 2: GIFU UNIVERSITY

INTRODUCTION: The single-leg jump, used in plyometric training, is one of the most effective ways to improve the short-distance running and jumping abilities of children (1). Age-related changes in the performance and kinetics of the lower limbs in single-leg jumping are similar to those of double-leg jumping, but with differences in some variables (2). Age-related changes in jumping performance depend on force performance (3) and jumping technique (4). Therefore, investigating how the jumping technique changes with age may us help to understand the causes of age-related differences in double- and single-leg jumping abilities. This study aimed to determine age-related changes in the kinematics of the lower limbs during double-leg and single-leg rebound jumps.

METHODS: Forty-five untrained males 7–15 years-of-age performed double-leg (RJ) and single-leg (SRJ) rebound jumps. Participants were verbally instructed to keep the contact time as short as possible and to jump as high as possible. Jump movements in the sagittal plane were filmed using a high-speed video camera (300 Hz) and were recorded using a force platform (1000 Hz). Seven body points and four calibration markers were digitized; the digitized coordinates were converted into real coordinates using four reference markers on the ground. The joint angle of the take-off leg was calculated using these coordinates. For each joint angle, differences between age groups were compared using a two-way analysis of variance (two exercises, four age groups).

RESULTS: The analysis showed no significant interactions for all variables. Significant main effects were observed between age groups for the ankle and hip joint angles of the RJ and the ankle-joint angle of the SRJ when landing ($p < 0.05$). In addition, a significant main effect on the hip-joint angle of the RJ was observed at take-off ($p < 0.05$). A significant main effect was observed between the exercises for the delta ankle joint angle of the RJ and SRJ of the flexion phase ($p < 0.05$). In addition, a significant main effect was observed for the delta ankle and knee joint angles of the RJ and SRJ of the extension phase.

CONCLUSION: The age-related changes in the ankle and knee joint angles at the point of landing and take-off showed similar trends in RJ and SRJ, whereas the age-related changes in hip angle showed different trends in RJ and SRJ. The delta-ankle angle of the flexion phase and delta ankle and knee joint angles of the extension phase in RJ were shown to be greater than that SRJ, except for some grades. These results suggest that age-related changes may cause differences in kinematics in the lower extremities during RJ and SRJ.

THE EFFECT OF TENDON STIFFNESS ON MUSCLE POWER PRODUCTION DURING COUNTERMOVEMENT JUMP

KURIYAMA, K., TAKESHITA, D.

THE UNIVERSITY OF TOKYO

INTRODUCTION: Making good use of the stretch-shortening cycle (SSC) is important for enhancing sport performance. Previous studies suggested that compliant tendon may contribute to augmentation of jump height due to SSC (Kubo et al., 1999; 2007). While this is consistent with the traditional idea that the compliant tendon is advantageous for utilizing elastic energy (Cavagna, 1977), the stored elastic energy itself should not affect the jump height (van Ingen Schenau et al., 1997) . However, the tendon stiffness might affect the power exertion by muscle fibers because the elongation of the tendon affects the contraction velocity of muscle fibers. Therefore, we aimed to systematically investigate the effect of the tendon stiffness on the muscle power production during movement with SSC using a computer simulation.

METHODS: A Hill-type muscle model was used to simulate countermovement jumps using only the ankle joint. The model consisted of a contractile component (CC), a series elastic component (SEC), and a mass. From the initial resting state, the mass typically exhibited countermovement-like motion. The moment when the mass passed the initial position with upward velocity once it had fallen some extent was defined as the take-off. The jump height was calculated from the velocity of the mass at the take-off. The neural inputs to CC were optimized using a genetic algorithm to maximize the jump height. The optimized motion for a different spring constant (100 to 400 kN/m) of SEC was obtained.

RESULTS: The jump height decreased with an increasing spring constant. Both the time from the initial state to the take-off and the time average of exerted power by CC (the product of these two is equivalent to the jump height) also decreased with an increasing spring constant. Regardless of the spring constants, the time series of the neural inputs was similar: it became almost none after the initial resting state, causing downward movement, and rose to the maximum level instantly at a certain moment, which we call the "rising phase". The CC power dynamics was significantly different among the motions with different spring constants at the rising phase. While the motion with compliant SEC showed positive CC power constantly, that with stiff SEC showed negative CC power at the former half of the rising phase. This negative power led to lower CC work and thereby lower jump height.

CONCLUSION: CC was able to perform larger work with compliant SEC than with stiff SEC for two reasons. First, the motion time of the compliant SEC model was long because the natural frequency, which is proportional to the square root of the spring constant, is low. Second, the time average of exerted power by CC was large for the compliant SEC because of slower force development, which enabled CC to exert positive power all the time during the rising phase . In conclusion, the compliant SEC enabled CC to exert high power over a long time, and therefore enhanced the jump performance.

AN UPPER LIMBS PLYOMETRIC PERFORMANCE COMPARISON BETWEEN EXPERIENCED AND NON-EXPERIENCED ATHLETES.

DHOTE, S., EON, P., GROSPRÊTRE, S.

UNIVERSITÉ DE FRANCHE-COMTÉ

INTRODUCTION: Lower limbs plyometrics is a topic that is extensively studied in scientific literature. There are however a very few studies about upper limbs explosive movements (1), performed with one's bodyweight only. Here, we aimed at

comparing the ability to perform the classical exercise of push-up in an explosive way, of Street Workout (SW) athletes, that are particularly trained on upper limbs, and athletes from various sports, by adapting classical tests usually performed on lower limb, and see if the behavior on upper limbs matches the latter ones.

METHODS: Eighteen healthy male participated to this study (22.6 ± 2.1 yrs, 71.9±6.6 Kg, 179.6±7.1 cm). They were divided into 2 groups : Nine were street workout athletes, and the nine others practiced various other sports.

They performed 3 different forms of the push-up : one in a concentric way (equivalent to squat jump), the 2 others were done in plyometric way (counter movement jump and drop jump), and they did a fatigue-inducing set. Jump heights, EMG (on PEC, DELT and TRI) and acceleration of the body were recorded.

Muscular ultrasonography was performed at rest on 4 muscles involved in the push-ups (pectoralis major (PEC), anterior deltoid (DELT), long and lateral head of triceps brachii (TRI LONG and TRI LAT)).

RESULTS: 3 types of PU :

An ANOVA revealed that SW group had higher jump heights than CO group (respectively 18.1±5.7 and 11.0±4.8 cm, $p< 0.001$), but the jump height did not differ between modalities of PU. They were no difference of the EMG between groups or modalities.

Accelerations :

The repeated measures of ANOVA showed no effect of modality or interaction effect of group*modality. The maximal values of acceleration were 2.94 ± 0.27 G for CONC, 2.99 ± 0.29 G for PLYO and 3.06 ± 0.26 G for .

Fatiguing PU Set (FS) :

T-tests showed that SW group maintained higher relative jump heights than CO group (92,2±22,8 % of the first repetition for SW and 74,9±29,9 % for CO). The mean ratio of EMG on the DELT was greater in CO group, but for TRI it were greater in SW group. There was no difference for PEC. The relative EMG activity increased for both groups, reaching up to 149 % of the first repetition.

Muscle architecture :

SW athletes had higher PEC and DELT muscles thicknesses (MT) than CO group ($p<0.05$), but there was no difference for TRI. SW had greater pennation angles than CO on PEC only (SW = 6.9 ± 2.9° ; CO = 3.7 ± 2.3° , $p<0.05$). The was no difference for DELT and TRI.

CONCLUSION: Highest values of MT in general, and of EMG in the FS tend to suggest that the greater height reached by SW athletes when doing the explosive push-up can be attributed mostly to peripheral adaptations, and in a smaller extent to neuromuscular ones. The transferability of plyometric abilities of lower limbs to upper limbs are questioned, even in trained athletes. Further studies should emphasize the validation of this kind of push up test to assess upper limbs plyometrics.

LOWER LIMB STIFFNESS: RUNNING AND SINGLE LEG HOPPING TEST, IS THERE A LINK ? A PILOT STUDY.

GODIN, A.1,2, LAHEURTE, S.2, BERNARD, N.2,3, MOUROT, L.1, CASSIRAME, J.4,5,6

1 EA3920, EPHI PLATFORM, UNIVERSITY OF FRANCHE-COMTÉ. 2 PHYSIO-SPORT BESANÇON. 3.EA481 UNIVERSITY OF FRANCHE COMTÉ 4 MTRAINING R&D. 5 C3S–UR 4660, UNIVERSITY OF FRANCHE-COMTÉ. 6 EA 7507, REIMS.

INTRODUCTION: Return to run is a step in the continuum of return to sport for many injuries such as ankle sprains or anterior cruciate ligament ruptures. Rehabilitation and screening prior to return to run can consist in hopping to estimate lower limb stiffness (1). Stiffness could be estimated during hopping (Kn) and during running (two indexes, Kleg and Kvert) with ground contact and flight time measurement (2,3). But even if the estimation of stiffness at these two motor tasks is based on the spring-mass model, only few evidence investigates the relation between them. The aim of this study is to evaluate the relationships between Kn, Kvert and Kleg to assess the possible interchangeability of these indexes.

METHODS: 25 recreational runners performed 3 sessions of 6-min bout of running on a treadmill (Monark Exercise AB, Vansbro, Sweden) followed by 20-second of single leg hop tests. Running speed was set at the preferred running speed (PRS). Runners performed the hop test with each limb at an imposed frequency of 2.2 Hz and at preferred hopping frequency (PHF)(4). Computation of Kn, Kvert and Kleg was performed from spatiotemporal parameters measured with the optoelectronic system Optogait (Microgate, Bolzano, Italy). A repeated measurement correlation coefficient (RmCorr, 3 sessions datas) was performed between Kn at 2.2 Hz or PHF and Kvert or Kleg at PRS (5).

RESULTS: There was no correlation between Kvert, Kleg and Kn at 2.2 Hz hopping condition ($p>0.05$). There was a significant correlation between Kvert at PRS and Kn at PHF ($p<0.05$). The strength of the correlation between Kvert and Kn was moderate ($r = 0.49$, CI 0.24-0.68) when comparing limb to limb (right lower limb vs right lower limb) or when comparing Kn to an overall Kvert value (right and left lower limb combined; $r = 0.50$, CI 0.25-0.69). The strength of correlation between Kleg and Kn was also moderate for limb-to-limb comparison ($r =0.35$, CI 0.07-0.58) or combined limb comparison ($r = 0.33$, CI 0.04-0.56).

CONCLUSION: Frequency of 2.2 Hz is recommended for the single hop test (6), but this frequency is not relevant to compare stiffness measured in running and hopping (single leg) condition. Fixed frequency imposes a contact time that influences the value of Kn and the joint involved in the stiffness and could explain our results (4). Kvert, Kleg and Kn at PHF appear to be moderately correlated, but the confidence interval of the correlation makes the clinical applications unrelia-

ble. This may be explained by the variety of speeds at PRS and running styles. Future studies should investigate speed and running style influence on the correlation between Kleg and Kn and asymmetry of these parameters.

LINEAR DISCRIMINANT ANALYSIS FOR AUTOMATIC CLASSIFICATION ON STANDARD MAXIMUM VERTICAL JUMP

RODRIGUES, C.M.B.

FACULTY OF ENGINEERING, UNIVERSITY OF PORTO

INTRODUCTION: Countermovement (CM) is a common element at several sports, with reversible action preceding the movement in the intended direction for efficient submaximal and powerful maximal action [1]. At lower limbs CM has been studied on standard maximum vertical jumps (MVJ) with long CM on countermovement jump (CMJ) and short CM on drop jump (DJ) for comparison to squat jump (SJ) without CM [2, 3]. Despite guidance provided to the performers on execution of SJ, CMJ and DJ there is a natural tendence to precede SJ with slight CM as well as on DJ to accomplish a long CM, thus leading to some mixture on the type of performed trials depending on subjects' jumping technique, and the need for improvement of automatic trials classification.

For this reason, we performed linear discriminant analysis (LDA) for segmentation-based learning on previous SJ, CMJ and DJ trials for subsequent automatic classification, reducing operator time consumption and improving objective classification supported by kinematic and dynamic extracted variables.

METHODS: A total of 46 dynamic and kinematic predictor variables were selected from best MVJ trial execution of 198 repetitions from 3 SJ, 3 CMJ and 3 DJ by two groups of nT=16 trained (T) athletes of the Portuguese national volleyball team (21.4±3.1)yrs, (85.2±5.8)kg mass and (1.93±0.04)m height and nU=6 untrained (U) students of sports and physical education degree, without specific sports records or injuries, ages (21.5±1.4)yrs, (76.7±9.3)kg mass and (1.79±0.06)m height.

Selected variables from 7 different categories of time (t), vertical resultant force (F), impulse (I), whole body vertical velocity (vz), vertical displacement (z), mechanical power (P) and work (W) were computed from ground reaction forces (GRF) acquired during impulse phase by an AMTI BP2416-4000CE force plate at 1000 Hz coupled to Mini Amp MAS-6 and grouped on four communities of (i) t-F-I, (ii) F-v-P, (iii) F-z-W, and (iv) global t-F-I-v-P-z-W community. LDA was applied to each community and results were compared among T, U groups individually and T&U together.

RESULTS: LDA yielded two statistically significative ($p<0.05$) discriminant functions with first function F1 accounting for larger explained variance (s2) at U, T, U&T for (i) 98.0%, 61.4%, 85.1%, (ii) 98.5%, 85.0%, 79.8%, (iii) 77.7%, 57.6%, 55.6%, (iv) 98.0%, 94.1%, 88.7%, whereas F2 accounts for the remaining s2.

CONCLUSION: F1 explained s2 point for a similar pattern at (ii)-(iv): U>T>U&T with (i): U>U&T>T and s2↓ with n↑. F1 explaining larger s2, discriminates more often SJ from DJ, whereas F2 discriminates mostly CMJ from SJ,DJ pointing for larger difference between SJ and DJ, with CMJ lower difference to SJ and DJ. LDA thus presented as powerful discrimination tool with learning ability for automatic classification of new MVJ trials.

EFFECT OF DIFFERENT GAIT PATTERNS ON VENTILATION AND MUSCLE ACTIVITIES IN RESPONSE TO SINUSOIDALLY CHANGING TREADMILL SPEED

FUJITA, M.1, KAMIBAYASHI, K.1, HORIUCHI, M.2, EBINE, N.1, FUKUOKA, Y.1

<1> DOSHISHA UNIVERSITY, <2> NATIONAL INSTITUTE OF FITNESS AND SPORTS IN KANOYA

INTRODUCTION: There is a U-shaped relationship between energy cost of transport per unit distance (CoT; J•kg-1•km-1) and gait speed (v) during walking and a linear relationship during running. The intersection between U-shaped and linear CoT-v relationships is termed energetically optimal transition speed (EOTS). We investigated the effect of different gait patterns on ventilatory and muscle activities in response to sinusoidally changing treadmill speed.

METHODS: Twelve healthy young subjects performed three sinusoidal exercise protocols on a treadmill. One sinusoidal protocol was the combination of walking and running (walk and run condition: WR) that the treadmill speed was sinusoidally changed in a range of individuals' EOTS ± 1.5 km•h-1. A second was the complete running (run condition: R) that the treadmill speed was changed in a range of ([EOTS ± 1.5 km•h-1] ± 1.5 km•h-1). A third was the complete walking (walk condition: W) that the treadmill speed was changed between 3 and 6 km•h-1. Breath-by-breath pulmonary ventilation (VE: integrating tidal volume [VT] and breathing frequency [Bf]) and metabolic demands (CO2 output [VCO2] and O2 uptake [VO2]) were measured under the WR, R, and W conditions. Muscle activities were measured by electromyography of the ankle dorsi-flexor (tibialis anterior [TA]) and ankle extensors (gastrocnemius [GAS] and soleus [SOL]) muscles throughout the sinusoidal walking.

RESULTS: Mean values of metabolic rate (VCO2 and VO2) and VE increased with the increase in gait speed (all $p<0.001$). The amplitude (Amp) response of VE, VCO2, and VO2 were significantly greater under the WR condition compared to the R or W conditions (all $p<0.001$). The mean and Amp values of the GAS muscle slightly increased under the R condition, but those values of the TA and SOL muscles decreased under the R condition. In addition, the significantly greater Amp response of VE under the WR condition was significantly associated with the greater Amp in VCO2 ($r2=0.97$, $p<0.001$) and VCO2 ($r2=0.90$, $p=0.003$) under the WR, but independent of the muscle activity.

CONCLUSION: Transition from walking to running induced a significant increase energy expenditure, hyperventilation, and a slight increase in the GAS muscle activity. On the other hand, the greater Amp response of ventilation at the EOTS may be primarily mediated by metabolic response rather than neural drive.

EFFECTS OF HIGH-INTENSITY INSPIRATORY MUSCLE WARM-UP ON HIGH-INTENSITY EXERCISE PERFORMANCE AND MUSCLE OXYGENATION

KOIZUMI, J.

CHUKYO UNIVERSITY

INTRODUCTION: The inspiratory muscles become fatigued during high-intensity exercise performed to exhaustion. Inspiratory muscle fatigue (IMF) causes a metaboreflex, which reduces blood flow to an active limb. Therefore, IMF can have a negative impact on high-intensity exercise performance by impairing oxygen supply to muscles in the active limb. Inspiratory muscle warm-up (IMW) increases inspiratory muscle function immediately and is used to decrease and delay IMF. However, the effects of IMW on high-intensity exercise performance and active limb oxygenation are not consistent1,2. High-intensity exercise requires higher ventilation, which increases the activity of the inspiratory muscles and recruitment of accessory inspiratory muscles. Most IMW studies have been conducted at moderate loads (40% maximal inspiratory mouth pressure [MIP])1,2 but accessory inspiratory muscles become further active at higher inspiratory loads. Therefore, higher-intensity IMW may be necessary when performing high-intensity exercise. This study investigated the effects of high-intensity IMW on high-intensity exercise performance and muscle oxygenation.

METHODS: Eleven healthy men (mean age, 22 ± 2 years; mean VO_2max 52.6 ± 4.9 ml/kg/min) performed constant-load exercise to exhaustion on a cycle ergometer at VO_2max under two conditions in randomized order. The two conditions were IMW before exercise, namely, a placebo condition (PLA), and a high-intensity condition (HIGH) with respective inspiratory loads set at 15%MIP and 80%MIP. MIP was measured before and after IMW. Total hemoglobin was measured in the right vastus lateralis by near-infrared spectroscopy during exercise. Perception of leg exertion was measured at 1 and 2 min into exercise.

RESULTS: Mean exercise tolerance time was significantly longer under HIGH than under PLA (238 ± 57 s vs. 220 ± 47 s, $p=0.042$). MIP was significantly increased after IMW under HIGH (from 123 ± 20 cmH_2O to 133 ± 25 cmH_2O, $p=0.018$). Total hemoglobin was significantly higher under HIGH than under PLA at 40% and 60% of total exercise time. Perception of leg exertion was significantly lower under HIGH than under PLA at 2 min of exercise.

CONCLUSION: Considering that total hemoglobin is considered to be an index of local blood flow, the results of this study suggest that high-intensity IMW increases blood flow to active limbs during exercise. The results may also reflect a reduction in perception of leg exertion. IMW may increase blood flow to active limbs and improve exercise performance.

TRANSFER FUNCTION ANALYSIS DETERMINED CEREBROVASCULAR CO2 REACTIVITY WITHOUT CARBON DIOXIDE INHALATION

OGOH, S.

TOYO UNIVERISTY

INTRODUCTION: The established methods for determining cerebrovascular carbon dioxide (CO2) reactivity (CVR), as an index of cerebral vascular regulation, require a CO2-inhalation challenge. However, CO2-inhalation potentially causes acute stress or hyperventilation that can modify CVR. The purpose of the present study was to test if CVR can be assessed without including a CO2-inhalation challenge.

METHODS: In twenty-one healthy participants, CVR was assessed by the transfer function analysis (TFA) between middle cerebral artery blood velocity (MCA V) and predicted arterial pressure of CO2 (PaCO2) during spontaneous respiration. TFA gain and phase were calculated to index the magnitude and time constant responses of CVR, and compared with CVR indices determined using a CO2-inhalation challenge. Response to orthostatic stress (50° head-up tilt; HUT) was ascertained because attenuates CVR indices determined using CO2-inhalation.

RESULTS: During HUT, the magnitude and time constant of MCA V responses to CO2-inhalation were decreased (P<0.001) and increased (P=0.001), respectively, indicative of attenuated CVR. In contrast, TFA gain in the very low-frequency range (VLF, 0.005-0.024 Hz) was unchanged, while the TFA phase in the VLF approached zero (–0.39±0.59 vs. 0.31±0.78 radians, P=0.003), indicative of enhanced CVR, during HUT.

CONCLUSION: These findings suggest that TFA-determined CVR during spontaneous respiration does not track HUT-evoked reductions in CVR identified using CO2-inhalation, suggesting that CO2-inhalation is necessary to assess CVR adequately.

IS THE VO2MASTER, A PORTABLE SPIROMETRIC DEVICE, A VALID TOOL TO ASSESS THE OXYGEN CONSUMPTION?

KUBICA, C.

INSTITUTE OF SPORT SCIENCE

INTRODUCTION: Measurements of human metabolism via indirect calorimetry are fundamental in many research areas such as health, exercise and training, and athletic performance. To date, laboratory-based gas analysis systems are considered as state-of-the-art measurements, however, several portable metabolic gas analyzers have emerged, allowing analysis in field-based setting[1] Field testing offers the possibility to replicate the actual demands of different sports disciplines, such as soccer, more realistically compared to laboratory-based assessments [2]. Recent research indicates that portable metabolic gas analyzers can be a valid and reliable tool in steady-state measurements [2], however, several analyzers show limitations in assessing moderate to vigorous intensities[3]. Therefore, this study aims to evaluate the validity of a novel portable spirometry (VO2Master Analyzer, VO2 Master Health Sensors Inc, Canada) compared to a stationary metabolic cart (Oxycon Pro, Jaeger, CareFusion, USA) in female soccer athletes.

METHODS: Twelve female amateur soccer athletes (Age: 22.2±3.7 years; BMI: 22±3.0 kg/m2; VO2max: 50.75±4.2 ml/min/kg) volunteered to participate in the randomized-controlled study which included two non-consecutive laboratory visits within one week. Demographic and anthropometric data were collected on the first visit, including age, weight, height, BMI, % body fat, and self-reported physical activity. On both test days, the same protocol was performed which included: assessments of heart rate (HR) and oxygen consumption (VO2) during 5min of running on a treadmill at a velocity of 7km/h (low intensity), and during an incremental step test on the treadmill until volitional exhaustion to measure the VO2peak (vigorous intensity). The incremental step test started at a velocity of 7km/h with an incline of 1%. Every minute the velocity was increased by 1km/h until volitional exhaustion. To assess VO2 and VO2peak, a portable spirometry (Vo2Master Analyzer) and a stationary criterion measure (Oxycon Pro, Jaeger) were used.

RESULTS: The results revealed a significant difference between the oxygen consumption under different loads assessed with the stationary metabolic cart (relative VO2peak: 50.75±4.2 ml/min/kg; low intensity: 1732.7±299.1 ml/min) and the portable spirometric device (relative VO2peak:43.44±5.8 ml/min/kg; low intensity: 1467.0±218.0 ml) (p<0.001; cohen's d=0.800 and p=0.001; cohen's d=0.423) in the female soccer athletes. Bland-Altman plots have shown a lack of reproducibility in the measurements between the two devices, with medium mean differences for the evaluated spirometric parameters and 30% of the measurements not being within the limits of agreement.

CONCLUSION: Our results don't support the use of the new portable spirometric device as a reliable spirometer for the assessment of various spirometric patterns in practice, but more data is needed in various populations is needed to verify the results.

PEAK OXYGEN UPTAKE IS SLOPE DEPENDENT: INSIGHTS FROM GROUND REACTION FORCES AND MUSCLE OXYGENATION

LEMIRE, M.1,2, MEYER, F.4, TRIGUERA, R.3, FAVRET, F.1,2, MILLET, G.P.3, DUFOUR, S.P.1,2

1 UNIV. OF STRASBOURG, FMTS, UR 3072, STRASBOURG, FRANCE; 2 UNIV. OF STRASBOURG, FAC. OF SPORT SCIENCES, STRASBOURG, FRANCE;

INTRODUCTION: This study explores the effect of treadmill slope on ground reaction forces and local muscle oxygenation as putative limiting factors of peak oxygen uptake (VO2peak) in graded maximal incremental running tests.

METHODS: Thirteen healthy subjects completed five maximal incremental running tests on treadmill at -15%, -7.5%, 0%, 7.5% and 15% slopes while cardiorespiratory and local muscle oxygenation responses as well as ground reaction forces were continuously recorded. Blood lactate concentration and isometric knee extensor torque were measured before and after each test.

RESULTS: VO2peak was lower at -15% slope compared to all other conditions (from –10% to –17% lower, $p < 0.001$), with no difference between -7.5 to +15% slope. Maximal heart rate and ventilation values were reached in all conditions. The negative external mechanical work increased from steep uphill to steep downhill slopes (from 6% to 92% of total external work) but was not correlated with the VO2peak reduction. Local muscle oxygenation remained higher in -15% slope compared to level running ($p = 0.003$). VO2peak can be reached in downhill running up to -7.5% slope.

CONCLUSION: At more severe downhill slopes (i.e., -15%), greater negative muscle work and limited local muscle deoxygenation occurred, even in subjects familiarized to downhill running, presumably preventing the achievement of VO2peak.

DIAPHRAGMATIC FUNCTION ASSOCIATED WITH AEROBIC ENDURANCE IN LONG DISTANCE RUNNERS

WU, H.1, LIN, Y.1, CHANG, W.1, CHENG, K.2, TSAI, Y.1,2

1 DEPARTMENT OF PHYSICAL THERAPY, COLLEGE OF MEDICINE, NATIONAL CHENG KUNG UNIVERSITY; 2 INSTITUTE OF ALLIED HEALTH SCIENCES, COLLEGE OF MEDICINE, NATIONAL CHENG KUNG UNIVERSITY

INTRODUCTION: Long-distance running has been proven be beneficial to the cardiopulmonary function in previous studies, and became a very popular exercise. Since the diaphragm is the most important respiratory muscle, the diaphragmatic function could be one of the key factors that influence the performance of long-distance running (Hellerstein & Moir, 1985; Zdziarski et al., 2016). However, to date none has investigated the diaphragmatic function in long-distance runners. The contributions of diaphragmatic functions to aerobic endurance remains unknown (Gopaladhas et al., 2014). Therefore, the main purposes of this study were to compare the diaphragmatic function in long-distance runners and young adults using the ultrasonography, and to investigate the correlations between the diaphragmatic function and aerobic endurance.

METHODS: This study was a case-control study including the 12 long-distance runners who have been regularly trained for at least 6 months (runner group), and 16 young adults without long-distance running experience (control group). All participants received the same measurement. Aerobic endurance including maximal oxygen uptake and exercise intensity were evaluated using the cardiopulmonary exercise testing (CEPT) (Ultima™ CardiO2®+ Corival CPET ergometer, MGC Diagnostic®, Saint Paul, USA). The diaphragmatic function including diaphragmatic mobility and thickness changes during maximal inspiration and expiration were assessed using the ultrasonography (ACUSON NX3TM Ultrasound system, Siemens Solution USA, Inc). In addition, diaphragmatic strength indicated as maximal inhalation and exhalation pressure (MIP, MEP) were tested using the gas gauge.

RESULTS: The results found that the MEP ($p=0.043$), maximal oxygen uptake ($p<0.001$) and maximal exercise intensity ($p=0.007$) for the long-distance runners were significantly higher than that for the control group. Group difference in MIP, diaphragmatic mobility and thickness change was not found. Furthermore, all diaphragmatic measures were significantly correlated with the maximal oxygen uptake ($r=0.22$ to 0.508, $p<0.05$), and MEP was correlated with the total exercise intensity ($r=0.515$, $p=0.01$).

CONCLUSION: Only diaphragmatic strength especially MEP was stronger in the long-distance runners but not diaphragmatic mobility and thickness change, although the runners have better aerobic endurance than the controls. However, the correlation analysis revealed that diaphragmatic function including strength, mobility and thickness change were all related to the aerobic endurance. Diaphragmatic training could be considered for the long-distance runners in the future.

ACUTE EFFECTS OF SINGLE VS. COMBINATORY INHALED B2-AGONISTS SALBUTAMOL AND FORMOTEROL ON TIME TRIAL PERFORMANCE, LUNG FUNCTION, METABOLIC AND ENDOCRINE PARAMETERS

BIZJAK, D.A., NUSSBAUMER, D., WINKERT, K., TREFF, G., TAKABAJASHI, K., MENTZ, L., SCHOBER, F., BUHL, J.L., JOHN, L., DREYHAUPT, J., STEEB, L., HARPS, L., PARR, M., DIEL, P., ZÜGEL, M., STEINACKER, J.

UNIVERSITY HOSPITAL ULM

INTRODUCTION: High prevalence rates of β2-agonists amongst athletes makes it tempting to speculate that illegitimate use of β2-agonists might boost performance in competitive sports. However, data regarding the underlying molecular basis of potential performance-enhancing effects of β2-agonists are scarce.

METHODS: To investigate single vs. combinatory doses of nonprohibited, effects of the short-acting β2-agonists salbutamol (SAL) and long-acting formoterol (FOR), 24 competitive endurance athletes (12f/12m) participated in a double-blinded balanced 4-way block cross-over trial to evaluate the performance-enhancing potential of SAL and FOR compared to placebo (PLA). Measurements included skeletal muscle gene and protein expression of nuclear NR4A receptors, endocrine regulation, urinary and serum β2-agonist concentrations, cardiac markers, cardiopulmonary and lung function as well as the 10-min time trial performance (TT) on a bicycle ergometer as main outcome variables. Blood and urine samples were collected Pre-, Post-, 3h Post-, and 24h Post TT.

RESULTS: Mean power output during TT was not different between the respective study arms. Treatment effects regarding lung function, echocardiographic and metabolic parameters were observable without any influence on performance as well as higher total serum β2-agonist concentrations in female athletes for SAL and FOR. Muscle and microarray analysis did not show any treatment effect on NR4A protein and NR4A1/NR4A3 gene expression, whereas a whole group treatment effect was observable for NR4A2 and further target genes with strongest effect by SAL+FOR. Noradrenaline, adrenaline, and transforming growth factor-β concentrations in blood were not affected by treatment or sex, whereas insulin-like growth factor, follicle-stimulating hormone, luteinizing hormone, and insulin concentrations showed a treatment effect at different time points.

CONCLUSION: There is no performance-enhancing effect in this study design with the used doses of β2-agonists either alone (SAL or FOR) or in combination (SAL+FOR) compared to PLA.

An acute effect on the lung and cardiac function as well as endocrine and metabolic parameters was observable without clinically relevant side effects and with presumably no impact on exercise performance capacity in healthy subjects, but the impact of chronic applications of β2-agonists to healthy individuals and sex-specific thresholds have still to be determined.

EXERCISE-INDUCED BRONCHOCONSTRICTION IN CHINESE ELITE ATHLETES OF OLYMPIC SUMMER SPORTS EVENTS

CHEN, S.1, LIU, M.2

1 VICTORIA UNIVERSITY. 2 SHANGHAI UNIVERSITY OF SPORT

INTRODUCTION: The aim of this study was to investigate the prevalence of exercise-induced bronchoconstriction (EIB) among Chinese elite athletes who participated in the Olympic Summer Games. The study also aimed to compare the prevalence of EIB across different sport events and analyze the characteristics of key indicators related to respiratory inflammation and ventilatory function in athletes with EIB.

METHODS: A total of 413 elite athletes (235 females and 178 males) of 15 different summer sports were recruited for this study. They were categorized, based on their environments in which they received trainings, into either indoor (pool- or land-based) or outdoor sport events (road- or venue-based), and based on their sport events characteristics into endurance, skill, speed & strength, or team sport. Respiratory symptoms during exercise, asthma history, and EIB information were collected through a questionnaire. Pulmonary function data, including forced expiratory volume in the first second (FEV1), maximum ventilation, forced vital capacity, expiratory peak air flow rate, were collected during a bronchial exercise provocation test, and the drop rate of FEV1 was used to diagnose EIB. The inflammatory responses of each athlete were evaluated through venous blood samples, and chi-square tests, independent sample t-tests, or repeated measures analysis of variance were used to identify the significance.

RESULTS: Of all the 413 elite athletes, a total of 109 athletes were diagnosed with EIB, resulting in an overall prevalence of 26.5%. Swimming (51.5%), hockey (40.7%), synchronized swimming (40.0%), rugby (38.5%), and track and field (33.3%) had the highest prevalence of EIB, while judo (11.1%), rhythmic gymnastics (10.5%), badminton (9.5%), weightlifting (9.5%), and wrestling (6.5%) had the lowest prevalence. Female athletes had a significantly higher prevalence of EIB compared to male counterparts (30.2% vs. 21.3%, P = 0.049). The prevalence of EIB was significantly higher in endurance events athletes than speed & strength events ones (37.3% vs. 20.0%, P = 0.038) and significantly higher in outdoor sports events athletes than indoor sports events athletes (33.1% vs. 21.6%, P = 0.05). There was no significant difference between the venue- and road-based events in outdoor environments. All pulmonary function parameters were significantly lower in athletes with EIB, indicating lower lung function than those without EIB. Athletes with EIB also had significantly higher levels of certain blood-related indexes, such as eosinophil count, neutrophil count, IL-6, IL-8, and CC16 levels, compared to athletes without EIB.

CONCLUSION: The findings of the study reveal that Chinese elite athletes who participated in the Olympic Summer Games were significantly impacted by EIB. Athletes with EIB exhibited lower levels of lung ventilation and severe airway inflammation. As a result, stakeholders such as athletes, coaches, and sports administrations should pay close attention to EIB problems and take appropriate measures to prevent them. Specifically, monitoring inflammatory indicators is recommended as an early preventative strategy.

FIRE PROTECTION EQUIPMENT LOAD AND MOVEMENT SPEED AFFECTS RESPIRATORY PARAMETERS AND SUBSTRATE UTILIZATION OF BRAZILIAN FIREFIGHTERS: A PILOT STUDY

RODRIGUES, N.A.1, SOUSA, F.A.B.1, SILVATTI, A.P.2, MARINHO, A.H.1, BALIKIAN, P.1, ARAUJO, G.G.1

1FEDERAL UNIVERSITY OF ALAGOAS; 2FEDERAL UNIVERSITY OF VICOSA

INTRODUCTION: Firefighters are often exposed to complex tasks and situations that demand physical strain, requiring good tactical and physical conditions to burden their occupational performance [1]. The use of protective garments by firefighter's influences their metabolic cost [2] and limits the maximum speed of running [3]. Considering the submaximal aerobic demands of firefighting tasks [1], this study aims to test the effect of carrying the fire protection equipment load under different submaximal running speeds on respiratory parameters and substrate utilization of Brazilian firefighters.

METHODS: Five firefighters performed three minutes of walking (4 km·h−1 - WALK) and running (8 km·h−1 - RUN), under the conditions of wearing light clothes (LIGHT) or their personal protective equipment (PPE). PPE was composed of boots, gloves, a bunker jacket, a bunker pants, hood, helmet, and oxygen cylinder, and averaged 22.8 kg. Relative oxygen consumption (VO2), energetic expenditure, minute ventilation, breathing frequency, tidal volume, respiratory quotient, and relative use of carbohydrate (CHO) as substrate were retained for analysis, using the breath-by-breath data analysis (QUARK, COSMED). Two-way ANOVA was performed to test for speed and condition effects, with Scheffés S procedure as post-hoc whenever the interaction significance was met ($p<0.05$).

RESULTS: Relative VO2 consumption presented no effect for condition (LIGHT = 21.6±9.1vs PPE = 21.7±7.9 ml·kg−1·min−1), despite the effect for speed (WALK = 14.2±2.0 vs RUN = 29.15±4.1 ml·kg−1·min−1). However, the energetic cost was higher in PEE (604±273 kcal·min−1) than LIGHT (450±203 kcal·min−1), confirming PPE's effect on the metabolic cost of running [2]. Minute ventilation was also affected by both condition ($p = 0.01$) and speed ($p <0.001$). However, breathing frequency was not significantly higher in PPE (27.9±6.0 b·min−1) than in LIGHT (25.4±4.7 b·min−1), leaving the tidal volume (PPE=1.72±0.60 vs LIGHT=1.39±0.50L·min−1; $p=0.04$) as the major contributor for PPE effect on minute ventilation. The only variables with a significant interaction between condition and speed were the respiratory quotient ($p=0.0041$) and substrate use ($p=0.002$).

This revealed higher values for CHO use in RUN+PPE condition (94.2± 8.4%) than RUN+LIGHT (32.2±14.9%), but not significant different values between WALK+PPE (7.7±6.6%) and WALK+LIGHT (4.4±6.0%).

CONCLUSION: The use of PPE by firefighters altered the energy expenditure, minute ventilation, and tidal volume during walking and running. Relative VO2 was not altered by the PPE load because it considered the total weight of the system (firefighter+PPE). PPE load also affected the respiratory quotient in favor of CHO use only in the running speed, suggesting the need for attention on CHO depletion of firefighters when under higher intensity activity.

MODERATE PHYSICAL ACTIVITY REDUCES THE LIKELIHOOD OF SARCOPENIA IN COMMUNITY-DWELLING OLDER WOMEN: A CROSS-SECTIONAL APPROACH

MACHADO, D.R.L.1,2,3, MARINI, J.A.G.2, ABDALLA, P.P.2, BOHN, L.3,4, MOTA, J.3, DUNCAN, M.5, SANTOS, A.P.2

1UNIVERSITY OF ALGARVE; 2UNIVERSITY OF SAO PAULO; 3CIAFEL-UNIVERSITY OF PORTO; 4LUSOFONA UNIVERSITY; 5COVENTRY UNIVERSITY

INTRODUCTION: The time spent in different intensities of physical activity (PA) is associated with the risk for sarcopenia in community-dwelling older women. We aimed to evaluate the role of sitting time and PA level as predictors of sarcopenia risk.

METHODS: In a cross-sectional study, physically independent older women (n=67) performed the six-minute walk test to identify functional limitations (≤400m). Sedentary time (as sitting time) and PA (light, moderate and vigorous) were obtained with the International Physical Activity Questionnaire (IPAQ) [1]. Sarcopenia was diagnosed by the Society of Sarcopenia, Cachexia and Wasting Disorders (SCWD) [2] recommendations. Sarcopenia risk (low muscle mass and functional limitation) was predicted by binary logistic regression, considering the weekly sitting time and PA, as independent variables.

RESULTS: Sarcopenia prevalence was 7.5% (n=5), with functional limitation present in 38.8% (n=26), and low muscle mass in 22.4% (n=15). The predictive model (p=0.014) involved moderate PA as the only significant predictor (OR=0.999; p=0.005; 95% CI: 0.998–1.000) of functional limitation. Moderate PA prevents sarcopenia risk. Each weekly hour of moderate PA decreased the risk of sarcopenia by 6%.

CONCLUSION: The time spent in moderate PA of community-dwelling older women was found to be independently associated with sarcopenia risk. PA level is significantly associated with the functionality of older adults. The sarcopenia risk in community-dwelling older women decreases by 6% for each additional hour/day moderate PA performed. Even so, it is a compensatory strategy for the imminent risk of sarcopenia, which is 18% for every year lived. In conclusion, the time spent in moderate PA can prevent sarcopenia regardless of sitting time.

AQUATIC AEROBIC EXERCISE TRAINING PERFORMED IN WARM VS. COLD WATER IN ELDERLY PATIENTS WITH TYPE 2 DIABETES

SUKSOM, D.1, SUNTRALUCK, S.2, TANAKA, H.3

1CHULALONGKORN UNIVERSITY, BANGKOK, THAILAND 2THAILAND NATIONAL SPORTS UNIVERSITY, SUKHOTHAI, THAILAND 3UNIVERSITY OF TEXAS AT AUSTIN, USA.

INTRODUCTION: Type 2 diabetes is a chronic condition with significant vascular complications. Aquatic aerobic exercise has shown promise as a therapeutic approach to improve vascular and other function in patients with diabetes, but the impact of water temperature on these effects remains unclear. This study aimed to compare the effects of warm water (36°C) and cold water (20°C) exercise training on macro- and micro-vascular function and other key indicators in elderly patients with type 2 diabetes.

METHODS: Twenty seven elderly participants (67 ± 1 years) with type 2 diabetes were randomly assigned to either a warm water (n=15) or a cold water (n=12) exercise training group. Both groups performed hip-level water cycling exercises with an intensity of 60-75% of their maximum heart rate, three times a week over a 12-week period. Exercise duration was gradually increased for 15 minutes in the first month, 20 minutes in the second month, and 30 minutes in the last month. Various parameters, including general characteristics, blood biochemistry, vascular function and quality of life, were measured before and after the training sessions.

RESULTS: The results showed that after 12 weeks, both warm water and cold water groups experienced decreases in heart rate at rest and systolic blood pressure ($p < 0.05$). Peak oxygen consumption measured on a cycle ergometer increased ($p < 0.05$) and quality of life improved in both groups. Both groups also experienced increases in plasma nitric oxide concentration, decreases in hemoglobin A1C, and lipid and lipoprotein concentrations ($p < 0.05$). Arterial stiffness as measured by brachial-ankle pulse wave velocity decreased and flow-mediated dilation in the popliteal artery improved in

both groups ($p < 0.05$ for both). Subcutaneous vasodilatory capacity increased in both exercise groups in the finger but only the warm exercise group improved it in the foot.

CONCLUSION: This study found that aquatic aerobic exercise training, regardless of water temperature, led to significant improvements in various functional measures in elderly patients with type 2 diabetes. However, warm water-based cycling exercise training was found to be more effective in improving subcutaneous vascular function.

PHYSICAL ACTIVITY LEVELS AND CARDIOMETABOLIC MARKERS IN INDIVIDUALS WITH NEWLY DIAGNOSED TYPE 2 DIABETES: A BASELINE ANALYSIS OF THE MOTIVATE T2D RANDOMIZED CONTROLLED TRIAL

LOW, J., HESKETH, K., LITTLE, J., MCMANUS, A., COCKS, M.
UNIVERSITY OF BRITISH COLUMBIA - OKANAGAN

INTRODUCTION: Physical activity (PA) is generally recommended to improve cardiometabolic health in people living with type 2 diabetes (T2D) with recent evidence suggesting that even small amounts of vigorous PA (up to 2 minutes per day) can lower mortality risk and improve cardiometabolic outcomes. However, the relationship between different levels of PA and metabolic health in people with newly diagnosed (<2 years) T2D needs further investigation. Our aim was to characterize device-measured PA in individuals with newly diagnosed T2D and explore relationships with measures of cardiometabolic health.

METHODS: This was a baseline analysis of the MOTIVATE T2D trial (NCT04653532); a feasibility RCT investigating an mHealth exercise intervention. Individuals aged 40-75 yrs (55.6 ± 8.9 years) living with newly-diagnosed T2D (12.6 ± 6.1 months diagnosis) living across Canada and the UK were recruited (N=120). Participants received self-testing health kits, via mail, at baseline to measure waist circumference (WC), height, weight, blood pressure (BP), HbA1c and PA levels. PA monitors (GENEactiv) were worn for 14 days. Sufficient wear time was defined as a minimum of 16 h per day on at least 5 days (11 ± 2 days). Relationships between HbA1c, BP, BMI and levels of PA were explored using multiple linear regression, with age and sex as covariates.

RESULTS: Data from individuals with complete anthropometrics (BMI: 34.4 ± 7.5 kg/m2), HbA1c (6.8 ± 0.9%), BP (SBP: 128 ± 13 mmHG, DBP: 81 ± 9 mmHG) and valid PA monitor days were used (n=88). Overall, individuals with newly diagnosed T2D completed an average of 157 ± 51 minutes of light activity (< 4 METS) per day, 32 ± 22 minutes of moderate activity (4-7 METS) per day, and 1 ± 2 minutes of vigorous activity (> 7 METS) per day. 49% (43/88) achieved > 30 minutes of MPA per day whereas only 18% (16/88) achieved VPA greater than 1 minute per day and 20% (18/88) achieved VPA greater than 2 minutes per day. There were no significant relationships between cardiometabolic health measures and levels of PA. Furthermore, additional explorations revealed no significant differences between age and sex amongst these variables.

CONCLUSION: Less than half of individuals with newly diagnosed T2D meet moderate exercise PA guidelines and spend very little time engaging in vigorous activity. Our preliminary results do not support a relationship between the outlined cardiometabolic markers and PA metrics in individuals with newly diagnosed T2D living across Canada and the UK. Results of this exercise/PA intervention should help to determine if increasing levels of PA can improve cardiometabolic health in newly-diagnosed T2D.

EFFECTS OF INSPIRATORY MUSCLE TRAINING AND NORDIC WALKING ON PHYSICAL FITNESS: A PILOT STUDY

MARCO-BARRIGUETE, I.1, ROLDÁN, A.1, MONFERRER-MARÍN, J.1, CORDELLAT, A.1, MONTEAGUDO, P.1,2, DÍAZ MARTÍNEZ, A.S.1, GONZÁLEZ, R.4, BLASCO-LAFARGA, N.M.1,4, MIR, C.4, NAVARRO-PÉREZ, J.3
1 UIRFIDE, PHYSICAL EDUCATION AND SPORT DEP, UNIVERISTY OF VALENCIA; 2 JAUME I UNIVERSITY; 3 HOSPITAL CLÍNICO VALENCIA, INCLIVA RESEARCH INSTITUTE; 4 CAP AREA CLÍNICO-MALVARROSA & DR. PESSET, VALENCIA

INTRODUCTION: Nordic Walking (NW) is a growing sport practise in Europe, specifically in older adults (OA) (1). Several studies have found interventions with positive effects in short and medium term (2,3). To expound on, the NW provide benefits on some aspects as gait pattern, gait velocity and step length, as well as in strength, balance, physical condition, and quality of life (3,4). Furthermore, the Inspiratory Muscle Training (IMT) increases VO2 peak, performance in exercise and inspiratory muscle strength (6,7). Up to our knowledge, it remains unknown the effect of combining NW and IMT on physical function and body composition in OA, which is the main objective of this intervention.

METHODS: Thirty-four OA was evaluated of body composition, dynamic inspiratory strength (S-Index) and physical condition (lower limbs: 5STS; manual gripping: HG; and cardiorespiratory fitness: 200m) before and after intervention. Thirty-four elderly were recruited from May and December 2022. Eighteen complete the final sample and were divided into two groups: Sham (S) (69.24±4.59yr; 72.32±11.65Kg; 27.80±3.31Kg/m2 n=9) and experimental (E) (68.43±4.33yr; 71.03±9.93Kg; 26.52±2.44Kg/m2, n=9). Combined training consisted in 8 weeks of three sessions for 60 minutes of NW (two supervised, one no-supervised), and 30 inspirations, twice daily, 7 days/week at 50% (experimental) or 15% (sham) of S-Index. Eighteen completed 70% of assistance. To find out the differences after intervention, two-way ANOVA repeated measures or Wilcoxon test were used according to the sample normality.

RESULTS: Eight weeks improved anthropometrical parameters. Fat mass (FM), Hip, Waist-Hip ratio and BMI decreased significatively in both groups (FM: S-IMT p=0.03, E-IMT p=0.049; Hip: S-IMT p=0.05, E-IMT p=0.012;ICC: S-IMT p=0.25, E-IMT p=0.26; BMI: S-IMT p=0.000, E-IMT p=0.04). Weight reduction trended to significance (p=0.54). Unexpectedly, we found a height improvement in both groups (S-IMT p=0.005, E-IMT p=0.02). Related to 200m, cardiorespiratory fitness enhanced only in the sham-IMT group (p=0.026, E-IMT p=0.33); and Handgrip only trended to a significance increase in the experimental group (p=0.05).

CONCLUSION: Up to our knowledge this is the first study to combined NW+IMT. Eight weeks are enough to improve body composition in both groups, despite cardiorespiratory fitness only improves in sham-IMT group. Despite the small sample, 8-weeks were also enough to improve 200m speed (3), which could be because the improvement in NW technique concerns an improvement of the gait technique. Waist-Hip ratio and fat mass decrease, helping a better cardiovascular health (1). Nevertheless, these results should be confirmed and the effect of adding IMT to NW regarding physical fitness should be investigated in future studies with a larger sample size.

CAN COOLING GARMENTS AID EXERCISE THERAPY IN PEOPLE WITH MULTIPLE SCLEROSIS?

STEVENS, C., SINGH, G., PETERSON, B., VARGAS, N., PERIARD, J.

SOUTHERN CROSS UNIVERSITY

INTRODUCTION: Multiple sclerosis (MS) is an autoimmune neurodegenerative disease affecting an estimated 2.3 million people worldwide. There is strong evidence for the benefits of exercise therapy for people with MS, however, up to 80% of people with MS report experiencing heat sensitivity, where MS symptoms become worse with elevated body temperature. Therefore, practical and effective strategies to reduce body temperature are needed for people with MS who want to be active outdoors, especially in warmer environments. A range of cooling strategies designed to assist people with MS to manage heat sensitivity have been investigated, predominantly cold-water immersion and the application of specialised water-perfused cooling garments. Lightweight cooling garments have received recent research interest, and potentially present a practical and effective strategy for people with MS to wear during exercise to overcome heat sensitivity and better engage in exercise therapy. Therefore, the purpose of this systematic review was to assess the use of cooling garments to aid exercise therapy in people with MS, as well as provide practical applications and future research directions.

METHODS: A systematic review adhering to the PRISMA guidelines was performed. The eligibility criteria required investigations to have conducted a randomised controlled trial or cross over study to assess the effect of a cooling garment to aid exercise therapy in people with MS. Studies must have contained empirical data and been published in a peer-reviewed journal.

RESULTS: 13 empirical studies, published before August 2022, were identified as meeting the eligibility criteria. The study's compromised of acute cross-over designs (61.5%), longitudinal independent groups designs (23.1%) or a combination of both (15.4%) and included a total of 386 participants with MS. The cooling garments that were investigated included active liquid-perfused cooling vests/tops (50.0%), phase-change cooling vests (38.9%), a cooling thigh cuff (5.6%) and a palm cooling device (5.6%). The cooling garments were consistently reported to improve walking time to exhaustion and walking distance in the 6-minute walk test, and findings from most studies pointed towards an improvement in the time to walk short distances, and in assessments of muscular strength. There is some evidence that the cooling garments improved balance, but only when the balance assessment was very challenging. The vast majority of studies that assessed fine-motor skills/manual dexterity did not observe any improvement in these measures.

CONCLUSION: Cooling garments can be used to aid exercise therapy in people with MS, including both expensive liquid-perfused garments and more practical and lightweight phase change cooling vests. We recommend that people with MS try different cooling garments to determine what their preferences are. Future research is needed on novel cooling garments designed for people with MS that have not yet been independently tested.

IMPACT OF DISABILITY ON PHYSICAL ACTIVITY AND HEALTH VARIABLES IN SCOTLAND

DAVISON, R.C.R., MCPHERSON, G., SMITH, P.M.

UNIVERSITY OF THE WEST OF SCOTLAND

INTRODUCTION: It is well recognised that regular physical activity including sport participation is important in the maintenance of health. Sedentary behaviour is now also recognised as an independent risk factor for numerous health conditions including For individuals with a disability, the achievement of the recommended amount of physical activity and the avoidance of sedentary behaviour is additionally difficult depending on the nature and severity of disability. In Scotland, the National Health Survey provides a significant resource to describe the characteristics and behaviours of the Scottish population.

METHODS: As we were interested in physical activity and sport participation in the disabled popiulation we use the 2019 National Health Survey data to explore the relationships.

One of the key limitations of the national health survey is its definition of disability is based on a self -report of a long -term illness (>12 months), which is limiting daily living. Using this definition of disability we explored the relationships between disability, physical activity defined by the UK Chief Medical Officers recommendations, sport participation, sedentary behaviour, obesity prevanance.

RESULTS: Only 23% of those with a disability met the CMO recommendations on MVPA and muscle strengthening exercises, and 53.6% met neither. We found that individuals with a disability had on average 130 min (95%CI 118-142mins) more sedentary behaviour (TV and Sitting) on week days compared to non-disabled. This difference is diminished slightly at the weekend (95%CI 93–119 mins) mostly due to those without a disability being more sedentary at the weekend vs those with limiting illness. Never the less this data shows that these individuals classified as disabled are exceeding 7h of sedentary

behaviour daily over the whole week, which has significant health implications. Those with a disability also had significantly lower sport minutes per week (95% CI 12–27 min) and this was evident in both moderate and vigorous sport activity.

We specifically looked at the relationship between disability, sport participation and obesity. People with a disability who take part in sport have a significantly better BMI profile than those who do not. Of those people with a disability who do not take part in a sport a high proportion are classed as Obese/morbidly (44.2%), significantly higher than the general non-disabled population.

CONCLUSION: This data reveals high levels of inactivity, obesity and sedentary behaviour as well as low sport participation for those individuals with a disability in Scotland. This suggests that this group are at a significantly greater risk of the development of co-morbidities on top of their existing disability contributing to a faster rate of health decline than the general population. Further research is required in the development of appropriate intervention strategies to improve the health behaviours of this group to enhance their health outcomes.

AQUATIC EXERCISES ENHANCE PHYSICAL PERFORMANCE AND MAINTAIN METABOLIC HEALTH IN OVERWEIGHT OLDER ADULTS

EBRAHIMPOUR NOSRANI, S., TARTIBIAN, B., TEIXEIRA, A.M.

1.ALLAMEH TABATABAI UNIVERSITY; 2.UNIVERSITY OF COIMBRA

INTRODUCTION: Being overweight and obese can lead to metabolic and cardiovascular disorders as well as physical dysfunction in older adults. Those with a higher BMI and body fat percentage not only perform poorly physically, but are also more likely to develop type 2 diabetes and cardiovascular disease. Healthy aging requires addressing overweight and obesity. Prescription of regular exercise has outstanding effects on metabolic and physical function. Aquatic exercise mode provides aerobic and strength training benefits to older adults, obese individuals and even those with arthritis due to reduced weight pressure on joints. We hypothesized that 28 weeks of combined aquatic exercise (aerobic and resistance) would improve daily physical performance and lower metabolic indices in overweight, healthy older adults.

METHODS: Thirty-two subjects of both genders (72.06±5.8) were randomly assigned into two groups: an aquatic exercise group (EG; n=19) and a control group (CG; n=13). Body composition, anthropometric measurements, blood pressure, lipid profile, fasting glucose, insulin, and leptin were assessed before and after the training program.

The Senior Fitness Test (SFT) was used to indirectly assess the main physical parameters associated with functional and motor ability. Leptin, and insulin were measured with ELISA kits.

RESULTS: There were no differences between or within groups in lipid profile, fasting glucose and insulin, or insulin resistance ($p>0.05$). There was a worsening of the lipid profile in the CG. In the aquatic exercise group, body fat mass, waist circumference, and leg circumference were reduced, while free fat mass was gained ($p\leq0.05$). A trend towards lower glycemia was also observed. Systolic and diastolic blood pressure significantly improved in the exercise group (P=0.003, P=0.001). A significant difference was found between the aquatic exercise group and the control group in aerobic endurance (P=0.008) and lower body flexibility (P=0.049). Also, upper body flexibility (P=0.001, P=0.020), lower and upper body strength (P=0.001, P=0.031), and handgrip (P=0.001, P=0.006), showed a significant difference after the exercise intervention.

CONCLUSION: The EG body fat decreased significantly (4.4%), but not enough to induce changes in leptin levels (a minimum weight loss of 10% is usually required). As a result of water properties, such as water viscosity, the motor cortex is more involved, resulting in more firing of motor neurons, which could explain the improvement in muscular strength and possible physical function. In addition, hydrostatic pressure facilitates venous return, aids fluid return to the heart and lymph nodes, which increases cardiac filling volume and reduces heart rate and blood pressure. Therefore, aquatic exercise has the potential to improve the daily physical performance of the aging population and prevent metabolic and cardiovascular diseases by improving blood pressure and body composition.

BACK AND HAMSTRING MUSCLE STRENGTH IN HEALTHCARE WORKERS WITH DIFFERENT INTENSITY OF BACK PAIN

HORNÍKOVÁ, H., KOTYROVÁ ŠTEFÁNIKOVÁ, G., ZEMKOVÁ, E.

FACULTY OF PHYSICAL EDUCATION AND SPORT

INTRODUCTION: Back pain is often associated with weakness of the back and hamstring muscles. The question, however, remains to what extent such an insufficient muscle strength contributes to first-time back pain occurrence in individuals who are at high risk of back problems. This study investigates the association of maximum isometric strength of the back and hamstring muscles with intensity of perceived back pain in healthcare workers with mild to moderate back pain and those with no pain.

METHODS: Altogether 55 healthcare workers (male: n=13, age 34.2±16.0 years, height 177.9±7.1 cm, body mass 84.2±13.3 kg; female: n=42, age 37.0±10.0 years, height 167.7±5.1 cm, body mass 63.6±10.7 kg) completed a Visual

Analogue Scale reflecting their intensity of back pain on a 0-10 Numerical Rating Scale. Accordingly, they were divided into three groups, i.e. no pain (score 0), mild pain (score 1-3) and moderate pain (score 4-6). Subjects performed three trials of maximum voluntary contraction (MVC) of the back muscles with the highest value used for data analysis. They also performed MVC of the hamstring muscles while average of better of the two trials of each leg was analysed. Peak force was measured using the FiTRO Back Dynamometer (FiTRONiC, Slovakia).

RESULTS: Peak force produced during MVC of the back muscles was significantly higher in healthcare workers with no pain (945.0±292.1 N) than in those with mild (696.9±181.9 N, p=0.002) and moderate pain (653.5±89.9 N, p=0.014). Similarly, MVC peak force of the hamstring muscles was significantly higher in healthcare workers with no pain (129.2±37.7 N) than in those with mild (96.1±31 N, p=0.005) and moderate pain (93.7±20.8 N, p=0.024). The intensity of their perceived back pain correlated with both maximum isometric strength of the back muscles (r=-0.433, p=0.001) and hamstrings (r=-0.427, p=0.001).

CONCLUSION: Findings indicate that healthcare workers suffering from mild to moderate back pain display lower maximum isometric strength of their back muscles by 27-31% and hamstrings by 25-27% as compared to those with no pain. Strengthening of these muscle groups may prevent their first-time back pain occurrence.

THE ASSESSMENT OF PATIENT OUTCOMES AT RETURN-TO-SPORT FOLLOWING A SPORT-RELATED KNEE SPRAIN INJURY: A REPORT FROM THE ATHLETIC TRAINING PRACTICE-BASED RESEARCH NETWORK

LAM, K.1, MARSHALL, A.2

1 A.T. STILL UNIVERSITY, MESA, AZ, USA; 2APPALACHIAN STATE UNIVERSITY, BOONE, NC, USA.

INTRODUCTION: Recent findings suggest that patients with ankle sprain injuries experience some degree of pain, functional limitation, and disablement at return-to-sport (RTS) despite being medically cleared for unrestricted participation. However, little is known whether similar deficits exist in patients returning from knee sprain injuries. Our purpose was to evaluate self-report of pain, function, improvement, and disablement at RTS following a knee sprain injury.

METHODS: We completed a retrospective review of electronic medical records created by athletic trainers (eg, physiotherapists) within the Athletic Training Practice-Based Research Network. Patient cases were included if the patient was diagnosed with a knee sprain injury, restricted from sport following injury, and subsequently cleared for unrestricted participation (RTS). Patients received usual care from an athletic trainer and completed a series of single-item patient-reported outcomes at RTS including self-report of pain (Numeric Pain Rating Scale [NPRS]), function (Global Rating of Function [GROF]), improvement (Global Rating of Change [GROC]), and disablement (Global Rating of Disability [GROD]). All measures have established measurement properties (eg, reliability, responsiveness). Descriptive statistics (percentages, frequencies, mean, median, interquartile range [IQR]) were used, as appropriate, to summarize patient demographics, sport, number of days to RTS, and patient-reported outcome scores at RTS including NPRS (0-10 points), GROF (0-100%), GROC (15-point Likert-scale) and GROD (7-point Likert-scale).

RESULTS: One hundred fifty-two patient cases (male=61.2%, age=17.2±2.8 years, height=171.9±12.3 cm, mass=75.6±20.3 kg) were identified for our study. Most knee injuries occurred during American football (32.2%, n=49), basketball (23.7%, n=36) or soccer (18.4%, n=28) and were diagnosed as medial collateral (57.9%, n=88), cruciate (23.7%; n=36), or lateral collateral (18.4%, n=28) ligament sprains. Patients received care for 33.4±63.9 days (median=11.0, IQR=3.0-25.8) before returning to sport. Despite being medically cleared for unrestricted participation, most patients reported some level of pain (63.8%, n=97; NPRS=1.7±1.8, median=1, IQR=0.0-3.0) and functional deficit (51.3%, n=78; GROF=85.4±15.2%, median=90.0, IQR=80.0-95.0) at RTS. Similarly, while most patients reported some level of improvement since injury (86.2%, n=131; GROC>"a little bit better"), 37.5% (n=57) reported some level of disablement (GROD>"very mild difficulty with my activities of daily living") at RTS.

CONCLUSION: Despite being medically cleared for unrestricted participation, patients continue to exhibit some level of pain, functional deficit, and disablement at RTS following a knee sprain injury. It has been recommended that patient outcome measures be used throughout care and to support RTS decision-making. Future research should determine if deficits at RTS predispose patients to recurrent injuries, chronic conditions, or lower quality of life.

LOWER LIMB KINEMATICS, FORCE, AND QUALITY OF LIFE AMONG RECREATIONAL ATHLETES AFTER AN ANTERIOR CRUCIATE LIGAMENT RUPTURE: A LONGITUDINAL STUDY OF THE FIRST THREE MONTHS AFTER AN ACL RECONSTRUCTION

YONA, T., PESKIN, B., FISCHER, A.

TECHNION ISRAEL INSTITUTE OF TECHNOLOGY

INTRODUCTION: Successful rehabilitation of ACL injuries requires a bio-psycho-social approach. Assessing gait kinematics involves analyzing joint angle minima/maxima, but it is also possible to analyze the kinematics over a full gait cycle using Statistical Parametric Mapping (SPM). Kinesiophobia is a common measure, but only a few studies have assessed anxiety. We aim to describe changes in lower limb kinematics, quadriceps force and Rate of Force developed (RFD), quality of life, anxiety, and kinesiophobia before and up to 3 months after ACL reconstruction.

METHODS: Gait kinematics, force, and RFD were evaluated 2 weeks pre-surgery (T1) and 3 months post-surgery (T3) using inertial measurement units (XSENS) and a handheld dynamometer (Microfet2). Quality of life, kinesiophobia, and anxiety were assessed at T1, T2 (2 weeks post-surgery), and T3 using IKDC, Tampa, and GAD-7 questionnaires, respectively. Limb Symmetry Index (LSI) was calculated for the force measurements. Kinematic assessment was done while walking in a 30-meter corridor. Mean±SD was used for descriptive statistics, and SPM was used to analyze the full-wave kinematics.

RESULTS: 25 recreationally-active participants were recruited (mean age 24.5±5.9). At T1, the knee flexion angle (KFA) of the injured leg during walking was higher than the contralateral KFA at 30-44% of the gait cycle, seen by a supra-threshold cluster exceeding the critical threshold of t=3.1. No differences were seen in hip and ankle joint kinematics.

At T3, the KFA of the injured leg was higher than the KFA of the contralateral knee at 33-47%, 68-74%, and 90-97% of the gait cycle, seen by three supra-threshold clusters exceeding the critical threshold of t=4.1. The hip flexion angle of the injured leg was lower than that of the contralateral knee at 68-82% of the gait cycle, seen by a supra-threshold cluster exceeding the critical threshold of t=3.9. No differences were seen in the ankle.

The T1 quadriceps LSI values for the peak force and RFD are 80±19.6% and 69.7±21.9%. The T3 peak force values were 46.2±27.3% and 30±26.6% for the RFD.

The IKDC score was 55±15 at T1, 26.8±13.4 at T2, and 49.8±14.4 at T3. The GAD-7 scores were 8.8±5.8 at T1, 7.7±5.4 at T2 and 6.3±7.1 at T3. Lastly, the Tampa scores were 43.9±8.1 at T1, 42.8±5.4 at T2, and 39.1±4 at T3.

CONCLUSION: Patients before an ACL surgery walk with their injured knee in a more extended position during weight bearing at the terminal stance phase of the gait cycle. Three months post-surgery, these deficits expand to the initial and terminal swing of the knee and the initial and mid-swing phases in the hip. Those deficits can be missed using the common minima/maxima analysis. Furthermore, looking only at the peak force might not be optimal as well, as the RFD is more affected than the peak force LSI. Lastly, although their quality of life almost returns to pre-surgery levels, their kinesiophobia and anxiety remain high, similar to before the surgery.

TOWARDS DETECTING NEUROMUSCULAR CONTROL DEFICITS INDICATIVE OF KNEE INSTABILITY DURING THE RETURN TO SPORTS PROCESS AFTER AN ACL INJURY

CALISTI, M.

UNIVERSITÄT INNSBRUCK

INTRODUCTION: A successful return to sport (RTS) after an anterior cruciate ligament (ACL) injury requires adequate neuromuscular control of the knee to protect the ACL [1]. However, detecting deficits in muscular control has proven challenging. We investigated single-leg jump-landings and hypothesized that compromised control might manifest as a change in (a) frontal plane knee stiffness [2], (b) fluency of the knee movement [3], or (c) smoothness of the overall (center of mass, COM) trajectory. The aim of the study was to detect compromised neuromuscular control in the knee movement (A) produced through a fatiguing intervention, or (B) due to a group comparison between volunteers with a previous ACL injury (ACLG) compared to healthy controls (CON).

METHODS: A convenience sample of 15 (11 females) and 22 (12 females) volunteers were recruited into ACLG and CON, respectively. We recorded 3D motion data (250 Hz) during single-leg forward hops (three per leg) onto a force plate (1000 Hz) before and after a fatiguing protocol (single-leg squats and step-ups). Participants were instructed to stabilize their body upon landing and to keep their lowest body position for 2s. Inverse kinematics were conducted in OpenSim from initial contact to the first local minimum of the knee flexion velocity. Frontal plane knee stiffness was quantified as the change in knee adduction/abduction angle. Knee fluency was calculated as the number of zero crossings (zc) of the medio-lateral knee joint velocity per second. Smoothness was quantified as the normalized vertical jerk of the COM trajectory [4]. Group-by-fatigue (2x2) mixed-factor ANOVAs ($\alpha = 0.05$) and effect sizes ($\eta 2$) were computed.

RESULTS: Fatigue affected knee fluency ($p < .001$; $\eta 2 = .50$; ACLG: fatigued: 15.1 zc/s vs. non-fatigued: 11.2 zc/s; CON: fatigued: 14.8 zc/s vs. non-fatigued: 11.2 zc/s). All other statistical results were non-significant.

CONCLUSION: One of the three hypothesized variables, knee fluency, proved sensitive to a fatigue-induced reduction in neuromuscular control. The likely underlying mechanism for this finding is compromised intermuscular coordination of hip and thigh muscles due to fatigue. Further, neither differences between ACLG and CON, nor interaction effects were significant; suggesting that in our convenience sample of previously ACL-injured individuals no chronic neuromuscular control deficits remained after they had all successfully returned to sport. Nor were they differently affected by fatigue than the control participants. We conclude that knee fluency is the most promising among the tested variables for detecting reduced knee control and that after a successful recovery no detectable difference remained in the knee stability of our ACL-injured volunteers.

LONG-TERM EFFECTS OF THE 11+ AND THE FOOTBALL+ WARM-UP PROGRAMS ON MOTOR PERFORMANCE AMONG FEMALE AMATEUR PLAYERS

ASGARI, M., SCHMIDT, M., TERSCHLUSE, B., SUECK, M., JAITNER, T.

TU DORTMUND UNIVERSITY

INTRODUCTION: Warm-up modalities, as the last phase of preparation before high intensive loads, should not only mitigate injury risk but also improve performance. Although acknowledgeable for injury prevention, the lack of a link to foot-

ball-specific goals and unclear effects on motor performance have raised serious concerns regarding the applicability of the 11+ program as a warm-up routine in amateur football and have resulted in low compliance and poor implementation of the program. Given that the 11+ effects on performance parameters among amateur female players have not yet been studied, this study aims to address the long-term effects of the 11+ and Football+, a newly developed warm-up, on motor performance in this population.

METHODS: Three female teams competing in German amateur leagues participated in this study and were assigned to the 11+ (n= 20, 23.6± 3.9 yrs, 1.69±0.05 h, 65.3±8.5 w), Football+ (n= 25, 26.5± 5.7 yrs, 1.69=±0.07 h, 63.4±7.5 w) and control (n=15, 22.53 ± 3.16 yrs, 1.66±0.08 h, 65.16±7.77 w) groups and underwent a 12-week intervention. Both warm-ups consisted of three parts, lasting 25 minutes, and required no additional equipment but differed in content. In comparison to the 11+, the Football+ included more plyometric and high-intensity exercises and more football-specific drills. The experimental groups performed their specific warm-up modality twice a week with 100% team compliance, whereas the control group followed its routine warm-up. Linear 20-m sprint, countermovement jump (CMJ), Illinois agility (IA), and dribbling test (DT) were performed in pre- and posttest. Means, SD, and effect sizes were calculated for each outcome measure. Intergroup differences were analyzed using one-way repeated-measures ANOVA at a significance level of $\alpha < 0.05$.

RESULTS: Significant time-group differences were observed for sprinting (p=002, $\eta 2$=0.20 power=0.92), IA (p=001, $\eta 2$=0.29, power=0.99), CMJ (p= 0.02, $\eta 2$=0.13 power=0.71) and DT (p=0.01, $\eta 2$=0.14, power= 0.76), with the Football+ and control groups having the best and poorest scores, respectively. A follow-up independent t test revealed no significant differences between the 11+ and CG in the 20 m sprinting (p= 0.26) and agility (p= 0.25) tests. However, the 11+ group outperformed the CG in the CMJ (p=001), while the CG outperformed the 11+ group in the dribbling test (p= 0.025).

CONCLUSION: Twelve weeks of application of Football+ significantly improved sprinting, agility, CMJ and dribbling skills compared to the 11+ and CG while having large effect sizes. Except for CMJ, the 11+ did not improve performance parameters but possibly reduced dribbling skill compared to the CG. Amateur female players are highly recommended to apply the Football+ program as a warm-up routine before training and benefit from the advantages it entails on motor performance. Further studies are required to evaluate the effects of Football+ on injury prevention and performance measures among other populations.

COMPENSATION STRATEGIES AFTER A COMPLETE AVULSION OF THE PROXIMAL RECTUS FEMORIS MUSCLE: A SINGLE CASE ONE-YEAR FOLLOW-UP

BAUMGART, C., GRIM, C., HEINKE, L., JAVANMARDI, S., RAPPELT, L., FREIWALD, J., HOPPE, M.W.

UNIVERSITY OF WUPPERTAL

INTRODUCTION: The rehabilitation after severe muscle injuries is an individual process, which follows no predefined time and criteria schedules. However, it is clear that biomechanical data can be helpful to optimize the return-to-sport and to evaluate long-term outcomes. This is the first study, which has investigated an one-year follow-up after the surgical treatment of a complete avulsion of the proximal rectus femoris muscle to get more functional insights into changes in neuromuscular control, structural muscle characteristics, and performance variations.

METHODS: Within the case report, a 41-year-old recreational endurance athlete (VO2max 58.7 ml/min/kg) was monitored during the rehabilitation process and frequently performed different biomechanical tests (e.g. EMG, isokinetic strength tests, MRI, cycling ergometry, leg volume) during the one-year follow-up. The endurance performance was revealed by an ergospirometry before the injury, as well as after six and twelve months after the surgery.

RESULTS: Almost no voluntary contraction of the rectus femoris muscle could be observed within the first month post-surgery. During early rehabilitation, a stepwise reduction in crank torque asymmetry was measured during cycling ergometry. Muscular intra-limb compensations were found at six months post-surgery and also after one year, which were in line with the long-term adaption of the muscle characteristics and leg volumes. During cycling ergometry, asymmetric muscle activation patterns revealed an altered motor control strategy, even while the power output was nearly symmetric and the endurance performance on a pre-injury level.

CONCLUSION: In the first month after surgery, an almost total neuromuscular inhibition of the rectus femoris muscle was present. Therefore, it is questionable to perform training sessions with the intention of selected muscle activation. Even if the endurance performance recovered after six months, asymmetries in neuromuscular control and structural muscle characteristics indicate the long-term presence of inter- and intra-limb compensation strategies. The impact of those long-term compensation strategies on subsequent injuries and/or physical health should be investigated in future studies.

THE EFFECTS OF CARBOHYDRATE LOADING ON BRACHIAL AND THIGH MUSCLES

KOJIMA, C.1, NAMMA-MOTONAGA, K.1, KAMEI, A.1, TAKAHASHI, Y.2, ISHIBASHI, A.2, TAKAHASHI, H.1,3

1 JAPAN INSTITUTE OF SPORT SCIENCES; 2 UNIVERSITY OF TOKYO; 3 UNIVERSITY OF TSUKUBA

INTRODUCTION: Muscle glycogen is a main energy source for prolonged exercise. Therefore, carbohydrate loading has already been investigated as a way to increase muscle glycogen content in the sport nutrition area. However, it remains unclear whether carbohydrate loading similarly increase glycogen content in upper and lower extremities. Since muscle recruitments are different depended on exercise characteristics and motilities, it is indispensable to understand the changes and specificities in each muscle. Therefore, the present study aimed to determine the changes in muscle glycogen content of the triceps brachii (arm) and vastus lateralis (leg) after 3 days of high carbohydrate intake without exercise.

METHODS: Eleven healthy participants (10 males and 1 female) were recruited in the present study (age: 29.3 ± 1.7 years, height: 173.2 ± 5.5 cm, weight: 70.2 ± 9.5 kg). They conducted 3 days of control period (6g/body mass/day of carbohydrate intake) followed by 3 days of loading period (10g/body mass/day of carbohydrate intake). Throughout the intervention period (6 days), physical activity was monitored using an accelerometer (Active style Pro, OMRON Healthcare, Japan). Muscle glycogen content in the triceps brachii and vastus lateralis were evaluated noninvasively using 13C-magnetic resonance spectroscopy (Magnetom Verio and Magnetom Skyra; Siemens, Germany) before, at 24 and 72 hours of the loading period. Body compositions were also measured before, at 24 and 72 hours of the loading period via a body composition analyzer (Inbody730, Inbody Japan, Japan).

RESULTS: Body mass (pre: 70.8 ± 8.9 kg, 72 h: 72.3 ± 9.4 kg), fat free mass (pre: 58.0 ± 7.2 kg, 72 h: 59.2 ± 7.6 kg) and water volume (pre: 42.5 ± 5.3 L, 72 h: 43.4 ± 5.6 L) were significantly increased by 72 hours of carbohydrate loading ($P < 0.05$). Although the muscle glycogen content in both muscles were significantly elevated at 72 hours of the loading period (triceps brachii: 122.8 ± 29.2 %, vastus lateralis: 122.5 ± 24.0 %, $P < 0.05$), there was no significant differences in the increase between the muscles ($P > 0.05$). On the other hand, the present study did not observe significant correlation in the changes between the two types of muscles ($P > 0.05$).

CONCLUSION: Three days of carbohydrate loading (10g/body mass/day) without exercise increased muscle glycogen content (approximately 23%) in both upper arm and thigh muscles. In addition, the present results indicate that the time-course changes in muscle glycogen content in the upper arm and thigh muscles within the same subject may not necessarily be equivalent.

THE EFFECT OF ACUTE RESISTANCE EXERCISE ON URIC ACID IN HEALTHY ADULTS FOLLOWING FRUCTOSE INTAKE

SU, Y.T., TSAI, S.H., CHENG, H.C., LIU, H.W.

NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: Regular exercise is an effective method to maintain or improve overall health, but strenuous exercise rapidly depletes adenosine triphosphate (ATP) in skeletal muscles and results in overproduction of uric acid [1]. Sports drinks help recuperate nutrients and fluids lost during exercise; however, fructose is a common component in sport drinks and its metabolism increases blood uric acid levels. This is due to lack of a negative feedback system for fructose metabolism that would otherwise to prevent excessive phosphorylation [2]. Therefore, both exercise and sports drinks can increase blood uric acid levels, which may synergistic effect and cause hyperuricemia. This study aimed to investigate the effect of acute resistance exercise combined with high fructose intake on uric acid levels.

METHODS: Twelve healthy young men (age: 23.00 ± 2.50 years, body mass index: 22.91 ± 1.61 kg/m2) participated in four randomized crossover trials (EF: fructose intake after exercise; EW: water intake after exercise; CF: fructose intake without exercise; CW: water intake without exercise). The participants performed 4 sets (8 repetitions × 3 sets + 1 failure set) of a whole-body resistance exercise (deadlift → bench press → squat → row) at 70% of 1-repetition maximum (1RM). A fructose drink was given by 0.75 g/kg of body weight. Blood uric acid and other laboratory parameters (blood lactate, heart rate, and blood pressure) were measured at fasting, before exercise, immediately after exercise, and 0.5 hr, 1 hr, 2 hr, 4 hr, and 24 hr after exercise. All testing data were analyzed using 4 (trial) × 8 (time) two-way repeated-measures analysis of variance. The level of significance was set at $\alpha=.05$.

RESULTS: Blood uric acid levels were increased after acute resistance exercise or fructose ingestion alone. This increase was further exacerbated by the combination of resistance exercise and fructose ingestion (EF: 9.03 mg/dL, ↑3.59 mg/dL, 63%; EW: 8.28 mg/dL, ↑2.52 mg/dL, 44%; CF: 6.24 mg/dL, ↑0.58 mg/dL, 10%; ps < .05). Blood lactate levels were similar: increases in conditions of either resistance exercise alone or fructose ingestion alone, and a greater increase with a combination of the two (ps < .05). Furthermore, heart rate was significantly higher in the EF trial than in the other three trials (p < .05). Blood pressure was not significantly different among trials (p > .05).

CONCLUSION: Fructose intake following resistance exercise induces greater increase in blood uric acid levels than either exercise or fructose intake alone, thereby demonstrating their synergistic effect on uric acid levels. Moreover, the combination treatment produced no differences in blood pressure, but blood lactate and heart rate increased more than re-

sistance exercise alone. These findings indicate that ingesting fructose-containing food should be avoided after resistance exercise.

THE EFFECT OF HIGH-FAT DIET ON INTRAMYOCELLULAR LIPID CONTENT IN HEALTHY ADULTS: A SYSTEMATIC REVIEW, META-ANALYSIS AND META-REGRESSION

ALQALLAF, J.1, ORANGE, S.2, MATU, J.1,3, GRIFFITHS, A.1,3, JOHNSON, K.4, STAVROPOULOS-KALINOGLOU, A.1, HOLLIDAY, A.2, WILSON, O.1

1,3 LEEDS BECKETT UNIVERSITY, UK; 2 NEWCASTLE UNIVERSITY, UK; 4 LIVERPOOL JOHN MOORES UNIVERSITY, UK

INTRODUCTION: Intramyocellular lipid (IMCL) may accumulate following consumption of a high-fat diet (HFD). Discrepancy across studies may be explained by differences in 1) diet fat content, 2) HFD duration, and/or 3) measurement techniques used to measure IMCL content. HFD is also associated with a reduction in insulin sensitivity, and this may occur alongside IMCL accumulation. The primary aim of this study was to synthesise evidence through a systematic review and meta-analysis of the effect of a HFD on IMCL content in healthy individuals. A secondary aim was to determine associations of diet fat content, HFD duration, and IMCL measurement technique with IMCL responses to a HFD by meta regression. The relationship between HFD-associated changes in IMCL content and insulin sensitivity was also investigated.

METHODS: Studies were included if they examined the effect of ≥3 days of hypercaloric or isocaloric HFD (>35% total daily energy intake from fat) on IMCL content in healthy individuals. A total of 16 studies met the inclusion criteria, having used microscopy, biochemical extraction, or 1H Magnetic Resonance Spectroscopy (1H-MRS) techniques to measure IMCL. Ten of the included studies reported insulin sensitivity, assessed by Homeostatic Model Assessment for Insulin Resistance (HOMA-IR) and/or the hyperinsulinemic-euglycemic clamp (Clamp). Changes in IMCL content and insulin sensitivity are presented as standardised mean difference (SMD) using random-effects model.

RESULTS: Compared with pre-HFD or post-control diet, IMCL content increased following a HFD (SMD = 0.58, 95% CI 0.29 to 0.87, p = 0.001). Meta-regression analysis revealed that the increase in IMCL content was not associated with the diet fat content (p = 0.735), or the duration (p = 0.858) of the HFD, or the type of technique used to assess IMCL content (p > 0.05). Insulin sensitivity decreased following a HFD when assessed by HOMA-IR (SMD = 0.51, 95% CI 0.07 to 0.95; p = 0.033) or Clamp (SMD = -0.36, 95% CI -0.56 to -0.16; p = 0.005). Meta-regression analysis revealed there was no relationship between the increase in IMCL content and reduction in insulin sensitivity following a HFD (p = 0.121).

CONCLUSION: Consumption of a hypercaloric or isocaloric HFD (>35% total daily energy intake from fat) for 3 days is sufficient to increase IMCL content in healthy individuals. Diet fat content, HFD duration, and the measurement techniques used to quantify IMCL were not associated with the increase in IMCL content. The reduction in insulin sensitivity was not related to IMCL accumulation, which suggests factors other than IMCL accumulation are more important in HFD-induced impairments in insulin sensitivity in healthy individuals.

FOUR-WEEK SUPPLEMENTATION OF SOY MILK POST DAILY TRAINING IMPROVES BLOOD LIPID STATUS AND INCREASES EXPLOSIVE POWER IN FEMALE SOCCER PLAYERS

BEI, W.

SHANGHAI RESEARCH INSTITUTE OF SPORTS SCIENCE (SHANGHAI ANTI-DOPING AGENCY)

INTRODUCTION: It has been widely accepted that protein supplement can promote the synthesis of skeletal muscle protein and relieve muscle injury induced by exercise. The most commonly used protein is whey protein derived from milk, but lactose in it will make people who do not produce enough lactase prone to diarrhea, nausea, stomach cramps and other symptoms of lactose intolerance, which will also interfere with the effect of protein supplement on fatigue recovery. Meanwhile, more and more vegan athletes or sports enthusiasts are seeking alternatives to animal protein supplements. Therefore, the purpose of this study is to evaluate the effects of long-term supplementation of soy protein after daily exercise training on the related indicators of fatigue, metabolism, inflammation, muscle damage and athletic ability, providing scientific basis for the effectiveness of soy milk as a substitute for whey protein for lactose intolerant people and vegan sports people.

METHODS: The study was designed as a randomized controlled experiment. Twenty professional female soccer players from Shanghai were recruited. The experimental group was supplemented with 500ml soy milk, and the control group was supplemented with 500ml water added isocaloric oligosaccharides after training from Monday to Saturday for 4 weeks. Blood samples were taken before and every Saturday morning through the study to evaluate their nutritional status, fatigue levels and inflammatory response changes, and their athletic ability (Counter Movement Jump CMJ, Squat Jump SJ, 20/30m sprint) were also assessed at the same time points.

RESULTS: During the four-week supplement period, compared with the control group, the body fat percentage of the soy milk group showed a downward trend, the muscle mass showed an upward trend, and the change of serum glycerol was significantly lower (30.69±2.99 vs. 39.43±2.83mmol/ml, p=0.042). The decrease in serum triglyceride (-0.23±0.05 vs. -0.04±0.05mmol/L, p=0.012) and the increase in HDL (0.14±0.02 vs. 0.02±0.04mmol/L, p=0.024) were both significantly higher after one week in the soy milk group than the control group. CMJ and SJ height and 20/30m sprint time showed an

upward trend, and the increase in SJ height was significantly higher in the soy milk group than the control group after four weeks of supplementation (1.97±0.86cm vs. 0.19±0.50cm, p=0.007).

CONCLUSION: The intake of plant-based soy milk immediately after daily exercise training can improve the blood lipid status and increase the explosive power of lower limbs. Long-term supplementation of soy milk may also increase muscle mass and reduce body fat. Soy milk can be used as an effective substitute for whey protein for lactose intolerant people and vegan sports people.

CO-INGESTION OF COLLAGEN WITH WHEY PROTEIN PREVENTS THE POST-EXERCISE DECLINE IN PLASMA GLYCINE AVAILABILITY IN HEALTHY YOUNG MALES

AUSSIEKER, T., JANSSEN, T., HOLWERDA, A., SENDEN, J., VAN KRANENBURG, J., SNIJDERS, T., VAN LOON, L.
DEPARTMENT OF HUMAN BIOLOGY, NUTRIM SCHOOL OF NUTRITION AND TRANSLATIONAL RESEARCH IN METABOLISM, MAASTRICHT UNIVERSITY, THE NETHERLANDS

INTRODUCTION: Whey protein ingestion during the recovery from exercise increases myofibrillar but not muscle connective protein synthesis rates. It has been speculated that whey protein does not provide sufficient glycine to maximize post-exercise muscle connective protein synthesis rates. In the present study, we assessed the impact of co-ingesting various amounts of collagen protein with whey protein as a dietary strategy to increase plasma glycine availability during recovery from a single bout of exercise.

METHODS: In a randomized, double-blind, cross-over design, 14 young men (age: 26±5 y; BMI: 23.8±2.1 kg/m2) ingested 30 g protein provided as whey protein with 0 g (WHEY), 5 g (WC05); 10 g (WC10) and 15 g (WC15) of collagen protein during recovery from a single bout of resistance exercise. Blood samples were collected frequently over 6 hours of post-exercise recovery to assess plasma amino acid availability. Time-dependent variables were analyzed by a two-factor repeated-measures ANOVA. Non-time-dependent variables were compared between treatment groups using a one-way ANOVA. A statistical level of $P<0.05$ was accepted. All data are expressed as mean±SD.

RESULTS: Protein ingestion strongly increased plasma amino acid concentrations ($P<0.001$) with no differences in total amino acid availability between treatments ($P>0.05$). The post-prandial rise in plasma leucine and total essential amino acid availability was greater in WHEY compared to the WC10 and WC15 treatments ($P<0.05$). Plasma glycine and total non-essential amino acid concentrations declined following whey protein ingestion, but increased following collagen co-ingestion ($P<0.05$). Post-prandial plasma glycine availability averaged -8862±5829, 9246±3736, 23108±6523 and 39818±10976 µmol·360 min/L in WHEY, WC05, WC10, and WC15, respectively ($P<0.05$).

CONCLUSION: Co-ingestion of a small amount of collagen (5 g) with whey protein (25 g) prevents a decline in plasma glycine availability during recovery from a single bout of resistance type exercise in healthy young males.

ANABOLIC SIGNALING IS NOT COMPROMISED IN LEAN HEALTHY OLDER MEN FOLLOWING RESISTANCE EXERCISE AND INTAKE OF ESSENTIAL AMINO ACIDS

HORWATH, O., EDMAN, S., MOBERG, M., PHILP, A., APRÓ, W.
THE SWEDISH SCHOOL OF SPORT AND HEALTH SCIENCES

INTRODUCTION: Ageing is associated with a slow and progressive decline in muscle mass and function, ultimately resulting in a condition referred to as sarcopenia. The etiology of sarcopenia is multifactorial, but a key underlying factor is believed to be the inability of aged muscle to properly respond to growth-promoting stimuli such as intake of essential amino acids (EAA) and resistance exercise. This phenomenon has been termed anabolic resistance and is defined by a dampened protein synthesis response in comparison to young individuals. However, much of the literature supporting the existence of such phenomenon have not used optimal doses of dietary amino acids and/or exercise volume. It is thus possible that optimal doses of EAA and high-volume, high-intensity resistance exercise (RE) may overcome anabolic resistance in older adults.

METHODS: Ten young (22 ± 1 years) and 10 older (70 ± 1 years) lean, healthy and physically active men performed 13 sets of unilateral resistance exercise (RE) at their 10-repetition maximum. Upon exercise completion, participants ingested 240 mg/kg body weight of EAA, a dose previously shown to maximally stimulate the mTORC1-pathway in young males. Muscle biopsies were collected before and immediately after exercise, and at 60 and 180 min after EAA intake in both the rested and the exercised leg. Phosphorylation and content of proteins involved in the regulation of protein synthesis and insulin signalling were measured using immunoblotting. Statistics were performed using mixed model analysis with Bonferroni correction.

RESULTS: Sixty minutes after EAA intake, phosphorylation of S6K1 at Thr389 was increased to the same extent (140-fold, $p<0.05$) in the exercised leg of both groups compared to pre-exercise values. However, in the rested leg, S6K1 at Thr389 phosphorylation was 345% higher ($p<0.05$) in the older group. Phosphorylation of eEF2 at Thr56 was reduced in the exercised leg at both 60 (67%, $p<0.05$) and 180 (40%, $p<0.05$) min compared to baseline with no difference between groups. Total levels of Rheb were 46% higher ($p<0.05$) in the old group compared to young. Phosphorylation of PRAS40 at Thr246 was increased in the exercised leg of both groups but was higher in young than old compared to baseline (81% vs 57%, $p<0.05$).

CONCLUSION: When assessing mTORC1-signalling, skeletal muscle of healthy, lean and physically active older men does not show obvious signs of anabolic resistance following intake of a large dose of EAA and performance of high-volume,

high intensity RE. Older muscle does however show signs of reduced insulin signaling as evidenced by lower PRAS40 phosphorylation. One would therefore expect a lower anabolic response in older individuals, but the lack of such may be explained by higher total levels of the protein Rheb, which is the most proximal upstream activator of mTORC1. This in turn may be a compensatory mechanism to maintain anabolic sensitivity in this population.

EFFECTS OF NUTRITION- AND EXERCISE-BASED PERFORMANCE ENHANCEMENTS IN ROWING: A NETWORT META-ANALYSIS

HELD, S., RAPPELT, S., DONATH, L.

IST UNIVERSITY OF APPLIED SCIENCES

INTRODUCTION: Previously rowing performance improvements were elicited via numerous different exercise-based approaches like (i) resistance training [1]; (ii) plyometric training [2]; (iii) high-intensity training [3]; (iv) blood flow restriction methods [4]; and (v) various nutritional supplementation strategies [5]. Therefore, network meta-analytical approach was used to examine all those rowing-specific findings within one analysis. Thereby, this network meta-analysis assessed via direct and indirect comparison the occurrence and magnitude of effects following different nutritional supplementation strategies and exercise interventions on acute and chronic rowing performance and its surrogates.

METHODS: PubMed, WebofScience, PsycNet and SPORTDiscus searches were conducted until march 2022 in order to identify studies with the following inclusion criteria: (a) controlled trials, (b) rowing performance and its surrogate parameters as outcomes (c) peer-reviewed published in English. A Frequentistic network meta-analytical approaches were calculated based on standardized mean differences (SMD) using a random effects model.

RESULTS: 71 studies with 1229 healthy rowers (21.5 ± 3.0 years) were included and two networks (acute and chronic) have been created. Both, networks revealed low heterogeneity and non-significant inconsistency ($I^2 \leq 35.0\%$ and Q statistics: $p \geq 0.12$). Based on P-score rankings, caffeine (P-score 84%; SMD = 0.43) revealed relevantly favorable effects in terms of acute rowing performance enhancement, whilst prior weight reduction (P-score 10%; SMD = -0.48) and extensive preload (P-score 18%; SMD = -0.34) impaired acute rowing performance. Chronic blood flow restriction training (P-score 96%; SMD = 1.26) and the combination of β-hydroxy-β-methylbutyrate and creatine (P-score 91%; SMD = 1.04) induced remarkably large positive effects, while chronic spirulina (P-score 7%; SMD = -1.05) and black currant (P-score 9%; SMD = -0.88) supplementations revealed impairment effects.

CONCLUSION: Homogeneous and consistent findings based on numerous studies indicate that choice of the nutritional supplementation strategy and the exercise training regime is vital for acute and chronic performance enhancement in rowing. While caffeine supplementation increases acute rowing time trial performance, prior weight reduction or extensive preload could impair performance. Furthermore, chronic rowing time trial performance was increased via blood flow restriction training and the combination of β-hydroxy-β-methylbutyrate and creatine supplementation. In contrast chronic spirulina and black currant supplementations might impair chronic rowing performance adaptations.

EFFECTS OF PLACEBO PERCEIVED-AS-PARACETAMOL ON CYCLING EXERCISE IN INDIVIDUALS WITH EXPERIMENTALLY INDUCED MUSCLE PAIN

PIRES, F.O., CANESTRI, C., VINÍCIUS, I., FRANCO-ALVARENGA, P.E., BRIETZKE, C., GOETHEL, M.F., SANTOS, T.M.

SCHOOL OF ARTS, SCIENCES AND HUMANITIES. UNIVERSITY OF SÃO PAULO AND FEDERAL UNIVERSITY OF PERNAMBUCO

INTRODUCTION: Endurance exercise performance is related to the ability to tolerate unpleasant sensations such as pain during exercise [1]. Pain is a three-dimensional phenomenon that involves a sensory-discriminatory, affective-motivational, and cognitive-evaluative dimension [2]. The ingestion of paracetamol is well-known to reduce pain and improve exercise performance through its action on the sensory-discriminatory dimension, but the effects of paracetamol-placebo are unknown. We investigated the effects of paracetamol placebo on physical performance, neurophysiological and perceptual responses in endurance cycling exercise in individuals with experimentally induced muscle pain.

METHODS: Twelve males (22.0 ± 3.5 years) sensible to a hypertonic saline solution (2.0 ml, 6% NaCl) performed in a randomized crossover design: 1) VO2MAX cycling test; 2) baseline time-to-exhaustion cycling test (TTE) without induced pain; 4) TTE with induced muscle pain and ingestion of placebo perceived-as-paracetamol (PCT); 4) TTE with induced muscle pain and ingestion of placebo perceived-as-placebo (PLA). A variety of neurophysiological (EEG, EMG and cardiopulmonary) and perceptual (pain sensation, RPE and affect) responses were sampled during exercise, then analyzed and paired at every 25% of the exercise bout (i.e., 25%, 50%, 75% and 100%) for comparisons in a repeated-measures mixed model. Results were reported as mean (SD) and effect size (d-Cohen).

RESULTS: Participants (WPEAK of 245.2 ± 28.4 W and VO2PEAK of 43.9 ± 4.6 mL·kg-1·min–1) improved their time-to-exhaustion ($p = 0.009$, $d = 0.31$) when in PCT (411.8 ± 152.1 s) when compared with PLA trial (356.0 ± 175.8 s). The improved cycling performance was accompanied by increased cardiopulmonary responses ($p = 0.03$, $d = 1.25$ for VO2; $p = 0.002$, $d = 1.75$ for VE and $p = 0.005$, $d = 1.23$ for HR), but lowered activation in vasto lateralis ($p = 0.01$, $d = 1.38$) and biceps femoris muscles ($p = 0.01$, $d = 1.43$). Differences between PCT and PLA trial were observed neither in EEG measures (Cz, F3 and P3 derivations) nor in effect and pain sensation, but participants reported a greater RPE throughout the cycling test after ingesting PCT ($p = 0.04$, $d = 0.87$).

CONCLUSION: Placebo perceived as paracetamol improved exercise performance in participants with prior induced muscle pain. Results of psychophysiological responses may suggest that placebo improved exercise performance by altering the affective-motivational dimension of pain.

A NOVEL CARBOHYDRATE HYDROGEL SYSTEM FOR THE DELIVERY OF SODIUM BICARBONATE MINI-TABLETS INCREASES ACID-BASE BUFFERING AND ALLEVIATES GASTROINTESTINAL DISCOMFORT

GOUGH, L., SPARKS, A.

BIRMINGHAM CITY UNIVERSITY, UK

INTRODUCTION: Sodium bicarbonate (SBC) is a popular ergogenic aid to enhance cycling performance, however, the gastrointestinal (GI) discomfort often deters athletes from ingestion. Recently, a novel SBC formulation using a combination of a carbohydrate-rich hydrogel and SBC mini-tablets has been created with the aim to minimise GI discomfort following ingestion. The purpose of this study therefore was to investigate the GI discomfort and acid base balance responses from a novel SBC supplement.

METHODS: Ten trained/well trained cyclists (maximal oxygen uptake (VO2max): 63 ± 5 ml·kg-1·min-1, power at VO2max: 406 ± 35 W) completed this randomised, single-blind, crossover trial consisting of three visits to the laboratory. In the initial visit, a VO2max test was conducted to assess cardiorespiratory fitness. Two separate trials were then completed whereby participants ingested a breakfast consisting of 1.5 g·kg-1 BM carbohydrate (CHO) approximately 2-3 h prior to ingestion of either 0.3 g·kg-1 BM SBC in vegetarian capsules (size 00, Bulk Powders, UK) (SBCCAP) or 0.3 g·kg-1 BM SBC in mini-tablets (Maurten, Sweden) (SBCMT) alongside 40 g of CHO hydrogel mix (Maurten, Sweden). Participants then remained rested for 5 h, whereby 10 blood samples were taken from the fingertip for blood bicarbonate (HCO3-) every 30 min. Symptoms of GI discomfort were also taken every 30 min using a VAS scale to assess frequency and severity of symptoms. Data was analysed using a t test to assess differences between time to peak HCO3-, the change from baseline to peak HCO3- and aggregated overall GI discomfort. Effect sizes (ES) were calculated using Cohen D thresholds with a Hedges g correction. Significance was accepted at $p<0.05$.

RESULTS: The time to peak HCO3- was achieved 39 min faster with SBCMT compared to SBCCAP (120 ± 35 vs. 159 ± 36 min; $p < 0.001$; ES = 1.05). The change from baseline to peak HCO3- was 1.5 mmol·l-1 greater following SBCMT compared to SBCCAP (8.2 ± 0.8 vs. 6.7 ± 1.4 mmol·l-1; $p < 0.001$; ES = 1.26). Higher GI discomfort was observed in the SBCCAP treatment, with 9/10 participants suffering one or more symptoms to at least a moderate level (>5/10 severity), whilst none experienced this with SBCMT (all <4/10 severity). Mean aggregated overall gastrointestinal discomfort (sum of all GI symptoms) was reduced following SBCMT versus SBCCAP (9 ± 9 vs. 85 ± 63 au; $p = 0.003$; ES = 1.62). Specifically, SBCMT reduced stomach cramps (6 vs 164 au), bowel urgency (10 vs 141 au), diarrhoea (0 vs 149 au), belching (6 vs. 46 au), and stomach-ache (14 vs 181 au) over the 5 h period compared to SBCCAP.

CONCLUSION: Based on the findings of this study SBCMT is a more suitable supplement to limit GI discomfort compared to SBCCAP. Moreover, SBCMT has the potential to improve exercise performance to a greater extent due to the larger increases in HCO3- from baseline to peak, which further research should investigate.

THE IMPACT OF ARTIFICIAL SWEETENER CONSUMPTION IN SPORTS DRINKS AND NUTRITION ON CARDIOVASCULAR HEALTH: PRELIMINARY DATA IN RODENTS AND HUMANS VESSELS.

PALLOT, F., BATTAULT, S., CUMPS, J., HORMAN, S., RISDON, S., SIGAUDO-ROUSSEL, D., DE SANTA BARBARA, P., BRIAND, L., LELOUP, C., MEYER, G., BOREL, A.L., ARVIEUX, C., ROUSTIT, M., WALTHER, G.

AVIGNON UNIVERSITY

INTRODUCTION: Sports drinks and nutrition contain many food additives including artificial sweeteners such as sucralose and acesulfame potassium (AceK). If currently the health authorities authorize the use of these sweeteners within the limits of the ADI, many recent studies question their physiological harmlessness, especially regarding the cardiovascular system. These molecules are known to activate the sweet taste receptors (Tas1Rs) in the oral cavity, but recent data, including our work, have also reported their expression in the vascular wall. Therefore, the aims of this study was to investigate the effects of artificial sweeteners, sucralose and AceK, on vasomotor function, used as an early cardiovascular risk marker, and to decipher the underlying mechanisms to understand the role of Tas1Rs.

METHODS: qPCR of Tas1Rs has been performed on mice and rat aortas as well as on human dermal micro-arteries. The direct effects of sucralose and AceK on vasoreactivity ex-vivo have been assessed using isometric tension measurements in organ bath systems in rodents (rats and mice including Tas1R3 KO mice) aortas and human omental arteries.

RESULTS: First, we observed with an ex-vivo approach that sweeteners, AceK and sucralose, induce direct vasoactive effects at high concentrations (around 10mM) in both human arterioles and rodent aortas. These sweeteners have antagonistic effects, which are endothelium-independent; AceK exhibits vasoconstriction while sucralose induces vasorelaxation. We then demonstrated the mRNA expression of Tas1R2 and/or Tas1R3, which form the heterodimer receptor of sweet taste, in the vascular wall and especially in the smooth muscle cells of our three models. Pharmacological inhibition (gurmarin in rodents and lactisol in humans) and the use of Tas1R3 KO mice models revealed that these vasomotor effects do not involve sweet taste receptors. Instead, they are more likely to rely on bitter taste receptors of the Tas2Rs family. To support this, using an analogous approach with different Tas2Rs agonists (quinine, denatomium benzoate, coumarine), we observed the same kind of vascular response as sucralose, suggesting that Tas2Rs isoforms are the most likely involved.

CONCLUSION: This evidence supports the idea that sweeteners can affect vasomotor signaling in vascular smooth muscle cells, thereby challenging the notion that these molecules are neutral. Contrary to our initial hypothesis, these vasomotor effects do not appear to be mediated by sweet taste receptors, but rather by bitter ones. The mechanism of action and the potential pathophysiological consequences of this phenomenon remain to be further explored.

THE EFFECTS OF INSTRUMENT ASSISTED SOFT TISSUE MOBILIZATION (IASTM) TECHNIQUE ON MECHANICAL PROPERTIES OF ANKLE MUSCLES AND DORSIFLEXION RANGE OF MOTION IN WRESTLERS

UZUN, S., GAZI, Ö., GERÇEK, N., TATAR, Y., SANLI, G.

MARMARA UNIVERSITY, FACULTY OF SPORT SCIENCE

INTRODUCTION: Instrument-assisted soft tissue mobilization (IASTM) is one of the most popular treatments for myofascial restriction. This technique has been used to increase ankle range of motion with decreasing tightness within the musculotendinous unit. Restricted DF in the ankle joint can cause acute and chronic ankle and knee injuries in elite athletes. It is thought that IASTM treatment stimulates the remodeling of connective tissue and therefore its use in professional athletes is increasing. The aim of this study was to determine the effect of IASTM technique on dorsiflexion ROM and passive mechanical properties (viscoelastic) of the ankle muscles and tendons in wrestlers.

METHODS: 25 wrestlers between the ages of 14-17 who have been licensed for at least 2 years were included in the study. Athletes' left lower extremities were selected for the IASTM application as the intervention group, and the right side was selected as the control group. Each IASTM session was applied for 15 minutes, 3 days a week, for a total of 10 sessions on the left ankle muscles, tendons and plantar fascia during a 3-week period. Passive mechanical properties (tonus, stiffness and elasticity) and lunge bearing dorsiflexion test were measured respectively. The Myoton-3 equipment was used to describe the viscoelastic parameters of the ancle muscles and tendons. Measurements were made a total of 3 times; before the sessions, after the first session and at the end of the10th sessions.

RESULTS: It was found that lunge bearing dorsiflexion test values were significantly increased after both the first and tenth sessions of IASTM application ($p<0,01$). After the first session, the tonus and stiffness of the left gastrocnemius medialis (GM) and gastrocnemius lateralis (GL) muscles decreased, while the elasticity of the left GM muscle increased significantly ($p<0,01$). No significant change was found in the passive mechanical properties of the tendons ($p>0,05$). After 10 sessions, tonus and stiffness of the left GM muscle and left plantar fascia; tonus of the left Achilles tendon and stiffness of the left tibialis anterior (TA) tendon increased significantly ($p<0,01$). In addition, the elasticity of the right GL, left TA tendon, right and left GM and TA muscles increased significantly after 10 sessions ($p<0,05$).

CONCLUSION: A single session of IASTM application can be included in the training programs of wrestlers as a method to decrease muscle tonus and stiffness while increasing ankle mobility and flexibility. After 10 sessions of IASTM application, the increase in elasticity of some ankle muscles and tendons that was observed also with the increase in tonus and stiffness, can be attributed to the strength development caused by the ongoing training programs of the wrestlers. As a result, integrating IASTM applications into the training programs can reduce the risk of injury of the athletes, as well as increase their movement capacity and contribute positively to their performance.

TRAINING EFFECTS OF STRETCHING ON RANGE OF MOTION: A SYSTEMATIC REVIEW WITH META-ANALYSIS

KONRAD, A.1,2, ALIZADEH, S.2, DANESHJOO, A.3, HADJIZADEH ANVAR, S.2, GRAHAM, A.2, ZAHIRI, A.2, GOUDINI, R.2, EDWARDS, C.2, SCHARF, C.1, BEHM, D.G.2

1 GRAZ UNIVERSITY 2 MEMORIAL UNIVERSITY OF NEWFOUNDLAND 3 SHAHID BAHONAR UNIVERSITY OF KERMAN

INTRODUCTION: Previous meta-analyses reported that stretch training can induce prolonged increases in joint range of motion (ROM) (Borges et al. 2018; Medeiros and Martini 2018). However, to date it is unclear which training variables might have greater influences on such improvements in flexibility. Thus, the purpose of this meta-analysis was to investigate the effects of stretch training on ROM in healthy participants by considering potential moderating variables such as stretching technique, intensity, duration, muscles stretched as well as sex-specific, age-specific, and/or trained state specific adaptations to stretch training.

METHODS: We searched through PubMed, Scopus, and Web of Science to find the eligible studies and finally assessed the results from 77 studies and 186 effect sizes by applying a random-effect meta-analysis. Moreover, by applying a mixed-effect model, we performed the respective subgroup analyses. Moreover, to find potential relations between the stretch duration or age to the effect sizes we performed a meta-regression.

RESULTS: We found a significant overall effect, indicating that stretch training can increase ROM with a moderate effect compared to the controls (ES = -1.002; Z = -12.074; CI (95%) -1.165 to -0.84; $p < 0.001$; I2 = 74.97). Subgroup analysis showed a significant difference between the stretching techniques (P=0.01), indicating that proprioceptive neuromuscular facilitation (PNF) and static stretching produced greater ROM changes compared to ballistic/dynamic stretching, respec-

tively. Moreover, there was a significant effect between the sexes (P=0.04), indicating that females showed higher gains in ROM compared to males. However, further moderating analysis showed no significant relation or difference.

CONCLUSION: When the goal is to maximize ROM in the long-term, PNF or static stretching rather than ballistic/dynamic stretching should be applied. Stretching volume and intensity might not play a significant role for the yields in ROM. Potential mechanisms for such an increase in ROM following stretch training are either chronic changes in muscle-tendon unit properties (e.g., a decrease in muscle stiffness (Nakamura et al. 2021) and/or changes in the perception to stretch or stretch tolerance (Freitas et al. 2018).

TWO-DIMENSIONAL MOTION ESTIMATION FOR MEASURING THE DISPLACEMENT OF THE BICEPS FEMORIS IN PASSIVE AND ACTIVE MOVEMENTS

CHOU, C.Y., WANG, H.K.

NATIONAL TAIWAN UNIVERSITY

INTRODUCTION: The biceps femoris long head (BFlh) is the most involved muscle in hamstring strain injury. The excessive strain of muscle tissue during sprinting is the proposed injury mechanism. However, no studies have measured the displacement of the BFlh during movement in vivo. Speckle-tracking ultrasonography (STU) is a semiauto-tracking method using consecutive ultrasonographs to estimate the displacement in dynamic conditions [1]. The tracking accuracy may be affected by BFlh inhomogeneity and contraction intensity. Therefore, this study aimed to establish a robust methodology with high accuracy and test–retest reliability for STU application in estimating BFlh displacement.

METHODS: STU was performed in 10 men (age: 23.4±0.7 years) twice 1 week apart; the protocol included 20°/s passive knee extension (PASS), knee flexion isometric contraction in 30° knee flexion (ISOM), and 20°/s knee flexion eccentric contraction tests (ECC). Scanning was conducted at the proximal and mid-BFlh, and the participants were tested in maximal and submaximal (85% MVIC) contraction intensities. The axial/lateral normalized cross-correlation (ANCC/LNCC), indicators of tracking accuracy, and intraclass correlation coefficient (ICC) of displacement (DISP) and the displacement angle (ANGL) were collected. These two outcomes were compared between the testing conditions using paired t-test and two-way repeated-measure ANOVA.

RESULTS: The normalized cross-correlation values were higher in the mid-BFlh than in the proximal mid-BFlh in PASS (LNCC: 0.94±0.04 vs. 0.91±0.04, p=0.03), ISOM (ANCC: 0.90±0.03 vs. 0.88±0.05, p=0.03; LNCC: 0.88±0.03 vs. 0.84±0.06, p<0.01), and ECC (ANCC: 0.84±0.03 vs. 0.82±0.04, p<0.01; LNCC: 0.80±0.04 vs. 0.75±0.05, p<0.001). The values were higher in the maximal than in the submaximal contraction intensity in ISOM (ANCC: 0.90±0.03 vs. 0.88±0.04, p=0.01; LNCC: 0.88±0.03 vs. 0.85±0.05, p=0.01); there were no differences in ECC.

The ICC values were higher in the mid-BFlh than in the proximal mid-BFlh in ISOM (DISP: 0.80 vs. 0.78; ANGL: 0.76 vs. 0.73) and lower in the mid-BFlh in PASS (DISP: 0.43 vs. 0.93; ANGL: 0.55 vs. 0.95) and ECC (DISP: 0.45 vs. 0.83; ANGL: 0.69 vs. 0.91).

Although mid-BFlh STU yielded poorer reliability in PASS and ECC, the displacement angle in the mid-BFlh showed the muscle moving toward the knee joint, which was consistent with the findings in the B-mode images. However, the proximal muscle displaced to the hip joint, which might be a sign of false tracking.

CONCLUSION: Mid-BFlh STU in combination with tests under maximal contraction intensity demonstrated better tracking accuracy and thus a potential for studying injury mechanisms. Further research should be implemented to improve the test–retest reliability.

COMPARISON OF DIFFERENT ULTRASOUND METHODS TO DETERMINE TRICEPS SURAE MUSCLE- AND TENDON DYNAMICS DURING LOCOMOTION

TILP, M., HABERSACK, A., KRUSE, A.

UNIVERSITY GRAZ

INTRODUCTION: Since the 1990s ultrasound (US) enables analyzing the dynamics of human muscles and tendons in vivo. This technique showed the independence of the overall muscle-tendon unit (MTU) and muscle length (ML) changes, e.g., during the stance phase of gait when the gastrocnemius medialis (GM) contracts near-isometrically despite eccentric behavior of the MTU (1). In the following years different methods using US were developed to determine ML and tendon lengths (TL) during human locomotion. The aim of this study was to identify and compare the different methods and their respective results.

METHODS: Different methods were identified in the literature and compared qualitatively.

RESULTS: Before determining ML and TL, all identified methods estimate total MTU length with equations based on cadaver measurements (2) or a musculoskeletal model (3). For these approaches, joint angles, e.g., from 3D motion capture, and individual anthropometrics for scaling are used to calculate MTU length. To determine ML and TL separately, Fukunaga et al. (1) were the first to use fascicle lengths and pennation angles from US measurements on the muscle belly. The length of the fascicle projected onto the aponeurosis represents the ML which is then subtracted from the MTU length to receive TL (i.e., serial elastic elements length). Important assumptions of this common method are that the geometry of the muscle is homogenous along its length and that TL represents tendon and aponeurosis lengths. A different approach (4) tracks the GM muscle-tendon junction (MTJ) with US to separate ML and TL during walking. Combined with 3D motion capture, this method allows to determine TL distal from the MTJ and ML by subtracting this value from the MTU length. Recently, a novel approach (5) combined MTJ tracking with direct measurement of the MTU length by placing markers at the origin and insertion of the gastrocnemii. This approach was validated for static measurements with MRI and does not need scaling of the MTU length due to direct individualized measurements, however, assumes that all parts proximal to the MTJ belong to the muscle, ignoring a proximal tendon.

CONCLUSION: ML and TL values from different approaches vary significantly because the underlying assumptions are very dissimilar. When ML is determined from US measurements on the muscle belly, the TL represents the length of all serial elastic elements and ML the length of the fascicle projected on the line of action. However, ML from US measurements on the MTJ represents the muscle belly length and the TL represents the Achilles tendon length only. While the scaling of musculoskeletal models is a valid approach, novel methods using individual landmarks may allow the direct determination of individual MTU lengths.

INFLUENCE OF TELOMERE LENGTH ON MUSCLE AND TENDON ADAPTATION IN THE ELDERLY FOLLOWING TO A STRENGTH TRAINING PERIOD

GROSSET, J.

UNIVERSITY OF TECHNOLOGY OF COMPIEGNE

INTRODUCTION: Telomere length (TL) decreases with aging, and contributes to cell senescence [1]. In observational studies, higher levels of physical activity are related to longer TL in various populations. Indeed, age is known to be associated with a marked decrease in muscle-tendon properties for maintaining balance. It has been clearly shown that resistance training (RT) improves muscle-tendon properties with stiffer tendon structures associated with increased balance ability [2]. Nevertheless, the relationship between the TL in older individuals and the response to training intervention remains unknown.

Thus, the aim of this study is to investigate the effect of high RT programs of the Quadriceps Femoris (QF) muscles on mechanical properties of the Patellar tendon (PT) changes in old men and the influence of TL.

METHODS: Healthy old men (OM80, (n=14, age 69.8 ± 4.4yrs) took part in a high training program (12 weeks RT program (3 times/week)) corresponding to 80% 1RM on QF muscle (using: leg press, leg extension). PT were scanned using a 1.5T MRI scanner before and after RT period. PT Cross Sectional Area (CSA) were determined every 10% of tendon length. Mechanical properties of PT were investigated from force and ultrasonographic measurements during maximal isometric ramp contractions. Blood samples were collected 1 week before the beginning of RT. TL was measured using an established quantitative real-time PCR technique. Pearson correlation analyses were conducted with the TL as dependent variable and the muscle-tendon characteristics as independent variables.

RESULTS: After training, QF volume was significantly increased (+4.2%, $p<0.05$). PT CSA was significantly increased in OM80 (+1.7%; P=0.002). An increase in PT force (+14.0%, p=0.008), stiffness (+34.5%, p=0.007) and Young's modulus (YM) (+34.8%, p=0.04) was found after 12-w RT. TL was significantly associated with gain in PT force (CC=0.67; p=0.049) and QF volume (CC=0.82; p=0.048). However, TL was not associated with gain in PT stiffness and YM despite a tendency (CC=0.70; p=0.14) and YM (CC=0.78; p=0.10).

CONCLUSION: The present study shows that the increase in QF volume, PT stiffness and YM following high strength training in old subjects was correlated with telomere length. Thus, the longer the telomere length is, the higher the muscle-tendon structures adaptations are. This may at least partly explain the heterogeneity in subjects' response following to strength training whatever the investigated adult population.

WRIST EXTENSOR TENDON FORCES DURING TENNIS FOREHAND ARE MODULATED BY PLAYER-SPECIFIC TECHNIQUE

GOISLARD DE MONSABERT, B.1, HERBAUT, A.2, CARTIER, T.1, VIGOUROUX, L.1

<1> AIX-MARSEILLE UNIVERSITY, CNRS, ISM, MARSEILLE, FRANCE; <2> HUMAN FACTORS & ERGONOMICS DEPARTMENT, DECATHLON SPORTSLAB RESEARCH AND DEVELOPMENT, LILLE, FRANCE

INTRODUCTION: Lateral epicondylalgia, also known as tennis elbow, is a major health issue among tennis players, affecting hand extensor tendons and resulting in pain and impairments for everyday life. Unfortunately, prevention remains limited by the lack of data regarding biomechanical risk factors, especially hand tendon forces which evaluation remains challenging. Musculoskeletal modelling is a non-invasive method to estimate muscle and joint loading from motion capture data and already provided data for the upper limb joints [1,2] but was less used for the hand [3]. The objective of this study was thus to develop a musculoskeletal model to provide a new insight into hand tendon loadings in tennis players.

METHODS: An Advanced player (ITN 3; grip strength: 653 N; eastern grip) and an Intermediate player (ITN 7; grip strength: 1195 N; semi-western grip) participated in a two-step protocol. First, players performed a series of grip force tasks to establish a relationship between electromyographic (EMG) activities and grip force. Second, players performed forehand drives, aiming a target with a ball at two shot speeds and with three rackets with different inertial properties.

Upper limb kinematics were tracked using reflective markers and a seven-camera motion capture system. EMG activities were synchronously recorded for four forearm muscles, including a finger extensor and a wrist extensor.

An EMG-informed musculoskeletal model was developed to estimate the tendon forces of 42 hand muscles. The model relied on an inverse-dynamics approach [3] with three main inputs: grip force estimated from EMG, wrist net moments deduced from marker data and four muscle forces estimated from EMG using force-length-activation relationships [4]. From the 42 tendon forces, muscle group forces of finger and wrist extensors were calculated by summing the forces of the four finger common extensor bellies and the three wrist extensors, respectively. Forces jut before impact were kept for further analysis.

RESULTS: Finger extensors' forces were close to 50 N and negligible compared to wrist extensors' ones, ranging from 400 N to 750 N. Wrist extensor tendon forces increased with shot speed but were moderately affected by racket properties. After normalizing by grip strength and shot speed, wrist extensors' loading in the Advanced player were up to three times higher than for the Intermediate one, suggesting player-specific biomechanical strategies.

CONCLUSION: The results of this study confirmed wrist extensors are exposed to high mechanical loadings and that player-specific characteristics, e.g., grip position, might modulate this loading. Further studies are required to clarify the individual factors influencing finger and wrist biomechanical loadings during tennis playing.

BICEPS FEMORIS APONEUROSIS STRUCTURE IS NOT CONTINUOUS BUT SEPARATED BY LOOSE CONNECTIVE TISSUE: A CADAVER STUDY.

MANTECON TAGARRO, C.J.1,2, NANIZAWA, E.3, OTSUKA, S.3, NAITO, M.3, MAAS, H.2, KAWAKAMI, Y.1

1. WASEDA UNIVERSITY, 2.VRIJE UNIVERSITEIT AMSTERDAM, 3.AICHI MEDICAL UNIVERSITY

INTRODUCTION: The biceps femoris long head (BFlh) is known to be prone to strain injury, and studies in the last decade suggest a role for its architectural complexity. Several studies on human cadavers have been performed to understand the structure-function relationship, particularly around the proximal region, where most injuries occurs (1). A particular and potentially relevant structure in this region is the intramuscular aponeurosis, e.g. a broad, sheet-like elastic structure, which is loaded both in the longitudinal and transverse axis during muscle contraction. In vivo studies have attempted to delineate the intramuscular aponeurosis using ultrasonography (2). However, this does not allow for studying its detailed anatomical structure. Hence, the aim of this study is to assess the structure of BFlh aponeurosis in detail.

METHODS: Both lower extremities of four embalmed human cadavers (male : female = 2 : 2, mean ± SD 84.5 ± 6.35 years old) were dissected. Morphometric data of the BFlh muscles were collected after separating them into blocks by cross-sectional (CS) cuts of the BFlh every 5% of its length. Care was taken to align the blocks to identify the path of the aponeurosis throughout the BFlh muscle length. Macroscopic analysis of each block surface was performed to differentiate dense connective tissue of the aponeurosis structure from loose connective tissue or adipose tissue based on the appearance and resistance to deformation induced by a forceps. Structures that were not clearly identified with these procedures were further processed for histological analysis.

RESULTS: Intramuscular aponeurosis was identified from 40% ± 5% to 70% ± 5% of BFlh muscle-tendon unit length. Infiltrations of loose connective tissue between the collagen bundles of the aponeurosis in the CS plane were observed in the macroscopic and histological analysis, i.e, there were divisions of aponeurotic continuity by the loose connective tissue. Inter-individual differences of the aponeurosis geometry and disrupted continuity were observed along the BFlh length. Significant changes were observed from 50 to 60% BFlh length, where the aponeurosis transformed its shape in the CS from a flat line to a hook-like or a T-shape.

CONCLUSION: The intramuscular aponeurosis of BFlh does not have a continuous structure transversely. The shape considerably changes along its length and across individuals. These features have implications for the region-specific and individual differences in strain injury proneness.

RESIDUAL FORCE ENHANCEMENT IN THE DESCENDING LIMB: IS THERE A LIMIT?

MANIEU SEGUEL, J., PATERNOSTER, F.K.

TECHNICAL UNIVERSITY OF MUNICH

INTRODUCTION: Residual Force Enhancement (rFE) is a property of skeletal muscle, defined as an increase in force during an isometric steady-state contraction after an active stretch compared to the force produced during a pure isometric contraction at the same joint angle and similar muscle activity. RFE has been shown to be present during the entire force-length relationships. In addition, rFE increases with stretch amplitude and muscle length up to a critical point. This study aimed to investigate if rFE keeps increasing with increasing muscle length only in the descending limb and if there is a limit where it does not appear anymore.

METHODS: Eight healthy male participants performed maximal isometric voluntary contractions (MVIC) of the knee extensors during the descending limb of their individual torque-angle relationship, with and without a preceding active stretch. In total three different stretch amplitudes (short = 15°, medium = 25°, long = 40°) where tested. For data analysis, torque, and EMG activity of the quadriceps muscles (rectus femoris, vastus medialis, and vastus lateralis) were tested during the isometric trials, as well as during the trials after an active stretch.

RESULTS: The results showed a significant decrease in torque between the reference MVIC (195.41 □ 46.90 Nm) and stretch-hold contraction (183.17 □ 59.93 Nm) for the short stretch condition, and a significant increase in torque between the reference MVIC (142.92 □ 34.81 Nm) and stretch-hold condition (159.29 □ 37.08 Nm) for the long stretch amplitude. RFE values ranged from 2 – 25%. Fascicle length from the vastus lateralis increased by an average of 1.90mm (4%) for the short stretch, 2,8mm (6%) for the medium stretch, and 3,4mm (6%) for the long stretch amplitude.

CONCLUSION: Although torque values decreased with the increase in fascicle length during the descending limb, the change percentage in torque was higher after the long stretch (20% change) compared to the medium stretch (10%). From these results, we can conclude that force enhancement exists at very long muscle lengths in the quadriceps femoris, that it is higher with higher stretch amplitudes and longer fascicle lengths, and that so far, it does not show a limit or point where it does not increase anymore.

THE CHARACTERISTICS OF LOWER LIMB MUSCLE STRENGTH IN ELITE JAPANESE ATHLETES: FOCUSING ON THE DIFFERENCE IN SPORTS TYPE AND COMPETITION SEASON

IMAWAKA, T., KAMEDA, M., INABA, Y.

JAPAN INSTITUTE OF SPORTS SCIENCES

INTRODUCTION: The competition and training environment varies depending on the competition season, i.e., summer or winter, not to mention that it varies depending on sports type. Therefore, physical characteristics of elite athletes are considered to be affected by the competition season as well as the sports. Previous studies have suggested that lower limb muscle strength is an important factor in a variety of sporting activities (1). There have been several reports that have examined lower limb muscle strength for different competitive events, but not in terms of the competition season and sports type. This study aimed at investigating lower limb muscle strength in elite Japanese athletes with a focus on the sports type and competition season.

METHODS: Elite Japanese male athletes of various competition events were involved in this study (N=1364). They were divided into 5 categories of sports type (2, 3) (a. SPRINT/POWER, b. ENDURANCE, c. ARTISTIC, d. BALLGAME, e. OTHER) and also into 2 competition seasons (Summer or Winter). Isokinetic knee extension and flexion strength tests were conducted at the angular velocities of 60 and 180 deg/s. The peak extension and flexion torque (PT) and those normalized to their body weight (PT/BW) were extracted from each velocity condition. Differences in PT and PT/BW of both knee extension and flexion at each angular velocity among the categories were tested by a two-way ANOVA (5 sports types × 2 seasons). Statistical significance was set at $p < 0.05$.

RESULTS: In 60 deg/s knee extension, significant main effects of the sports type and season were found, without any interaction. Winter season athletes showed significantly higher PT/BW than summer season athletes. Post-hoc multiple comparison revealed that PT/BW in SPRINT/POWER was significantly higher than OTHER. On the other hand, significant interactions were found between the sports type and season for PT/BW in 180 deg/s knee extension, and 60 deg/s and 180 deg/s knee flexion. In 180 deg/s knee extension, there were significant differences between Summer (S-) and Winter (W-) in PT/BW of ENDURANCE (S-ENDURANCE < W-ENDURANCE) and OTHER (S-OTHER < W-OTHER). Significant differences were also found between the seasons in PT/BW of 60 deg/s knee flexion for ENDURANCE (S-ENDURANCE < W-ENDURANCE) and BALLGAME (S-BALLGAME > W-BALLGAME) and in PT/BW of 180deg/s knee flexion for SPRINT/POWER (S-SPRINT/POWER > W-SPRINT/POWER), ENDURANCE (S-ENDURANCE < W-ENDURANCE) and BALLGAME (S- BALLGAME > W- BALLGAME).

CONCLUSION: Our results suggest that not simply the sports type but also the season of them affect the lower limb muscle strength of elite athletes substantially. Seasonal differences may be due to the season-specific feature in sporting movement, e.g., forward-bent posture and tonic muscle contraction in skiing and skating.

UPPER LIMB JOINTS COORDINATION DURING JUMP PULL-UPS IN ROCK CLIMBERS

HUGUES, X., CAHOUET, V., ROGUE, R., QUAINE, F.

GIPSA-LAB

INTRODUCTION: The pull-up exercise is a complex motor task involving multiple joints. The jump pull-up (JPU) is representative of climber's skill and is given as a relevant upper-limb power test (1), but JPU's joint coordination is not described in the literature. JPU task can be related to squat or counter-movement jumps where complex motor task rules the activation joint from proximal to distal (2) (3). This study investigates the coordination pattern of the upper limb joints during JPU exercise with or without stretch shortening cycle.

METHODS: Six skilled climbers (over 7c French lead climbing grade.) performed 4 trials of two forms of JPU : counter-movement JPU and stato-dynamic JPU. Climbers were asked to jump in order to ascend their two hands as high as possible. Each participant was equipped with an adapted Qualisys® marker set to measure upper limbs displacements. Two 3-axis force sensors were used to measure each hand reaction force during the JPU. Upper joint angular kinematics and hands maximal height were estimated from Qualisys measurements. The onset times of maximum joint velocities (NT) were normalized to JPU duration. t-test were performed to realize statistical analysis.

RESULTS: Statistical tests realized on NT deviation between the wrist and elbow joints (14.1 ±5.8 % NT of JPU, $p<0.05$) and the elbow and shoulder joints (38.7 ±12.0 % NT of JPU, $p<0.05$) indicate significant differences. The joints were involved from the shoulder to the wrist in a proximal to distal sequence. No significant difference of the height reached by the hands between the two JPU exercises were found.

CONCLUSION: This study demonstrates that the recruitment pattern of the upper limb joints obeys the proximal-distal order when performing JPU. This is consistent with the observations conducted on lower limb squat jumps. However, the comparison of the two JPU forms performed reveals no significant improvement in jump high performance due to the presence of a stretch shortening cycle. Further investigation should be conducted in order to confirm these findings.

UPPER LIMB KINEMATICS OF AN ELITE CLIMBER DURING A POWER SLAP TASK

BRILEY, S., MITCHELL, J., TAYLOR, N., CHIDLEY, J., OUTRAM, T.

UNIVERSITY OF DERBY, UK

INTRODUCTION: Climbing coaches can benefit from quantifying upper limb kinematics during climbing activities to develop training programs. However, kinematic analyses of climbing tasks are rare due to technological limitations, and coaching relies on qualitative observation or video data (2). Inertial measurement units (IMUs) are wearable, portable, and require minimal preparation and can be undertaken in real-world settings. However, prior to their widespread use the validity of these tools for climbing tasks warrants investigation. The study aims to quantify upper limb kinematics of an advanced climber during climbing-specific tasks and compare the accuracy of IMU-derived kinematics to optical motion capture.

METHODS: A male climber (age: 23 years; body mass: 61.1 kg; top boulder grade: V11; climbing experience: 14 years) provided written informed consent to participate in this study. A twelve-camera motion analysis system and five Blue Trident IMUs (Vicon, Motion Systems Ltd) simultaneously acquired kinematic data. Retroreflective markers and IMU sensors were attached to the torso, pelvis, upper arms, and forearms. Following a self-selected warm up the climber performed two repetitions of a power slap test. The test begins with a two-armed hang on a 45mm rung, followed by an

explosive pull-up where one arm slaps the scale board above. Upper limb kinematics were calculated using inverse kinematics following the OpenSense workflow (3) within OpenSim 4.4.

RESULTS: The mean distance attained during the power slap was 1.0 m for both arms. The dominant hand slap showed higher humeral flexion, abduction, and internal rotation (126.2°, 56.8°, and 45.8°) compared to the non-dominant hand slap (120.6°, 43.6° and 41.9°). Whereas torso lateral flexion and rotation were lower in the dominant hand slap. IMU and optical capture kinematic differences ranged from 1.1° to 7.9°, with the largest occurring in humeral internal rotation.

CONCLUSION: This work presents novel insights into the upper limb kinematics of a highly explosive climbing task performed by an elite climber. Despite attaining similar heights between dominant and non-dominant limbs during the power slap the climber exhibited differences in upper limb kinematics suggesting slight alterations in coordination. IMU-derived upper limb kinematics were comparable to the optical capture system during both the two-armed hanging position phase and the single-arm slapping phase of the power slap. Despite these promising results further work is necessary to further evaluate the accuracy of IMUs in quantifying upper limb kinematics in climbers which should include a larger sample size and wider array of climbing tasks. The notable asymmetries in upper limb kinematics may provide coaches with additional cues to observe when developing climbers.

COMPARISON OF GROUND REACTION FORCES ON FULL AND CONTROLLED DRIVER SHOTS IN MALE PROFESSIONAL GOLFERS

HIRANO, T.1, KASHIWAGI, Y.2, SHIMATANI, S.3, TSUNODA, N.1, FUNATO, K.1

1: KOKUSHIKAN UNIVERSITY, TOKYO, JAPAN

INTRODUCTION: Shot distance and accuracy in golf are achieved by adjusting club head velocity (CHV). A prior study indicated that the horizontal reaction force of the front leg is diminished when a reduced shot distance is achieved with a 6-iron club [1]. However, the regulation of ground reaction force (GRF) with different CHVs of driver shots has yet to be elucidated. This study aimed to determine how skilled golfers adjust GRF variables during full and controlled driver shots.

METHODS: Eight right-handed male professional golfers (age: 35.7 ± 1.7 years; height: 173.6 ± 7.7 cm; body mass: 75.1 ± 9.4 kg) participated in the study. Each golfer executed a full driver shot (aiming for maximum distance) and a controlled shot (aiming for the center of the fairway). Two Kistler force plates and 12 Vicon cameras were used to record GRF data for each leg and clubhead kinematics data during the swing. The maximum CHV and magnitude and angle of the front and rear leg GRF were calculated for the backswing and downswing phases. A paired t-test using statistical parametric mapping (SPM) was done to compare the GRF magnitude and vector angle of the shots [2].

RESULTS: The full shot had a greater maximum CHV than the controlled shot (51.8 ± 3.7 vs. 49.5 ± 2.2 m/s, respectively, $p < 0.05$). SPM analysis indicated that, for both legs, the GRF magnitude in the backswing phase did not differ between the shots. In contrast, during the downswing phase, only the vertical GRF of the front leg was significantly greater in the full shot than in the controlled shot, in the range of 55%–74%. No difference was observed in the GRF vector angle between shot types.

Our results indicated that skilled golfers increased the front leg vertical GRF in the mid-downswing phase of a full driver shot. This differs from the prior study, which reported a reduction in the horizontal GRF component of the front leg with reducing shot distance using a 6-iron club [1]. This discrepancy may be due to the difference in swing using a driver or an iron. Another study showed that the magnitude of the vertical GRF of the front leg on the downswing is a major predictor of ball velocity [3]. Thus, the skilled golfer may have pushed downwards harder with the front leg during the full shot with the driver. Furthermore, adjusting the GRF magnitude without changing the GRF angle between shots may promote shot distance and accuracy in terms of leg coordination and performance, as shown in a previous study [1].

CONCLUSION: A comparison of full and controlled driver shots of skilled golfers suggested that the full shot had a higher CHV due to a greater vertical GRF of the front leg after the mid-downswing phase.

PERFORMANCE COMPARISON BETWEEN WATERFOWL AND SYNTHETIC FEATHER SHUTTLECOCKS IN BADMINTON: FOCUSING ON THE SHUTTLECOCK MOVEMENTS IMMEDIATELY AFTER BEING SMASHED

NAKASHIMA, H., KAMEDA, M., ANDO, R., LEE, M., GOH, W., TAN, K., BOEY, D., OZAKI, H.

JAPAN INSTITUTE OF SPORTS SCIENCES

INTRODUCTION: The Badminton World Federation approved substituting the waterfowl feather shuttlecock (hereinafter "WFS") for synthetic feather shuttlecocks (hereinafter "SFS") at international tournaments from 2021. Thus, players need to adapt to the SFS and play on it. Although the manufacturers reported similar performance between SFS and WFS, no de-

tailed data has been presented. Therefore, we investigated the kinematic characteristics of the WFS and SFS focusing on the shuttlecock movement immediately after being smashed in this study.

METHODS: Twenty collegiate badminton players smashed the shuttlecocks coming out of the knock machine to the target area 12 m far from the hitting location. To record the shuttlecocks' movements immediately after being smashed, a high-speed camera was placed laterally and perpendicular to the shuttlecock's trajectory. The camera was set at a frame rate of 2,000 fps. One of each trial where the racket speed at impact was maximal in WFS (TOURNAMENT, YONEX) and SFS (TECH FEATHER 03, Mizuno) was selected for analysis. The cork head and both ends of the feather tip were manually digitized. Racket speed at impact, initial shuttlecock speed, shuttlecock/racket speed ratio, vertical launch angle, and attitude angle of shuttlecock, which is defined as the angle between the long axis of the shuttlecock and the initial velocity vector, were calculated. To compare these parameters between WFS and SFS, an unpaired t-test was used. The significance level was set at $p<0.05$.

RESULTS: Significant differences were not found for racket speed (WFS: 63.3±9.5 m/s, SFS: 63.8±8.9 m/s, p=0.48), initial shuttlecock speed (WFS: 73.6±8.5 m/s, SFS: 71.8±7.0 m/s, p=0.07), vertical launch angle (WFS: –9.0±2.6 degrees, SFS: –9.2±2.6 degrees, p=0.40). Shuttlecock/racket speed ratio for WFS was larger than that for SFS (WFS: 1.17±0.06, SFS: 1.13±0.07, p=0.03). Maximum attitude angle of shuttlecock for WFS was smaller than that for SFS (WFS: 41.0±4.9 degrees, SFS: 45.4±4.4 degrees, p=0.01).

CONCLUSION: The participants smashed both shuttlecocks at almost the same initial speed and vertical launch angle to hit the same target area; therefore, the difference in flight characteristics between the two shuttlecocks was found to be negligible at a glance. However, the shuttlecock/racket speed ratio for SMS is smaller; thereby, there is a possibility that the participants might have adjusted the racket speed slightly, although no statistical difference were found in racket speed. Moreover, the drag force acting on SFS might be slightly larger because SFS had a larger attitude change. Badminton players have extremely sensitive senses to perform well, especially at the international level. In our future work, it is required to reveal how they adapt to the SFS and the risk of injuries associated with it through the motion analyses. In addition, revealing the aerodynamic characteristics of shuttlecocks is also required through the wind-tunnel experiments.

ACCELEROMETERY VS. VIDEO-DERIVED STROKE PARAMETERS IN HIGH-LEVEL SWIMMERS

MUSSON, C.

NELSON MANDELA UNIVERSITY

INTRODUCTION: Swimming is a multifaceted sport with nuanced performance parameters that tend to vary according to the swimmer's stroke style [1]. The extraction and analyses of swim parameters, such as lap time (LT), stroke length (SL), stroke rate (SR) and velocity are time-consuming [2]. This may be eased, and to some extent automated, by the use of cost-effective tri-axial accelerometers.

OBJECTIVES:

To determine the validity of tri-axial accelerometers across all four stroke styles, and to investigate kinematic differences in stroke styles using accelerometer-based data.

METHODS: Twelve elite swimmers were recruited for the study. The group consisted of five male (age: 22.2 ± 2.6 years; height: 1.84 ± 0.08 m; weight: 76.2 ± 3.6 kg) and seven female (age: 20.7 ± 2.1 years; height: 1.68 ± 0.08 cm; weight: 62.0 ± 6.3 kg) swimmers. A 4 x 50-m individual medley was completed in a 25-m pool, with tri-axial accelerometers fitted to the swimmer's left wrist and upper-back, sampling at 100Hz. Accelerometer data (reference method) were compared to high-speed video (criterion method) to evaluate the validity of the key stroke parameters.

RESULTS: There was a small but significant bias for accelerometery data compared to video data for most parameters evident from the mean bias differences across all stroke styles for swimming velocity (Mdiff = -0.05m/s, $p<0.019$), SR (Mdiff = -0.02str/sec, $p<0.047$, except freestyle, Mdiff = -0.01str/sec, $p = 0.083$) and lap time (Mdiff = 1.38 sec, $p<0.001$). No statistical differences were evident for SL (Mdiff = 0.01m/str, $p = 0.795$) and stroke count (Mdiff = 0.19, $p = 0.280$). However, the accelerometery-derived SR, SL and velocity can be considered practically useful based on the training requirements of coaches, with a two one-sided t-test indicating that these parameters fell well within their equivalence bounds for all strokes (velocity = ±0.10m/s, SR = ±0.04str/sec, and SL = ±0.02m/str). Parameters derived from video analysis compared to accelerometery were highly correlated ($r > 0.91$) and therefore consistent regardless of the method of analysis.

CONCLUSION: Slight statistical differences were present between the video and accelerometer data, suggesting that the accelerometers may not be a "true" surrogate compared to video data. The accuracy of the results obtained were on par with those of other studies, even though the sample investigated were different [3,4]. Hence, the accelerometers showed potential for monitoring of swimmers in training, with the practical usefulness for coaches. Future research should investigate real-time feature extraction, effects of injury and/or fatigue, and whether training interventions yield detectable changes in stroke mechanics when using accelerometery.

RELATIONSHIP BETWEEN BATTING VELOCITY AND UPPER EXTREMITIES ISOKINETIC MUSCLE STRENGTH DURING BASE-BALL TEE BATTING

HO, C.C., LU, S.D., HUANG, B.X., LIN, Y.A., LIN, J.Z.
NATIONAL TAIWAN UNIVERSITY OF SPORT

INTRODUCTION: The increasing swing velocity can help increase decision time, reduce swing time, and increase ball exit velocity. The latter can make the ball fly faster and farther, creating challenges for the opponents' defense (1). Batting velocity affects batted ball distance. To increase ball exit velocity, hitters must increase swing velocity (2), which demonstrates the importance of both swing and batting exit velocities. However, most researchers have focused on lower extremity joint performance (3), with studies lacking on the upper extremity joints that perform movements. Therefore, the purpose of this study was to investigate the relationship between batting exit velocity and isokinetic muscle strength of the upper extremities.

METHODS: Three college baseball players were recruited for this study. The participants used wood bats (850 g; Louisville Slugger) to hit the ball positioned on a tee; they were instructed to hit the ball with full strength into a net (87 cm x 87 cm). The swing velocity parameters of the reflective balls on the bat were obtained using Vicon systems. The Biodex System 4 Pro was used for the isokinetic muscle strength tests of the shoulder, elbow, and wrist joints, collecting peak torque and power parameters at 60, 120, and 180°/s. We used Pearson product difference correlation analysis.

RESULTS: According to the results of the Pearson correlation analysis, the batting exit velocity was significantly positively correlated with the shoulder 60°/s internal rotation PT/BW ($r = 0.997$; $P = 0.047$); no correlation was found with the parameters of the elbow and wrist joints. The swing velocity was significantly positively correlated with the elbow 180°/s extension PT/BW ($r = 0.999$; $P = 0.026$), shoulder 60°/s internal rotation PT ($r = 1$; $P = 0.015$), 120°/s internal rotation PT/BW ($r = 0.999$; $P = 0.032$), and 60°/s internal rotation AVG PT ($r = 0.998$; $P = 0.036$). However, it did not correlate with the wrist joint parameters.

CONCLUSION: The batting exit velocity was significantly positively correlated with the peak torque of the internal rotation of the shoulder joint, indicating that batting is a continuously coordinated action, and the kinetic chain transmits energy from the lower to the upper limb (4). The main energy may come from the rotation of the lower limb and torso. Many factors affect the batting exit velocity, including the launch angle, swing velocity, and pitching velocity, among others. Therefore, the isokinetic muscle strength in the upper limb joints has a low impact on the batting exit velocity. The results of this study showed that shoulder internal rotation and elbow extension are highly correlated with batting. In the future, to improve batting performance, the focus should shift to shoulder and elbow joint strengthening. These results provide a batting training reference for coaches and players.

EFFECT OF ADJUSTMENT OF SADDLE HEIGHT AND RIDING TIME ON CYCLE PEDALING

YOON, S., KIM, D.H.
KOREA NATIONAL SPORT UNIVERSITY

INTRODUCTION: Road cycling is one of the most popular sports not only for professional athletes but also for recreational players around the world. The saddle height of road cycling, which rides more than 100 km a day on average, is a very important factor in increasing cycling efficiency. However, unlike professional athletes with professional trainers, recreational players have limited information on choosing their own optimal saddle height. In addition, since the traditional saddle height chosen by general fitters is calculated for professional players, it is difficult to apply it to recreational players (1-2). Therefore, the purpose of this study was to help the cycling club riders(recreational players) to prevent injuries and improve their athletic performance based on the data from comparison of lower extremity movements according to saddle height and running time during cycling pedaling.

METHODS: Eleven healthy adult males (age: 33.18±7.51 yrs, height: 175.49±6.14 cm, weight: 69±8.72 kg, career: 7±5.53 yrs.), whose dominant foot is right one, and who have been cycling for more than three years with no lower extremity musculoskeletal injury within the past six months participated in this study. Raw data of this study were collected for three days and test protocol was conducted under the same conditions, including hour and time period, except for saddle height. A 3-Dimensional motion analysis with eight infrared cameras(sampling rate: 200 Hz) and five-channel of EMG(sampling rate: 1000 Hz) was performed. A two-way ANOVA with repeated measures was conducted to verify the intervention effect and the statistical significance was set at α=.05.

RESULTS: As saddle height increased, the hip joint revealed the largest ROM followed by knee and ankle joints. For all saddle height, the third phase, where the lower extremity joint was at maximum extension, showd the largest change in joint ROM. Also the joint angular velocity revealed similar to that of the joint ROM. In addition, higher saddle height led to more decrease in angular velocity over time in all joints. Finally, as saddle height increased, it was shown that a tendency of higher muscle activation and greater decline in muscle activity over time.

CONCLUSION: This study quantified the saddle height adjustment method for recreational riders, which was studied only for elite riders regardless of East and West. The results of this study seems to contribute to relieving the discomfort of recreational riders while riding, and to help research on more efficient saddle height adjustment methods in the future.

DIFFERENCES IN LOWER EXTREMITY BIOMECHANICS BETWEEN PATIENTS WITH PATELLOFEMORAL PAIN SYNDROME AND HEALTHY ADULTS DURING STATIONARY BIKE RIDING

ZHENG, Y.Q., LIN, Z.Y., LIN, W.T.
KAOSHOUNG MEDICAL UNIVERSITY

INTRODUCTION: Cycling is less of a load on the knee joints, but long-term repetitive pedaling may easy to cause knee injury. The most common injury is Patellofemoral Pain Syndrome (PFPS), whose symptoms include anterior knee pain, paresthesias, and functional deficits. Although there is no definite conclusion on the cause of PFPS, most scholars believe that abnormal joint movement, unbalanced muscle contraction and so on are all possible causes. This study wants to know about the activation of lower limb muscles in patients with PFPS during cycling, with different resistances and different seat heights at a fixed riding speed.

METHODS: In this study, the subjects were divided into the PFPS group and the healthy group. Two kinds of seat cushion heights that were commonly used in the past and three different resistances that were often used in the actual riding were used alternately. Use the EMG system to observe the activation of the contraction of the Gluteus Medius (GM), Vastus Medialis (VM), Rectus Femoris (RF), and Vastus Lateralis (VL) while riding. To compare the differences between the two groups and find out which one is more suitable for patients with PFPS.

RESULTS: The VL ($\beta = -0.105$, $p < 0.05$) & VM($\beta = -0.139$, $p < 0.05$) activation in the pain group is less than that in the health group. When using the high seat height, the activation of VL is significantly greater than the low seat height.($\beta = -0.133$, $p < 0.05$) Conversely, VM activation was significantly lower with higher seat height ($\beta = 0.129$, $p < 0.05$).

In the PFPS group, GM EMG activation was significantly greater than in the healthy group($\beta = -0.201$, $p < 0.001$); and in higher seat height, EMG activation was significantly greater than low seat height($\beta = 0.161$, $p < 0.001$); There was no significant correlation in muscle activation between different resistances.

Different resistances have a significant impact on the activation of RF($\beta = 0.102$, $p < 0.05$). As the resistance increases, the activation of RF increases.

CONCLUSION: Strengthening the GM, VM, and VL muscles in patients with PFPS to reduce muscle compensation when riding a bicycle. In addition, due to the dislocation of the joints of the lower limbs, it is necessary to pay more attention to whether the joint angle is too large, so as to reduce knee varus, thereby reducing joint pain.

THE INFLUENCE OF RACKET SIZE ON SERVE BIOMECHANICS IN YOUNG TENNIS PLAYERS

MARTIN, C., TOUZARD, P., LECOMTE, C., FADIER, M., FOUREL, L., CANTIN, N., BIDEAU, B., KULPA, R.
UNIVERSITE RENNES 2 - ENS RENNES

INTRODUCTION: Scaling the equipment of young athletes is justified by the constraints-led approach introduced in motor learning. Tennis coaches are encouraged to scale the equipment in children's sport to improve motor patterns acquisition and to favor the emergence of efficient and safe technical skills in a fun and exciting environment. Among all the possible interventions on equipment, scientists encourage coaches to ask young tennis players to play with different racket size in the theoretical hope of facilitating racket handling ability, decreasing upper limb joint loadings, promoting more variability, increasing performance (speed and accuracy), increasing segmental and joint angular velocities. However, the short-term effects of the racket scaling constraint on serving performance, kinematics and joint loadings are unknown. As a consequence, this study aimed to assess the effect of racket size on the serve biomechanics and performance parameters for young tennis players

METHODS: 9 young intermediate competitive tennis players (age: 9.9 ± 1.0 years) performed maximal effort successful flat serves with 3 different rackets (scaled 23 inches, scaled 25 inches and full-size 27 inches) in a randomized order. A radar measured ball speed while shoulder and elbow loadings and upper and lower limb kinematics were calculated with a motion capture system. Repeated measures ANOVAs were used to compare the effect of the three racket sizes.

RESULTS: Ball speed ($P = 0.187$), maximal racket head velocity ($P = 0.368$) and percentage of serve in ($P = 0.713$) were not significantly different between the three rackets. The lowest maximal upper limb loadings (shoulder internal rotation, shoulder abduction and elbow varus torques) and the highest upper limb maximal angular velocities (forearm pronation, elbow extension and wrist flexion) were obtained with the scaled 23 inches racket while the full-size 27 inches racket induced higher maximal angles of front knee ($P = 0.005$) and back ankle flexion ($P = 0.033$), higher maximal extension velocities of the back knee ($P = 0.004$) and back ankle ($P = 0.008$).

CONCLUSION: The current results show that scaling racket from 23 to 27 inches would not have immediate effect on ball speed, maximal racket head velocity and percentage of serves in but would decrease shoulder and elbow loadings. Moreover, the manner in which the body produced joint angular velocities differed between the three racket sizes, with scaled rackets promoting more distal angular velocities and the full-size racket facilitating more proximal angular velocities from the lower limbs. Our results suggest that serving with a full-size racket provides beneficial biomechanical opportunities for the lower limbs but detrimental boundaries for the dominant upper limb in young intermediate tennis players. Finally, our study shows that modifying racket characteristics constitutes a short-term and relevant practical intervention that provides immediate new learning opportunities for young intermediate tennis players.

THE IMPACT OF PHASE DURATION AND ITS VARIABILITY ON ARCHERY SHOOTING PERFORMANCE: A CASE STUDY

LIN, Y.1, KING, L.T.2, GUO, C.W.1, HUANG, C.C.1, LIN, T.C.1, CHEN, S.Y.1, KUO, W.J.2, CHEN, Y.H.1
1 NATIONAL TAIWAN SPORT UNIVERSITY; 2 NATIONAL YANG MING CHIAO TUNG UNIVERSITY

INTRODUCTION: The recurve bow shooting movement could be divided into several phases including set-up, drawing, aiming, clicker reaction time (CRT), and follow through (1). Previous studies have addressed the importance of the aiming duration and CRT; however, the results were inconsistent (1,2,3), and the other phases were not examined. Moreover, most studies used cross-sectional design where participants were required to shoot a limited amount of arrows in one experiment. Therefore, the aim of this study was to systematically investigate the relation between shooting performance and each phase duration as well as its variability with a longitudinal design.

METHODS: We recruited one skilled male archer (19 years) who had 7 years of recurve archery experience. In each experiment, the archer was required to shoot 12 ends of 6 arrows at a 122-cm target face at 70 m outdoors. 10 experiments were conducted, resulting in 720 arrows collected. A customized mechanical switch was attached under the clicker of the participant's bow to record the fall of the clicker in each shot. Moreover, one marker was attached on the participant's wrist and its movement was captured by one video camera (30Hz) and input to Kinovea for digitization. Each shot cycle was then divided into 4 phases with 5 specific movements (i.e., set-up, drawing, anchor, clicker fall, and release to define the phases of set-up, drawing, aiming and CRT). Separate one-way repeated measures ANOVAs were used to compare the difference of the duration and duration variability of each phase under different scores (10, 9, 8, and under 7 points, respectively). The Pearson product-moment correlation coefficient was used to examine the relation between performance and the duration as well as the duration variability in each phase. The level of significance was set to $\alpha = .05$.

RESULTS: The percentage of the shots in 10, 9, 8, and under 7 points were 20±6.4%, 37.9±6.0%, 25.5±3.8%, and 16±6.3%, respectively. The duration of set-up, drawing, aiming, and CRT was 2549±217ms, 1605±187ms, 3488±619ms, and 193±37ms, respectively. The average duration variability of set-up, drawing, aiming, and CRT was 144±29ms, 115±28ms, 647±201ms, and 33±9ms, respectively. Particularly, there was a significant main effect of score in the duration of set-up phase $F(3,27)=3.725$, $p<.05$, $\eta p2=.293$, with the 10-point arrows (2514±177ms) shorter than the 8-point ones (2569±165ms) Furthermore, the duration variability of drawing phase was negatively correlated with scores ($r=-.826$, $p<.05$).

CONCLUSION: Our results revealed that the duration and duration variability in certain phases may crucially impact the shooting performance. On the one hand, these results partially replicated previous findings in literature. On the other hand, the discrepancy of the results from previous studies might highlight the importance of collecting data in a more ecological setting that simulated the competition and in a longitudinal design.

SERUM CONCENTRATION OF SELENIUM, FOLATE, VITAMIN B12 AND FERRITIN IN FEMALE ELITE FIELD HOCKEY PLAYERS

VORSPOHL, V., DE MARÉES, M., PLATEN, P.
RUHR UNIVERSITÄT BOCHUM

INTRODUCTION: Micronutrients play an essential role in maintaining health and performance of athletes. In addition to their role as components and biocatalysts of metabolic processes, micronutrients also function as regulators of the immune system (1). The serum concentrations of the micronutrients selenium, folic acid, vitamin B12 (Vit B12) and ferritin in female elite hockey players have either not been investigated in depth so far (e.g. selenium, folic acid and Vit B12) or are still of interest due to poor implementation of substitution recommendations. The aim of this study was to analyse the serum concentrations of these micronutrients in the players of the German field hockey national team in order to detect possible deficits and develop sport- and gender-specific recommendations for micronutrient substitution.

METHODS: 33 German female hockey players (age: 23.9 ± 3.5 years; weight: 65.4 ± 6.7 kg; height: 170.4 ± 5.6 cm) playing in the first German national league and in the German national team were included. Venous blood sampling was done in the morning in a fasting state during the days of the yearly sport medical health examination. Whole blood was analysed for the concentrations of selenium and folic acid, and serum was analysed for Vit B12 and ferritin. The analyses were done by Ganzimmun Diagnostics GmbH, Mainz and their specific reference values (RV) were used. Results were corrected for haematocrit concentration. Descriptive statistics are presented as mean ± standard deviation (range, RV).

RESULTS: The mean concentrations of the four micronutrients were: selenium 122.0 ± 23.9 ng/ml (90-181 ng/ml, 101-170 ng/ml); folic acid: 220.0 ± 88.8 (112-570 ng/ml, 126-651 ng/ml); Vit B12: 318.0 ± 80.0 (168-493 ng/ml, 211-911 ng/ml; ferritin: 65.0 ± 39.4 (16-163 ng/ml, 35 (stage 1 iron deficiency)-150 ng/ml). The following number of athletes had values below the respective RV: selenium: n=5; folic acid: n=2; Vit B12: n=4; ferritin: n=10.

CONCLUSION: Mean concentrations of selenium, folic acid, vitamin B12 and ferritin were within the reference ranges. A relevant number of athletes, however, had values below the respective lower limit. This was especially true for selenium. A deficiency in the selenium supply might lead to weakness of the immune system or impaired antioxidant capacity in

situations of high training or competition loads (1). Some athletes were stage-1 iron deficient which might sooner or later lead to anaemia and reduced endurance capacity if the stores are not filled properly (2). Folic acid and Vit B12 were only reduced in a few athletes and might lead to anaemia when not substituted properly (1). Reduced selenium blood values are justifying a general supply of female athletes with selenium supplements. Ferritin should be checked on a regular basis in this population and iron substitution should be provided based on the individual value.

EFFECT OF ARGININE-CITRULLINE SUPPLEMENT ON SKIN-GAS ACETONE CONCENTRATION FOLLOWING MAXIMAL RUNNING EXERCISE

YAMADA, K.1, MATSUDAIRA, H.1, TAKEHARA, K.1, IWATA, Y.1, HAGINO, Y.1, SATO, T.1, ITO, R.1, HASHIMOTO, R.1, ONO, F.1, TAKEUCHI, A.1, MIYAZAKI, M.2, TSUDA, T.1, ITOH, H.1

NAGOYA INSTITUTE OF TECHNOLOGY

INTRODUCTION: Ketones (β-hydroxybutyrate, acetoacetate and acetone) are generated in mitochondria of the liver, mainly from the oxidation of fatty acids, and are exported to peripheral tissues, such as the brain, heart, kidney, and skeletal muscle for use as energy fuels (1). We previously demonstrated that exercise increased skin-gas acetone concentration (2,3). Recent studies reported the combination of oral L-arginine and L-citrulline immediately and synergistically increases plasma arginine and nitrite/nitrate (NOx) concentrations (4), therefore, during exercise arginine-citrulline supplement improved blood flow in muscle tissues, muscle energy metabolism, mitochondrial respiration, and exercise performance due to increased nitric oxide (NO) bioavailability (4). However, no one has confirmed the effect of arginine-citrulline supplement on skin-gas acetone concentration during exercise. The present study demonstrated the effect of arginine-citrulline supplement on skin-gas acetone concentration and performance following maximal running exercise.

METHODS: A double-blind randomized placebo-controlled 2-way crossover study was employed. Ten healthy male students (23.0 ± 1.5 years; mean ± SD) consumed arginine-citrulline supplement (VELOX Charge: Kyowa Kirin Co., Ltd., Japan) or placebo orally 1 h before incremental maximal running exercise exhausting within 30 min. The skin-gas samples were obtained from the dominant hand by covering with a polyethylene bag in which pure nitrogen gas (250mL) was introduced for 100 sec, and collected in a sampling bag at rest and 0, 5, 10, 15, 30 min recovery of the exercise. Acetone concentration was analyzed by gas chromatography. Blood flow measured using a laser tissue blood flow meter (Omegaflo, Omega Wave, Japan). Blood samples were obtained from fingertip to measure lactate concentrations using Lactate Pro (arkley, Co., Ltd., Japan).

RESULTS: The arginine-citrulline supplement significantly ($p<0.05$) increased running time and distance compared to the placebo. Significant higher levels were observed in skin-gas acetone concentration ($p<0.001$) and blood flow ($p<0.001$) following the maximal exercise, thus there was a significant interaction in skin-gas acetone concentration ($p<0.05$) and blood flow ($p<0.001$) between the arginine-citrulline supplement and the placebo.

CONCLUSION: Significantly higher levels of skin-gas acetone concentration have indicated that the arginine-citrulline supplement increased acetone production in mitochondria of the liver and efluxed into skin-gas during the maximal exercise. These results suggest that increased NO bioavailability by the arginine-citrulline supplement improved not only blood flow in muscle tissues, muscle energy metabolism, and mitochondrial respiration, but also acetone production in the liver.

INTRODUCTION: The rising of cardiovascular disease and obesity is a pandemic issue over the past years. High-intensity interval training (HIIT) has been shown to improve aerobic capacity, increase metabolic rate, and improve obesity. Lactobacillus plantarum TWK10, a type of probiotics isolated from Taiwan pickled vegetables, was also found to provide similar performance and metabolic outcome. However, the additive effects of probiotics with HIIT are unclear. Therefore, the purpose of this study was to investigate the additive effects of probiotics supplementation in combination with HIIT on cardiopulmonary fitness, anthropometry and metabolic syndrome blood biomarkers.

METHODS: The placebo-controlled, double blinded study recruited obese women (n = 23, age = 45.8 ± 6.4 y, height = 159.2 ± 4.9 cm, weight = 62.9 ± 9.2 kg, body fat % = 39.3 ± 3.8 %) and assigned into two groups: probiotics group (TWK10) and placebo group (PLA). Participants in both groups consumed supplements daily before breakfast and participated in a self-monitored HIIT training (treadmill running 7 x 2 minutes at 85-90 % VO2max with 1-minute resting interval)

for 3 sessions per week for 8 weeks. Cardiopulmonary fitness - VO2max and time to exhaustion, anthropometry - body weight, waist and hip circumferences, and blood sugar and lipid profile - fasting blood glucose (FBG), triglyceride (TG), and high-density lipoprotein (HDL) were measured at baseline and after the exercise intervention. Data was analyzed using paired t-test and ANCOVA.

RESULTS: Time to exhaustion significantly increased in both TWK10 (+ 11.4 %, p = .008) and PLA (+ 8.8 %, p = .004). Hip circumference reduced significantly only in TWK10 group (- 2.1 %, p = .018) and waist circumference increased significantly only in PLA group (+ 1.7%, p = .008). No significant group effects were found in waist and hip circumference respectively. FBG increased significantly in PLA group (+ 4.5 %, p = .027) but no significance was found in TWK10 group and between both groups. No significant time and group effects were found in VO2max, body weight, TG, and HDL.

CONCLUSION: Probiotics supplement in combination with HIIT may only control body circumferences and stabilize FBG over time, but does not have additive benefits in overall cardiopulmonary fitness and metabolic biomarkers.

FREE, BIOAVAILABLE 25-(OH)D, 1,25-(OH)2D AND SKINFOLD THICKNESS IN INDOOR AND OUTDOOR ATHLETES

KSIAZEK, A.

WROCŁAW UNIVERSITY OF SPORT AND HEALTH SCIENCES, POLAND

INTRODUCTION: There has been suggested that some functions of vitamin D may be more closely related to the free or bioavailable fraction of vitamin D than to total serum 25-(OH)D concentrations [1]. Current studies strongly support the significant impact of vitamin D on multiple aspects of adipose tissue biology [2]. Body composition/size is overlooked predictor of vitamin D status in athletes. It is still unknown whether adiposity should be taken into consideration while assessing vitamin D requirements in athletes. The aim of our study was to determine the relationship between free, bioavailable 25-(OH)D, 1,25-(OH)2D and skinfold thickness in indoor and outdoor athletes.

METHODS: Forty athletes (16 judoists – indoor, 24 football players – outdoor) participated in the study. Free (25-(OH)DF), bioavailable 25-(OH)D (25-(OH)DB) concentration were evaluated by calculation, using serum albumin and vitamin D binding protein levels. Total 25-(OH)D (25-(OH)DT), 1,25-(OH)2D were assessed using LM-MS/MS. Skinfold thickness was measured with a Harpenden skinfold calliper and percentage body fat was assessed using seven site method. Multiple regression was performed to analyse association between 25-(OH)DF, 25-(OH)DB, 25-(OH)DT, 1,25-(OH)2D levels and skinfold thickness. A statistical level of $p<0.05$ was accepted.

RESULTS: We found that 42.5% (n = 17) of the athletes had 25-(OH)DT concentration <20 ng/ml, which is defined as vitamin D deficiency. In group of indoor players there was no statistical association between 25-(OH)DF, 25-(OH)DB, 25-(OH)DT, 1,25-(OH)2D and skinfold thickness. In group of outdoor players was a significant correlation between serum 25-(OH)DF and midaxillary ($p<0.051$), biceps ($p<0.007$), subscapular ($p<0.08$) skinfold thickness. There was association between serum 25-(OH)DB and biceps ($p<0.008$) skinfold thickness in football players. 25-(OH)DT levels was correlated with midaxillary ($p<0.010$), biceps ($p<0.027$) skinfold thickness in outdoor players.

CONCLUSION: Based on the result of our study, we concluded that 25-(OH)DF, 25-(OH)DB levels are linked with skinfold thickness in football players. The different relationship between 25-(OH)DF, 25-(OH)DB and skinfold thickness in indoor and outdoor athletes might be related with lifestyle physical activity and behaviour of their training.

PLASMA-INDUCED CHANGES IN THE METABOLOME FOLLOWING POLYPHENOL CONSUMPTION.

SQUIRES, E., WALSHE, I., CHEUNG, W., WOOD, J., HOWATSON, G.

NORTHUMBRIA UNIVERSITY

INTRODUCTION: There is increasing evidence to suggest tart cherry (TC) supplementation has beneficial effects on health indices and recovery following strenuous exercise. However, little is know about the mechanisms and how TC might modulate the human metabolome. The aim of this study was to evaluate the influence of an acute high- and low-dose of Vistula TC supplementation on the metabolomic profile in humans.

METHODS: In a randomised, double-blind, placebo controlled, cross-over design, 12 healthy participants (nine male and three female, mean ± SD age, stature and mass were 29 ± 7.46 years old, 174.75 ± 9.30 cm and 77.29 ± 10.52 kg, respectively) visited the lab on three separate occasions (high dose; HI, low dose; LO, or control; CON), separated by at least seven days. After an overnight fast a baseline venous blood sample was taken. Participants consumed a standardised breakfast followed by dose conditions (HI, LO, or CON). Subsequent blood draws were taken 1, 2, 3, 5 and 8 h post consumption. Following sample preparation, an untargeted metabolomics approach was adopted and ran through LCMS/MS.

RESULTS: When all time points were collated, principal component analysis showed a significant difference between conditions, such that the CON trial had homogeneity and HI showed greater heterogeneity. In addition, when conditions were examined at each time point, this same trend was evident up to 5 h, but was reduced by 8 h post supplementation ($P < 0.05$).

CONCLUSION: The doses induced different kinetics. The LO dose provided an initial up regulation at 1 and 2 h (2 h peak) but was reduced thereafter. The HI dose provided a slower up-regulation of global metabolites, however this up regulation is maintained for longer (3 h peak) and can still be observed at 8 h. These data provide new information on the dose-response of Vistula TC following HI and LO doses. This information can be used to inform future intervention studies where changes physiological outcomes could be influenced by metabolomic shifts following acute supplementation.

INTEREST IN VEGAN DIET TARGETING FEMALE ATHLETE STUDENTS

CHO, C.

INTERNATIONAL PACIFIC UNIVERSITY

【introduction】 It is well known that a balance between training, rest, and exercise is important for athletes to improve their performance, but recently the quality of each has been emphasised. Many athletes who switch from a normal diet to a vegan diet experience better physical condition, lighter weight, less fatigue, and fewer injuries compared to before switching to a vegan diet. Thus. this study aimed to investigate the differences in interest in vegan diets depending on the purpose of sport among female athlete students.

【Method】 The participants were 306 female physical education students enrolled in a sports nutrition course. There were 161 valid responses, corresponding to a response rate of 52.6%. A questionnaire survey was conducted using Google Forms. Survey items included the current diet and knowledge of veganism. In this study, questions were asked regarding grades, departments, and club activities. Regarding knowledge of veganism, we asked about awareness of veganism and the current status of the vegan diet. For the analysis, the subjects were divided into two groups, the competition group (CG, n=76) and the healthy group (HG, n=85), according to the purpose of the exercise, and cross-tabulation was performed. The chi-square test was used for the two groups and question items. Differences were considered statistically significant at $p<0.05$.

【Result】Regarding knowledge of veganism, 29% of the CG and 32% of the HG were unaware of veganism. Those who were aware composed of 69% in the CG and 68% in the HG, with no significant difference observed. Further, 79% of the CG and 81% of the HG had no previous experience with a vegan diet, whereas 18% of the CG and 19% of the HG had at least one experience, with no significant difference observed. Regarding whether they followed a vegan diet in their daily lives, 77% of the CG and 72% of the HG did not follow it at all. Additionally, 20% of the CG and 25% of the HG had eaten a vegan meal. Four participants from each group did not answer the questions. In the CG, there were two participants whose almost every meal was vegan and one whose every meal was vegan. In HG, one participant's every meal was vegan. When asked whether they wanted to adopt a vegan diet, 57% of the CG and 46% of the HG did not. In addition, 42% of the CG and 51% of the HG wanted to adopt the diet, with no significant difference observed.

【Conclusion】 This study aimed to clarify the differences in interest in vegan diets depending on the purpose of sport. There was no significant difference in interest in vegan diets for any of the questions. Athletes in previous research improved their performance by changing to a vegan diet, but only a few of the target female physical education students had accurate knowledge of veganism. Therefore, it is important to educate people in order to experience vegan diets close to them, acquire accurate knowledge, and subsequently select foods that suit their current situation.

THE EFFECT OF C8 MEDIUM CHAIN TRIGLYCERIDE SUPPLEMENTATION ON THE COGNITIVE PERFORMANCE OF YOUNG AND HEALTHY ADULTS.

ASHTON, J.

LIVERPOOL HOPE UNIVERSITY

INTRODUCTION: Medium chain triglycerides (MCTs) supply the brain with an alternative energy source than glucose via both direct (medium chain fatty acids) and indirect (ketone bodies) pathways, meanwhile causing chronic physical adaptations to the brain. Research has unveiled that MCT supplementation leads to cognitive improvements in diseased and/or elderly individuals, and our previous work using MCTs with a C8:C10 ratio of 30:70 discovered that these cognitive improvements also apply to young and healthy adults. The aim of the present study is to see if these results will be replicated using MCT gels that are comprised of 100% C8.

METHODS: 30 participants were randomly divided into three groups of ten: 10g MCT/day, 20g MCT/day and Placebo (carbohydrate gel) and were all provided with three weeks' worth of gels. The 10g MCT/day and Placebo groups were instructed to take 1 gel per day 30 minutes prior to breakfast. The 20g MCT/day group's dosage was increased incrementally to reduce the risk of gastronomical side effects. They were instructed to take 1 gel per day 30 minutes prior to breakfast for the first week, then to take an additional gel 30 minutes prior to their evening meal for the final two weeks. Participants visited the laboratory for approximately 45 minutes once a week for 4 consecutive weeks (baseline, test weeks 1-3) where they underwent a battery of cognitive tests; Trail Making, Digit Span and Spatial Span. Fingertip blood capillary samples were also taken each week to assess blood ketone levels.

RESULTS: After 1 week of supplementation, the two MCT groups exhibited enhanced performances in cognitive tasks, including Trail Making A (-1.42 ± 0.96 secs), Trail Making B (-6.86 ± 4.67 secs) and Digit Span Backwards (1.25 ± 0.97 points) compared to baseline, before performance plateaued in weeks 2 and 3 (ps> 0.05). In Digit Span Forwards, there was a significant main effect of time ($p< 0.001$). In all cognitive measures, there were no significant differences between the two MCT groups (ps> 0.05) nor any effect of treatment or learning in the carbohydrate placebo group (ps> 0.05).

CONCLUSION: MCT supplementation improved some aspects of cognitive function after just 1 week, with there being no differences between ingesting 10g and 20g MCT/day. This raises the possibility of the cognitive improvements being attributed to an acute effect of the C8 gels (i.e. via immediate availability of medium chain fatty acids and/or ketone bodies), rather than the physical adaptations linked with high C10 MCTs.

THE EFFECTS OF A VEGAN MULTI-INGREDIENT PRE-WORKOUT SUPPLEMENT IN BODY COMPOSITION, RESTING METABOLIC RATE AND PERFORMANCE IN MIDDLE-AGED PERI- AND POST-MENOPAUSAL WOMEN

PUENTE-FERNANDEZ, J., JIMENEZ, A., GONZALEZ-FRUTOS, P., LOPEZ, A., NACLERIO, F.

UNIVERSITY OF GREENWICH

INTRODUCTION: Pre-workout multi-ingredient (PMTN) supplements are specialised dietary supplements widely used to increase willingness to train and maximise exercise performance outcomes. In the last years, there has been an increased interest in plant-based protein multi-ingredients among vegan athletes and physically active middle-aged and older adults. The aim of the present study was to compare the effects of ingesting a vegan protein-based PMTN vs an isocaloric-only carbohydrate (CHO) supplement comparator on body composition, training volume, and muscular endurance performance over a 6-week training period in recreationally trained peri- and post-menopausal women (n=24, 53±4.3 y.o.)

METHODS: Following a double-blinded randomised parallel design, thirty women were initially assigned to either a PMTN (n=15) or a CHO (n=15) group. Both groups followed an 8-exercise resistance training protocol (3 days/week) for 6 weeks (18 workouts). Supplements were administered 15 minutes before each workout session. The following dependent variables were assessed at pre- and post-intervention: (i) relative volume (total kilograms lifted divided by body mass) lifted per workout (ii) muscle thickness from the vastus lateralis of the quadriceps, and elbow flexors using ultrasonography, (iii) waist and hip circumferences and (iv) fat mass, and fat-free mass via air displacement plethysmography.

RESULTS: No significant differences were observed between groups at baseline for any of the analysed variables. Both groups significantly increased relative workout volume, vastus lateralis and elbow flexors muscular thickness, and fat-free mass. However, only the PMTN group showed a significant post-intervention reduction of fat mass (26.02±6 vs 25.13±6; p=0.029, d=1.33) and waist circumference (79.5±6 vs 77.9±6; p=0.007, d=0.62). No further differences or interaction effects were identified between groups post-intervention.

CONCLUSION: Compared to the ingestion of carbohydrates alone, a pre-workout vegan protein-based multi-ingredient including caffeine and amino acids promoted fat mass and waist circumference reduction after a 6-week resistance training programme in women over 45 years old. Nonetheless, both supplements were similarly effective to influence resistance training volume and promoting fat-free mass gain and exercise-induced hypertrophy. The current findings suggest that ingesting a pre-workout plant-based protein multi-ingredient with caffeine may maximise fat reduction but not fat-free mass gain or higher training volume in middle-aged peri-menopausal and postmenopausal women.

VOLUNTARY REHYDRATION AT A POST-EXERCISE MEAL IS INADEQUATE TO REPLACE FLUID LOST AFTER EXERCISE-INDUCED DEHYDRATION: A BLINDED STUDY

CABLE, T.G., MEARS, S.A., JAMES, L.J.

LOUGHBOROUGH UNIVERSITY

INTRODUCTION: Starting exercise dehydrated can impair exercise performance, but athletes regularly present at training with raised urine osmolality/specific gravity (indicating dehydration). Better understanding of post-exercise rehydration strategies is thus warranted. Most hydration studies do not blind participants to their hydration status which may influence behaviour and confound outcomes. The aim of this study was to assess short-term (single post-exercise meal) rehydration with participants blinded to their hydration status.

METHODS: 7 healthy males (age 25 ± 2 y; $\dot{V}O_2max$ 48 ± 7 mL·kg-1·min-1) completed blinded euhydrated (EU) and dehydrated (DH) trials, with the primary outcomes (performance/physiology responses) published previously[1]. Participants completed a preload (8x15 min cycling at 50% PPO, 5 min rest) and a 15-min performance test in the heat (34°C, 50% RH), with water or dummy infusions delivered to the stomach via a gastric tube in the preload to replace sweat loss (EU) or induce dehydration (DH). 20 min post-exercise, participants were provided a standard ad-libitum buffet meal (food and drink) and were instructed to eat/drink until fully recovered. Body mass, blood-based (serum osmolality, AVP, plasma volume) and perceptual (thirst, hunger, fullness) responses were determined throughout trials. Energy and macronutrient intake were determined by weighing buffet items pre/post.

RESULTS: Post-exercise body mass loss (DH -3.0±0.3%, EU -0.7±0.1%, P=0.002), plasma volume loss, serum osmolality (DH 299±3 mosmol/kg, EU 290±2 mosmol/kg), thirst (DH 85±8 mm, EU 65±15 mm) and AVP were all greater in DH (P≤0.038). Hunger, fullness and core temperature were not different between trials (P>0.05), and neither was post-meal thirst. Total (DH 1695±437 g, EU 1233±370 g, P=0.002) and drink (DH 1474±409 g, EU 943±283 g, P=0.002) water intake were greater, but food water was less (DH 221±108 g, EU 289±119 g, P=0.026) in DH. Energy (DH 5780±1303 kcal, EU 4951±1016 kcal, P=0.106) and carbohydrate (DH 154±60 g, EU 125±31 g, P=0.133) intake were not different between trials, but protein intake was less in DH (DH 53±17 g, EU 44±15 g, P=0.008). Total water intake showed moderate/strong association with serum osmolality (r=0.525, P=0.054), plasma AVP (r=0.746, P=0.002) and thirst (r=0.670, P=0.009). Water intake replaced 73±17% (DH) and 235±77% (EU) of fluid losses (P<0.001).

CONCLUSION: These data show that voluntary fluid intake at a single post-exercise meal only replaces ~73% of fluid loss after exercise dehydration of ~3%, which only increased by ~460 mL compared to a euhydrated trial. This suggests, in situations where a subsequent exercise bout occurs in close proximity to dehydrating exercise, voluntary rehydration may not ensure the athlete is euhydrated at the start of the next bout.

IMPACT OF LOW FLUID INTAKE ON HUMAN ADIPOSE TISSUE GENE EXPRESSION IN LEAN, ACTIVE MEN

RODRIGUEZ-SANCHEZ, N., FERREIRA, D., GALLAGHER, I., PAVAL, R., DI VIRGILIO, T., GALLOWAY, S.D.R.
UNIVERSITY OF STIRLING

INTRODUCTION: Water is essential for life, and without it, humans can only survive for a few days. Accumulating evidence suggests that insufficient water intake may increase the risk of developing cardio-metabolic diseases if sustained for long enough. Some observational studies indicated that inadequate water intake might play a role in developing cardio-metabolic diseases, such as Type II Diabetes (T2D). Carrol et al. (2015) reported a negative correlation between plain water intake and T2D risk score. In contrast, Roussel et al. (2011) found self-reported water intake to be inversely associated with the risk of developing hyperglycemia.

METHODS: We assessed differences in gene expression and changes in plasma levels of several metabolic parameters in response to suboptimal hydration practices. Nine lean, healthy and active young males were instructed to follow either 48h of a low fluid intake (LF; 1.1 ± 0.2 L/d) or adequate fluid intake (AF; 2.9 ± 0.5 L/d), followed by a lab visit for urine, blood, and adipose tissue collection to assess hydration biomarkers, appetite-related hormones, inflammation and glycemic control, and global gene expression.

RESULTS: The LF protocol resulted in mild dehydration (-1.23 ± 0.64 %; $p > 0.05$). Despite no significant changes in differential gene expression at an individual level (FDR > 5% for all genes), gene set enrichment analysis yielded 15 gene sets that were differentially expressed (FDR < 10%), with up-regulation of categories related to coagulation, oxidative stress, immune response and glucose metabolism, and a paradoxical downregulation of the inflammation response category. In addition, glucagon was significantly elevated in the LF condition (AF 44.6 ± 20.8 vs LF 63.0 ± 27.6, $p < 0.05$), while changes in c-peptide were negatively associated with changes in urine osmolality ($r = -0.70$, $p < 0.05$).

CONCLUSION: Overall, these results suggest that two days of a low fluid intake regimen might be enough to influence the expression of genetic pathways implicated in the physiological consequences of acute to chronic dehydration and alter glycemic regulation. However, further research is needed, potentially using a more ample sample and a more prolonged protocol (i.e., 3 to 5 days in a row or 1-2 days repeated for several weeks) to confirm and expand the results of this study.

PARALYMPIC SPORT AND SPORT-RELATED CONCUSSION: A SINGLE CASE STUDY

CHANG, Y.Y., GEMMERICH, R., RODRIGO, L., LAUSBERG, H., ARUN, K.M., FUNKEN, J., HELMICH, I.
INSTITUTE FOR MOVEMENT THERAPY AND MOVEMENT-ORIENTED PREVENTION AND REHABILITATION, GERMAN SPORT UNIVERSITY COLOGNE, GERMANY

INTRODUCTION: Sport-related concussions are common in para sport and are associated with short-term effects on cognitive functions. Due to the heterogeneous impairments in para-sport, the circumstances of handling sport-related concussion are difficult to assess. We therefore investigated in a single-case study of a Paralympic swimmer several motoric, behavioral, and neuro-cognitive parameters (before and after head collisions) that have been previously reported to be of diagnostic value in the assessment of post-concussion deficits.

METHODS: We investigated a nineteen-year-old Paralympic swimmer with dysmelia (resulting in pronounced deformities of the hands, arms, and legs). The investigations were conducted before and after four head collisions against the wall in a swimming pool (identical collisions as the swimmer regularly performs to end competitions). Head acceleration was recorded during each collision by an accelerometer and video analyses. Before and after the collision we assessed post-concussion symptoms, the positive and negative affect schedule (PANAS), cognitive functions (working memory (wm), King Devick), nonverbal hand movement behavior and brain oxygenation (by applying functional Near InfraRed Spectroscopy (fNIRS) above precentral cortices of both hemispheres during rest (for connectivity analyses) and during the working memory task).

RESULTS: The average head acceleration during the four head collisions was 15 g ± 5.5. Preliminary results showed that post-concussion symptoms increased from before to after the four head collisions. The positive affect scores decreased. There were no differences in the King Devick. The athlete performed less nonverbal hand movements after the collision when compared to before the intervention. Working memory scores showed 22 percent less correct answers and 195 milliseconds longer reaction times for after the fours head collisions than before. Functional brain oxygenation during the

wm task was reduced from before to after head collision. Brain connectivity was reduced from before to after the head collision.

CONCLUSION: The present findings indicate that repeated head collisions in swimming are related to increased post-concussion symptoms that are accompanied by reduced cognitive and brain functions. Thus, Paralympic swimming with dysmelia may be affected from an increased risk of long-term effects similar to those of repeated concussive incidents. Although it is a challenge to manage sport-related concussions in paralympic disciplines because of the heterogeneous impairments, this issue ought to be considered in future research and the implementation of actual preventive actions.

PRELIMINARY EVALUATION OF A PROPOSAL OF AN INCREMENTAL TESTING PROTOCOL FOR INDIVIDUALS WITH SPINAL CORD INJURY

APARICIO, I., SÁNCHEZ-JIMENEZ, J.L., SENDRA-PÉREZ, C., PÉREZ-SORIANO, P., MARZANO-FELISATTI, J.M., PRIEGO-QUESADA, J.I.

UNIVERSITY OF VALENCIA. RESEARCH GROUP IN SPORTS BIOMECHANICS

INTRODUCTION: Exercise testing is a relevant issue in training and rehabilitation monitoring. Nevertheless, results may be influenced by the test selected [1], especially when specific populations (e.g., with spinal cord injury) with high inter-individual variability are assessed. In the population with spinal cord injury exist a diversity in the tests conducted in the studies [1], making difficult the comparison of their results. Therefore, it is necessary to develop a standardized test which allows the adjustment of people with spinal cord injury and guarantees similar physiological stress.

METHODS: 13 physically active participants were included in the study, and they were divided in three groups: Control [n = 8 (6 male; 2 female); age: 29 ± 5 years; body mass: 75.3 ± 14.4 kg; height 176 ± 9 cm]; Paraplegia (PP) [n = 3 (2 male; 1 female); level of lesion: D7-L1; completeness: complete; age: 37 ± 15 years; body mass: 71.0 ± 19.8 kg; height 170 ± 14 cm] and Tetraplegia (TP) [n = 2 (1 male; 1 female); level of lesion: C5-C7; completeness: complete and incomplete; age: 45 ± 3 years; body mass: 65.0 ± 21.2 kg; height 175 ± 7 cm].

They visited the laboratory one time and completed an incremental test on an arm crank ergometer. Control and PP started with 30W and TP with 15W and increasing steps every three minutes of 5W, 10W and 15W, respectively. Lactate samples were collected at rest and after each interval (Lactate Plus, Waltham, USA) and the second lactate threshold (LT2) was calculated by the ModDmax model using the "lactater" package in RStudio. The rate of perceived exertion (RPE) was asked after each interval using a BORG scale (6-20). Heart rate (HR%) was monitored during all the test employing a Polar V800 (Polar Electro Oy, Finland), and normalized respect maximum heart rate of the test.

RESULTS: All the groups completed 6 ± 1 stages in the incremental test. LT2 was determined between two steps in all the participants [72 ± 19W (Control), 70 ± 27W (PP) and 50 ± 28W (TP)]. For this reason, the difference between the next and the previous step of LT2 in all the variables was calculated to normalise the data. Despite the differences observed in absolute power output at LT2 between Control/PP and TP, the difference between stages of internal load variables presented similar values between groups: RPE [2 ± 2 (Control), 2 ± 0 (PP), 3 ± 1 (TP)] and the HR% [9.5 ± 0.1% (Control), 10.9 ± 0.1% (PP), 8.8 ± 0.0% (TP)].

CONCLUSION: An incremental arm test with different power output in the start step and the increments of each group produced similar physiological responses between groups. Therefore, it could be suggested that this test is valid for those studies which compare different grades of spinal cord injury and people without it.

CHARACTERISTICS OF HEART RATE RESPONSE IN ELITE JAPANESE PARALYMPIC ATHLETES WITH AND WITHOUT SPINAL CORD INJURY DURING ARM CRANK ERGOMETER TEST

KAMEDA, M., IIZUKA, S., MATSUBAYASHI, T., HAKAMADA, N.

JAPAN INSTITUTE OF SPORTS SCIENCES

INTRODUCTION: It is well documented that heart rate (HR) is a useful tool for determining training prescription in able-bodied participants. However, limited HR-based training prescription or assessment is available for Paralympic sitting sports athletes who depend mainly on upper body work. In addition, their HR response could be different for their disabilities, e.g., with/without spinal cord injury. Previous research indicates that a slightly lower HR max is generally obtained during arm than during leg exercise testing [1]. Thus, this study aimed to compare the HR response of elite Japanese Paralympic athletes with spinal cord injuries to those without them during an arm crank ergometer incremental test.

METHODS: The participants were 20 Paralympic athletes. They were divided into two groups: athletes with spinal cord injuries (SCI: n=10) or athletes without them (Others: n=10, leg amputation, etc.). HR and Blood lactate concentration (BLa) were measured during the arm crack ergometer incremental test. Protocols of the incremental test were tailored to individual athletes according to their disabilities: one typical example, for male wheelchair tennis players, was that the load was started at 40W and was increased by 20 W in every 3 minutes stage, with 1-minute rest between stages. The athletes were asked to maintain a cranking speed of 60 rpm until BLa exceeded 4 mmol/L. The HR and workload equivalent to 2 mmol/L and 4 mmol/L of BLa were calculated. Also, body weight, lean body mass (LBM), and body fat percentage were assessed by means of the air displacement plethysmography method. Mann-Whitney U tests were applied for examining the difference in those indices between SCI and Others.

RESULTS: No statistically significant difference was found in HR at 2 mmol/L (118 ± 10 bpm vs 118 ± 12 bpm) and in HR at 4 mmol/L (147 ± 9 bpm vs 148 ± 15 bpm) between SCI and Others. The workload for the arm crank incremental load test at these intensities was comparable (at 2 mmol/L: 52.0 ± 15.8 W vs 52.5 ± 19.8 W, at 4 mmol/L: 81.5 ± 20.3 W vs 79.3 ± 26.3 W, respectively). Body composition indices were also comparable (body weight: 61.6 ± 11.9 kg vs 54.4 ± 12.4 kg, LBM: 44.2 ± 7.1 kg vs 41.5 ± 10.4, body fat percentage: 27.2 ± 7.5% vs 24.0 ± 3.6%, respectively).

CONCLUSION: The current results suggest that the HR responses of SCI showed similar responses to Others. Previous studies reported that athletes with spinal cord injuries were not sufficiently able to increase their HR compared to able-bodied athletes [2], implying that they have a disadvantage in aerobic work. However, our results showed that SCI was very well trained, and their HR responses were comparable to those of other Paralympic athletes without spinal cord injuries. It is important to keep in mind that HR-based training prescription for athletes with spinal cord injuries could be the same with other disability athletes.

THE ASSOCIATION BETWEEN PA STATUS AND THE PREVALENCE OF ALCOHOL USE DISORDER IN KOREA

LEE, Y.S., KIM, Y.S.

SEOUL NATIONAL UNIVERSITY

INTRODUCTION: Previous studies have suggested that physical activity (PA) can prevent or delay the onset of different mental disorders. However, substance use disorders such as alcohol use disorders (AUD) have so far less frequently been a matter of investigation.[1] Some evidence indicates a positive relationship between alcohol use and physical activity in the general population [2], while there are contradictions that a physically active lifestyle increases drinking consumption [3]. This study aims to investigate the association between PA status and the prevalence of alcohol use disorder in Korea.

METHODS: 5,511 participants aged 18 ~ 79 in the National Mental Health Survey of Korea 2021 (NMHSK 2021) were included in this study. The Korean version of the Composite International Diagnostic Interview 2.1 (K-CIDI) was used in this survey. PA status was defined by The International Physical Activity Questionnaire (IPAQ). Participants were categorized into three PA groups: high(n=1,150), moderate(n=2,654), and low(n=1,636). Logistic regression analysis was used to estimate the odds ratios (ORs) and 95% confidence intervals (CIs) of the prevalence of alcohol use disorder according to the PA group.

RESULTS: After adjusting for age and sex, alcohol use disorder and PA had associations in the high PA group in lifetime prevalence (OR 1.12; 95% CI 1.03-1.23), likewise in 1-year prevalence (OR 1.07; 95% CI 1.03-1.23). Alcohol dependence disorder also had associations in the high PA group in lifetime prevalence (OR 1.05; 95% CI 1.01-1.08) and in 1-year prevalence (OR 1.08; 95% CI 1.00-1.15). However, alcohol abuse disorder had no significant association with PA.

CONCLUSION: The prevalence of alcohol use disorder and alcohol dependence disorder had an association with high PA levels, and alcohol abuse disorder had no association. This study does not support a common alcohol–physical activity relationship. However, a cause-and-effect relationship cannot be convinced due to the limitation of a cross-sectional study. Future research, including personal history, the severity of the disorder and the PA domain, is needed to identify precise correlation and effect of PA.

LAMP : NEW DNA AMPLIFICATION TECHNOLOGY AS A POINT OF CARE TOOL TO AVOID PROPAGATION OF EHV-1 AND EHV-4 PATHOGENS BETWEEN HORSES DURING HORSE RACE

THIBAULT, T., VALOT, L., SIMONNET, M., LACAZE, A., SCHIEB, D., THIERY, L.

ENALEES

INTRODUCTION: LAMP technology (Loop mediated isothermal AMPlification) is a NAAT technology (Nucleic Acid Amplification test) which can occur at constant temperature, unlike PCR which need thermal cycles. This allow the use of this technology near a sick animal and the obtention of the result in only 30 min. This technology can be really useful to detect highly contagious pathogens during a sportive event, ie : detection of EHV-1 or EHV-4 in horses during a horse competition to allow the isolation of a contaminated horse to avoid a pandemic.

METHODS: Specific LAMP primers for EHV-1 and EHV-4 were designed and LAMP reactions were performed on viral genome and on nasopharyngeal swab samples extracted by our own specific quick extraction. Performances of these tests were evaluated in our lab and compared to PCR performed in an external lab.

RESULTS: LAMP tests have a limit of detection for amplification between 3-40 copies/reaction dependant of the test. The limit of detection of all method (quick extraction and LAMP test) is similar or better of the limit of detection of all method (extraction on column and PCR test) obtained in a conventional analysis laboratory. LAMP test which was designed are really specific for the target (>95% specificity) and are really sensitive for the target (>90% sensibility).This technology is really fast (<30 min) and can be performed near a sick animal.

CONCLUSION: LAMP tests are a new generation of DNA/RNA amplification test, really specific, really sensitive which can be performed near a sick animal and can give a result in only 30 min. These parameters allow the consideration to use this technology in sportive events to analyse quickly potential pathogens holder and realize quickly a diagnostic to avoid an pandemic.

EFFECTS OF LUMBR EXTENSION-BASED TRUNK CONTROL EXERCISE ON PHYSIOLOGICAL AND CLINICAL PARAMETERS OF MUSCLES IN PATIENTS WITH FLAT BACK SYNDROME

EUM, Y.B., LEE, Y.H., CHANG, J.S., LEE, H.S.

DANKOOK UNIVERSITY

INTRODUCTION: Flat back syndrome (FBS) is a type of sagittal imbalance in the spine, and it is characterized by loss of the lordotic curve (Harrison & Oakley, 2018). Trunk control exercise can be altered by changing trunk muscle activities or lengths and improve of proprioceptive (Kavcic et al., 2004). The purpose of this study was to test the hypothesis that lumbar extension-based trunk control exercise would be a positive effect on physiological and clinical parameters of muscles compared to stretching exercise.

METHODS: A total of 35 FBS with lumbar lordosis angle of less than 30° were randomly divided to lumbarextension-based trunk control exercise group (EEG, n=12), stretching exercise group (SEG, n=11) and control group (CON, n=12). EEG and SEG were performed for 40 minutes, three times a week and for 8 weeks. Physiological [muscle activity (PHE), muscle tone (GM, BF,ES)] and clinical parameters [trunk control (JPS, SFL, SKE, BKFO, LL), lumbar lordosis angle and lower back pain (ODI)] were measured before and after 8 weeks each exercises.

RESULTS: The results revealed that muscle activity of GM during PHE significantly increased after exercise in the EEG compared to SEG and CON ($p<.05$). Muscle activity of ES during PHE significantly decreased after exercise in the EEG compared to CON ($p<.05$). Muscle tone of GM significantly increased after exercise in EEG compared to CON ($p<.05$). Muscle tone of BF significantly decreased after the exercise in SEG compared to CON ($p<.05$). Muscle tone of ES significantly decreased after exercise in EEG compared to CON ($p<.05$). Trunk control of JPS, SFL, and LL significantly decreased after exercise in EEG compared to SEG and CON ($p<.05$). SKE significantly decreased after exercise in SEG compared to CON ($p<.05$). ODI significantly decreased after exercise in EEG compared to CON ($p<.05$).

CONCLUSION: These results indicate that lumbar extension-based trunk control exercise reduces lower back pain by improving muscle activity, muscle tone, and trunk control in patients with flat back syndrome. In particular, lumbar extension-based trunk control exercise partially improved muscle physiological and clinical parameters of muscles compared with stretching exercise.

THE EFFECTS OF ECCENTRIC-FOCUSED EXERCISE ON SHOULDER MOBILITY, STRENGTH, PAIN, SCAPULAR KINEMATICS AND MUSCLE ACTIVATION IN SYMPTOMATIC OVERHEAD ATHLETES WITH POSTERIOR SHOULDER TIGHTNESS

HUANG, S.

NATIONAL YANG MING CHIAO TUNG UNIVERSITY

INTRODUCTION: Posterior Shoulder Tightness (PST) is a common pathology in overhead athletes due to repeated high tensile loading during overhead throwing. PST is highly related to glenohumeral internal rotation deficit and scapular dyskinesis, leading to an increased risk of subacromial impingement syndrome (SIS). Eccentric exercises that improve the eccentric strength and neuromuscular control of posterior shoulder muscles have the potential to enhance the ability to withstand repetitive eccentric loading. Despite the limited intervention studies focusing on PST in individuals with shoulder pain, no previous research has investigated the impact of shoulder eccentric exercises on PST in overhead athletes. Thus, the purpose of this study was to investigate the effects of additional shoulder eccentric exercise training on PST in overhead athletes with SIS.

METHODS: This single-blind randomized controlled trial (RCT) has recruited ten amateur baseball athletes with PST and SIS. The athletes were randomly assigned to one of two groups: the eccentric-focused (EF) group or the general treatment (GT) group. The GT group received a four-week intervention program that included hot pack application on the shoulder region and stretching exercises, while the EF group received additional eccentric exercises. The study assessed various outcome measures including the range of motion (ROM) of shoulder external rotation (ER), internal rotation (IR), horizontal adduction (HAD), total ROM (TROM), isokinetic rotator cuff functional strength ratio, visual analogue scale (VAS), Disability of Arm, Shoulder and Hand (DASH) questionnaire, shoulder endurance test (SET), scapular kinematics, and muscle activation.

RESULTS: There was no significant difference in demographic data between two groups. Repeated measures ANOVA showed a significant time by group interaction for the rotator cuff functional strength ratio ($p=0.031$). There were also time effects for the VAS score ($p=0.001$). Both groups improved their TROM ($p=0.043$ and 0.043) and DASH scores ($p=0.043$ and 0.042), while only the EF group showed improvement in HAD ROM ($p=0.042$) and the SET ($p=0.043$) after the four-week intervention.

CONCLUSION: This is the first RCT to compare the effects of additional eccentric shoulder exercises and general treatment in symptomatic overhead athletes with PST. After the four-week intervention, both groups demonstrated equal effectiveness in improving shoulder TROM, DASH, and reducing VAS score. The EF group exhibited a greater improvement in the isokinetic functional strength ratio of the rotator cuff and SET, which is reasonable because only the EF group received the strengthening exercise program. However, the enhancement in rotator cuff strength was found to be only associated with

an increase in shoulder HAD ROM but not TROM. The studys small sample size of ten athletes limits the validity of the results, and further recruitment is underway to ensure the findings.

RADIOGRAPHIC ASSESSMENT OF SCAPULAR ROTATION AND TILT IN SUBACROMIAL IMPINGEMENT SYNDROME

XI, R.1, ZHOU, J.B.2, HE, C.2, GAO, F.2, ZHAO, P.1, LI, G.P.2

1 CHINA INSTITUTE OF SPORT SCIENCE,2 CHINA NATIONAL INSTITUTE OF SPORTS MEDICINE

INTRODUCTION: People with subacromial impingement syndrome (SIS) present differences in movements of the scapula when compared with asymptomatic individuals. Some authors have studied scapular position and motion in SIS using three-dimensional motion capture system, and identified reduced posterior tilting and external rotation in the subjects with SIS. The method adopted in their reports was regarded as highly reliable, but it is not thought to be always accurate in determining the same points on the scapula while the arm is being raised. We used a simple and accurate method of evaluating both scapular upward and axial rotational tilts by using plain antero-posterior (AP) radiography. The purpose of this study was to identify the types of scapular rotational tilt disorders that affect shoulder impingement.

METHODS: A total of 75 subjects completed the study, 50 patients in the SIS group and 25 healthy volunteers in the healthy group. Three parameters of scapular rotation and tilt were measured by shoulder antero-posterior (AP) radiography at 0 °, 60 ° and 90 ° of shoulder abduction in SIS patients and healthy volunteers: the scapular upward rotation angle (SURA), which was adopted as the parameter of the upward rotational tilt ;the coracoid upward shift distance (CUSD), which evaluate the axial rotation tilt of the scapula; the length of the scapular spine line (LSS), which corresponds to the parameter of the protraction- retraction tilt of the scapula. The results of the two groups of subjects were compared.

RESULTS: At 0°and 90°shoulder abduction, the SURA in the two groups was not significantly different（P＞0.05）; At 60°, however, the SURA was 21.1±6.3° for SIS group and 25.1±8.1° for healthy group , showing a significant difference (P=0.022)。The standardized CUSD at 0° shoulder abduction has no significant difference (P =0.058); For 60°shoulder abduction, the standardized CUSD were 3.1±2.5 mm for SIS group and 6.0±4.0 mm for healthy group , showing a significant difference (P =0.003). At 90°shoulder abduction, the standardized CUSD was 7.4±2.8mm for SIS group and 10.2±5.0mm for healthy group , for an even more significant difference (P = 0.016). No significant differences were observed between the standardized LSS at each of the abduction angles in the two groups.

CONCLUSION: Our study confirms that a wide supraspinatus outlet may be created by scapular posterior tilting and upward rotations, so that subacromial impingement can be avoided in normal shoulder elevation. For the assessment of SIS, early evaluation of scapular functional tilt is important. It is necessary to classify the patients with subacromial impingement syndrome to determine the specific classification of scapular movements abnormalities, which is conducive to targeted rehabilitation training.

EFFECTS OF AN 8-WEEK OF THERMAL AQUATIC EXERCISE ON KNEE STRENGTH, ROM, AND WOMAC INDEX IN FEMALE PATIENTS OVER 50 YEARS OLD WITH KNEE OSTEOARTHRITIS

HAN, K.M.1, KIM, K.H.2, KIM, T.U.2, MIN, J.W.2, SONG, S.H.2, KEUM, H.H.2, LEE, S.H.2, JUNG, W.J.2, SON, J.H.2, YU, J.B.2, PARK, J.S.2, KIM, B.K.2

1CALIFORNIA STATE UNIVERSITY, NORTHRIDGE, 2DANKOOK UNIVERSITY, CHEONAN

INTRODUCTION: According to the 2019 Global Burden of Disease, approximately 1.71 billion people are in a condition related to musculoskeletal disorders, 528 million people have osteoarthritis (OA) and 19 million of them lived with disability worldwide (1,2), OA affects more women than men, especially women over 50 (3). Pain-free weight-bearing exercises, weight control, and knee pain reduction are essential elements of a rehabilitation program for knee OA patients. Many OA patients, especially obese individuals, are precluded from a land-based exercise. Aquatic exercise minimizes the risk of injury by reducing joint stress than a land-based exercise and warm water lowers pain perception and knee stiffness. The purpose of this study was to investigate the effects of 8 weeks weight-bearing isotonic and ROM exercises in a spa pool at 32-34°C for female knee OA patients aged 50 years or older.

METHODS: Twenty-six female knee OA patients over 50 years old volunteered. Subjects were randomly assigned to either thermal aquatic exercise (TAE: n=10, 60.3±4.6 yrs, 158.6±6.8 cm, 59.1±9.1 kg, 33.2±6.3 BFP) or control (C: n=16, 52.2±8.5 yrs, 158.4±5.7 cm, 58.4±8.6 kg, 32.6±5.9 BFP) groups. The TAE group visited the aquatic center twice a week for 8 weeks to perform isotonic (concentric and eccentric) and ROM exercises using own body weight and water resistance for the ankle, knee, and hip joints in a spa pool at 32-34°C. Exercise duration was 90 minutes per visit and exercise intensity was set between Borg RPE 12-16. All subjects' height, body mass, muscle mass, fat mass, body fat percentage, BMI, isokinetic knee strength, knee flexion ROM, and WOMAC Index were measured before and after 8-week of the intervention. Two-way mixed-design ANOVAs were used for statistical analyses.

RESULTS: The TAE group showed significant improvements in muscle strength (60°/sec peak torque: knee extension, p=0.025; knee flexion, p=0.006), muscle power (60°/sec average torque: knee extension, p=0.041; knee flexion, p=0.041), muscle endurance (180°/sec total work: knee extension, p=0.040; knee flexion, p=0.003), knee flexion ROM (p=0.014), and WOMAC Index (p=0.010) when compared to the C group. After the intervention, no significant differences were observed between groups on weight (p=0.988), muscle mass (p=0.478), fat mass (p=0.707), body fat percentage (p=0.293), and BMI (p=0.947).

CONCLUSION: A 8-week thermal aquatic exercise protocol in a spa pool at 32-34°C with full weight-bearing isotonic strengthening and full ROM exercises in the lower extremity helps to increase muscle strength, muscle power and muscular endurance of the knee, and improve knee pain, stiffness, and joint dysfunction for female OA patients 50 years and older.

HOW LONG DOES IT TAKE TO PHYSICALLY AND PSYCHOLOGICALLY RECOVER AFTER AN INJURY IN FOOTBALL?

BRAUERS, J.J.1, DEN HARTIGH, R.J.R.2, NEUMANN, N.D.2, VAN DER LINDE, M.3, FRENCKEN, W.1,3, LEMMINK, K.A.P.M.1, BRINK, M.S.1

UNIVERSITY MEDICAL CENTER GRONINGEN

INTRODUCTION: When football players sustain an injury, they generally have to recover, both physically and psychologically. The process of recovery after an adversity such as an injury can be defined as resilience. (1) Despite its importance, individual resilience after a time-loss injury has never been quantified before. Therefore, this study aimed to quantify resilience in terms of both physical and psychological variables after time-loss injury in individual football players.

METHODS: We included 21 football players who sustained time-loss injuries during the 2021/2022 season. For each individual, we monitored the training load, perceived recovery, motivation, self-efficacy, mood, and enjoyment for every training and match day. We quantified resilience using these variables following injury by fitting multiple growth models. Next, we identified the best one using the Bayesian information criterion. (2) Then we used the predicted values from the selected model to identify the time point at which the physical and psychological variables should return to baseline levels.

RESULTS: Eight of the 21 football players experienced a significant drop in physical or psychological variables following an injury. For three football players, the psychological variables self-efficacy and mood did not return to baseline levels even though these players resumed training. Accordingly, the average duration between the day of the injury and the predicted day of return to baseline was lower for the physical variables (training load = 20.5 days and recovery = 73.5 days) than for the psychological variables (motivation = 358 days, self-efficacy = 114.8 days, mood = 104.4, and enjoyment = 70.25 days). However, these trajectories were highly individual-specific.

CONCLUSION: Injuries often lead to a significant decrease in the physical and psychological variables of football players. Although the recovery trajectory after an injury is highly individual-specific, the recovery of psychological variables often requires more time than the recovery of physical variables. Practitioners can use these findings during the multidisciplinary and personalized rehabilitation of injured players.

EFFECTS OF 8-WEEK PROPRIOCEPTIVE NEUROMUSCULAR FACILITATION STRETCHING AND STATIC STRETCHING ON MUSCLE-TENDON PROPERTIES, MUSCLE STRENGTH, AND JOINT FUNCTION IN CHILDREN WITH SPASTIC CEREBRAL PALSY

KRUSE, A.1, HABERSACK, A.1,2, WEIDE, G.3, JASPERS, R.T.3, SVEHLIK, M.2, TILP, M.1

1 UNIVERSITY OF GRAZ, GRAZ, AUSTRIA; 2 MEDICAL UNIVERSITY OF GRAZ, GRAZ, AUSTRIA; 3 VRIJE UNIVERSITEIT AMSTERDAM, AMSTERDAM, THE NETHERLANDS

INTRODUCTION: Based on animal studies, stretching or orthoses are usually applied to induce longitudinal muscle growth to prevent and/or counteract muscle contractures in individuals with spastic cerebral palsy (SCP). However, while the effect of static stretching (SS) as treatment in individuals with SCP is questionable [1,2], recent results suggest that a combination with activation might be promising to cause positive effects on muscle-tendon level [3]. Therefore, the study aim was to investigate the effects of an 8-week PNF stretching intervention on the gastrocnemius medialis (GM) muscle-tendon properties, muscle strength, and joint function in children with SCP in comparison to SS.

METHODS: Twenty-four children were randomly assigned to a PNF stretching or SS group stretching their calf muscles four times a week for eight weeks at home. In the SS group, the ankle joint was moved into maximal dorsiflexion and held for 30s. The PNF group additionally performed an isometric contraction [4] for 3-5s before placing the joint in greater dorsiflexion for the remaining ~25s. Either ten static or PNF stretches were applied on both legs alternating the knee joint position (extended/flexed). Pre- and post-assessments of GM muscle-tendon properties, isometric muscle strength, and ankle joint function were performed using 3D motion capture, 2D ultrasound, dynamometry, and electromyography. Data was tested for normal distribution and analyzed by use of a mixed ANOVA.

RESULTS: Despite high training adherence in both stretching groups (PNF: 93.1%; SS: 94.4%), no significant changes ($p>0.05$) were observed in the mechano-morphological muscle-tendon properties, muscle strength, and ankle joint parameters after the interventions. Moreover, no differences ($p>0.05$) were found between the stretching techniques.

CONCLUSION: This is the first study investigating the effects of 8-week PNF stretching in comparison to SS on GM muscle-tendon properties, muscle strength, and joint function in children with SCP. Our findings support the idea of other authors

that manual stretching (PNF or SS) performed in isolation for eight weeks may not be appropriate to evoke significant changes on muscle-tendon and joint level in this population. Shifting our focus and looking for other/new efficient treatment strategies is needed.

ARE THE SHOULDER JOINT FUNCTION, STABILITY, AND FLEXIBILITY TESTS PREDICTIVE OF HANDSTAND EXECUTION?

MALÍR, R.

FACULTY OF PHYSICAL EDUCATION AND SPORT, CHARLES UNIVERSITY

INTRODUCTION: Handstand is unstable element used across multiple gymnastic disciplines (1). The quality of any element's execution plays an important role, which is evaluated accordingly. Multiple strategies are used to maintain a handstand (2–4), where the shoulder joints seem to play an essential role (5, 6). The function of the shoulder joint is affected by its stability and mobility (7). The purpose of this study is to examine the relationship between shoulder joint function (flexibility and stability) and the quality of handstand execution.

METHODS: The handstand execution of university students (n = 111) was evaluated using two qualitative scales, 'Assessment of the Quality Value" (AQV) and E score. The stability and mobility of the shoulder joint were assessed by two standardized field tests: Upper Quarter Y Balance Test (UQYBT) and the Closed Kinetic Chain Upper Extremity Stability Test (CKCUEST). We also evaluated the active range of motion (aROM) in flexion using a specific Sit Position Test (SPT). In two ordinal logistic regression models, we evaluated the relationship between the quality of handstand execution (UQYBT, CKCUEST, and SPT) and the AQV and E-score.

RESULTS: In the first model (AQV), the proportional odds ratio (POR) of the UQYBT (1.06 [0.98, 1.14]), CKCUEST (0.99 [0.89, 1.09]), and SPT (1.43 [0.76, 2.74]) were not statistically significant contributors to the handstand execution quality. Similar results were observed in the second model (E score), where the POR of the UQYBT (0.97 [0.91, 1.03]), CKCUEST (1.00 [0.91, 1.09]) and SPT (1.16 [0.64, 2.07]) also did not show a statistically significant contribution to the execution of the handstand.

CONCLUSION: In our sample, we did not observe any relationship between the shoulder function tests (UQYBT, CKCUEST, and SPT) and measures of handstand execution quality. This pattern of results may be caused mainly due our sample's limited ability to perform the handstand sufficiently well.

PROGRESSIVE USE OF A PASSIVE SHOULDER-EXOSKELETON IN MANUAL MATERIALS HANDLING

JAKOBSEN, L.S., DE ZEE, M., SAMANI, A., DESBROSSES, K., MADELEINE, P.

AALBORG UNIVERSITY

INTRODUCTION: Occupational exoskeletons are seen as attractive solutions to lower the physical load of workers conducting manual handling tasks, since reduced muscle activities during exoskeleton-use has been reported [1]. However, literature is still lacking field studies reflecting real-life settings [2]. Additionally, companies start implementing exoskeletons without considering a familiarization process, which increases the risk of failure of integration [3]. This study aimed to investigate in-field changes in muscle activity and acceptance when using a passive shoulder-exoskeleton pre and post a 5-week familiarization period.

METHODS: Ten workers from a Danish logistics company (INT) underwent a 5-week familiarization period of progressive use of a passive shoulder-exoskeleton (from 7.5 h/week to 37 h/week), while ten other workers acted as controls throughout the period (CON). Test sessions pre and post the familiarization involved four typical work tasks based on observations of their daily work. All four tasks included lifting merchandise from a shelf to a truck in a rotational movement

with the exoskeleton (EXO) and without (NoEXO). Surface electromyography (sEMG) of erector spinae, deltoideus anterior, and upper trapezius was recorded bilaterally. Additionally, perceived effort and perception of acceptance (usefulness, ease of use, emotions, attitude, and comfort) of the exoskeleton was assessed using a Borg CR10 scale and a questionnaire. The sEMG amplitude was normalized to maximal voluntary contractions, and the 10th and 90th percentiles were calculated. Two-way RM-ANOVAs were conducted to assess the effects of the exoskeleton and familiarization.

RESULTS: No effects of familiarization were revealed in sEMG amplitude nor in perceived effort. Perceived usefulness ($p<.001$), emotions ($p<.001$), attitude ($p<.001$), and comfort ($p=.005$) of the exoskeleton decreased in both INT and CON group after the 5-week period. The use of EXO resulted in significant decreases of the 10th and 90th percentile of sEMG amplitude of the anterior deltoid muscles and of the 10th percentile of the upper trapezius muscles across all lifting conditions ($p<.05$). Additionally, decreases were revealed in perceived effort ratings in lifts conducted above shoulder height ($p=.003$).

CONCLUSION: The exoskeleton reduced the muscle activity of the neck-shoulder musculature and perceived effort as earlier reported in the literature. On the other hand, the perception of acceptance of the exoskeleton also decreased during the familiarization period. This illustrates a challenge for this company for a sustainable implementation of a shoulder exoskeleton in their business. This work also showcases the importance of a holistic approach when trying to implement exoskeletons in real working situations.

EFFECTIVENESS OF TELEHEALTH PROGRAM ON SELF-REPORTED FUNCTION, FUNCTIONAL PERFORMANCE, AND PHYSICAL ACTIVITIES IN PATIENTS WITH KNEE OSTEOARTHRITIS: A SYSTEMATIC REVIEW AND META-ANALYSIS.

LUO, P.1, WANG, H.N.1,2, ZHANG, X.2,3

1 BEIJING SPORT UNIVERSITY, 2 UNIVERSITY OF CALGARY

INTRODUCTION: Knee Osteoarthritis (OA) is the most common chronic degenerative bone and joint disease in the middle-aged and elderly worldwide. It is characterized by cartilage deterioration, joint space narrowing, osteophyte formation, and sclerosis of the subchondral bone. Digital technologies may be a feasible solution given that people with knee OA have limited access to hospital and physiotherapy clinic. The objective of this systematic review and meta-analysis was to evaluate the telehealth program on self-reported function, functional performance, and physical activities in the treatment of patients with knee osteoarthritis (KOA).

METHODS: A systematic review was conducted by searching six electronic databases, namely MEDLINE (PubMed), Cochrane, EMBASE, Web of Science, SPORTDiscus (EBSCO), PEDro Six electronic databases were searched to identify trials comparing telehealth program and conventional intervention in a population with KOA. Studies were selected according to the inclusion and exclusion criteria. Outcome measureswere compared by standardized mean differences (SMDs) or mean difference (MD) with 95% confidence intervals (CIs). The Higgins's (I2) statistic was calculated to evaluate heterogeneity. The methodological quality of selected studies and the quality of evidence were evaluated for included studies.

RESULTS: Of 3687 articles identified, a total of nine studies were included in this meta-analysis, with very low to moderate risk of bias. The pooled results showed telehealth program group have greater improvement on Timed-up and go test (MD = -0.90 [95%CI: -1.59, -0.20], P = 0.01, I2 = 17%) than control group. However, no significant difference between telehealth program group compared to control group for KOA, including self-reported function (SMD = -0.05 [95%CI: -0.17, 0.26], P = 0.66 I2 = 77%), 30-s chair stands (MD = 1.43 [95%CI: -0.34, 3.20], P = 0.11, I2 = 89%), physical activity levels (MD = -8.65 [95%CI: -17.92, 0.63], P = 0.07, I2 = 20%).

CONCLUSION: Data from pooled studies showed telehealth program may have greater improvement for treating patients with KOA on Timed-up and go test. However, no evidence showed telehealth program is beneficial to self-reported function and physical activities More evidence with high quality is needed in further research for its effectiveness and feasibility.

ACTIVE VERSUS PASSIVE PHYSIOTHERAPY FOR SHOULDER PAIN: A SYSTEMATIC REVIEW AND META-ANALYSIS.

WANG, R., WANG, J.

CHINA INSTITUTE OF SPORT SCIENCE

INTRODUCTION: Shoulder pain, second only to back and neck pain, is one of the most prevalent musculoskeletal pain in primary care. Epidemiology shows that the lifetime prevalence of shoulder pain in adults worldwide ranges from 7% to 67%. Treatment of shoulder pain poses tremendous economical pressure on patients. A study in the Netherlands showed

that the average total cost per patient for shoulder pain in primary care was estimated to be $689 within six months since the first consultation.

Physiotherapy is normally the preferred intervention for shoulder pain in the absence of evidence for its standard treatment. David A in 2021 proposed the "active" and "passive" of physiotherapy, as well as the dispute between them and their future development. According to existing studies, active physiotherapy (AP) includes therapeutic active activities carried out by patients during the intervention process, while passive physiotherapy (PP) is mainly done by the therapist or equipment. Recently, the effect of traditional PP was questioned and labeled as "low-value care". Jeremy Lewis also suggested that the physical therapy profession was embracing an inflection point where active therapies and more patient self-reliance will move physical therapy away from an overreliance on passive therapies of the past.

Therefore, this review aims to compare the effects of AP and PP on pain intensity and function in patients with shoulder pain in the hope of providing reference value in future clinical practice of physiotherapy.

METHODS: Two independent researchers searched PubMed, Cochrane library, Embase, Web of science, CINAHL and PEDro from the beginning to September 7, 2022. All included studies were evaluated for risk of bias by the Cochrane risk-of-bias tool and the certainty of results was rated using the Grading of Recommendations Assessment, Development, and Evaluation (GRADE) approach. Randomized controlled trials (RCTs) involving patients with shoulder pain were included. The treatment must be AP versus PP.

RESULTS: Altogether 21 studies, including 1011 patients, were included. The primary result: Compared with passive manipulation, AP was superior in the pressure pain threshold (PPT) of shoulder (SMD-0.09, 95%CI: -0.42 to 0.24, P=0.59), pain intensity (SMD-0.37, 95%CI: -0.71 to -0.03, P=0.03) and function (SMD-0.22, 95%CI: -0.43 to -0.01, P=0.04). AP had an advantage over physical factor therapy in terms of pain intensity (SMD-1.32, 95%CI: -2.34 to -0.29, P=0.01) and function (SMD-0.64, 95%CI: -1.15 to -0.14, P=0.01). The secondary result: AP was superior to PP at short-term and medium-term follow-up, with no difference at long-term follow-up.

CONCLUSION: Evidence with moderate to very low certainty suggests AP was superior to PP in pain and functional improvement in patients with shoulder pain at short-term and medium-term follow-up, but this advantage was not observed in the long-term follow-up.

ISOKINETIC STRENGTH PROFILE OF THE ROTATOR MUSCLES OF HIGH-LEVEL TABLE TENNIS PLAYERS

ROSE, C.

INSEP

INTRODUCTION: The practice of high-level table tennis require high muscular strength in the shoulders and the intensity of the strokes associated with a lot of repetitions can lead to overload particular joints [1]. However, few studies have explored the isokinetic profile of the rotator muscles of the table tennis players. Our objective was to describe and compare isokinetic muscle profiles of the shoulders of high-level table tennis players by laterality and gender.

METHODS: 8 male (22 ± 4.6 years old; 181 ± 3.9 cm, 71 ± 7 kg) and 4 female (23 ± 8.2 years old; 168 ± 7.2 cm, 59 ± 10 kg) of the Table Tennis French Team were enrolled in this cross-sectional study. A clinical examination and a bilateral shoulder isokinetic test were carried out for all the athletes of the Table Tennis French Team as part of the annual medical check-up. The muscle strength of the internal rotators (IR) and external rotators (ER) of the shoulder were measured on an isokinetic dynamometer (Biodex system 4, Biodex Medical Systems, New York, USA) in the concentric mode at 60°/s and 180°/s, and the eccentric mode at 60°/s. The conventional ratio (ER : IR at 60°/s concentric mode) and the mixed ratios (ER in the eccentric mode at 60°/s to IR in the concentric mode at 180°/s for the throwing movement ; IR in the eccentric mode at 60°/s to ER in the concentric mode at 180°/s for the arming movement) were also calculated.

RESULTS: The statistical analysis of the data in males shows only difference between the dominant arm and the non-dominant arm on the internal rotators in the concentric mode at 180°/s (0.66 ± 0.16 vs. 0.55 ± 0.11, P = .008). No difference was found in females between the two shoulders in any mode for the IR and the ER peak torque. There was no significant difference between sides for each of the ratios, in males and females.

CONCLUSION: The isokinetic profile of high-level table tennis players, men and women, appears to be symmetrical between the racket arm (considered as the dominant one) and the non-dominant arm, with the possible exception of the internal rotators peak force in a high velocity condition (concentric mode at 180°/s), which is higher on the dominant side in males. Thus, it would be interesting to research in our high-level table tennis players suffering from pathology of the shoulder, if there is an imbalance of the muscular profile of the dominant side compare to those results.

EVALUATION OF TWO METABOLIC CARTS FOR CARDIOPULMONARY EXERCISE TESTING (CORTEX METALYZER 3B AND JAEGER OXYCON PRO) IN DIFFERENT ENVIRONMENTAL CONDITIONS

BOURGOIS, G.1,2, MUCCI, P.2, BOURGOIS, J.G.1,3, BOONE, J.1,3, COLOSIO, A.L.1

1 DEPARTMENT OF MOVEMENT & SPORTS SCIENCES, GHENT UNIVERSITY ; 2 UNITÉ DE RECHERCHE PLURIDISCIPLINAIRE SPORT SANTÉ SOCIÉTÉ, UNIVERSITÉ DE LILLE; 3 CENTER OF SPORTS MEDICINE, GHENT UNIVERSITY HOSPITAL

INTRODUCTION: To evaluate the measurement accuracy and consistency of two metabolic gas analyzers, using breath-by-breath technology, for cardiopulmonary exercise (CPX) testing in different environmental conditions (ambient temperature and relative humidity) with a metabolic simulator (MS) as verification procedure.

METHODS: In a climatic chamber, six different combinations of ambient temperature (18, 27 and 36°C) and relative humidity (45% and 75%) were set to test two regularly maintained metabolic carts, i.e, Metalyzer 3B (Cortex Biophysik GmbH, Germany) and Jaeger Oxycon Pro (Viasys Healthcare GmbH, Germany). Calibration procedures according to the manufacturers recommendations were performed in each environmental condition before testing with the MS (Relitech Systems BV, The Netherlands). The CPX mode of the MS was applied to simulate metabolic gas exchange by controlled pure gas (N2 and CO2) input at 4 different respiratory exchange ratios (RER; 0.75, 0.85, 0.95 and 1.05), with according respiratory rates (RR; 10, 20, 40 and 60 b/min) and a fixed tidal volume of 2 L. Primary outcome parameters were oxygen consumption (VO2), carbon dioxide production (VCO2), and ventilation (VE). Acceptable difference was set within 3%, based on the precision/specified accuracy of the metabolic carts and MS combined.

RESULTS: The overall differences, irrespective of environmental condition or metabolic intensity, were -3.7, -1.0 and -2.2% (Metalyzer 3B), and 4.3, 6.0 and 2.6% (Jaeger Oxycon Pro), respectively for VO2, VCO2 and VE. For the Metalyzer 3B, there was no change in VO2 difference across the three ambient temperatures, while the lowest metabolic intensity (i.e., RER = 0.75), had the largest difference (-9.7%). The largest underestimation of VE (-4.2%) occurred at the highest ambient temperature. Overall difference of VCO2 was -1.0%, although, the range varied between -8.2 and 7.7%. For the Jaeger Oxycon Pro, overestimation of VO2 values increased with increasing intensity (respectively 2.6, 4.2, 6.9 and 7.3%). VE was within acceptable range except for the lowest intensity (7.3%). Only 4/24 VCO2 measurements were within acceptable range, with the smallest difference at the highest ambient temperature (3.4%).

CONCLUSION: For the Metalyzer 3B, 39/72 obtained values were whitin 3% difference compared to MS, while this was only 29/72 for the Jaeger Oxycon Pro. There was no clear influence of environmental conditions on the detected errors. Although, trends regarding the influence of temperature, humidity and intensity on outcome parameters (VO2, VCO2 and VE) can provide a better understanding of the operational functioning of metabolic carts in general. Maintenance of measurement systems and components, together with regular verification of pulmonary gas exchange variables obtained during CPX testing using a MS, is necessary to ensure quality of testing for adequate guidance of athletes and patients in sports and rehabilitation.

DEVELOPMENT OF EQUATION PREDICTING STROKE VOLUME TO ASSESS CARDIOVASCULAR STRAIN.

TSOUTSOUBI, L.1, IOANNOU, L.G.1, CIUHA, U.1, FISHER, J.T.1, POSSNIG, C.2, SIMPSON, L.L.2, LAWLEY, J.2, FLOURIS, A.D.3, MEKJAVIC, I.B.1

1 JOŽEF STEFAN INSTITUTE, 2 UNIVERSITY OF INNSBRUCK, 3 UNIVERSITY OF THESSALY.

INTRODUCTION: The advances in wearable technology have been popularized for monitoring individuals heart rate during recreational activities of the general population or the athletes, but there are also wearables that have been used to monitor occupational heat stress. Some of them are based on core and skin temperature and some others based on heart rate. To our knowledge, there are no devices that estimate the cardiovascular strain based on stroke volume or cardiac output. One of the problems is the lack of suitable algorithms that would provide such an index on the basis of relevant physiological responses. Cardiac strain reflects heat strain and can be estimated by cardiac index, which is derived from the ratio of cardiac output (the product of stroke volume and heart rate) to the body surface area. The main hurdle in determining the cardiac index is the determination of cardiac output, particularly the determination of stroke volume, which normally requires complex clinical methods. The present study aimed to develop and validate a formula for predicting stroke volume from measurements of blood pressure

METHODS: Fourteen individuals participated in the study. During each trial we monitored their cardiovascular response in four positions: sitting, standing, supine and 60° head up title. During the test we measured arterial blood pressure with a sphygmomanometer. Blood pressure was also measured with finger photoplethysmography which also provided beat-by-beat measures of stroke volume and cardiac output.

RESULTS: A multiple linear regression analysis was performed to develop the predictive formula for stroke volume.

CONCLUSION: The present study developed an equation predicting stroke volume with a regression of R2=0.704.

RUNNING STYLE AND PERFORMANCE: PERCEPTION OF EFFORT OR CARDIOMETABOLIC FITNESS?

MARCORA, S., MARTINEZ-GONZALEZ, B., NIGRO, F., SIMONI, M., CIACCI, S., SAKAGUCHI, M., ABE, S., TANIGUCHI, N.

UNIVERSITY OF BOLOGNA

INTRODUCTION: Based on various parameters (vertical oscillation of the head, arms movement, pelvis position at ground contact, foot position at ground contact, and strike pattern) runners can be classified as having an aerial or a terrestrial style. The main aim of this causal-comparative study was to investigate the physiological and perceptual effects of running style in a group of competitive runners.

METHODS: Thirty athletes competing in distance running were recruited. Two or three experienced coaches classified each participants running style using the Volodalen method [1]. Participants were then matched for gender for a final grouping of 12 aerial runners (AER; 10 males and 2 females) and 12 terrestrial runners (TER). During the first visit, maximal oxygen consumption (VO2 max), peak treadmill speed (PTS) and ventilatory thresholds (VTs) were measured. During the second visit, participants performed two 10-min runs on a treadmill at a constant speed corresponding to the first VT (low-intensity run, LI) and the second VT (high-intensity run, HI) followed by a 3k time trial (TT). During all three runs, heart rate (HR), rating of perceived exertion (RPE), and blood lactate (La) were measured. During LI and HI, gas exchange and gait parameters were also measured.

RESULTS: Volodalen score was higher in AER (17 ± 1) than in TER (12 ± 2; $p < 0.001$). The duty factor (a global gait parameter) [2] was lower in AER (0.746 ± 0.049) than in TER (0.833 ± 0.051; $p < 0.001$). The 5-km personal best time was better in AER (1007 ± 93 s) than in TER (1081 ± 98 s; $p = 0.018$). AER (20.5 ± 1.6 km/h) achieved a higher PTS than TER (19.6 ± 1.1 km/h; $p = 0.039$) despite no significant differences in VO2 max (AER: 62.2 ± 7.3 ml/kg/min; TER: 64.9 ± 6.0 ml/kg/min). During LI, no significant differences were found for cost of transport (CT), running economy (RE), HR, La, RPE:speed, and RPE:HR. During HI, RPE:HR was lower in AER than in TER ($p = 0.034$), and a trend ($p = 0.057$) was found for lower RPE:speed in AER than in TER. No significant differences were found for CT, RE, HR and La. During the TT, AER ran 0.82 km/h faster than TER ($p = 0.050$). HR in AER was 10 bpm higher than in TER ($p = 0.028$). RPE:HR was lower in AER than in TER ($p = 0.050$), and a trend ($p = 0.052$) was found for lower RPE:speed in AER than in TER. No significant differences were found for La.

CONCLUSION: Our study confirms previous findings that running style does not affect CT and RE at moderate intensity [3] and extends them to high-intensity running. Furthermore, we found that, despite no significant metabolic differences, AER ran faster than TER during both the incremental running test and the TT. These significant differences in performance may be explained by lower perception of effort at high running speeds.

CARDIOVASCULAR RESPONSES AND METABOREFLEX ACTIVATION FOLLOWING EXERCISE-INDUCED MUSCLE DAMAGE.

ZAMBOLIN, F.

MANCHESTER METROPOLITAN UNIVERSITY

INTRODUCTION: The aim of the present study was to investigate whether exercise-induced muscle damage (EIMD) influences cardiovascular responses to isometric exercise and isolated metaboreflex activation. We hypothesized that EIMD would lead to muscle afferent sensitisation and altered blood pressure responses to exercise and isolated muscle metaboreflex activation using post-exercise cuff occlusion (PECO).

METHODS: Twenty subjects performed unilateral isometric knee extension at 30% of maximal voluntary contraction (MVC) for 3-minutes, followed by 2-minutes of PECO and 3min recovery pre- and 48 h post-EIMD while recording cardiovascular response (CV) with a beat-by-beat blood pressure monitoring device. EIMD protocol consisted of 200-250 maximum eccentric knee-extension contractions on the same leg performing the cardiovascular assessment.

RESULTS: EIMD elicit a significant decrease in MVC from 634.6 ± 229.3 to 504.0 ± 160, and an increase in perceived soreness (VASSQ) from 2.3 ± 1.5 to 39.5 ± 27.3 mm (all $p < 0.001$). CV response to exercise and PECO were not different from pre- to post-EIMD (all $p > 0.05$), however increases in mean arterial pressure (MAP) were found during recovery phase (Delta-Rec) post-EIMD ($p < 0.05$). Moreover, significant associations were found between increases in MAP during contraction (Delta-Con) and VASSQ, Rate of Perceived Exertion (RPE) and Pain only post-EIMD (all $p < 0.05$).

CONCLUSION: These results indicate that EIMD does not influence cardiovascular responses to isometric exercise and isolated metaboreflex activation, suggesting that metaboreflex is not increased post-EIMD. Results from single correlations analysis may advance the hypothesis of an altered cardiovascular responses to exercise linked to pain, soreness, and exertion through mechanisms other than metaboreflex.

EXERCISE TRAINING INDUCES BENIGN RIGHT VENTRICULAR HYPERTROPHY ALONG WITH FUNCTIONAL IMPROVEMENT AND WITHOUT PATHOLOGICAL PROCESSES OR ARRHYTHMOGENICITY IN A RODENT MODEL OF ATHLETE'S HEART

OLÁH, A., BÓDI, B., SAYOUR, A.A., RUPPERT, M., BARTA, B.A., VIRÁG-TULASSAY, E., BOTTLIK, O., PAPP, Z., MERKELY, B., RADOVITS, T.

SEMMELWEIS UNIVERSITY

INTRODUCTION: Regular sport activity leads to the adaptation of cardiac structure and function, the so-called athlete's heart. Research projects over the last years have focused on exercise-induced adaptation of the right ventricle (RV), because the disproportionate load on the RV - when compared with the left ventricle - might lead to pathological consequences, such as myocardial interstital fibrosis or chamber dilation. We aimed at investigating RV alterations induced by regular aerobic exercise training in a rat model of athletes heart.

METHODS: Young, adult rats were divided into control (Co) and exercised (Ex) groups (n=12-12). Exercised rats underwent a 12-week-long swim training program. In vivo electrophysiological study and in vitro cellular force assessments on isolated cardiomyocytes were carried out to investigate electrical and functional RV alterations, respectively. Molecular biological (qRT-PCR, Western-blot) and histological investigations were applied to reveal underlying mechanisms.

RESULTS: Exercise training was associated with increased RV cardiomyocyte diameter (12.5±0.1 µm Co vs. 13.8±0.2 µm Ex, $p<0.05$), that was associated with hyperphosphorylation of protein kinase B (Akt). RV cardiomyocytes from exercised animals showed improved calcium sensitivity and increased maximal force development. We found increased length of repolarization as reflected by prolonged QT interval and ventricular effective refracter period (VERP: 44.0±1.6 ms Co vs. 52.8±2.1 ms Ex, $p<0.05$) along with decreased gene expression of potassium channels (Kcnd2, Kcnj2). Picrosirius staining did not reveal fibrosis, that was associated with unchanged protein expression of connective tissue growth factor (CTGF) and gene expression of profibrotic markers (such as TGF-β). Gene expression of apoptotic markers (Bax, Bcl-2) and fetal gene program (such as β-MHC) did not differ between groups.

CONCLUSION: According to our data, regular swim training induced RV hypertrophy, that was associated with functional improvement (improved calcium sensitivity and maximal force) and prolonged repolarization without characteristic pathological alterations in myocardial tissue.

LOCAL MUSCLE CONTRACTIONS SUPPRESSE DECLINE IN METABOLIC CAPACITY CAUSED BY INACTIVITY

TANIMURA, R.

UNIVERSITY OF TSUKUBA

INTRODUCTION: Physical inactivity due to aging, bed rest after injury, spinal cord injury, etc. is a risk factor of chronic diseases such as skeletal muscle wasting and obesity. On the other hand, it is well known that physical activity (exercise) can improve body composition and prevent diseases associated with physical inactivity. Although regular exercise training is one of the most effective ways to combat physical inactivity, its application to people with exercise difficulties is not possible. To address this issue, we have focused on "muscle contraction" from the complex components of exercise. Indeed, it has been reported that an electrical stimulation (ES) model to induce local muscle contraction in the mouse lower leg activates representative molecular signals that are activated during exercise (Tanimura et al., 2022). In this study, we aimed to investigate the effects of ES on the metabolic capacity of skeletal muscle and adipose tissue during inactivity.

METHODS: All the experimental procedures performed in this study were approved by the Institutional Animal Experiment Committee of the University of Tsukuba, Tsukuba, Japan (22-397). Male ICR mice aged 7 weeks were used in this study. After one week of acclimation, mice were underwent sciatic nerve transection surgery (denervation: DEN) or performed sham operation. Two weeks after surgery, the gastrocnemius muscles were stimulated percutaneously (30V, 100Hz) with an electrode (ES) or left sedentary (CON) for 4weeks. Mice were divided into four groups: Sham + CON group (n = 6), Sham + ES group (n = 5), DEN + CON group (n = 6), DEN + ES group (n = 6).

RESULTS: The weight of the gastrocnemius muscle was lower in the denervated limb than in the sham-operated limb and it showed a tendency to increase by ES. Thus, we observed collateral evidence of ES and DEN. The wet weight of inguinal white adipose tissue (iWAT) was significantly lower in ES and ES+DEN groups than non-ES groups. Furthermore, DEN induced reductions of mitochondria related proteins in gastrocnemius and iWAT, which were partially suppressed by 4-weeks of ES. Based on several results such as the expression of IL-6 receptor in iWAT and plasma IL-6 immediately after acute ES, interleukin-6 (IL-6), one of the muscle-derived secreted proteins, could be involved in metabolic remodeling of adipose tissue.

CONCLUSION: Local muscle contraction by electrical stimulation could suppress the decline in metabolic capacity of skeletal muscle and adipose tissue during inactivity. In addition, contractile muscle-derived IL-6 might be involved in this mechanism in iWAT.

THE POTENTIAL HARMS OF SEDENTARY BEHAVIOUR ON CARDIOMETABOLIC HEALTH ARE MITIGATED IN HIGHLY ACTIVE ADULTS - A COMPOSITIONAL DATA ANALYSIS

VANHERLE, J.1, FRANSSEN, W.1, JERMEI, J.1, SAVELBERG, H.2, OP T EIJNDE, B.1

1. HASSELT UNIVERSITY 2. MAASTRICHT UNIVERSITY

INTRODUCTION: Insufficient physical activity and sedentary behaviour (SB) are important factors that determine cardiometabolic health and the development of non-communicable diseases. The aim of this study was to investigate the modifying effects of moderate-to-vigorous physical activity (MVPA) on the association between SB and cardiometabolic health within highly active adults.

METHODS: In a cross-sectional design, 61 (male/female: 41/20) highly trained adults (age: 33.6 ± 10.7 years; BMI: 22.4 ± 2.3 kg/m2) performed a maximal cardiopulmonary exercise test from which indicators for peak performance were determined. Physical activity and SB were assessed using the activPAL3™ accelerometer. In addition, anthropometrics, blood pressure, plasma lipids and insulin sensitivity were assessed. These cross-sectional associations between a daily movement behaviour composition and cardiometabolic health parameters were investigated using a compositional data analysis approach.

RESULTS: Participants spent 600 ± 86 min/day in SB and engaged in almost 1.5 hours per day of MVPA. No association was found between SB and cardiometabolic health related variables, whereas MVPA (β = 8.07 ± 2.18; r2 = 0.544; $p < 0.001$) was only significantly associated with oxygen uptake, relative to all other remaining behaviours.

CONCLUSION: No associations were found between the time spent in SB and cardiometabolic health related outcomes, possibly due to the high amount of time spent in MVPA within highly active adults.

VERBAL OUTCOME PREDICTION IN BASKETBALL – A BEHAVIORAL STUDY

JUNGE-BORNHOLT, L.E., WACHSMANN, F.D., MAURER, H., HEGELE, M., MÜLLER, H., MAURER, L.K.

JUSTUS LIEBIG UNIVERSITY GIESSEN

INTRODUCTION: Professional basketball players like to show off that they can predict the outcome of their throws. Studies confirm a high perceptual sensitivity in experienced players to discriminate hits from misses (Cañal-Bruland et al., 2015; Maglott et al., 2019). The present study shows that this perceptual sensitivity is related to verbal prediction accuracy. Herein, this measure of verbal prediction accuracy controls for strategic response patterns and individual throwing performance.

METHODS: 19 participants (6w, 13m; 23.7 ± 4.8 years; average basketball experience of 11.2 ± 4.9 years) performed 500 free throws, in which they verbally predicted the outcome (hit/miss) of every second trial. Visual and auditory feedback was withdrawn for 2.5 seconds after ball release using liquid crystal glass goggles and in-ear headphones. Individual, strategy-controlled, prediction accuracy was calculated based on Maurer et al. (2022). In addition, d' was computed to detect the players' sensitivity to discriminate hits and misses.

RESULTS: On average, participants could predict significantly above their individual chance level with a mean accuracy of 12.97 % and a standard deviation of 9.00 % ($t(18) = 6.28$, $p < 0.001$, $d = 1.44$). The according d' value reached an average of 0.36 and a standard deviation of 0.26 ($t(18) = 6.10$, $p < 0.001$, $d = 1.40$) and an average response bias λ of -0.14 with a standard deviation of 0.40. The two parameters prediction accuracy and d' show a high correlation ($r(17) = 0.99$, $p < 0.001$).

CONCLUSION: To be able to predict the result of one's own basketball free throws, participants have to rely on prerelease kinesthetic and efferent information. Although this perceptual information is noisy, and decisions have to be made under time constraints, expert players are able to discriminate and verbally predict their own throwing outcomes above an individual level of chance. The high correlation between the verbal prediction accuracy and the d' values underlines the assumption that the players have conscious access to the online predictions of their sensorimotor system.

RECRUITMENT PROPERTIES OF SPINAL REFLEX OF THE THIGH MUSCLE IN ELITE SPRINTERS

NAKAGAWA, K., KAKEHATA, G., KANEKO, N., MASUGI, Y., KANOSUE, K., ISO, S., NAKAZAWA, K.
WASEDA UNIVERSITY

INTRODUCTION: Activation timing of thigh muscles is important in high-performance of sprint running. Especially, sharpness of switch from onset to offset of thigh muscle activation during sprint running is superior in top sprinters (Kakehata et al. 2021). These characteristics of activation pattern of thigh muscles in sprinters could be produced by specific function of central nervous system, especially neural circuits including motoneurons. The purpose of this study was to examine the recruitment properties of spinal reflex in sprinters.

METHODS: Ten sprinters and ten control subjects participated in this experiment. We used transcutaneous spinal cord stimulation (tSCS) to evoke posterior root-muscle reflex from lower limb muscles (Courtine et al. 2007). Stimulation electrodes were attached at abdomen (anode) and the midline of the back between L1 and L2 (cathode). tSCS was applied with various stimulation intensities from subthreshold to the above intensity inducing the plateau amplitude of spinal reflex. We evaluated the recruitment curves of the reflex amplitudes in the bicep femoris and soleus muscle. From the recruitment curves, we calculated the maximal slope, plateau amplitude, and threshold (Higashihara et al. 2022).

RESULTS: The maximal slope of the recruitment curve of the spinal reflex of the biceps femoris was significantly higher in sprinters than control subjects ($P < 0.05$). Meanwhile, there was no significant group-differences in the maximal slope of the soleus. Furthermore, the plateau amplitude and threshold did not differ between the group irrespective of muscles.

CONCLUSION: The observed sharper slope of the recruitment curve of spinal reflex in sprinters without differences in plateau amplitudes would mean that higher motor output induced by reflex can be delivered with small changes in sensory input in sprinters. This specific recruitment property of spinal reflex of the biceps femoris in sprinter could reflect plastic change of spinal neural circuits by long-term sprint training. In conclusion, elite sprinters show the muscle-specific recruitment pattern of spinal reflex.

THE IMPACT OF VOLLEYBALL SPIKE AND DEFENSE TRAINING ON DEFENSE ANTICIPATION ABILITY

CHU, H.H., HUANG, C.C., LIN, C.F., KUO, C.Y., CHEN, Y.H.
NATIONAL TAIWAN SPORT UNIVERSITY

INTRODUCTION: In volleyball, the defense is extremely important as it can avoid losing points at first. Moreover, a successful defense can further create the opportunity to organize the latter attack (1). The ability to anticipate the attack correctly allows players to better prepare the defense (2,3). Perceptual and motor experiences of the observed action (e.g., attack) have been shown to enhance the ability to anticipate its results in athletes (2, 3). However, studies with perceptual or motor training intervention remained limited (4-6). Moreover, the action anticipation ability is often tested with the temporal or spatial occlusion paradigms and did not require participant to respond with the actual movement involved (but only with a key press) which might decrease the perception and action coupling (4). Therefore, in this study we investigated how perceptual and motor training of volleyball attacks would influence players' anticipation of the attacks, and the action anticipation ability was tested in a reaction time paradigm in which players had to anticipate the direction of the attack by performing a defense movement.

METHODS: Eighteen male collegiate volleyball players were recruited. We filmed 4 volleyball players spike action on a real indoor volleyball court from the perspective of the player ready to defend at the position #6. Each video clip was occluded 1 frame (33ms) before the ball left the scene. During the experiment, the video clips were projected on a 1.56 m × 1.59 m projection screen. Participants were required to present the real defense reaction. The control group accepted regular practice, and the spike group accepted more spike practice and less defense practice. Both training last for 5 weeks with the frequency of 2 days per week. After the intervention training session, participants took the anticipation and spike post-test. The retention test was performed 7 days after post-test. A 2 (Group) × 3 (Test) ANOVA repeated measurement was used to examine the anticipation and spike performance.

RESULTS: There was no significant difference in anticipation accuracy, reaction time, and spike accuracy between groups and tests. The anticipation consistency of the retention test of each group was significantly higher than the pre-test(PREcontrol = 78.22 ± 4.52, REcontrol = 81 ± 3.50, PREspike = 79.33 ± 4.27, REspike = 82.44 ± 4.07, $F(1, 16) = 4.985$, $p = .013$, $\eta p2 = .238$, $p = .037$)

CONCLUSION: Apparently, anticipation capacity, especially accuracy and reaction time, would not be enhanced after 5 weeks spike training intervention that did not improve motor skill. It appears that the spike training intervention should be more directly related to the aspect of technique, rather than merely accumulating experience. In addition, the examination of spike ability should consider not only accuracy but also technical parts. By doing so, we can not only monitor training effectiveness, but also explore the relationship between motor skill improvement and anticipation performance.

ATTENTIONAL FOCUS EFFECTS ON LOWER LIMB MUSCULAR STRENGTH IN ATHLETES: A SYSTEMATIC REVIEW

POMPA, D., CARSON, H., BEATO, M., DI FRONSO, S., BERTOLLO, M.
UNIVERSITY G. DANNUNZIO OF CHIETI-PESCARA

INTRODUCTION: Evidence suggests that the attentional focus contributes to enhancing strength performance [1]. However, additional research is needed to investigate the applicability of these studies beyond the tasks and population currently

examined. This study aimed to systematically review studies about attentional focus effects on strength characteristics during lower-limb exercise tasks in athletes

METHODS: Scopus, web of Science, and EBSCO databases were searched using Prisma PERSIST [2] guidelines and keywords related to the focus of attention, force production processes, and athletes. Inclusion criteria required an age ≥16 years and to be a healthy competitive athlete. Exclusion criteria were applied for research about technical skills, postural control, and asymmetry comparisons. Based on the literature [3], athletes were categorized in four tiers or a 'mixed group': World-class (Tier 5); Elite (Tier 4); Highly trained (Tier 3); Trained /Developmental (Tier 2); and Tier mixed (different levels). Information used from each eligible study were the aims and design, participants characteristics, strength task, attentional focus conditions, outcome measures, findings, risk of bias calculation, and assessment of certainty against several established methodological issues identified within the literature.

RESULTS: 15 out of 296 studies were initially found, met inclusion criteria. The study aims addressed the focus of attention on performance (n=6), between skill level (n=2), for learning (n=5), as a preference on performance (n=1) and one study did not state the aim. Studies used either a cross-over within-subjects (n=9) or RCT (n=6) design. Participants (n=440 males vs. n=96 females) consisted of one elite, four highly-trained, eight developmental, and two mixed group samples. Studies mainly used single tasks: jump (n=8), running acceleration (n=3), isokinetic knee extension (n=1), and isometric lift (n=1), performed with pretension mechanisms (n=6), influenced by stretch-shortening cycle reflex (n=5), isometric (n=1), isokinetic (n=2) muscle action. Outcomes measured were kinetics (n=13) or combined with EMG (n=2). Few studies reported an advantage for the external focus of attention across conditions (n=2; g=0.13-0.419) performing CMJ and IMTP tasks with Tier 2 and Tier mixed athletes, with an average risk of bias score of Excellent. However, findings suffered in the assessment of certainty when reviewed against key criteria identified by authors in the field.

CONCLUSION: Research does not address the needs of elite athletes and there is limited evidence on each type of strength characteristics and muscle action. There is also a need to incorporate methodological steps to ensure fair comparisons between attentional foci conditions. Research should focus on contextualized information within the professional practice to offer stronger translational implications for athletes and coaches

TACTILE SENSORY FUNCTION IN ATHLETIC POPULATIONS: A COMPARISON OF TWO POINT DISCRIMINATION THRESHOLDS

BAYRAM, I.1,2, CERRAH, A.O.1,2, SOYLU, A.R.3

1 ESKISEHIR TECHNICAL UNIVERSITY, ESKIŞEHIR, TURKEY; 2 SENSIBALL VR, ESKIŞEHIR, TURKEY; 3 HACETTEPE UNIVERSITY, ANKARA, TURKEY

INTRODUCTION: Two Point Discrimination (TPD) test is a widely used method for assessing the ability of the skin to discriminate between two distinct points of pressure. Although it has been previously used to evaluate sensory loss in conditions such as nerve injuries and peripheral neuropathy (1), its use in athletic populations as an indicator of proficiency level has not been well established (2). The purpose of this study was to compare TPD sensation in professional soccer players, amateur soccer players, physically active people, and sedentary individuals.

METHODS: A total of 105 participants were recruited, including 25 SoccerPro, 24 SoccerAmateur, 31 ActiveSport, and 25 Sedentary. TPD tests were performed on the inside and outside of the dominant foot using a calibrated calliper. The selected areas have dual significance as they are commonly used in soccer practice and innervated by different dermatomes (inside: Saphenous Nerve, outside: Superficial Peroneal Nerve). The distance between two points was reduced until the participant couldnt differentiate, and the resulting threshold distance was recorded. The length (FL) and width (FW) of the foot were also measured. For statistical analysis a more useful index is defined: Touch Sensor Density Index (TSDI) was used from the formula TSDI=(FL.FW)/TPD. Logically it is useful for the body/foot/etc. normalization (if area is high TPD is high and vice versa). Some of the variables were not normally distributed so Kruskall-Wallis (nonparametric version of ANOVA) with Dunn's multiple comparisons tests were used for comparisons.

RESULTS: For the inside region, group medians were statistically different ($p<0.001$). The median TSDI of SoccerPro ($p<0.002$) and SoccerAmateur ($p<0.009$) were both significantly higher than that of Sedentary. But there was no difference between SoccerPro and SoccerAmateur median TSDI values ($p>0.9$). For the outside region, group medians were also different ($p<0.0004$). The median TSDI of SoccerPro ($p<0.0002$) and SoccerAmateur ($p<0.04$) were both significantly higher than that of Sedentary. But there was no difference between SoccerPro and SoccerAmateur median TSDI values ($p=0.071$).

CONCLUSION: The results of this study suggest that professional soccer players have a greater sensor density per area to discriminate between two distinct points of pressure compared to sedentary individuals. This finding may be attributed to the repeated tactile stimulation associated with soccer-related practice over the years. The TPD-based TSDI could be a useful method for assessing sensory function in athletic populations, particularly in sports that require significant tactile stimulation. Further research is needed to determine the effects of training (i.e. field training vs VR training) and other factors such as haptic feedback (3) on TPD sensation in athletic populations.

THE COMPARISON OF EEG SIGNALS OF REAL PERFORMANCE AND MOTOR IMAGERY IN THE BADMINTON

ABBASPOUR, K.1, FATHIREZAIE, Z.1, AGHDASI, M.T.1, SCHNEIDER, S.2, ZAMANI SANI, S.H.1

1. UNIVERSITY OF TABRIZ, TABRIZ, IRAN, 2. GERMAN SPORT UNIVERSITY COLOGNE, COLOGNE, GERMANY

INTRODUCTION: Examining sensory information in sports and the study of its neurological views provides a perspective for studying performance, where both cognitive and physical demands are high. In the past decades, psychological research in sports has mainly focused on the decision-making and one of the studied areas is brain activity during real performance and motor imagery. In the sports domain, motor imagery can improve cognitive and motor functions. However, this may be varying with their abilities to perform of an action. Therefore, the main purpose of the project is to comparison of EEG signals of real performance and motor imagery in the badminton.

METHODS: In this causal-comparative research study, the statistical population includes 9 skilled badminton players in the youth age group. Badminton players performed a reaction test in response to monosensory (visual, auditory) and multisensory (audio-visual) in four modes (1. visual, 2. auditory, 3. visual-auditory congruent and 4. visual-auditory incongruence) stimuli. Overall, 96 reaction trials conduct (24 per condition). Also, this study was conducted in 2 conditions (1. during real performance and 2. during motor imagery). Badminton players, based on their position and based on the information they received, had to make the best decision and execute the correct answer with their hand and racket movements. In the second condition, the subject imagery the same movements related to the task for 40 seconds. This task took about 30 minutes for one participant. PsychoPy software was used to design the task. While performing this task, a 32-channel electroencephalogram (EEG) was used to identify the neural activation pattern corresponding to mono and multisensory stimulation. Finally, brain waves were analyzed in EEGLab and Matlab software. Repeated Measures ANOVA was used with a significance level of 0.05 in SPSS23.

RESULTS: Results of the repeated measures ANOVA 2(real performance and motor imagery) ×15 (waves and areas) showed that main effect of performance (motor and imagery) ($F=5.91$, $p=0.04$), main effect of waves ($F=20.03$, $p=0.001$) and the interactive effects of performance*waves were significant ($F=24.54$, $p=0.0001$). Further, the results indicated that there is significant difference in frontal, central, parietal, temporal and occipital areas of theta, alpha and beta waves.

CONCLUSION: So that the alpha wave was higher at the imagery condition in the temporal, central and frontal area and specially with more rate in parietal and occipital area than real performance. In addition, it was showed that beta wave was higher parietal, occipital and frontal and also theta wave was higher in the parietal and frontal area in the real performance than motor imagery condition. The high amount of alpha wave during imaging was consistent with the function of this wave. Also, more activity of frontal and parietal regions is justified in their performance in the field of sensory-motor functions and decision-making.

TRAIN BRAIN INSTEAD OF MUSCLE: IMMEDIATE EFFECT OF NEURO-ATHLETIC TRAINING ON FLEXIBILITY, SERVICE AND UPPER EXTREMITY PERFORMANCE IN ELITE VOLLEYBALL PLAYERS - A RANDOMIZED CONTROLLED TRIAL.

SOYLU, Ç., ALTUNDAG, E., ISGUZAR, G., UN YILDIRIM, N.

UNIVERSITY OF HEALTH SCIENCES

INTRODUCTION: The aim of this study was to evaluate the immediate effects of neuro-athletic training on flexibility, service, and upper extremity performance in elite volleyball players.

METHODS: A total of 20 young healthy elite male volleyball players aged 18-25 years were included in the study. Participants were randomized evenly into one of two groups; the control group (CG) and the neuro-athletic training (NAT) group. The flexibility was assessed by using the sit and reach test; A pocket radar ball coach speed gun was used to measure the serve speed, and upper extremity performance was measured by the Closed Kinetic Chain Upper Extremity Stability Test pre-and post-treatment. Neuro-athletic training included visual reset drills, vestibulo ocular reflex drills, optokinetic training, brock string drills, and convergence and divergence drills. Control participants received no intervention.

RESULTS: Significant improvements were observed in flexibility ($p<0.01$; effect size: 0.91), serves speed performance ($p<0.01$; effect size: 0.93), and upper limb performance ($p<0.01$; effect size: 0.90) in the neuro-athletic group, while all parameters in the control group were similar to before the training.

CONCLUSION: The results of this study showed that neuro-athletic training acutely increased flexibility, serve speed, and upper limb performance. The beneficial outcomes seen in the current study imply that these neuro-athletic training approaches might be used in addition to routine training programs.

ARE YOUR HURDLES REAL, OR JUST IN YOUR MIND? DIFFERENTIATING HURDLING MOVEMENT PATTERNS USING POINT LIGHT DISPLAYS

LO, C.T., LIU, Y.T.
NATIONAL TAIWN NORMAL UNIVERSITY

INTRODUCTION: Hurdlers develop specific hurdling coordination from practicing jumping over hurdles. Hurdlers have also participated in shadow practice: hurdling without hurdles. The constraints model proposes that the coordination patterns of human movement result from organismic, environmental, and task constraints (1). Shadow practice changes the task constraint in producing the movement coordination. Point light display has been used to identify characteristics of coordination patterns. Therefore, the purpose of the study was to examine if the hurdlers could differentiate hurdling movement patterns with or without hurdles using point light displays.

METHODS: Participants included 24 collegiate hurdlers, 25 collegiate non-hurdler athletes, and 25 young adults without sport training. Eight videos, shot from 4 hurdlers practicing with and without a hurdle, were digitized to make the point light display testing videos. As the duration of the original video (normal speed) was too short (~ 0.8 s), we edited the videos to half the original speed to make a set of slow speed videos. A pair of 2 hurdling videos from the same hurdler, one with and one without hurdle, were presented consecutively to the participants who were then asked to identify which video was with hurdle. Two copies of each videos were used in the test for the consistency check. A one sample t test was used to compare the correct rates and the consistent rate to 0.5 and 0.7, respectively. The correct rate was examined using the background (3) by playback speed (2) mixed design ANOVA, with the playback speed as the repeated factor.

RESULTS: The result of the one sample t test on the correct rate for the slow/hurdler group was significantly higher than 0.5 ($p<.05$). The consistent rates of the slow/hurdler and normal/hurdler group were not different from 0.7, while all other groups were lower than 0.7. The ANOVA result showed a significant interaction effect, $F(2,71)=5.48$, $p<.01$. The post hoc simple main effect of experience showed a significantly higher correct rate for hurdlers versus the other 2 groups for the slow speed ($ps<.05$). For the simple main effect of playback speed, only the hurdlers showed significant superior performance on the slow speed than the normal speed ($p<.01$).

CONCLUSION: Hurdlers were able to differentiate hurdling with and without hurdles through the point light display of the joint movement. The superior performance from the hurdlers, especially at the slow speed condition, suggests that perception of biological motion is influenced by the action experience of the observers. The results provide evidence that task constraints influence the movement coordination patterns and shadow practicing hurdling may not facilitate the development of hurdling movement coordination.

HUMANS CAN PREPARE TO MOVE FOR DIFFERENT PURPOSES IN PARALLEL: INFORMATION AND DYNAMICAL SYSTEMS IN DYNAMIC DECISION-MAKING

WAKATSUKI, T., HIBINO, T., HIRAKAWA, T., YAMADA, N.
TOKYO UNIVERSITY OF AGRICULTURE AND TECHNOLOGY

INTRODUCTION: In sports, there are often situations where one must respond appropriately to multiple possibilities under strict time constraints. For example, a baseball batter waits for a fastball; however, when the time comes, batters are able to handle a slow ball like changeup. The batter's swing is not a predetermined swing, which means that the batter has two possibilities, a fastball and a slow ball, and tries to respond to each. In perceptual information processing, just as Rubins vase can appear to be a vase or two faces, multiple perceptual states can be present on a single time axis. However, it is difficult to understand how this theoretical concept can be applied to physical movements that eventually converge to a single state. Then, we focused on the change in motion in mid-air from shooting to passing during a basketball jump shot and examined how far the shooter can respond to the change when the purpose, which was initially uncertain, is suddenly clarified. Furthermore, the final goal of this study is to graphically explain the interaction of information and dynamical systems under uncertain and strict time constrained situations.

METHODS: Ten basketball players performed jump shots with the possibility of the purpose being changed to a pass. The timing of the visual stimuli presentation, which signifies the change in purpose to a pass, was determined and set from the premeasured hangtime of each participant. The light timing was divided into eight conditions (0, 10, 20, 30, 40, 50, 60, and 70%) in increments of 10% from 0% to 70% when the time was normalized to 0% at the take-off time and 100% at the landing time for a total of nine conditions, including the before-jump condition in which the lights were turned on when both feet touched the ground. The success rate of shooting and passing in each condition and the time series coordinate data related to the elbow joint were obtained.

RESULTS: The shots maintained a high success rate regardless of the time at which the visual stimuli were turned on; furthermore, the success rate of the pass did not reach 0% until just before the ball was released (at least approximately 50 ms ago). Furthermore, when analyzing the movements during a possible change in purpose, strategies were observed in which individuals paused the elbow joint angle in mid-air and delayed the timing of the ball release.

CONCLUSION: The most important result, in which the success rate did not reach 0% after the minimum reaction time required to make a choice during the execution of the movement, suggests that the shooters can prepare to shoot and pass in parallel rather than in series. Then, the uncertain state in the information system is reflected in the "pausing" of the

movement (extension of the elbow joint) in the dynamical system. This is an example of how humans prepare to make multiple movements with different purposes in parallel, which can be transferred to either pattern if the movement is analogous to common motions.

TIMING TO PASS THE CENTER OF A DISCRETE MOVEMENT IS MORE ACCURATE THAN FOR STOPPING AT THE END OF A DISCRETE MOVEMENT

LIU, Y.T.1, NEWELL, K.M.2

1 NATIONAL TAIWAN NORMAL UNIVERSITY, TAIPEI, TAIWAN; 2 UNIVERSITY OF GEORGIA, ATHENS, USA

INTRODUCTION: Many superb human performances are time related acts such as the spike from a volleyball attacker and the swing of the bat to hit a home run in baseball. However, the focus of the majority of discrete aiming movement studies has been on spatial accuracy. The impulse variability model of motor control assumes a strong relation between the variability of impulse and the variability of movement in space and time. One of the assumptions from the impulse variability model is symmetry between the acceleration and deceleration profiles. Studies of rapid timing tasks where the goal of the task was passing through a spatial location with a specified target time were mainly based on this assumption (1). The purpose of the study was to examine if movement time was more accurate at the middle of the discrete movement where the peak velocity occurred than at the end of the discrete movement.

METHODS: Twenty-two participants were randomly assigned to a passing through or stopping group. The task was to draw a horizontal line of 30cm on a digital tablet with the target time of 300ms. The participants in the passing-through group were required to pass a vertical line located at the 15cm position 300ms after the start of the task whereas those assigned to the stopping group were to stop at the end of the 30cm line in 300ms. All participants performed 100 trials with the latter 80 trials analyzed. Independent t tests were used to examine the mean movement time (MT), absolute error (AE) of MT and the variable error (VE) of MT between groups.

RESULTS: The passing-through group showed significantly shorter mean MT (316 vs. 372ms), $t(20) = 2.76$, $p = .012$, lower AE (30 vs. 77ms), $t(20) = 2.57$, $p = .018$, and lower VE (35 vs. 51ms), $t(20) = -2.30$, $p = .032$, than the stopping group.

CONCLUSION: With the same goal MT of 300ms, the passing through group was more temporally accurate and less variable than the stopping group. The average velocity of the passing through condition was lower than that of the stopping condition. This was not consistent with the literature where temporal variability tends to decrease with increasing average movement velocity. The instantaneous velocity at the midline is close to the peak velocity of the trajectory whereas the instantaneous velocity drops to zero on stopping. A more comprehensive examination of the temporal accuracy when aiming for passing at different locations of the movement trajectory may provide a better understanding of the control mechanism of temporal performance.

ABNORMAL MOTOR UNIT FIRING PATTERNS AND A STEPPING AGILITY SKILL IN OLDER ADULTS

HIRONO, T.1,2, TAKEDA, R.1, NISHIKAWA, T.1, OKUDAIRA, M.1, WATANABE, K.1

1 CHUKYO UNIVERSITY, JAPAN; 2 RESEARCH FELLOW OF JSPS, JAPAN

INTRODUCTION: Normally, low-threshold motor units discharge at high frequency, whereas high-threshold motor units discharge at low frequency during submaximal contractions. This is well-known as 'onion skin phenomenon'. However, the onion skin phenomenon is often negated in older adults [1]. In older adults, many motor skills, such as an agility, are often impaired. Since the agility skill could be influenced by both neural input to the muscles and muscular functions, we hypothesized that stepping skill would be impaired in older adults with abnormal motor unit firing patterns. We aimed to investigate the difference in the stepping agility skill between older adults with normal or abnormal motor unit firing patterns.

METHODS: Forty-eight community dwelling older adults aged 65 years or older (mean age: 73.6±4.3 years) participated in this study. They performed maximum voluntary isometric contraction (MVC) in knee extensors. High-density surface electromyography was recorded from vastus lateralis muscle during submaximal ramp-up contraction to 50% of MVC. After individual motor units were decomposed, recruitment threshold and firing rate at 40-50% of MVC were calculated. To assess the motor unit firing patterns, participants whose data showed 5 or more motor units could be detected were included in the further analysis. The older adults with normal or abnormal motor unit firing patterns were divided based on the p-values of regression analysis between recruitment threshold and firing rate of individual motor units within individual participants. For stepping test, they were seated in a chair and were instructed to open and close their legs to step across two parallel lines (30 cm apart) as fast as possible for 20 s. The interval times between each step were recorded and the mean and coefficient of variation (CV) of each stepping time were calculated during the whole duration and every 5-s interval.

RESULTS: Thirty-eight older adults were analyzed based on the criteria. The participants were divided into two groups, 15 older adults with normal motor unit firing patterns (N group) with $p < 0.05$ calculated by regression analysis between recruitment threshold and firing rate of individual motor units, and 23 older adults with abnormal motor unit firing patterns (AN group). Mean time and CV of stepping time during the whole duration were not different between two groups ($p = 0.687$, $p = 0.066$, respectively), but the peak CV among every 5-s interval was significantly higher in AN group than N group ($p = 0.044$).

CONCLUSION: Older adults with abnormal motor unit firing patterns would have the impaired ability to perform rapid and regular stepping, which would rely on neural control. The findings suggest the importance of normal motor unit firing patterns for maintaining motor functions in older adults.

IN HEALTHY YOUNG ADULTS, MAT PILATES INDUCES NEUROMUSCULAR FACILITATION OF MAXIMAL ISOMETRIC FORCES DURING KNEE FLEXION AND EXTENSION MOVEMENT

HATTA, A.1, UEMURA, S.1, SHIMODA, M.2, FUKUMOTO, H.2, ISONO, K.3

1 TOKAI UNIVERSITY, KANAGAWA, JAPAN; 2 TOKYO UNIVERSITY OF AGRICULTURE AND TECHNOLOGY, TOKYO, JAPAN; 3 GENERAL INCORPORATED ASSOCIATION PILATES ALLIANCE, TOKYO, JAPAN.

INTRODUCTION: Pilates exercise has become popular for strengthening trunk muscle and increasing flexibility. Recent research found that mat Pilates induced improved multiple isokinetic torque parameters (1) (2) and maximal isometric forces from knee extension and flexion (3) in elderly women. However, limited studies have been conducted to validate the effects of Pilates on isometric muscular strength in young adults. This study aimed to investigate whether mat Pilates training improved maximal isometric forces during knee extension and flexion movements in healthy young adults.

METHODS: The study included 23 college students (aged 21.0 ± 1.0 years) divided into two groups: Pilates group (PG; n = 11) and control group (CG; n = 12). Participants in PG performed a 60-minute mat Pilates exercise once a week for 12 weeks under the supervision of a licensed instructor. CG received no Pilates intervention and was instructed to spend as much of their daily life as possible without physical activity. The maximal isometric forces during knee extension and flexion movements were measured in both PG and CG before and after the intervention.

RESULTS: Height and bodyweight did not differ significantly different between groups. When comparing the pre- (203.96 ± 6.5 Nm) and post 12-week intervention (224.77 ± 14.2 Nm), the PG demonstrated a significant improvement in peak torque of knee extensor muscles during maximal isometric knee extension movement ($p < 0.01$). Furthermore, there was a significant improvement in peak torque of knee flexor muscles during maximal isometric knee flexion movement ($p < 0.05$), when comparing pre- (88.18 ± 7.2 Nm) and post-intervention (96.46 ± 7.7 Nm). Conversely, there were no significant differences for the CG in any of the analyzed variables in the intra-group comparison, pre- and post-intervention.

CONCLUSION: Mat Pilates improves maximal isometric forces during knee flexion and extension movements. These findings imply that Pilates exercise aids in the neuromuscular facilitation of the lower limbs as well as improvement of knee flexor and extensor muscular function in young adults.

THE EFFECTS OF TACTILE STIMULUS ON BIPEDAL POSTURAL SWAY IN EARLY ADOLESCENTS

KOÇ, I., PEKEL, H.A., PEKEL, A.Ö., CENGIZEL, Ç.Ö., CENGIZEL, E.

GAZI UNIVERSITY INSTITUTE OF MEDICAL SCIENCES

INTRODUCTION: The purpose of this study was to investigate the effects of painful and indolent tactile stimulus which was applied through the skin of calf area over bipedal postural sway in early adolescents.

METHODS: 156 adolescents volunteered in the study (n girls=82, n boys=74). They were divided randomly into 3 groups as Painful Stimulus Group (PS) (n=47), Indolent Stimulus Group (IS) (n=55) and the Control Group (C) (n=54). GYKO inertial sensor was used for bipedal postural sway measurements. The data considered from sway measurements were Elliptical Area (EA), Length (L), Mean Distance (MD), Velocity (V) on Medio-Lateral (ML) and Antero-Posterior (AP) directions. PS and IS groups were respectively asked for bipedal postural sway measurement, prone position for 1-minute bilateral calf stimulus and bipedal postural sway measurement again. C group distinctly just lied down for 1-minute without stimulation between the tests. One way ANOVA was used for intergroup comparison and paired sample t-test was used for intragroup comparison.

RESULTS: There was no significant difference between the groups in pre and post-tests. All three groups showed significant increases between the tests in V, AP-L, AP-V. In addition, the PS group showed statistically significant difference in L, ML-L and ML-V. Although there were significant differences, the effect sizes were determined as trivial or small, and the bipedal postural sway responses of girls and boys to tactile stimuli differs.

CONCLUSION: In conclusion investigating the effects of sensory manipulations on bipedal postural sway, we should notice the quality of the stimulus matters. The application area and the quality of the tactile stimuli can affect the bipedal

postural sway parameters differently. This study should be applied for investigating the age and gender effects in different age and gender groups and for customizing the effects of the stimuli characteristics the stimuli should be applied on different body parts.

EFFECTS OF PULSE DURATION AND FREQUENCY ON ELECTROSTIMULATION-EVOKED FORCE: COMPARISON BETWEEN THREE MUSCLE GROUPS

POPESCO, T., GARDET, Q., BOSSARD, J., MAFFIULETTI, N., PLACE, N.

UNIVERSITY OF LAUSANNE

INTRODUCTION: Neuromuscular electrical stimulation (NMES) consists in the application of transcutaneous stimuli to superficial muscles with the goal to evoke visible contractions. The technique is commonly used to improve muscle function but has inherent limitations such incomplete motor unit recruitment and discomfort. Over the recent years, the so-called wide-pulse high-frequency (WPHF) NMES has been introduced to partially overcome these limitations. It has indeed been shown that low-intensity NMES delivered with a pulse duration of 1 ms and a frequency of 100 Hz can generate a progressive increase in plantar flexor tetanic force through central recruitment of motor units called extra force (EF) (Collins, 2007; Wegrzyk, 2015). However, the combination of stimulation parameters other than 1 ms-100 Hz to maximize EF has not been investigated and it is currently unknown if the EF response differs between muscle groups with different composition, architecture or function. The aim of the present study was to assess the impact of the stimulation parameters on the NMES evoked force profile in plantar flexors, knee extensors and elbow flexors of the same participants.

METHODS: Sixteen volunteers, 14 men and 2 women (29±6 yrs, 177±6 cm, 74±11 kg) participated in a familiarization session followed by 3 experimental sessions (one per muscle group), which included twelve 10-s NMES trains separated by at least 2 min of rest and delivered at an intensity set initially to evoke 10% of the maximal voluntary contraction force. Stimulation trains were randomly delivered with a combination of frequencies (20, 50, 100 and 147 Hz) and pulse durations (0.2, 1 and 2 ms). The development of EF was calculated as the relative percent increase in force between the last and the 2nd second of the stimulation.

RESULTS: For the plantar flexors, greater EFs were generated with frequencies of 100 and 147 Hz (80±77%) compared to 20 and 50 Hz (51±57%, $p<0.001$) and with durations of 1 and 2 ms (74±71%) compared to 0.2 ms (48±51%, $p<0.001$). For the knee extensors and the elbow flexors, no difference in EF was observed between any parameter (respectively 51±109% and 26±74%). Higher EFs were generated for plantar flexors (92±76%) compared to elbow flexors (14±39%, $p=0.005$) using the standard WPHF stimulation parameters (100 Hz, 1 ms) but EFs were not significantly different between knee extensors and the two other muscle groups with this frequency and pulse duration.

CONCLUSION: Despite individual variability in the generation of EF depending on the parameters, the wider pulses (1 and 2 ms) and higher frequencies (100 and 147 Hz) induced greater EFs than the other tested parameters for the plantar flexors. The composition, architecture and function of the stimulated muscle seem to influence the generation of EF, which was the highest for the plantar flexors and the lowest for the elbow flexors.

EFFECT OF LEGS STARTING BLOCK POSITION ON KINETICS AND KINEMATICS OF AN HEMIPLEGIC/BRAIN IMPAIREMENT T37 ELITE SPRINTER

MATHONAT, L., MILLOT, B., PRADON, D., SLAWINSKI, J.

NATIONAL INSTITUTE OF SPORTS SCIENCE

INTRODUCTION: Brain impairment (BI) significantly slows down the movement and leads to a reduction of the range of motion of the movement (ROM) and forces (Bezodis et al., 2020; Connick et al., 2015). Specifically, for hemiplegic, this loss of force is not the same in the right or the left side (Beckman et al., 2016). Thus, in starting block sprint phase, the force developed by the right and left leg should be different and the ability of the sprinter to have a balance of force between the right and left could be a strategy to improve sprint performance. The purpose of this study was to compare legs starting block position on kinetics and kinematics of a hemiplegic elite sprinter

METHODS: An elite sprinter (T37) performed 6 maximal 40-m sprints from starting blocks. The athlete realised three sprints with the paretic side in the front position (PSF) in the starting block and three sprints with the paretic side in the rear position (PSR). Average forces, impulses, were measured from the start to the 4th step using force plate (Kisler ; 1000 Hz). During the entire race, instantaneous velocity, maximal velocity, time contact, time flight, steps rate and lenght (V, Vmax,Tc, Tv, SR and SL) were measured using radar (Stalker Pro II; 48 Hz) and an optojump (Microgate, Bolzano). Using the velocity time curve and the model proposed by Samozino et al. (2016), the theoretical force (F0), velocity (V0) and maximal power (Pmax) were calculated.

RESULTS: The results demonstrated that lateral force and impulse were lower in the PSF condition (84 ± 75 vs 70 ± 46 N and 29 ± 41 vs 20 ± 23 N.s-1). Tc, Tv, SR and SL, averaged on the entire sprint, were not different between PSF and PSR, respectively for Tc, 0.142 ± 0.018 vs 0.145 ± 0.022 s for Tv, 0.103 ± 0.021 vs 0.102 ± 0.02 s, for SR 4.1 ± 0.1 vs 4.1 ± 0.4 Hz and for SL 168.5 ± 36.7 vs 168.4 ± 37.1 cm. Concerning the force velocity profile, F0 and Pmax

were greater for PSF condition (respectively for F0 373 ± 25 vs 358 ± 1 N and for Pmax 795 ± 49 vs 766 ± 8 W).

CONCLUSION: For this elite athlete used to start with both feet in front or in a rear position, starting in the PSF condition was the best option. Indeed, less lateral force and impulse are created and a lesser variability in Tc, Tf and SR from the 1st to the 12th step for PSR condition was observed. In addition, F0, Pmax, forces and impulses were greater in PSF compared to PSR (around 4%). The PSF departure may allow a more favourable force transmission during the first step that lead to an improvement of the acceleration phase.

EFFECT OF DIFFERENCES IN TORQUE AND ANGULAR VELOCITY DURING ECCENTRIC MUSCLE CONTRACTION ON SUBSEQUENT REACTIVE STRENGTH

SHIMA, N.

TOKAI GAKUEN UNIVERSITY

INTRODUCTION: eactive-strength qualities have important roles in athletic movements and sports performance. Very little research has investigated the motor control of the reactive strength. The effects of differences in muscle strength and angular velocity during movement in the opposite direction on muscle force have not been clarified. The aim of this study was to investigate the effect of differences in torque and angular velocity during eccentric contraction on subsequent reactive muscle strength.

METHODS: Thirteen male subjects (21±1 yrs) with no injury to the knee joint were performed maximum isometric strength after eccentric contraction at maximum and submaximum (about 50%) with different angular velocity (30°, 90°/sec). The maximum isometric torque, the rate of torque development (RTD), and the muscle activity of the vastus lateralis (VL) by using electromyography (EMG) were measured. In the sitting position, the range of motion of the knee joint was 60 degrees (eccentric contraction from 30° to 90°), and the knee joint was flexed at 90 degrees as the switching point for the measurement of maximum isometric torque.

RESULTS: Maximum isometric torque and its RTD significantly decreased when eccentric muscle contraction was performed at a high angular velocity (90°/sec) and submaximum contraction. However, the EMG of VL was no different between slow and fast angular velocity and eccentric contraction at maximum and submaximum effort.

CONCLUSION: To obtain strong reactive strength and high RTD, it is considered effective to have large muscle strength and slow velocity, and suggesting that it is important not to create slack in the muscle-tendon unit before exerting muscle strength. In conclusion, torque and angular velocity during eccentric contraction affect subsequent reactive muscle strength.

BOY-MAN DIFFERENCES IN THE NEURAL STRATEGY USED TO DEVELOP TORQUE DURING FAST HIGH-INTENSITY CONTRACTIONS

WOODS, S., MCKIEL, A., HERDA, T., KLENTROU, P., HOLMES, M., GABRIEL, D., FALK, B.

BROCK UNIVERSITY

INTRODUCTION: It has been demonstrated that, during maximal contractions, children have a lower rate of torque development than adults (1,2). It has been suggested that this age-related difference in explosive capacity may be due to children's lesser ability to activate their higher-threshold, type-II motor units (MUs)(3). No studies have examined whether MU activation differs between children and adults during contractions performed at high rates. Therefore, this study aimed to examine age-related differences in discrete-MU activation during high-intensity contractions performed at high rates.

METHODS: Nineteen boys and 17 men completed two laboratory sessions. Following a habituation session, maximal knee extension torque (MVC) was determined before completing trapezoidal contractions at 70% MVC at 35%MVC/s (2s to 70%MVC). Trapezoidal contractions were then sustained at the target torque for 12s before being released back to baseline. Surface electromyography of the vastus lateralis was captured by a Delsys Trigno Galileo sensor and mathematically decomposed into individual MU action-potential trains. Average MUAP amplitude (MUAPamp), recruitment threshold (RT), and MU firing rates (FR) at recruitment were then calculated. To characterize the size of MUs recruited with each contraction, MUAPamp was expressed relative to its RT. Group differences in FR at recruitment and the MUAPamp-RT relationship were assessed using ANOVA and linear regression, respectively.

RESULTS: The rate of torque development achieved was not different between boys (30.4±3.2%MVC/s) and men (31.5±2.7%MVC/s)($p=0.32$). The y-intercept, but not the slope of the MUAPamp–RT relationship was significantly ($p=0.008$) greater in men (0.044mV) compared with boys (0.021mV). Additionally, FR at recruitment was significantly greater in men (4.94±1.58pps) compared with boys (4.16±1.58pps) ($p<0.001$; $d=0.42$).

CONCLUSION: During high-intensity contractions at high rates, boys recruited smaller MUs, with lower FR at recruitment compared with men. Moreover, the significantly higher y-intercept of the MUAPamp–RT relationship in men compared with boys suggests that men recruit their larger MUs earlier than boys. Unexpectedly, the MUAPamp–RT slope was not different between groups. This may reflect the need for boys to recruit more MUs compared with men to compensate for their lower FR at recruitment. Overall, our results suggest that boys and men utilize different neural strategies to generate torque at high contraction rates.

TRICEPS SURAE HYPERTROPHY AFTER STANDING VERSUS SEATED CALF-RAISE TRAINING

KINOSHITA, M.1, MAEO, S.1, KOBAYASHI, Y.1, EIHARA, Y.1, ONO, M.1, SATO, M.1, SUGIYAMA, T.1, KANEHISA, H.2, ISAKA, T.1

1 RITSUMEIKAN UNIVERSITY, JAPAN, 2 NATIONAL INSTITUTE OF FITNESS & SPORTS IN KANOYA, JAPAN

INTRODUCTION: The triceps surae consists of the medial gastrocnemius (MG), lateral gastrocnemius (LG), and soleus (SOL). They all cross the ankle joint and function as the main planter flexors. Among them, MG and LG are biarticular muscles crossing the knee joint, and lengthened more in the knee-extended than knee-flexed position. Previous studies have shown that muscle hypertrophy is greater after training at long muscle lengths than training at short muscle lengths, by manipulating a joint angle of the two joints the target biarticular muscles cross (e.g. seated > prone leg curl for the hamstrings, [Maeo et al., 2021] and overhead > push down cable elbow extension for the triceps brachii [Maeo et al., 2022]). Based on these findings, this study examined the effectiveness of calf-raise exercise training performed in a standing position (long muscle lengths) versus seated position (short muscle lengths) for triceps surae hypertrophy.

METHODS: Fourteen untrained healthy young adults participated in this study. They performed calf-raise exercise with one leg in a standing/knee-extended position (Standing-Leg) and the other leg in a seated/knee 90°-flexed position (Seated-Leg) at 70% of one repetition maximum of the corresponding task. Each leg performed 5 sets of 10 repetitions per session (2 s for each of the concentric/eccentric phases), 2 session per week for 12 weeks. Before and after the intervention, T1-weighted axial 3-T MRI scans (FOV: 200*200 mm, slice thickness & gap: 5 mm) were obtained to assess muscle volume of the MG, LG, SOL, and the whole triceps surae.

RESULTS: After the intervention, muscle volume significantly increased in all three muscles and the whole triceps surae for both legs, except for the MG and LG of the Seated-Leg. The changes in muscle volume were significantly greater for the Standing-Leg than Seated-Leg in the MG (9.2% vs 0.6%), LG (12.4% vs 1.7%) and whole triceps surae (5.6% vs 2.1%) ($P \leq 0.011$), but similar in the SOL between Standing-Leg and Seated-Leg (2.1% vs 2.9%, $P = 0.410$).

CONCLUSION: Standing calf-raise is more effective than seated calf-raise for muscle hypertrophy of the triceps surae, especially the MG and LG. However, seated calf-raise is also recommended when one attempts to selectively target the SOL.

EXPLORING MOVEMENT-RELATED CORTICAL POTENTIALS, REACTION TIME AND FORCE PRODUCTION DURING THE SPRINT BLOCK START OF EXPERT AND NOVICE SPRINTERS: A CASE SERIES

BOTHA, M.

STELLENBOSCH UNIVERSITY

INTRODUCTION: Research have identified reaction time and force production as the most important factors for a successful sprint start, which accounts for 5% of the 100 m running time. Additionally, executive functions, sensory integration and motor programming are required to carry out the actions of the sprint start. Relating to cognitive processes, the neural efficiency hypothesis states that those with more experience require less cortical activation to execute a well-trained skill, when compared to someone with less experience. This hypothesis has been extended to athletes, but these brain-body connections have not been investigated in sprinters. This pilot study set out to describe MRCP (movement-related cortical potentials) of novice and expert sprinters before and during the sprint block start to understand movement-related brain activity changes during the movement preparation stage of the sprint block start. Secondary aims were to describe the reaction time, relative force production, speed and acceleration of multiple novice and expert sprint cases during a sprint block start.

METHODS: A case series design was used and four cases (two novice and two expert sprinters) were recruited. Cases completed ten sprint block start trials on an indoor track, while MRCP were recorded via 64-channel EEG. Additionally, reaction time, relative force, speed and acceleration were measured by the FAST start blocks.

RESULTS: The prefrontal cortex and the parietal lobe were identified as hubs of brain activity during the sprint block start, with statistically significant differences found across conditions in the parietal lobe. Lower prefrontal theta, alpha 1, alpha 2 and beta power were observed for the expert sprinter case. Parietal theta, alpha 1, alpha 2 and beta power of all cases appear to be quite similar, but this is inconclusive.

CONCLUSION: The statistically significant differences in parietal alpha and theta power, found across conditions, possibly indicate an increase in working memory and focused attention from the initial rest period until the response to the starting signal. Whereas the lower prefrontal power of the expert sprinter case potentially reflects a decrease in the reliance on executive functions and supports the neural efficiency hypothesis. The similar parietal power of the four cases may be because, regardless of skill level, all cases still had to anticipate the starting signal, integrate the sensory information and prepare the appropriate motor response.

These observations show that MRCP recording during the sprint block start is possible, and contributes new information to the novel field of applied mobile-EEG in cue-based closed-skill sport performance. Currently EEG cannot be used as a tool in the everyday sprint training setup due to the many factors affecting the EEG response and the expertise required to process and interpret the data. In future, with development, EEG may possibly be used as a load monitoring tool to screen for fatigue and impaired performance.

RELATIONSHIP BETWEEN MUSCLE ACTIVITY AND SINGLE-LEG STANDING PERFORMANCE ON A SLACKLINE: A PRELIMINARY STUDY OF NOVICE PLAYERS

KODAMA, K.

TOKYO METROPOLITAN UNIVERSITY

INTRODUCTION: This study aimed to shed light on the skill of slacklining, which is a balance sport that requires players to maintain their body balance dynamically and flexibly. Researchers have investigated the effect of slackline training on balance ability. However, knowledge on the skill of slacklining remains scarce.

In slacklining practice, experienced instructors teach learners ways to maintain balance on a swinging flat belt—a slackline—such as by moving both hands in parallel and concentrating on the perception of the self–environment relationship, while relaxing all body muscles.

Previous studies have shown differences between novices' and experts' skills in terms of upper body coordination, exploratory behavior in lower limbs, and perception (e.g., proprioception, interoception). However, muscle activity during slacklining has not been investigated. We hypothesized that single-leg standing on a slackline is a fundamental slacklining skill and that reducing muscle activity of lower limbs may contribute to whole-body dynamic balancing on a slackline.

METHODS: Six novice (five women, mean ± SD, 21.0 ± 2.0 years old) players who had no slacklining experience participated in our experiment. They were required to perform a single-leg standing task on a slackline that included four 3-minute sessions with 2-minute intervals.

To measure participants' muscle activity during slacklining, we attached an electromyogram sensor on the tibialis anterior (TA), lateral gastrocnemius (LG), vastus lateralis (VL), and biceps femoris (BF). We evaluated the slackline performance by persistence time (PT), which represents the duration for which participants can maintain a single-leg standing on a slackline. Additionally, the average muscle activity during the task was assessed. After choosing the top three trials of PT for each participant, correlations between persistence time and muscle activity were also calcul

RESULTS: As a result of analyzing slackline performance, we identified two different skill groups: novice (n=4, mean PT = 14.1 seconds) and intermediate (n=2, mean PT = 76.0 seconds) levels. By analyzing the correlation between the novice level group's PT and muscle activity, negative correlations were observed for TA (r = -0.46), LG (r = -0.56), and VL (r = -0.66), whereas no correlation was observed for BF (r = -0.14).

CONCLUSION: Reducing muscle activity may boost the slackline performance (i.e., PT) of novice players. Comparisons of lower limb muscle activity indicated that TA, LG, and VL activities increased when postural stability became unstable. Therefore, these muscle activities were correlated with PT. However, no significant correlation with PT was found for BF, probably because relaxing the VL causes flexion of the knee joint.

Further investigations should compare novice players with intermediate and expert players using larger samples. Understanding slackline skills can contribute to the practical application of balance training for sports athletes and facilitate rehabilitation.

COMPARING THE EFFECTS OF A HYPOXIC REPEATED SPRINT TRAINING ON PERFORMANCE IN NORMOXIA BETWEEN MALES AND FEMALES

PIPERI, A., VAN DOORSLAER DE TEN RYEN, S., WARNIER, G., BENOIT, N., FRANCAUX, M., DELDICQUE, L.

UNIVERSITÉ CATHOLIQUE DE LOUVAIN

INTRODUCTION: Males and females exhibit gender-specific characteristics and they therefore respond differently to physical exercise. Yet, females are under-represented in sports and exercise physiology research when compared to males. Due to this gap in research, women are currently given the same training recommendations as men, which may potentially lead them to suboptimal performance. Repeated sprint ability (RSA) is important for sport performance, as it is a key factor in most team and racket sports. Repeated sprint training in hypoxia (RSH) has demonstrated greater improvements in sea-level repeated sprint performance than similar training in normoxia (RSN) in male athletes but has never been investigated in women. This study is therefore investigating the effects of hypoxic repeated sprint training on repeated sprint performance in normoxia in females compared with males.

METHODS: Thirteen male and five female recreational athletes (24.7 ± 0.6 y, practicing a team/racket sport 4.8 ± 1.6 h/week) completed 7 weeks of cycling in normoxia (RSN, FiO2: 0.209, males: n=7, females: n=2) or hypoxia (RSH, FiO2: 0.143, males: n=6, females: n=5). The training consisted of three sets of five 10-s sprints with a recovery of 20 s between sprints and 5 min between sets, twice per week. Before (Pre-) and after (Post-) training, anaerobic performance was evaluated in normoxia by a RSA test and a 30-s Wingate test on the cycle ergometer.

RESULTS: From Pre- to Post- training, the number of sprints during the RSA test increased by 1 repetition in males (11 vs 12) and females (9 vs 10) in RSN. In RSH, the number of sprints increased by 10 (13 vs 23) in males and by 3 (7 vs 10) in females. The average power output of all sprints in males increased by 2% in RSN (623 ± 77 vs 634 ± 91 W) and by 5% in RSH (608

± 61 vs 639 ± 50 W). Similarly in females, power output increased by 1% in RSN (444 ± 56 vs 450 ± 50 W) and by 7% in RSH (451 ±58 vs 485 ± 58 W). In RSN, average power output during the Wingate test increased by 4% in males (653 ± 75 vs 679 ± 58 W) and by 2% in females (450 ± 28 vs 460 ± 1). In RSH, average power output increased by 6% in males (636 ± 51 vs 678 ± 57) and by 8% in females (441 ± 59 vs 478 ± 57).

CONCLUSION: Those preliminary results show that a 7-week hypoxic repeated sprint training improved repeated sprint ability in females in a similar way than in males, through an increase in the number of sprints and in the average power output during the sprints. With the increased participation of women in sport, it is essential to further study their physiology and consequently help them improve exercise performance.

CHANGES IN THE PREFRONTAL CORTEX OXYGENATION LEVELS AFTER 4 AND 8 WEEKS HIGH INTENSITY EXERCISE TRAINING

KUO, Y.H.1, WU, H.J.1,2, CHIANG, T.L.2, LIN, Y.C.2, CHAN, S.H.2

CHINESE CULTURE UNIVERSITY

INTRODUCTION: The near-infrared spectroscopy (NIRS) can evaluate haemodynamic in prefrontal cortex during maximal exercise, and propose to the aerobic fitness influences cerebral oxygenation during exercise [1,2]. Polarized training (POL), and high interval intensity training (HIIT) have been proposed to improve aerobic endurance performance [3]. The impact of these training on cerebral oxygenation levels of changing metabolic demand is less clear. The purpose of this study was to observe which of these two training concepts provides the greatest response on cerebral oxygenation of endurance performance.

METHODS: Twenty-one male college students (age, 19.4 yrs; height, 1.74 m; weight, 67.6 kg) were randomly assigned to receive 8 weeks of either the POL group [zone (Zn) 1, 75%; Zn3, 25%], HIIT group (Zn3, 100%), and control (CON) group. Data were collected from the tests before training (pre-test), after 4 weeks training (mid-test) and after 8 weeks training (post-test), as regards the cerebral oxygenation in prefrontal cortex were continuously monitored, including total hemoglobin (tHb), oxygenated hemoglobin (O2Hb), deoxygenated hemoglobin (HHb), and tissue saturation index (TSI), when performed the Bruce protocol treadmill tests. The maximal oxygen uptake (VO2max) was evaluated during the tests.

RESULTS: The change of VO2max was significantly increasing in POL after 4 weeks (+ 8.4 %) and 8 weeks (+ 12.5 %) than that in CON ($p < .05$). In addition, HIIT was significantly increasing the change of VO2max after 8 weeks (+ 14.0 %) than that in CON ($p < .05$); however, no significant differences after 4 weeks ($p > .05$). During the tests, the O2Hb of prefrontal cortex were significantly higher in POL at mid- and post-tests than at pre-test. Besides, the O2Hb in HIIT at post-test was higher than at pre-test ($p < .05$). No significant differences in tHb, HHb, and TSI were found between groups.

CONCLUSION: After 8 weeks of the differences of high intensity exercise training, both POL and HIIT can improve aerobic capacity. The POL has an earlier physiological effect in healthy college students. These results demonstrated that the improvement of aerobic fitness may relate to improve prefrontal O2 for supplying.

EFFECTS OF EIGHT WEEKS OF ALTITUDE TRAINING ON THE ERYTHROPOIESIS, IRON METABOLISM AND AEROBIC CAPACITY

GAO, H.

SHANGHAI RESEARCH INSTITUTE OF SPORTS SCIENCE

INTRODUCTION: This research was conducted to evaluate the effects of eight weeks of altitude training on erythropoiesis, iron metabolism and aerobic capacity in trained rowers.

METHODS: Twenty-eight trained rowers were divided into altitude training group (AG) or sea-level training group (SG). During the eight-week training camp, the training plan and the training load were almost the same in both groups. VO2peak, the level of red blood cell count (RBC), reticulocyte% (RET%), reticulocyte production index (RPI), high fluorescent reticulocyte(HFR), medium fluorescent reticulocyte(MFR), low fluorescent reticulocyte(LFR) and hemoglobin (Hgb), and the concentration of serum erythroferrone (ERFE), ferritin (FER) and soluble transferrin receptor (sTfR) were measured before and after the eight weeks training camp.

RESULTS: (1) Compared with the pre-value, the VO2peak and the VO2peak to body mass (RVO2peak) increased significantly after eight weeks of training in AG. And no obvious difference of VO2peak and RVO2peak were observed in SG. The change of VO2peak and RVO2peak between AG and SG were significant (+9.41% vs +3.03%, $P=0.038$; +12.83% vs +0.80%, $P<0.01$). (2) After eight weeks of training, the RBC, Hgb and hematocrit (HCT) increased obviously in AG but no statistical difference in SG. The change of Hgb and HCT between AG and SG were significantly (+4.95% vs -3.21%, $P=0.003$; +6.48% vs -1.57%, $P=0.002$). A significant trend of RBC change between the two groups was observed (AG vs SG, +3.19% vs -3.61%, $P=0.061$). Compared with pre-value, no significant change of RET% and RET-He were founded in both groups after eight-week of training. In AG, it exhibited significant elevation of LFR and reticulocyte production index (RPI) while significant decrease of MFR and HFR. There were no group difference in the change of RET%、RET-He、LFR、MFR、HFR and IRF. However, the change of RPI after the training camp between AG and SG was significant（+30.60% vs -4.52%, $P=0.020$）. (3) In AG, no remarkable change of serum ERFE, a significant decrease of serum FER and obvious increase of serum sTfR and sTfR/logFER were observed after eight weeks of training. No statistical change of serum FER, sTfR and sTfR/logFER while a significant increase of serum ERFE were exhibited in SG. The change of serum FER, ERFE, sTfR and sTfR/logFER differed significantly between AG and SG (+17.99% vs +121.31%, $P=0.013$; -36.16% vs -2.96%, $P=0.040$; +82.77% vs -8.87%, $P=0.025$; +108.40% vs -6.96%, $P=0.011$). (4) There was a positive

and significant association between the change of VO2peak and serum sTfR, and the ratio of sTfR to logFER after eight weeks of training.

CONCLUSION: Eight weeks of altitude training appears more effective than sea-level training for improvement of oxygen delivery capacity of the blood and aerobic capacity in trained rowers. Serum sTfR may play an important role in improving the maximal aerobic performance. In the later stage of eight weeks of altitude training, the erythropoiesis is still active.

RELIABILITY OF MUSCLE OXYGEN SATURATION MEASURED WITH A NIRS DEVICE AT VENTILATORY THRESHOLDS DURING INCREMENTAL EXERCISE TESTING ON A BICYCLE ERGOMETER

SCHOCH, R., WAGNER, J., GASSER, B., SCHMIDT-TRUCKSÄSS, A., KNAIER, R.

UNIVERSITY OF BASEL

INTRODUCTION: Measuring muscle oxygen saturation (SmO2) during exercise by Near InfraRed Spectrometry (NIRS) is a non-invasive method to determine muscle oxygen usage. Some studies investigated reliability of this method under steady-state conditions, at different intensities during ramp protocols and maximum load [1] but not at certain intensities as the ventilatory thresholds (VT) during an incremental exercise test typically used for characterization of submaximal exercise capacity. This study intended to evaluate the reliability of SmO2, measured by the PortaMon device at rest, warm-up, VT1, VT2, peak oxygen consumption (VO2peak), and recovery phase in healthy athletes during an incremental exercise test.

METHODS: Twenty-three healthy athletes participated in this investigation. Each subject underwent two cardiopulmonary exercise tests with the same ramp protocol at the same time of day, separated by 7 days. VT1 and VT2 were determined in Test1 and SmO2 was measured with a portable NIRS device (PortaMon, Artinis Medical Systems, Amsterdam, Netherlands). Parameters for Test2 were measured at the same power as the ventilatory thresholds in Test1 to ensure comparability of parameters between both tests. Intraclass correlation coefficients (ICC) were examined for all parameters.

RESULTS: All participants completed two ramp tests with measurement of gas exchange and NIRS. For men, mean VO2peak was 59.2±4.9 mL/kg/min and SmO2 decreased from 66.5±3.3% at rest to 49.9±6.2% at VO2peak and for women, mean VO2peak was 54.0±3.4 mL/kg/min and SmO2 decreased from 67.6±3.3% at rest to 59.9±3.51% at VO2peak.

For rest, warm-up, VT1, VT2 and VO2peak, the ICCs of SmO2 between Test1 and Test2 were r=0.74 (CI95%: 0.48, 0.88), r=0.75 (CI95%: 0.50, 0.89), r=0.86 (CI95%: 0.70, 0.94), r=0.90 (CI95%: 0.79, 0.96), and r=0.77 (CI95%: 0.53,0.90), respectively.

For recovery phase, the ICCs of SmO2 was r=0.41 (CI95%: 0.01, 0.70).

CONCLUSION: The results indicate that the PortaMon device reliably measures SmO2 in healthy athletes during an incremental exercise test on a bicycle ergometer. Test-retest reliability was acceptable for rest, warm-up and VO2peak, good to excellent for VT1 and VT2 and poor for recovery phase. Since ventilatory thresholds are important for evaluating functional capacity in a clinical setting and for prescribing exercise at certain intensities [2], PortaMon may provide useful information on muscle oxygen consumption at these intensities.

COMBINING NEAR-INFRARED SPECTROSCOPY AND HEART RATE VARIABILITY DERIVED THRESHOLDS TO ESTIMATE THE CRITICAL INTENSITY OF EXERCISE

FLEITAS-PANIAGUA, P.R.1, AZEVEDO, R.A.1, TRPCIC, M.1, MURIAS, J.M.1, ROGERS, B.2

1 UNIVERSITY OF CALGARY; 2 UNIVERSITY OF CENTRAL FLORIDA

INTRODUCTION: Establishing the critical intensity of exercise often requires costly tools and/or several testing sessions. Noninvasive approaches such as the muscle deoxyhemoglobin concentration breakpoint ([HHb]BP) and the heart rate variability threshold (HRVT2) determined during ramp incremental (RI) test generally show good group agreement but can display relatively large individual variation. Since these modalities depend on different physiologic subsystems, combining these approaches could decrease that variability. Therefore, this study evaluated whether averaging the heart rate (HR) and oxygen uptake (VO2) responses associated with the [HHb]BP and the HRVT2 improved the accuracy of identifying the HR and VO2 at the respiratory compensation point (RCP).

METHODS: Ten recreationally trained females and eleven males (age range 18-50), performed a 6 min cycling within the moderate intensity domain (60-80 W to calculate VO2 mean response time) prior to a 15 W/min RI test until task failure. Gas exchange, near infrared spectroscopy (NIRS) and, RR interval data recorded during the RI test were used to assess the RCP [1], [HHb]BP [2], and HRVT2 [3] as previously described. Data were reported as means ± standard deviation (SD). The Pearson's r coefficient and the intraclass correlation coefficient (ICC) were calculated for all measurements. The agreement was assessed by Bland Altman plots with limits of agreement (LOA) (±2SD). Comparisons between variables were made using paired t-test accepting a $p \leq 0.05$ as statistically significant.

RESULTS: The HR (158±14, 156±13, 160±14 and, 158±12 bpm) and VO2 (3.08±0.69, 2.98±0.58, 3.06±0.65, and 3.02±0.60 L/min) at the RCP, [HHb]BP, HRVT2, and the combined HRVT2&[HHb]BP (H&HAv), respectively were not significantly different (p>0.05). The mean bias and LOA for VO2 and HR were not significantly different when comparing the RCP vs [HHb]BP (0.10±0.52 L/min; 2±20 bpm), the RCP vs HRVT2 (0.02±0.59 L/min; -2±18 bpm), and the RCP vs H&HAv (0.06±0.47 L/min; 0±15 bpm). The Pearson's r coefficient between H&HAv vs RCP was higher compared to the coefficient between [HHb]BP vs RCP and HRVT2 vs RCP for both, HR (r= 0.85; r= 0.73; r= 0.79, p>0.05) and VO2 (r= 0.94; r= 0.93; r= 0.91, p>0.05). ICC between RCP, [HHb]BP, HRVT2 and H&HAv was 0.93 for VO2 and 0.79 for HR.

CONCLUSION: This study demonstrated that both, the [HHb]BP and the HRVT2 independently provided VO2 and HR responses that strongly agreed with those at the RCP. More importantly, combining [HHb]BP and the HRVT2 (i.e., H&HAv) resulted in estimations of the VO2 and HR at the RCP that displayed smaller variability compared to each modality alone. Thus, the information presented supports the use of the [HHb]BP and the HRVT2 as valuable tools for approximating the VO2 and HR responses at the critical intensity within practical settings.

BLOOD PRESSURE AND SKELETAL MUSCLE OXYGENATION DURING EXERCISE IN HEALTHY YOUNG SUBJECTS

VALTONEN, R., YLINEN, V., MÄKELÄ, K., STENBÄCK, V., TULPPO, M.

UNIVERSITY OF OULU

INTRODUCTION: A large differences is obvious in systolic blood pressure at the same relative exercise intensity in young healthy subjects. Near-infrared spectroscopy (NIRS) techniques measures oxyhemoglobin, deoxyhemoglobin, total hemoglobin, and tissue saturation index (TSI) as a markers of skeletal muscle oxygenation, expressed as surrogates of microcirculation and mitochondrial function, during exercise. We hypothesized that skeletal muscle oxygenation, measured by NIRS technology, is associated with systolic blood pressure and rate pressure product (heart rate x systolic blood pressure) responses at the same submaximal exercise intensity in healthy young subjects.

METHODS: Female (n=8, 29±8 years) and male (n=10, 25±6 years) subjects performed maximal exercise test starting from 0 W (5 min), following incremental protocol starting from 40 W and, increasing load at every 2 min (15 W for females and 20 W for males) until exhaustion. Breath-by-breath gas exchanges and ventilation (Vyaire Medical) was measured continuously to analyze oxygen uptake and respiratory compensatory point (RCP). Heart rate was measured continuously (Polar H10) and blood pressure at every load (Schiller BP 200-plus). NIRS signals were measured from vastus lateralis (Artinis Oxymon Mk III). Baseline blood pressure and heart rate were measured in sitting position before exercise test. The association between systolic blood pressure, rate pressure product and TSI was analyzed at the intensity of RCP.

RESULTS: Maximal oxygen uptake was 42±6 (range 35-50) and 50±7 (range 40-60) ml/kg/min for female and male, respectively. At the intensity of RCP, oxygen uptake was 80±8 % of maximal oxygen uptake, heart rate 88±9 % of maximal heart rate, respiratory exchange ratio 1.00±0.05, systolic blood pressure 185±22 (range 145-230) mmHg and rate pressure product 30159±4877 (range 24000-42550). The change in TSI from baseline (0 W) to the intensity of RCP (-18±10, range from -6 to -34) was strongly correlated with the changes in systolic blood pressure (62±16, range 38-96 mmHg, r=-0.63, p<0.005) and rate pressure product (22183±4610, range 16311-34624, r=-0.65, p<0.004) from baseline to the intensity of RCP (Spearman´s correlation). The change in systolic blood pressure or rate pressure product from rest to RCP did not correlate with maximal oxygen uptake or age.

CONCLUSION: Cardiac workload response to equal submaximal exercise intensity (RCP) is strongly associated with skeletal muscle oxygenation properties in young healthy subjects. Highly elevated cardiac workload during exercise may be triggered by altered skeletal muscle oxygenation probably due to the impaired microcirculation and/or mitochondrial function even in healthy young subject.

THE EFFECTS OF REMOTE AND LOCAL ISCHEMIC PRECONDITIONING ON LOCAL MUSCLE ENDURANCE AND TISSUE OXYGENATION

IDA, A., IMASHIOYA, R., SASAKI, K.

UNIVERSITY OF TOKYO

INTRODUCTION: Ischemic preconditioning (IPC) has been used for improving exercise performance but its effect on local muscle endurance is still controversial. Because IPC not only induces cardiovascular and endocrine responses but may also have an impact on local tissue oxygenation, we hypothesized that the effect of IPC on local muscle endurance depends on where IPC is applied. The purpose of this study was to investigate the acute effect of IPC with two different locations on the number of repetitions, muscle tissue oxygenation, and muscle activity in low-load elbow flexion exercise.

METHODS: In Experiments 1 and 2, eight healthy males performed unilateral elbow flexion exercise at 30% of one repetition maximum to failure on two occasions at least four days apart. Before the exercise, four sets of pneumatic compression and subsequent release (5 minutes each) were applied with an occlusive (220 mmHg, IPC) or light (20 mmHg, SHAM) pressure. Biceps brachii muscle activity and tissue oxygenation were recorded using surface electromyography and near-infrared spectroscopy, respectively, during the exercise and then averaged for 5 repetitions each at the beginning, in the middle, and at the end of exercise. Rate of perceived exertion (RPE) was measured immediately after the exercise.

To examine the effect of remote (RIPC) and local IPC (LIPC), a pneumatic cuff was attached to both thighs in Experiment 1 and to the exercise arm in Experiment 2, respectively. A washout period of at least 2 weeks was allowed between Experiments 1 and 2.

RESULTS: In Experiment 1, the application of IPC did not affect the number of repetitions (RIPC 80.0 ± 12.7; SHAM 71.2 ± 20.1, P = 0.241), RPE, muscle activity or muscle tissue oxygenation dynamics during exercise. In Experiment 2, although the application of IPC did not affect the number of repetitions (LIPC 87.0 ± 24.7; SHAM 81.4 ± 38.9, P = 0.501), RPE or muscle activity, significant interactions between time and condition were found for oxygenated hemoglobin (P = 0.011) and total hemoglobin (P = 0.023). Post-hoc analysis revealed significant differences in oxygenated hemoglobin (adjusted P < 0.01) and total hemoglobin (adjusted P = 0.024) between IPC and SHAM at the end of exercise.

CONCLUSION: These results suggest that local but not remote IPC influences tissue oxygenation dynamics in the working muscle. The increase in oxygenated blood volume, however, may not improve local muscle endurance probably because of the decreased oxygen utilization at the end of exercise.

THE EFFECTS OF MATCHED INCREASES IN CEREBRAL BLOOD FLOW WITH EXERCISE OR HYPERCAPNIA ON SERUM AND PLASMA BRAIN-DERIVED NEUROTROPHIC FACTOR IN YOUNG ADULTS

NORTHEY, J., MCWHIRTER, L., GOLDSMITH, C., MCCARTHY, V., RATTRAY, B.

UNIVERSITY OF CANBERRA

INTRODUCTION: Despite the volume of research attempting to characterise the brain-derived neurotrophic factor (BDNF) response to exercise, there are few studies designed to investigate mechanisms of the transient increases observed. We propose that increases in cerebral blood flow and resultant shear stress are a likely target as it is the only exercise-related mechanism that stimulates both endothelial and platelet release of BDNF. This study utilised matched increases in cerebral blood flow using exercise or hypercapnia to attempt to isolate this specific mechanism of BDNF release.

METHODS: Six healthy younger adults (27.8 ± 5.5 years; female: n = 2) completed three experimental conditions in a randomised-counterbalanced-cross-over order: 1) 20 minutes of moderate-intensity cycling on a stationary recumbent bicycle; 2) 20 minutes of seated mild-hypercapnia where participants inhaled a mixture of room air and a medical grade gas (10% CO2, balance air) from an open-ended mixing reservoir; or 3) a time-matched rested control. Mean cerebral blood velocity in the middle cerebral artery (MCAvmean) was monitored using 2Mhz transcranial doppler ultrasound throughout each intervention. The exercise and hypercapnia conditions were designed to elicit matched increases in MCAvmean of 30%. Pre- and post-blood samples were collected to measure the circulating concentrations of BDNF in serum and plasma. A full blood count at both time points allowed for the determination of free vs platelet-bound BDNF levels and accounted for platelet release during the experimental conditions. The study was approved by the University of Canberra Human Research Ethics Committee (HREC-2046) and participants provided written informed consent.

RESULTS: MCAvmean increased compared to baseline and the control condition by similar levels for the exercise and hypercapnia conditions. Serum BDNF, which represents the total circulating BDNF, increased for exercise (effect size β: 1.03) and hypercapnia (β: 0.56), compared with control. By comparison, plasma BDNF, which reflects the bioavailable pool of BDNF, increased by similar levels following exercise (effect size β: 1.21) and hypercapnia (effect size β: 1.27). There was a slight increase in platelet count with exercise (β: 0.45) and a decrease with hypercapnia (β: -0.33), which may explain some of the differences in the response of serum BDNF between exercise and hypercapnia.

CONCLUSION: These initial findings suggest that increases in cerebral blood flow may be an important pathway for acutely increasing the circulating concentration of BDNF, particularly the bioavailable pool in the plasma. Designing exercise interventions to target the mechanisms of BDNF release specifically may offer a novel and efficient research method and intervention to optimise brain health. The use of hypercapnia may also be a novel technique to isolate the effects of blood flow and vascular health on BDNF and broader brain health.

SIMULATED HYPOXIA PROCEDURES: ORIGINAL INSIGHTS AND PERSPECTIVES FROM THE CLINICAL PHYSIOLOGY OF HYPOXIC RESPONSE PROJECT

BONDI, D., SANTANGELO, C., PIETRANGELO, T., FULLE, S., ANNARUMMA, S., VERRATTI, V.

UNIVERSITY OF CHIETI - PESCARA

INTRODUCTION: The organ-level response of humans as altitude increases has been an intriguing field of research for the past century. In addition to field studies, stress tests for clinical purposes and special training sessions are used as altitude simulation procedures. Indeed, hypoxic exercise tests, performed under normobaric conditions, appear to be relevant in preventing high-altitude pathology and can be conducted prior to further exposure. This study aimed to fill the gap of simulated procedures in hypoxia both from the point of view of exercise testing and personalized training.

METHODS: A total of 17 healthy young students (9 f and 8 m, 23.3±4.9 years old, BMI 23.60±4.50 kg/m2) were recruited for this cross-over study consisting of three trials: control (≈160 m asl), moderate (≈2,500 m asl), and high (≈3,500 m asl) simulated altitude, conducted on separate days. The procedures were carried out using the Everest Summit II altitude generator associated with a tent (Hypoxico, USA) and participants spent ≈ 30 minutes each time inside the tent. Mean Arterial Pressure (MAP) was calculated as (2*DBP+SBP)/3 by measuring BP before and 1 minute after the experiment. Peripheral saturation (SpO2) was measured with a finger probe used before and at the end of the experiment. RM-ANOVAs with one between (sex) and two within (hypoxia and before-after) factors were used for analysis of MAP and

SpO2 responses, after controlling for sphericity, homogeneity of variances, and Q-Q plots. All trials were medically supervised.

RESULTS: Randomization of administration was confirmed: only 4 participants (22.2%) guessed the order of trials (expected proportion: 16.7%, χ2 test p=0.527). The volume of CO2 in the inhaled air during the time spent in the tent followed a one-phase exponential decay, very similar between the control (O2=20.38%, CO2=0.25%) and hypoxic trials (O2=15.40%, CO2=0.26%). MAP was overall lower in females than males (p=0.005, η2p=0.425, η2G=0.327) and did not differ across conditions. SpO2 decreased at the end of the experiment in both hypoxic conditions (p<0.001, η2p=0.937, η2G=0.758), down to 91.2±1.6% and 86.9±1.9% at 0.150±0.002 and 0.135±0.002 of FiO2, respectively, with no differences by sex. The SF ratio increased from control (481±6) to hypoxia (609±12 at moderate and 645±14 at high simulated altitude). The trend of SF followed a linear regression of the equation SpO2 = 1.416*FiO2 + 68.83 (r=0.852; Sy.x=1.731).

CONCLUSION: The procedures proved to be safe. Troubleshooting included climatic stresses inside the tent (possible hot temperature and low relative humidity) and possible data acquisition problems from the devices due to altered air composition. Accurate measurement of FiO2 and FiCO2 can be implemented in bioenergetic studies during simulated hypoxia to correct data from metabolimeters calibrated outside the tent. The typical and personal profile of SF ratio should be defined to optimize and monitor hypoxic training.

EXERCISE RESPONSES TO HEART RATE CLAMPED CYCLING WITH GRADED EXTERNAL LIMB COMPRESSION

GIRARD, O., LI, S.N., SHAYKEVICH, A., IHSAN, M.

THE UNIVERSITY OF WESTERN AUSTRALIA

INTRODUCTION: Understanding how an additional stressor to exercise can alter the internal-external load relationship (e.g., heart rate achieved in reference with work done) is important for optimizing exercise prescription. For instance, environmental manipulations (i.e., acute exposure to systemic hypoxia or heat stress) may reduce the mechanical demand of exercise without a concomitant decrease in cardiovascular stimulation. Heart rate clamped cycling with graded external limb compression represents a potential therapeutic solution for individuals with acute (e.g., athletes recovering from an injury) or chronic dysfunction (e.g., patients suffering from musculoskeletal disorders) who may be unable to fully load their locomotor system. This study aimed to quantify the acute effects of graded external limb compression on the interaction between changes in mechanical output, muscle oxygenation trends and perceptual responses to heart rate clamped cycling.

METHODS: On the same day, twenty-five adults (21 men) performed six, 6-min cycling bouts (24 min of recovery) at a clamped heart rate corresponding to their first ventilatory threshold at 0% (unrestricted), 15%, 30%, 45%, 60% and 75% of arterial occlusion pressure (AOP) with the cuffs inflated bilaterally from the fourth to the sixth minute. Power output, arterial oxygen saturation (pulse oximetry) and vastus lateralis muscle oxygenation (near-infrared spectroscopy) were monitored during the final three minutes of pedaling, while perceptual responses (modified Borg CR10 scales) were obtained immediately after exercise.

RESULTS: Compared to unrestricted cycling, average power output for minutes 4–6 decreased exponentially for cuff pressures ranging 45–75% of AOP (P<0.001). Peripheral oxygen saturation (~96%) remained unchanged (P=0.472). Deoxyhemoglobin changes were larger at 45–75% versus 0% of AOP (P=0.036), whereas higher total hemoglobin values occurred at 60–75% of AOP (P<0.001). Sense of effort, ratings of perceived exertion, pain from cuff compression, and limb discomfort were exaggerated at 60–75% versus 0% of AOP (P<0.001).

CONCLUSION: When cycling at a clamped HR, cuff pressures of at least 45% of AOP applied bilaterally are required to reduce mechanical output significantly in reference to non-BFR, with exponential power decrements occurring thereafter. However, practitioners need to be cognizant that higher occlusion levels also accentuate muscle deoxygenation and exercise-related sensations.

CP-MH30 Injury Prevention in Sports Medicine

THE USEFULNESS OF THE JAPANESE INJURY SURVEILLANCE SYSTEMS FOR SPORTS INJURY PREVENTION

MASHIMO, S., OGAKI, R., OGURA, A., NISHIDA, S., ITO, A., WAKI, H., HIRONO, J., HIRAMATSU, Y., HAGIWARA, M., HARA, K., ODA, K., YOSHIDA, N.

1. OSAKA ELECTRO-COMMUNICATION UNIVERSITY

INTRODUCTION: Injury surveillance systems (ISSs) are necessary to continuously record high-quality sports injury data. There are 15 ISSs in the world [1]. Five ISSs are in Japan, most of which are based on insurance benefits or condolence payment systems [2]. Guidelines such as the Australian Sports Injury Data Dictionary (ASIDD) and consensus statements have been published with recommendations on definitions and methods of collecting sports injury data [3]. This study assessed the usefulness of the ISSs in Japan for injury prevention by comparing the included variables within the ISSs with variables recommended in the ASIDD.

METHODS: The ASIDD provides guidelines for classifying sports injury data collection. It classifies data into three categories: core, strongly recommended, and recommended [3]. Two authors independently assessed the amount of information in the Japanese ISSs according to the ASIDD guidelines by using a scoring system [4]. The two authors discussed and reached a consensus in case of disagreements. The scoring system was '1' for data item present (could be coded according to the ASIDD guidelines) and '0' for data item absent (in the ASIDD but not in the Japanese ISSs). The k statistic was used to analyse inter-rater agreement.

RESULTS: The inter-rater agreement ranged from k = 0.096 (Japan Rugby Football Union Condolence Benefit System) to k = 0.449 (Personal Accident Insurance for Student Pursuing Education and Research). In comparison with the ASIDD, the Japan Rugby Football Union Condolence Benefit System had the highest overall score of 21 out of 30. In the category of core, all items recommended by the ASIDD were included in all five Japanese ISSs. In contrast, the score in the strongly recommended category ranged from 6 (Personal Accident Insurance for Student Pursuing Education and Research) to 10 (Japan Rugby Football Union Condolence Benefit System) out of 15. The scores in the recommended category ranged from 2 (Sport Safety Association Accident Insurance and International Budo University Sports Club Injury Survey) to 4 (Japan Rugby Football Union Condolence Benefit System) out of 8. Items recommended by the ASIDD that were not captured in all five Japanese ISSs included specific injury place, advice given to the injured person, referral, grade/level of play, time of presentation for treatment, and reason for presentation.

CONCLUSION: The five ISSs in Japan included all core data items recommended by the ASIDD. However, only 67% (10 out of 15) of the strongly recommended items and 50% (4 out of 8) of the recommended items were included. Therefore, the excluded items need to be included in future ISSs in Japan for sports injury prevention.

GENES WITHIN THE TGF-BETA SUPERFAMILY AND RECEPTORS ARE ASSOCIATED WITH RISK OF ACL INJURY IN A LARGE INTERNATIONAL COHORT.

LAGUETTE, M.N., LEGETT, C., BRENT, M., DLAMINI, S., CIESZCZYK, P., FICEK, K., HAGER, C., STATTIN, E., NILSSON, K.G., ALVAREZ-RUMERO, J., EYNON, N., FELLER, J., TIROSH, O., POSTHUMUS, M.

UNIVERSITY OF CAPE TOWN

Collins, M., September, A.V.

INTRODUCTION: ACL rupture is an acute musculoskeletal soft tissue injury with a lengthy recovery time, which can have a large economic burden because of possible loss of income and high cost of surgical repair. Alterations to the biomechanical properties of the joint can predispose patients to other conditions such as early-onset knee osteoarthritis post-surgery. Variants within genes of the transforming growth factor beta (TGF-beta) family and their receptors, namely TGF-beta receptor III (TGFBR3), and adhesion protein TGF-beta-induced (TGFBI), were recently implicated with risk of ACL rupture in a South African (SA) population using de novo data from whole exome sequencing. The aim of this study was to Investigate the association of variants TGFBR3 rs1805113 A>G, TGFBR3 rs1805117 T>C and TGFBI rs1442 G>C with ACL rupture risk in other populations.

METHODS: A large case-control genetic association study was conducted comprised of 1329 physically active and unrelated participants from SA (n=459), Sweden (SWE n=211), Poland (POL n=291), and Australia (AUS n=368). Genotyping was performed using Taqman© SNP genotyping assays and the QuantStudio 3™ Real-Time PCR System and software (Applied Biosystems, Waltham, MA, USA). Statistical analysis was performed using R statistical packages and correction for multiple testing was achieved using false discovery rate (FDR) method.

RESULTS: The TGFBR3 rs1805117 T/T genotype was significantly associated with increased risk of ACL ruptures (p= 0.007, OR: 0.70, 95% CI: 0.54 - 0.91) as well as a non-contact ACL ruptures. When sex stratification was performed, the A allele of TGFBR3 rs1805113 A>G (OR: 1.42, 95% CI: 1.07-1.89) was associated with an increased risk of injury while the G allele of TGFBI rs1442 G>C (OR: 0.70, 95% CI: 0.53-0.93) was associated with reduced risk of injury (p=0.042) in female participants. No association was observed in males after correction for multiple testing.

CONCLUSION: Similar to the original SA study, TGFBR3 rs1805113 and TGFBI rs1442 modulated the risk of ACL ruptures in females of a larger international cohort. Moreover, TGFBR3 rs1805117 modulated the risk of ACL rupture when all participants were analysed. This work supports the hypothesis that variation within the transforming growth factor beta family plays a partial role in modulating susceptibility to knee ligament injuries. Further work is warranted to improve our understanding of genetic sequence variability at these gene loci together with other genes in the extracellular remodelling pathway in susceptibility towards identifying potential novel therapeutic targets.

HOW TO REDUCE PEAK FORCES IN ARTISTIC GYMNASTICS TO PREVENT IMPACT INJURIES?

AARTS, M.J.J.J.1,2, VAN MEURS, S.M.2, EBBEN, I.2

FONTYS UNIVERSITY OF APPLIED SCIENCES / INNOSPORTLAB S-HERTOGENBOSCH

INTRODUCTION: Artistic Gymnastics is characterized by high impacts on the body through push-offs, landings and dismounts on apparatuses like floor and balance beam. Due to this many high impact forces, injuries may occur [1,4,5]. The most common cause of gymnastics injuries originates in the contact between the gymnast and the surface [2-4]. Because of the high impact forces and the large amount of gymnast-surface contacts in Artistic Gymnastics, reducing the impact forces seems an appropriate strategy to reduce the incidence and severity of gymnastics injuries [2,3]. A possible solution

is 'soft gymnastics' in which more damping materials and softer apparatuses are used. This research aims to study the damping characteristics of often used additional materials in training practice to prevent impact injuries in Artistic Gymnastics.

METHODS: Impact studies with several gymnastics materials and apparatuses like damping mats, Airtracks and softer beams were performed to determine the damping values of these commonly used materials in Artistic Gymnastics' training and competiton. The maximal impact force (Fmax), deflection and rebound of a falling weight (impactor) on the surface of a number of gymnastics apparatuses with and without damping materials were measured using a drop hammer measuring system. In this way the supposed damping effects of these often used additional materials were determined.

RESULTS: A commonly used Airtrack with a thickness of 10 cm, inflated to a pressure of 155, 205, and 245 millibars, led to an average decrease of Fmax of 824 N (21%), 611 N (15%), and 450 N (11%) respectively, compared to the commonly used competition floor. When the Airtrack was placed on top of the competition floor, the decrease was even larger (1512 N (38%), 1392 N (35%) and 1320 N (33%)) when compared to the floor alone. Using a multimat or protection padding on top of the Balance Beam resulted in a decrease of Fmax of 4426 N (50%) and 2892 N (33%), respectively when compared to Balance Beam alone. The protection padding on the vault table only showed a small decrease in Fmax (159 N (3%)), which was comparable to the result of a multimat on the floor (172 N (4%)).

CONCLUSION: In conclusion, using damping gymnastics materials or apparatuses result in a decrease in Fmax, but the extent of the decrease varies widely with the used damping materials and is largely dependent on the characteristics of these materials. The use of these materials seems, despite the large variation, an effective strategy to reduce Fmax in Artistic Gymnastics training practice. Innovations concerning apparatus equipment, competition rules and training adjustments can contribute to the further development and implementation of 'soft gymnastics' in training as well as competitions to prevent or diminish high impact related gymnastics injuries.

TEMPORAL ADAPTATIONS IN MUSCLE SYNERGY ACTIVATION DURING CHANGE-OF-DIRECTION MOVEMENTS FOLLOWING 8 WEEKS OF NEUROMUSCULAR AND TECHNIQUE TRAINING

MOHR, M., SCHARBERT, J., FEDEROLF, P.

UNIVERSITY OF INNSBRUCK

INTRODUCTION: Injury prevention exercise programs (IPEPs) that include specific drills to improve change-of-direction (COD) technique can reduce movement-related risk factors for non-contact anterior cruciate ligament (ACL) ruptures, e.g. a high peak knee abduction moment upon initial contact [1]. What is unknown are the underlying changes in muscle activation patterns. This information is important because muscle activation regulates how knee movement and external knee moments affect ACL loading.

Research question: What are the effects of an 8-week IPEP combined with either COD-specific or unspecific training on the activation patterns of lower extremity muscle synergies during a 135° COD?

METHODS: Sports science students (n=21, 43% female) completed a supervised 8-week IPEP including strength and balance exercises plus either COD drills (CODG, n=11) or linear sprinting drills (control group, CTRG, n=10). Excitations of nine muscles of the right (cutting) leg were measured pre- and post-training using surface EMG during six maximum-speed COD trials. The filtered and normalized EMG signals were subjected to non-negative matrix factorization to build one muscle synergy model for both groups and time points consisting of four synergy modules (M1-M4) and corresponding synergy activations. This model explained over 90% of variance in the input EMG data. Principal component analysis was used to extract the three principal features of each synergy activation waveform. The corresponding principal component scores were investigated for 'group*training' interactions using a two-way repeated measures ANOVA (alpha=0.017 [corrected for multiple comparisons], effect size (ES) partial eta-squared).

RESULTS: A significant interaction effect (p=0.002, ES=0.392) was observed for the third principal waveform feature of synergy module M1. This module predominantly represented hamstring muscle activation with co-activation from quadriceps and gluteus medius muscles throughout the final foot contact of the COD. The CODG showed a more constant activation of M1 throughout the ground contact phase following training, while the CTRG showed an opposite trend leading to the interaction effect. We did not observe significant interaction effects (p>0.023) for any other waveform features of M1-M4 although some showed large effect sizes (ES>0.14).

CONCLUSION: An 8-week IPEP including COD-specific drills resulted in different adaptations of synergistic muscle activation profiles compared to an IPEP with linear sprinting drills. Detecting such adaptations to IPEPs might improve our understanding of the underlying mechanisms through which IPEPs prevent injuries. For example, the more constant co-activation of hamstrings, quadriceps, and gluteal muscles observed in the current study may help to prevent knee valgus collapse and limit ACL strain during a COD [2].

DIFFERENT SPRINTING STRATEGIES IN SPRINTERS WITH AND WITHOUT CHRONIC ANKLE INSTABILITY

ARAKAWA, H.1, OKUDAIRA, M.2, TANIGAWA, S.1, MAEMURA, H.1, TAKASHI, F.1

1: UNIVERSITY OF TSUKUBA, 2: CHUKYO UNIVERSITY

INTRODUCTION: Chronic ankle instability (CAI) is a chronic disorder caused by acute lateral ankle sprains (1). During gait, CAI patients exhibited altered movement patterns characterized by augmented ankle inversion and plantarflexion, which could increase the risk of subsequent ankle sprains and any other joint injuries (2). In sprinting, the ankle joint demonstrated greater plantarflexion at touchdown compared to slow running (3). Since sprinting is a vital component of many explosive sports events, it is imperative for clinicians to understand the effects of CAI on sprinting. Thus, this study aimed to compare the sprinting kinematics of the lower extremities in individuals with CAI and healthy controls.

METHODS: Seven male Japanese college sprinters with CAI and 7 matched healthy control sprinters performed 5-second steady-speed running at 7.5 m/s on a treadmill (ORK-7000, Ohtake Root Kogyo). Three-dimensional marker motion was recorded using an 18-camera motion capture system (Vicon Motion Systems, Ltd., Oxford, the UK). We calculated the joint angles using the joint coordination system of each hip, knee, and ankle joint. The running cycle was normalized to 100%, with the ground contact to subsequent ipsilateral ground contact. Statistical parametric mapping method (SPM) was used to analyze mean lower extremity kinematics between groups. The significance level was set at 0.05.

RESULTS: During the stance phase, the CAI group demonstrated increased ankle dorsiflexion angle (9% of gait phase, $p<0.05$; 0-19% of gait phase, large effect size), increased knee flexion angle (1–9% of gait phase, $p<0.05$; 0-20% and 93-100% of gait phase, large effect size), and increased hip flexion angle (0–15% and 64–100% of gait phase, large effect size) compared to the control group. There were no significant differences in ankle, knee, and hip joint angles in the horizontal and frontal planes during the whole sprinting cycle.

CONCLUSION: This study showed that individuals with CAI had unique lower extremity kinematics in the sagittal plane during sprinting at 7.5 m/s. CAI group represented the increments of ankle dorsiflexion angle and knee and hip flexion angle from the late swing phase to the stance phase. This altered kinematics can have protective effects which may help resist large external loads during sprinting. However, this protective kinematics contrasts with general sprinting kinematics. Therefore, these adaptations could potentially lead to a decrease in sprinting performance. Further research is needed to determine the influence of other biomechanical factors such as kinetics and muscle activity.

USING MACHINE LEARNING TO IDENTIFY RISK FACTORS FOR RUNNING-RELATED INJURIES – RESULTS FROM THE 1-YEAR PROSPECTIVE COHORT STUDY (SMART INJURY PREVENTION).

HOLLANDER, K., SANCHEZ-ALVARADO, A., FOHRMANN, D., CREMANS, K., BREUKER, K., HOENIG, T., STÜRZNICKEL, J., ROLVIEN, T., RAHLF, L.

MSH MEDICAL SCHOOL HAMBURG

INTRODUCTION: Despite its popularity and definite health benefits, running is associated with a high number of running-related injuries (RRI). Several risk factors have been elaborated over the last decades, such as training-related, biomechanical, and medical parameters and an interrelation of these parameters seems plausible. Thus, a machine learning approach was used in this study to determine RRI risk factors and their interplay.

METHODS: A prospective cohort study was conducted over 12 months including competitive adult runners (running at least 20km per week and being injury-free for at least 3 months).1 Baseline assessment included medical examination, questionnaires (demographics, sport and injury history, menstruation, medication), and musculoskeletal blood laboratory tests. Furthermore, biomechanical evaluation was performed in a laboratory with motion capture (Qualisys AB, Sweden) and markerless software (Theia Markerless, Canada) and on a 400m track with inertial measurement units and magnetic cells (Humotion GmbH, Muenster, Germany). During the 12 months, individual continuous data were collected weekly for occurring injuries (OSTRC2; athletemonitoring.com; FITSTATS Technologies, Inc., Moncton, N-B, Canada) or per training session for biomechanical data (Humotion GmbH, Muenster, Germany) as well as training load (session duration, rating of perceived exhaustion and GPS data, strava.com; Strava, Inc., San Francisco, CA, USA). Any occurring injury was followed up and precisely diagnosed by a medical assessment with possible imaging in specialized running/sports medicine clinics. The main outcome was the injury incidence (injuries per 1000h of running exposure). A machine learning model will be used to learn the interrelation and ranking of possible risk factors with a sensitivity analysis.

RESULTS: For this study, 120 runners (33.3% female, 40.4±10.1 years, 176.4±7.9 cm, 70.6±9.5 kg, BMI 22.6±10.1 kg/m2) were included. Of these, 6 (5%) did not start reporting. Overall, included participants (95%) reported 11717.7 hours of cumulative running. Furthermore, 95 injuries were reported from 48 participants (prevalence 42.1%, 95%CI 30.2-54.0). RRI incidence was 8.1/1000h of running exposure (95%CI 6.5-9.7). The most frequent diagnoses were Achilles tendinopathy (n=13), iliotibial band syndrome (n=8), and hamstring muscle strains (n=5). As of writing the abstract, the machine learning analysis is still to be conducted.

CONCLUSION: This study is the first prospective cohort study in runners to use continuous data collection combined with an extensive medical, bone health, and biomechanical baseline assessment analyzed via machine learning. The results

of this study will give an insight into the interplay of RRI risk factors and may be a basis for possible multidimensional risk reduction strategies using novel machine learning techniques.

CO-CREATING AN INTERVENTION TO REDUCE INJURY RISK IN COMPETITIVE ADOLESCENT DISTANCE RUNNERS ENROLLED ON ENGLAND ATHLETICS' YOUTH TALENT PROGRAMME.

MANN, R.H.1, DAY, J.1, CLIFT, B.C.2, BARKER, A.B.1

1. UNIVERSITY OF EXETER; 2. UNIVERSITY OF BATH.

INTRODUCTION: Efforts to reduce the risk of injury in youth athletes have typically adopted a 'top-down' approach where previous interventions have been developed for athletes, rather than allowing athletes (and other key stakeholders) to be involved in this process. Such an approach often leads to a decreased intervention effect in real-world settings. To counteract this issue, we co-created an intervention to reduce injury risk in competitive adolescent distance runners (16-18 years) enrolled on England Athletics' Youth Talent Programme.

METHODS: Adopting a 'co-creation approach' to intervention development, we completed six sequential steps: (1) identifying and describing the problem; (2) establishing a stakeholder group to help support intervention development; (3) surveying potential end-users to assess knowledge, behaviours, and preferences about injury risk reduction; (4) delivering stakeholder workshops to discuss information created from steps 1 and 3, and generate ideas about possible intervention content and form; (5) hosting sub-group meetings to discuss how existing evidence can support intervention content and form; and (6) developing content to include as part of a 'minimum viable product.' Each step informed the next, whereby the research team actively reflected upon and tailored the co-creation process.

RESULTS: A total of 21 stakeholders (9 females), across England, participated in the intervention development, including adolescent distance runners (n = 4), their parents/carers (n = 5), England Athletics coaching staff (n = 6), healthcare professionals (n = 3), and research scientists (n = 3). Across six workshops and two sub-group meetings, informed by the development of four short reports (including survey results), agreement was reached that an intervention to reduce the risk of injury in competitive adolescent distance runners should: (1) be focused on gradual onset (i.e., overuse) lower limb musculoskeletal injuries; (2) prioritise primary prevention; (3) include a diverse set of content (i.e., physical and psychosocial); and (4) improve competitive adolescent distance runners' self-awareness and knowledge of injury risk, whilst being framed positively ('healthy performance'). The agreed intervention content included nine topics: (1) training load and pain management; (2) recovery and nutrition; (3) specific exercise programmes; (4) description of typical injuries; (5) injury psychology; (6) sport specialisation; (7) growth and maturation; (8) relative energy deficiency in sport; and (9) female athlete health. The intervention will be accessible online and is intended to be used by competitive adolescent distance runners (end-user) year-round.

CONCLUSION: Using a 'co-creation approach' has led to the development of a broad and integrative intervention to reduce the risk of injury in competitive adolescent distance runners. Adopting this approach should improve the acceptability, feasibility, and effectiveness of the intervention when implemented in real-world settings.

on behalf of the Intervention Development Stakeholder Group.

GENETIC VARIATION WITHIN STRUCTURAL GENES COL12A1 AND TNC EXPLAIN SOME OF THE VARIABILITY OF KNEE ROTATION MEASUREMENTS

SEPTEMBER, A.V., BECKLEY, S., DEY, R., STINTON, S., VAN DER MERWE, W., BRANCH, T., POSTHUMUS, M., COLLINS, M.

UNIVERSITY OF CAPE TOWN

INTRODUCTION: Understanding the functional components of the collagen fibril, the major building block of tendon and ligament, remain an area of investigation of connective tissue injury. To this end, variants within COL1A1 and allelic interactions between variants within COL5A1, COL11A1 and COL11A2 have been reported to associate with modulating specific measurements of knee laxity within the non-dominant leg. The COL1A1, COL5A1, COL11A1 and COL11A2 genes encode for α chains within types I, V and XI collagen, which are structural components of the collagen fibril within ligaments and other connective tissues. Type XII collagen, on the other hand, is located on the surface of the fibril and is a homotrimer encoded by COL12A1. Similarly, to the other collagen encoding genes, COL12A1 mutations have been implicated in connective tissue disorders with joint hypermobility as one of the symptoms. Although not a member of the collagen family, tenascin C, which is encoded for by TNC plays a critical regulatory role in connective tissue biology. Both TNC and COL12A1 have been found to share a putative stretch responsive enhancer region. Therefore, the expression of both genes are upregulated by mechanical loading. The aim of this study was to investigate whether COL12A1 and TNC variants are associated with knee laxity measurements and computed knee ligament length changes. The dominant leg undergoes more adaptation to repeated loading in comparison to the non-dominant leg. Therefore, due to the presence of the stretch responsive region within the COL12A1 and TNC promoters, these associations were investigated in both the non-dominant and dominant legs.

METHODS: One hundred and fourteen healthy participants were assessed for genu recurvatum (knee hyperextension), anterior-posterior tibial translation, external-internal tibial rotation, and ligament length changes during knee rotation of both legs. Participants were genotyped for COL12A1 (rs970547 A/G) and TNC (rs1061494 T/C, rs2104772 T/A and rs1138545 G/A).

RESULTS: The TNC rs1061494 TT genotype was associated with significant decreased measurements of external (TT: 4.8 [4.0; 5.6] °; TC: 5.8 [4.7; 6.9] °; CC: 5.4 [5.0; 6.2] °; P=0.008) and internal (TT: 5.2 [4.5; 5.8] °; TC: 5.9 [4.9; 6.7] °; CC: 6.1 [5.9;

6.3] °; P=0.002) tibial rotation, as well as slack (TT: 15.6 [13.8; 17.7] °; TC: 18.9 [14.9; 21.3] °; CC: 18.1 [16.7; 18.9] °; P=0.011), in only the dominant leg. Similarly, the COL12A1 rs970547 AA genotype was also associated with significant decreased measurements of external (AA: 5.0 ± 1.3°; AG+GG: 5.9 ± 1.5°; P=0.011) and internal (AA: 5.5 ± 0.9°; AG+GG: 6.0 ± 1.3°; P=0.042) tibial rotation in the dominant leg. The TNC rs1061494 CC genotype was associated with significant larger measurement changes during internal to external rotation of the ACL bundles (posterior ACL - TT: 2.7 ± 1.3 mm; TC: 2.6 ± 1.0 mm; CC: 4.0 ± 1.5 mm; P<0.001) within the non-dominant knee. The TNC rs1061494 TT and COL12A1 rs970547 AA genotypes, together with male sex explained 26% of the variance in external rotation of the dominant leg. Within the dominant leg, these two genotypes, together with COL1A1 genotypes and body mass explained 26% of the variance in internal rotation, while only the TNC genotype together with COL1A1 genotypes, sex and BMI explained 28% of the variance in slack.

CONCLUSION: These findings suggest that COL12A1 and TNC genotypes are associated with internal-external rotation of the dominant knee in healthy individuals, while the TNC genotype is associated with ACL length changes in the non-dominant knee. Taken together, it is reasonable to propose that loading conditions may potentially impact the ACLs length during internal to external rotation and that an individual's genetics may play a partial role in this response.

ARE COMMERCIAL GENETIC INJURY TESTS PREMATURE?

COLLINS, M., SEPTEMBER, A.V.

UNIVERSITY OF CAPE TOWN

INTRODUCTION: Several direct-to-consumer (DTC) genetic testing companies have emerged that claim to be able to test for susceptibility for musculoskeletal injuries. Although there are several publications on the emergence of this industry, none have critically evaluated the evidence for the use of genetic polymorphisms in commercial tests. The aim of this review was to identify, where possible, the polymorphisms and to evaluate the current scientific evidence for their inclusion.

METHODS: Companies that market DTC genetic tests for risk of exercise-associated injuries were identified. The product, genes tested and claims about the test were extracted directly from the company's webpage and/or the sample report the company has placed in the public domain. A review of the literature was performed for the major identified polymorphism included in the commercial tests.

RESULTS: The most common polymorphisms included COL1A1 rs1800012, COL5A1 rs12722 and GDF5 rs143383. The current evidence suggests that it is premature or even not viable to include these three polymorphisms as markers of injury risk. A unique set of injury specific polymorphisms, which do not include COL1A1, COL5A1 or GDF5, identified from genome-wide association studies (GWAS) is used by one company in their tests for thirteen sports injuries. However, of the 39 reviewed polymorphisms, 22 effective alleles are rare and absent in African, American and/or Asian populations. Even when informative in all populations, the sensitivity of many of the genetic markers was low and/or have not been independently validated in follow-up studies.

CONCLUSION: Therefore, the current evidence suggests it is premature to include 36 of the reviewed polymorphisms identified by a GWAS approach in commercial genetic tests. However, the association of MMP7 rs1937810 with Achilles tendon injuries, and SAP30BP rs820218 and GLCCI1 rs4725069 with rotator cuff injuries should be further investigated. Based on current evidence it remains premature to market any commercial genetic test to determine susceptibility to musculoskeletal injuries.

PREDICTING NON-CONTACT ANKLE SPRAINS THROUGH ASSESSMENT OF ASYMMETRICAL LOWER-LIMB FUNCTIONAL PERFORMANCE: A PROSPECTIVE STUDY WITH 318 YOUTH TAEKWONDO ATHLETES

GUAN, Y.1,2, BREDIN, S.2, TAUNTON, J.2, WARBURTON, D.2

1 YUNNAN UNIVERSITY; 2 UNIVERSITY OF BRITISH COLUMBIA

INTRODUCTION: The ankle sprain is the most common type of non-contact injury in Taekwondo [1,2]. Due to the unilateral nature of Taekwondo kicks, inter-limb asymmetries in the lower extremities may develop in the long-term training and competition [3]. The use of inter-limb asymmetries in tests such as the unilateral jump tests and the Star Excursion Balance Test (SEBT) has been widely reported in predicting non-contact sport injuries [4,5]. Evaluating the risk of non-contact ankle sprains in youth Taekwondo athletes through inter-limb asymmetries in the performance of these commonly used and easily accessible tests would be of great value. Thus, this study aimed to examine the relationship between inter-limb asymmetries in the jump tests and SEBT performance and non-contact ankle sprains in youth Taekwondo athletes.

METHODS: 318 male youth Taekwondo athletes, aged 6-17, participated in this prospective study. Baseline assessments were performed to determine inter-limb asymmetries in the single-leg countermovement jump, hop, triple-hop test, and SEBT. The athletes were then followed for a period of 12 months to record any incidents of non-contact ankle sprain injuries.

RESULTS: A total of 23 athletes suffered from a non-contact ankle sprain injury during the study. Athletes with higher inter-limb asymmetry in single-leg countermovement jump height showed a significantly increased risk of non-contact ankle sprain (odds ratio [OR] for 1% increase in asymmetry, 1.051; 95% Confidence Interval [CI], 1.017-1.085; p = 0.003). An asymmetry of 14.16% in single-leg countermovement jump height was found to be a cut-off point for evaluating the risk of non-contact ankle sprain in female youth Taekwondo athletes (asymmetry □14.16% vs. <14.16%: OR, 5.130; 95% CI, 2.002-13.143; p = 0.001).

CONCLUSION: Inter-limb asymmetry in single-leg countermovement jump performance can be used to predict non-contact ankle sprains in male youth Taekwondo athletes. Proper evaluation of such asymmetries has the potential to enhance injury prevention strategies for youth athletes participating in sports.

SEX DIFFERENCES IN EXOGENOUS GLUCOSE OXIDATION FOLLOWING AN ORAL GLUCOSE TOLERANCE TEST IN HEALTHY ACTIVE ADULTS

ESTAFANOS, S., WEST, D., KOUSSIOURIS, A., ANTONEN, E., FRIESEN, B., GOVETTE, A., MOORE, D.R., GILLEN, J.B.

UNIVERSITY OF TORONTO

INTRODUCTION: Females have been reported to have blunted exercise-induced improvements in insulin sensitivity in response to a 75g oral glucose tolerance test (OGTT) compared to males. However, providing the same absolute dose of glucose to males and females typically results in a larger relative glucose dose in females when normalized to body surface area, body mass, or fat-free mass, which may complicate interpretations of sex-comparative studies in exercise metabolism. Furthermore, the measurement of blood glucose during the OGTT only reflects glucose clearance from the blood and not its metabolic fate. Enriching a 75g OGTT with a 13C-labelled stable isotope tracer allows for the measurement of glucose oxidation via breath sampling, which can provide insight into the impact of exercise or inactivity on the metabolic fate of orally ingested glucose. To enhance our understanding of the relationship between sex and postprandial glucose metabolism in response to an OGTT, this project aimed to characterize blood glucose concentration and glucose oxidation during an OGTT in healthy males and females.

METHODS: Males (n=10; 24±5 yr; 72±9 kg; 22±2 kg/m2) and females (n=9; 24±7 yr; 61±7 kg; 22±2 kg/m2) completed an at-home metabolic trial via Zoom. Following 3 days of physical activity monitoring and a 12 h overnight fast, participants consumed a 75g OGTT enriched with 75mg (0.1%) [U-13C6] glucose tracer. Breath samples and finger-stick capillary glucose measurements were collected while fasted, and every 30 min postprandially for 3 h. Breath samples were analyzed for 13CO2 enrichment via isotope-ratio mass spectrometry (IRMS). Estimated carbon dioxide production (VCO2) was used to determine exogenous glucose oxidation, expressed as cumulative percent dose recovery (PDR) of the 75g glucose drink.

RESULTS: Blood glucose (peak, mean, and area under the curve) during the OGTT was not different between males and females ($p>0.05$). Interestingly, females exhibited greater exogenous glucose oxidation than males, with a PDR at 3h of 62.0±12.3% versus 48.8±6.5% in males ($p=0.008$). Neither postprandial mean blood glucose nor glucose oxidation were related to total body mass ($r=0.1$-0.2, $p>0.05$), lean mass ($r=-0.2$-0.3, $p>0.05$), body surface area ($r=-0.2$-0.3, $p>0.05$), pre-trial step count ($r=-0.1$-0.3, $p>0.05$) or moderate-to-vigorous physical activity ($r=-0.2$-0.3, $p>0.05$).

CONCLUSION: Despite similar postprandial blood glucose concentrations in response to a 75g OGTT between sexes, females oxidize a greater amount of ingested glucose than males over 3 hours of recovery. Sex differences in glucose oxidation could not be explained by differences in body anthropometrics or pre-trial physical activity. These results may be important to consider when designing sex-comparative studies investigating the effects of exercise on postprandial glucose metabolism.

SUB-MAXIMAL OXYGEN CONSUMPTION ENHANCED BY 4 WEEKS OF HIGH-INTENSITY TRAINING WITH BLOOD FLOW RESTRICTION

GERNIGON, M., DESANLIS, J., COLIN, A., COTTIN, F., GORDON, D.

UNIVERSITÉ PARIS-SACLAY, FRANCE

INTRODUCTION: Blood Flow Restriction (BFR) training consists of exercising with inflated pressure cuffs to occlude venous return and limit oxygen delivery to the muscle [1]. Improvements in central and peripheral adaptations have been evidenced following high-intensity interval training (HIIT) combined with BFR [2]. However, cardiorespiratory adaptations during submaximal exercise following HIIT+BFR are poorly documented. Thus, this study aimed to determine if HIIT+BFR is effective in enhancing sub-maximal cycling efficiency.

METHODS: 25 participants (11 females, 14 males; 19 ± 7 years old; 175 ± 8 cm; 67 ± 8 kg) were trained 3 times a week for 4 weeks with BFR at different levels of occlusion (G1 = 20 mmHg (SHAM); G2 = 40% Limb Occlusion Pressure (LOP); G3 = 60% LOP). Training consisted of 4 to 7 cycling bouts of 90s HIIT+BFR performed at 90% of VO2max, interspersed with 2 min recovery bouts, with deflated cuffs. Pre-and post-training VO2max, Gas Exchange Threshold (GET) and Respiratory Compensation Point (RCP) were assessed. Pre-and post-submaximal responses were assessed during 10 min at baseline (BL; i.e. 50w for females, 100w for men), 6 min at moderate (MOD; i.e. BL+50%(GET – BL)), 10 min at BL, and 6 min at heavy (HEV; i.e. GET+20%(RCP – GET)) intensities. Filtered and averaged last 2 min of each bout were compared using mixed ANOVA and post hoc analysis.

RESULTS: Despite having no effect on VO2max, HIIT+BFR had an effect on submaximal respiratory data only for G3, with a significant decrease of VO2/kg during the first BL (G3: 20.3 ± 2.3 vs 17.3 ± 2.8 mL/min/kg, $p < 0.01$), and the second BL

bout of the sub-maximal test (G3: 20.2 ± 2.9 vs 17.9 ± 2.9 mL/min/kg, $p < 0.05$). Training also decreased VCO2 for G3 on the first (G3: 1.3 ± 0.2 vs 1.1 ± 0.2, $p < 0.01$) and the second BL bouts (G3: 1.2 ± 0.3 vs 1.1 ± 0.2, $p < 0.05$), but increased VCO2 for HEV bout (G3: 2.7 ± 0.6 vs 2.9 ± 0.6 L/min, $p < 0.05$).

CONCLUSION: 4 weeks of HIIT+BFR was sufficient to increase the sub-maximal cycling efficiency only for G3 by reducing VO2 and VCO2 at baseline intensity. The application of greater pressure probably increased the blood pooling in the muscles and the metabolites accumulation [3]. Thus, these findings highlight the utility of using higher pressures for BFR, particularly when training is performed at high intensity.

EFFECT OF AT-HOME BODYWEIGHT INTERVAL EXERCISE BEFORE OR AFTER BREAKFAST ON POSTPRANDIAL GLYCEMIA, AND POST-EXERCISE PERCEPTIONS OF APPETITE AND FAT OXIDATION IN FEMALES

GOVETTE, A., GILLEN, J.B.

UNIVERSITY OF TORONTO

INTRODUCTION: Bodyweight interval exercise (BWE) is a form of interval training that can be performed without specialized exercise equipment or facility access. It has been demonstrated that performing BWE at home 3 times per week for 12 weeks improves cardiorespiratory fitness (1); however, the physiological response and metabolic health benefit of a single session of at-home BWE is not well characterized. Considering that nutrient provision around exercise can modify physiological responses to exercise (2), characterizing the effect of low-volume BWE performed before vs. after a meal may increase translation to real-world settings. The purpose of this study was to investigate the effects of a single session of at-home BWE, performed before or after breakfast, on postprandial glycemia and post-exercise perceptions of appetite and fat oxidation.

METHODS: In a randomized and counterbalanced order, 12 females (age: 23±2 yr; BMI: 22±2 kg/m2) completed two virtually monitored trials in the follicular phase of the menstrual cycle. Participants followed a pre-recorded exercise video at home involving 10 x 1-min whole-body exercises, interspersed with 1-min recovery, either 5 min before (EX-FED) or 10 min after (FED-EX) a liquid mixed-macronutrient breakfast (470kcal). Heart rate (HR) and rating of perceived exertion (RPE) were measured during exercise, and capillary blood samples were obtained every 15 min for 2 h postprandial. A portable breath analyzer (Lumen©) and visual analog scales measured fat oxidation and perceptions of appetite during 3 h of exercise recovery, respectively.

RESULTS: There was no difference in exercise-induced mean HR (85 ± 5% HRmax) or RPE (14 ± 2) between FED-EX and EX-FED ($p>0.05$). Postprandial glucose concentration was lower in FED-EX vs. EX-FED at 30 min (6.4 ± 1.1 vs. 7.8 ± 1.2 mmol/L; $p<0.01$) and 45 min (5.9 ± 0.7 vs. 7.1 ± 1.1 mmol/L; $p<0.05$), and increased significantly from baseline in EX-FED (7.8 ± 1.2 vs. 5.3 ± 0.45 mmol/L; $p<0.0001$) but not FED-EX (6.4 ± 1.2 vs. 5.5 ± 0.68 mmol/L; $p>0.05$). Perceptions of appetite were also lower in FED-EX vs. EX-FED at pre-exercise (20.25 ± 12.55 vs. 55.77 ± 19.85 mm, $p<0.001$), post-exercise (25.15 ± 15.61 vs. 47.08 ± 18.19 mm, $p<0.05$) and cumulatively over the 3.5 h trial as reflected by a more negative AUC for overall appetite perceptions (-87.63 ± 58.51 vs. -42.06 ± 34.96 mm, $p<0.05$). Compared to pre-exercise, fat oxidation was transiently elevated 0-30 min post-exercise (4.03 ± 0.37 vs. 4.29 ± 0.33 %CO2, $p<0.05$), but was not different between conditions.

CONCLUSION: Performing at-home BWE after, compared to before, breakfast lowers postprandial glycemia and perceptions of appetite in healthy inactive females. These findings suggest that performing exercise after rather than before a meal may optimize the acute metabolic health benefits of exercise.

CHANGES IN TEMPERATURE AND PH INFLUENCES THE EFFICIENCY OF MUSCLE MITOCHONDRIA IN MICE

TRANBERG, C.

UNIVERSITY OF COPENHAGEN

INTRODUCTION: It is well known that there is a decline in exercise efficiency during moderate to high intensity exercise. The cellular energetics and homeostasis are challenged during exercise, which is considered to influence the efficiency of the mitochondrial oxidative phosphorylation. However, the mechanism behind the loss of efficiency within the exercising muscles during exercise is not fully understood. We know that the temperature in the exercising muscle increases during exercise while the pH decreases.

Therefore the aim of the present study was to examine how increased temperature and decreased pH influences the mitochondrial efficiency and respiratory capacity in isolated mitochondria from the quadriceps muscle of wild type mice.

METHODS: Mice were euthanized at 12-16 weeks of age, and the quadriceps muscle was extracted, and then homogenized for isolation of mitochondria (n= 10). The measurements of the mitochondrial respiration were conducted using High Resolution Respirometry (Oxygraph-2k; Oroboros, Innsbruck, Austria) with four different temperature and pH settings: 1. 37°C, 7.4 pH, 2. 37°C, 6.8 pH, 3. 40°C, 7.4 pH and 4. 40°C 6.8 pH.

Mitochondrial efficiency was estimated by determining the ratio between the amount of ATP produced per oxygen atom reduced, also termed the P/O ratio. The protocol for the isolated mitochondria consisted of pyruvate (5 mmol/l) + malate (2 mmol/l) (state 2) followed by a small non-saturating amount of ADP (200 µmol/l) to determine the P/O ratio. When the flux rates reached baseline levels (state 4), a saturating concentration of ADP (5 mmol/l) and Mg (3 mmol/l) was added. A two-way ANOVA was performed to test for the effect of temperature and pH.

RESULTS: The study showed that a combination of increased temperature and decreased pH resulted in a significant lower P/O ratio ($p<0.05$) and a significantly higher state 2 and 4 leak respiration ($p<0.0001$ and $p<0.001$) in the isolated mitochondria. However, the change in temperature itself did not affect the P/O ratio significantly. The increased temperature did result in an increased leak respiration during state 2 ($p<0.01$). Furthermore, the P/O ratio and leak respiration was not significantly affected by the lower pH.

CONCLUSION: According to the results, the efficiency of the mitochondrial oxidative phosphorylation seems to be affected by a combination of an increased temperature and a decreased pH, which is the same homeostatic alterations that happens in the muscles during exercise. Though several other homeostatic perturbations occur in muscle cells during exercise, these findings suggest that mitochondrial efficiency seems to decline during exercise, which may play a role in the decline in exercise efficiency.

CROSS-VALIDATION OF A NEW GENERAL POPULATION RESTING METABOLIC RATE PREDICTION EQUATION BASED ON BODY COMPOSITION

GEPNER, Y.

TEL AVIV UNIVERSITY

INTRODUCTION: Current prediction equations for resting metabolic rate (RMR) validated in a relatively small sample with high-individual variance. This study determined the accuracy of five common RMR equations and proposed a novel prediction equation, including body composition.

METHODS: A total of 3,001 participants (41±13y;BMI 28.5±5.5kg/m2;48% males) from nutrition clinic in Israel were measured by indirect calorimetry to assess RMR. Dual-energy X-ray absorptiometry used to evaluate fat mass (FM) and free-fat mass (FFM). Accuracy and mean bias were compared between the measured RMR and the prediction equations. A random training set (75%, n=2,251) and a validation set (25%, n=750) were used to develop a new prediction model.

RESULTS: All the prediction equations underestimated RMR. The Cunningham equation obtained the largest mean deviation [-16.6%;95% level of agreement (LOA) 1.9,-35.1], followed by the Owen (-15.4%;95% LOA 4.2,-22.6), Mifflin-St. Jeor (-12.6;95% LOA 5.8, -26.5), Harris-Benedict (-8.2;95% LOA 11.1,-27.7), and the WHO/FAO/UAU (-2.1;95% LOA 22.3,-26.5) equations. Our new proposed model includes sex, age, FM, and FFM and successfully predicted 73.5% of the explained variation, with a bias of 0.7% (95% LOA -18.6,19.7).

CONCLUSION: This study demonstrates a large discrepancy between the common prediction equations and measured RMR and suggests a new accurate equation that includes both FM and FFM.

MEASURED AND PREDICTED RESTING METABOLIC RATE OF PARALYMPIC ATHLETES

WEIJER, V.C.R., JONVIK, K.L., RISVANG, L., VAN DAM, C.H.J., RAASTAD, T., VAN LOON, L.J.C., VAN DIJK, J.W.

HAN UNIVERSITY OF APPLIED SCIENCES

INTRODUCTION: Resting metabolic rate (RMR) is an important determinant of daily energy expenditure. In Paralympic athletes, resting metabolism may be affected by a unique body composition, missing or inactive body parts, and neurological conditions. This study aimed to assess the RMR and its potential predictors in Paralympic athletes. Secondly, we evaluated the level of agreement between athletes' measured and predicted RMR.

METHODS: In this cross-sectional study, the RMR of 67 Paralympic male (n=37) and female (n=30) athletes competing in various sports was assessed. Disabilities that may affect RMR included spinal cord injury (n = 22), neurological disorders (n = 8) and spasms (n = 16). RMR was assessed by ventilated hood indirect calorimetry, body composition was assessed by dual energy X-ray absorptiometry and a fasted blood sample was collected by venipuncture. Multiple regression analyses were conducted with measured RMR as dependent variable and based on previous literature, age, fat free mass, blood concentrations of triiodothyronine (T3) and thyroxine (T4), the presence of a spinal cord injury, neurological condition and spasms as independent variables. Furthermore, measured RMR was compared with estimated RMR according to commonly used prediction equations (including revised Harris and Benedict (H&B), Cunningham, Schofield, and others) and prediction equations developed for spinal cord injury patients (Chun and Nightingale). Differences between measured and predicted RMR were analyzed by Bland-Altman analysis, individual accuracy, and intraclass correlation (ICC).

RESULTS: The age, height, body mass and fat free mass were 29±10 y, 1.62±0.19 m, 63.1±11.2 kg and 43.9±7.3 kg for females, and 26±8 y, 1.71±0.20 m, 69.7±14.5 kg and 55.5±10.5 kg for males, respectively. The measured RMR was 1386±258 and 1686±302 kcal/day for females and males, respectively. Regression analysis identified fat free mass, T3 concentration and the presence of a spinal cord injury as the main predictors of RMR (adjusted $R2=0.71$; $F=50.3$; $p<0.001$).

Despite minor proportional bias (r=-0.220; p=0.009), the Chun equation scored best on accuracy (63% of individuals within 10% of measured RMR), had a good reliability (ICC 0.79) and a low bias and limits of agreement (-67 kcal; -433.9 to 300.2 kcal) compared with measured RMR. Also, the H&B equation, based on weight instead of fat free mass, predicted RMR with small bias (13 kcal), good reliability (ICC 0.77), but slightly higher limits of agreement (-369.1 to 395.6 kcal) and less individual accuracy (56% of individuals within 10% of measured RMR) compared with the Chun equation.

CONCLUSION: In conclusion, fat free mass, T3 concentration and the presence of a spinal cord injury are the main predictors of RMR in Paralympic athletes, accounting for 71% of the variance in measured RMR. Both the Chun and the H&B equations show good agreement with the measured RMR, and should therefore be considered the preferred prediction equations for the RMR of Paralympic athletes.

EXOGENOUS LACTATE AUGMENTS EXERCISE-INDUCED IMPROVEMENT IN MEMORY BUT NOT IN HIPPOCAMPAL NEUROGENESIS

DEUNSOL, H., JISU, K., SUNGHWAN, K., INKWON, J., TAEHO, K., HUN-YOUNG, P., KIWON, L.

PHYSICAL ACTIVITY & PERFORMANCE INSTITUTION / EXERCISE & NUTRITION LABORATORY

INTRODUCTION: Adult hippocampal neurogenesis (AHN), the lifelong process of formation of new neurons in brain, plays an important role in learning and memory. Therefore, promoting AHN is considered a substantial way to prevent or ameliorate cognitive deficits, which is important for improving the quality of life. Exercise substantially promotes AHN; however, the molecular mediators of exercise-induced AHN are unknown. Notably, lactate was considered as a key mediator of exercise-induced AHN. Therefore, we hypothesized that exercise with lactate intake could augment exercise-induced AHN.

METHODS: This study conducted for 5 weeks with 7-week-old ICR male mice and was comprised two independent experiments. Experiment 1 (n=9 per group) was mainly for biochemical analysis, immunoblotting (IB) and immunohistochemistry (IHC), and experiment 2 (n=8 per group) was for behavioral analysis, Y-maze test and Radial arm maze (RAM). Mice were randomly divided into four groups: sedentary without lactate intake (vehicle, VEH), sedentary with lactate intake (LAC), exercise without lactate intake (EXE+VEH) and exercise with lactate intake (EXE+LAC). 3g/kg of sodium lactate was orally administrated. Lactate administration and exercise training was conducted 5 times per week. EXE+LAC were administrated lactate immediately after every exercise training. Exercise training was performed at moderate intensity (60 %VO2max) using treadmill. At the end, Y-maze test and RAM was performed to measure spatial working memory and reference & retention memory respectively. From dissected hippocampus, neurogenesis and expression of AHN-relevant proteins were evaluated by IHC and IB respectively.

RESULTS: From results of IHC, cell proliferation (Ki67+) of LAC tended to increase compared to that of VEH (p=0.064) and neuronal differentiation (DCX+) of LAC significantly increased compared to that of VEH (p=0.03). However, there was no difference between EXE+VEH and EXE+LAC in Ki67+ and DCX+. From results of RAM, performance of the task of EXE+LAC was significantly improved most rapidly. Furthermore, the improved reference memory was significantly retained only in EXE+LAC. Also, from results of Y-maze, the spatial working memory was significantly improved only in EXE+LAC. From results of IB, expression of AHN-relevant hippocampal FNDC5 of EXE+LAC was significantly enhanced compared to that of EXE+VEH (p=0.007). Additionally, hippocampal BDNF, PGC1α, and MCT2 expression of EXE+LAC was higher than that of EXE+VEH by 20%, 9%, and 19%, respectively (but not statistically significant).

CONCLUSION: Our study shows that exercise with lactate did not augment exercise-induced AHN. Nevertheless, the co-treatment augmented exercise-induced improvement in memory. Furthermore, AHN-relevant hippocampal proteins were effectively upregulated by the co-treatment. Therefore, we suggest that lactate has a potential to be developed as a novel supplement that improves the positive effects of exercise on the hippocampus and memory.

THE INDIVIDUAL AND COMBINED EFFECTS OF EXERCISE AND THREE CONSECUTIVE NIGHTS OF PARTIAL SLEEP DEPRIVATION ON EXECUTIVE FUNCTIONS

BADARIOTTI, J.I., MAYES, H.S., MILLER-DICKS, M., WILLIAMS, T.B., PARKER, M.O., ANDO, S., COSTELLO, J.T.

UNIVERSITY OF PORTSMOUTH

INTRODUCTION: Partial sleep deprivation (PSD) has been shown to impair executive function (EF) performance in humans [1]. Conversely, moderate-intensity exercise (MIE) has an ergogenic effect on acute EF performance. However, the potential for MIE to ameliorate any impairments in EF after PSD has not been thoroughly investigated. Therefore, this study examined the individual and combined effects of PSD and MIE, on acute EF performance.

METHODS: In a randomised control crossover study, twelve healthy adults (7 males, 5 females) [mean ± SD, age: 23 ± 2 years; height: 170.8 ± 11.3 cm; mass: 66.2 ± 10.1 kg; body mass index 22.6 ± 2.2 kg·m-2; VO2max 42.1 ± 6.8 ml·min·kg-1] undertook four experimental trials. Before and after 3-nights of PSD (< 5-hours per night) and a control condition (~8 hours in bed), with a > 7-day wash out. Throughput (response rate score which integrates accuracy and reaction time) was assessed at rest, and after 20-mins of MIE (~45 % VO2max) in each trial using a computer based EF test battery. Mood and sleepiness were assessed pre and post exercise. Cerebral oxygenation and cardiorespiratory variables were collected throughout. Plasma cortisol was also collected upon the completion of each trial. Actigraphy and sleep diaries were used to record sleep parameters. Paired sample T-tests were used to assess sleep differences between the PSD and control conditions. Throughput, haemoglobin, oxyhaemoglobin, deoxyhaemoglobin, and cortisol were analysed using a 2

(Sleep status: Control, PSD) x 2 (Activity: Resting, Exercise) repeated measures ANOVA, exploring main effects and interactions. Statistical significance was set at $P < 0.05$ and data are presented as mean ± SD.

RESULTS: Participants slept less (123 ± 39 min), and spent less time in bed (172 ± 37 min) during PSD ($P < 0.001$). Of the EF tests, only the 2-choice reaction time task at rest (Control: 150.3 ± 14.7, PSD: 143.6 ± 12.7; $P = 0.02$) was reduced after the PSD. Regardless of condition, an increase in Throughput was observed in all 6 EF tests after MIE (all $P < 0.05$). Cerebral total haemoglobin, oxyhaemoglobin, and deoxyhaemoglobin increased after MIE in both conditions ($P < 0.05$). Cortisol was significantly reduced following MIE ($P = 0.011$), but did not differ after PSD. Sleepiness increased with the PSD protocol at rest ($P < 0.001$) and returned to baseline values with MIE. PSD reduced perceived vigour and increased perceived fatigue, however both were reversed with MIE.

CONCLUSION: These novel findings suggest that, regardless of sleep status, MIE appears to improve acute EF performance. Further research is needed to determine the (psycho)physiological mechanisms mediating these improvements.

COEFFICIENT OF FRICTION BETWEEN SLIP RESISTANT SAFETY SHOES AND DIFFERENT TYPES OF FLOORS

MUNK-HANSEN, M.1, LARSEN, A.H.2, GRØNLYKKE, T.3, MADELEINE, P.1

1 AALBORG UNIVERSITY 2 UNIVERSITY OF SOUTHERN DENMARK, ODENSE UNIVERSITY HOSPITAL 3 SPRAINO

INTRODUCTION: The surface we walk on has a great impact on how we walk. One of the most important factors is the friction between the shoes and the surface. A lack of friction can cause a slip which challenges the balance. In the worst case, a slip can lead to fall and cause an injury [1]. Friction is influenced both by the shoes and the surface, which means that the best shoe on a hard concrete floor may not necessary the best shoe on a carpet. In occupational settings, safety shoes are often mandatory to meet the workplace specific safety regulations and are often characterized by an anti-slip outer sole [2]. Safety shoes are often tested with a SRA standard where the shoes outsole is tested on a ceramic tile with soap solution, or a SRB standard where it is tested on a steel plate with glycerin, the effects of other floor types and the safety shoe's friction needs to be investigated.

METHODS: A modified British Pendulum [3] was used to collect friction data between a safety shoe and tree different type of surface (carpet, linoleum, and metal) each of these with different hardness and elasticity. Kinetic data was collected at 1000 Hz using a force plate (AMTI, OR6-7-1000, Advanced Mechanical Technology, Inc. Watertown MA, USA). When testing the angle of the shoe was adjusted to simulate a toe off event with a plantar flexion of 30 degrees relative to the force plate at initial contact.

RESULTS: The highest friction was found between the safety shoe and the carpet (coefficient of Friction (CoF): 1.04±0.11, velocity: 2.36±0.14 m/s) the second highest friction was found between the safety shoe and linoleum (CoF: 0.99±0.10, velocity: 3.50±0.29 m/s), and the lowest friction was between the safety shoe and metal (CoF: 0.84±0.03, velocity: 2.85±0.08 m/s).

CONCLUSION: There were trends towards differences in CoF with the lowest value reported for metal, but the velocity differed among the three surfaces. Still our findings point at potential differences in friction that can increase the risks of slips and trips even when slip-resistant safety shoes are used. Future studies are needed to confirm these findings.

EFFECTS OF IMMEDIATE FEEDBACK ON TACKLE TECHNIQUE IN RUGBY USING 3-DIMENSIONAL MOTION ANALYSIS: A CASE STUDY

YAO, N.

TOKAI UNIVERSITY

INTRODUCTION: Rugby is a collision sport in which players incur many more injuries of the head, neck, and shoulders than in other sports. The majority (>50%) of injuries in rugby union occur during the tackle. Proficient tackling ability can play a role in injury prevention. Player and coach education on correct tackle techniques have been used as a preventative measure for reducing tackle injuries. It's suggested that feedback tools (post-hoc video analysis and real time verbal coaching feedback) during tackle practice be implemented to ensure correct body positioning. Therefore, the aim of this

study was to investigate effect of immediate feedback and clarifying focus points with coach on tackle technique while presenting a video by 3-demensional motion analysis system in each trial.

METHODS: The participants were 2 rugby union players, Participant A (PA); BKs, Age:19, Hight 178cm, weight 83kg, Participant B (PB); Position: BKs, Age:21, 177cm, 80kg. Participants were instructed to perform their usual tackles to tackle-bag at full contact speed. Ten trials were performed each participant. PA was shown the video of the trials after each trial for feedback by himself, and a coach also gave him feedback of each trial. Then a focus point in the next trial was decided by PA and the coach. PB, on the other hand, was shown the video of the trial for feedback by just himself, and no feedback and instruction or focus points of the next trial were given by the coach. Trials were recorded by the tackling motions using an infrared motion-capture system. Eleven synchronized infrared cameras were placed around a 10 × 10–m2 field to provide an unobstructed 360° view of the subject. Forty-one reflective markers were placed onto the subjects body surface. Kinematic variables were analyzed the trunk lean angle (TLA), neck joint extension angle (NJEA), the shoulder rotation angle (SRA) and knee joint flexion angle (KJFA).

RESULTS: Kinematic variables for PA were 86.3 ° for TLA, -26.4 NJEA, 58.8 ° for SRA and 109.4 ° for KJFA in the first trial, then the kinematic variables were changed in the 10th trial such as, 85.3 ° for TLA, -4.9 ° for NJEA, 81.8 ° for SRA and109.4 ° for KJFA. Some focus points were improved in the last trial. Feedback from coach made PA clarify the focus points, (1) lower shoulder hit area by bending knee in front foot, (2) head up, and (3) reaching arms for binding. Kinematic variables for PB were 71.2 ° for TLA, -35.7 ° for NJEA, 97.4 ° for SRA and 79.5 ° for KJFA in the first trial. The kinematic variables were change in the 10th trial such as, 65.7 ° for TLA, -26.8 ° for NJEA, 90.6 ° for SRA and123.0 ° for KJFA. The tackle technique for PB was changed inconsistently.

CONCLUSION: Immediate feedback using video footage can be useful for players to recognize own performance. In addition, feedback or instruction from coach intend to make players more focus on the target clearly. It is sometimes hard to identify the problem or points to work on by only players.

VELOCITY PATTERN OF NATIONAL LEVEL FEMALE ATHLETES OF BANGLADESH IN 200M SPRINT

ISLAM, M.

JESSORE UNIVERSITY OF SIENCE AND TECHNOLOGY

INTRODUCTION: During running competition an athlete cannot maintain uniform speed throughout the course in spite of his best possible effect. Velocity pattern indicates the change of velocity at different phases of a race. Purpose of the present study was to analyze the velocity pattern of 200m sprint for National level female junior athletes of Bangladesh.

METHODS: Ten junior national level sprinters attending national coaching camp were selected as subjects. The total running distance of 200m was divided into eight equal zones of 25m each. Mean zonal times of all the eight zones for the subjects were measured. From (Distance-time) information of different zones, zonal velocities were calculated and velocity-distance curve was developed for the 200m race. Velocity pattern of the junior level female sprinters for 200m race was analyzed.

RESULTS: Results indicated that mean zonal velocity increased from start and the maximum zonal velocity was achieved during (100-125) m zone. Thereafter the zonal velocity gradually decreased for the rest part of the race. The reduction in locomotion velocity was about 10% of the maximum.

CONCLUSION: This decrease in velocity in later part of the race might be due the lack of sprint endurance of the athletes. So, the results of this study may be used as diagnostic factors for 200m sprint performance of the subjects.

HOME OFCE VERSUS ERGONOMIC WORKSTATION - IS THE ERGONOMIC RISK INCREASED WHEN WORKING AT THE DINING TABLE? AN INERTIAL MOTION CAPTURE BASED PILOT STUDY

OHLENDORF, D., MAURER-GRUBINGER, C., FRAEULIN, L., GRONEBERG, D.A., HOLZGREVE, F.

GOETHE UNIVERSITY, OCCUPATIONAL, SOCIAL AND ENVIRONMENTAL MEDICINE

INTRODUCTION: In order to reduce the risk of infection with Sars-Cov-2, work practices have been shifted to the home ofce in many industries. The frst surveys concerning this shift indicate an increase in musculoskeletal complaints of many employees. The aim of this study was to compare the ergonomic risk in the upper extremities and trunk of working in a home ofce with that of working in an ergonomically optimized workplace.

METHODS: For this purpose, 20 subjects (13w/7m) aged 18–31 years each performed a 20-minute workplace simulation (10 min writing a text, 10 min editing a questionnaire) in the following set up: on a dining table with dining chair and laptop (home ofce) and on an ergonomically adjusted workstation (ergonomically optimized workplace). The subjects were investigated using a combined application of a motion capture kinematic analysis and the rapid upper limb assessment (RULA) in order to identify diferences in the ergonomic risk.

RESULTS: Signifcantly reduced risk values for both shoulders (left: $p<0.001$; right: $p=0.02$) were found for the ergonomically optimized workstations. In contrast, the left wrist ($p=0.025$) showed a signifcantly reduced ergonomic risk value for the home ofce workstation.

CONCLUSION: This study is the frst study to compare the ergonomic risk between an ergonomically optimized work-

place and a home ofce workstation. The results indicate minor diferences in the upper extremities in favor of the ergonomically optimized workstation. Since work-related musculoskeletal complaints of the upper extremities are common among ofce workers, the use of an ergonomically optimized workstation for home use is recommended based on the results.

ASYMMETRY INDEX OF KNEE EXTENSORS USING PEAK TORQUE VERSUS ANGLE-SPECIFIC ANALYSIS IN HEALTHY SUBJECTS

BARRUÉ-BELOU, S., DEMARET, M.A., WURTZ, A., BOTHOREL, H., FOURCHET, F.

LA TOUR HOSPITAL

INTRODUCTION: Isokinetic dynamometry remains the gold standard of strength assessment in clinical practice, sports or research settings. Previous studies have already underlined that conventional analyses of torque-angle relation strongly reduce the continuous data recorded during anisometric contractions to single values (e.g. peak torque), may lead to a loss of information [1] and may neglect the impact of joint position (angle) on torque production. Furthermore, strength deficits in patients may be increased in a particular range of motion (ROM) in comparison with peak torques [2]. However, asymmetry indexes (AI) are still calculated with peak torque in clinical practice [3] and angle-specific analysis are only practiced in research field [4]. The aim of the study was to compare the two approaches in order to question the method of evaluation of AI. We hypothesized that knee extensors AI in healthy subjects will be reduced using peak torque compared with angle-specific analysis.

METHODS: Sixty-seven healthy trained volunteers (35 women and 32 men) performed 5 maximal voluntary contractions of knee extensors in concentric and eccentric mode at 2 different angular speeds (30 and 60°/s) with right and left lower limb. Dynamic phase of the contraction was systematically preceded by a 1 s isometric maximal pre-activation and 35 s of rest were given between each trial. A classical AI was calculated for each participant with values of peak torque (AIp). A moving AI at each measuring point (e.g. 2 kHz frequency) was also calculated (AIm). The median value of AIm was computed and the proportion of ROM with Aim higher than AIp was calculated for each angular speed. After normality distribution check with Shapiro-Wilk test, paired Student's t-tests were used.

RESULTS: For 70 to 73 % of the ROM studied (e.g. 5° to 85°), AIm was greater than AIp. AIm was systematically increased from the angle at peak torque to 5° knee flexion, regardless of the contraction mode and angular velocity. The median value of AIm was significantly higher than AIp (between +38% to +61% depending on the angular speed), ($p < 0.001$).

CONCLUSION: Inter-limb strength asymmetry is a key outcome used by clinicians to guide the rehabilitation process and help in return to sport decision [3]. Our findings highlight that classical calculation of AI in clinical practice may strongly underestimate strength deficits between limbs given that angle at peak torque for knee extensors is part of the ROM at which AI are the more reduced in healthy subjects (e.g. between 55 to 70°). A moving AI through the full range of motion may allow to evaluate more precisely subjects or patients capacities without further testing procedure, but only by exploiting the usual recorded data during anisometric contractions.

TOWARDS A NEW METHOD FOR EVALUATING IN VIVO HEAD KINEMATICS MEASURED BY INSTRUMENTED MOUTHGUARDS: A LABORATORY PROCEDURE FOR TIME-SYNCHRONISING WITH 3D MOTION CAPTURE

IZRI, E., BEZODIS, N.E., WALDRON, M., JONES, C., KILDUFF, L.P., BROWN, M.R.

SWANSEA UNIVERSITY

INTRODUCTION: Instrumented mouthguards (iMG) are often validated against a reference sensor using a mechanical impactor and dummy headform. However, the testing conditions used do not represent the head kinematics experienced on-field. In vivo comparisons of the head kinematics measured from iMG and 3D motion capture systems (mocap) will aid in contextualising on-field measurements and in determining the signal characteristics of true- and false-positive head impacts. To permit a like-for-like comparison, development of an iMG-mocap time-synchronisation method is necessary. We aimed to assess the agreement in the relative timing of signal peaks between simultaneously measured iMG and mocap signals.

METHODS: Two participants wore custom-moulded iMGs (PROTECHT, SWA, UK) which were tightly coupled to the upper dentition. A mocap system (T20, Vicon, UK; 250 Hz) tracked the 3D displacement of a 14 mm reflective marker attached to the end of a rigid metal rod (100 mm length, 6 mm diameter). Sixteen trials of 10 rod-to-iMG impacts were recorded (N=160 impacts) with the iMG continuously recording linear acceleration at 1000 Hz throughout each trial. An impact consisted of an experimenter moving the rod horizontally towards the mouth and contacting the iMG without any intentional deceleration, before returning to the start position. Each impact was separated by at least 5 s.

The iMG linear acceleration and marker displacement, velocity, and acceleration vector norms were calculated from their respective 3D arrays. All signals remained unfiltered and no marker trajectory gaps were present. Displacements were differentiated to velocity and acceleration using the first central difference method. The signal peaks for each impact were

identified using the findpeaks function in R (R Studio, US). The 'number of peaks' parameter was set to 10 and 'minimum distance between peaks' set to 4 s based on the protocol and visual inspection of traces. The time (s) period between signal peaks, T, was calculated for every consecutive pair of signal peaks, yielding 9 periods per 10 impacts in each signal. A total of 144 T values from 160 impacts were compared between the iMG and three mocap signals using Bland-Altman analysis.

RESULTS: The mean bias +/- 95% limits of agreement for iMG vs marker displacement, velocity and acceleration T values were -0.047 +/- 0.770 s, -0.026 +/- 0.353 s and -0.027 +/- 0.346 s, respectively. Paired t-tests revealed no differences in T for either signal comparisons (P>0.05).

CONCLUSION: The data indicate difficulties in accurately aligning iMG and mocap signals. The random error is likely a function of the iMG-rod impact protocol, the selection of analysed variables, and the algorithm used to identify signal peaks. Further work is needed to refine these aspects, whilst maintaining practicality. Method refinements will aid in standardisation of a procedure for time-synchronising iMG and mocap head kinematic signals for future research.

THE CHARACTERISTICS OF DISTRIBUTION OF VOLLEYBALL PASSING FOR SEVERAL DISTANCES

OZAWA, Y., NAKAMURA, S., YAMADA, H., MIYAZAKI, S.

TOKAI UNIVERSITY

INTRODUCTION: In human movement, movement errors must not be avoided. In the case of sports movement, it also applies such as baseball pitching, and soccer kicking. Although the accuracy had a trade-off with the movement speed, the relationship between accuracy and pass distance was not obtained. Volleyball passing required accuracy than pass speed, and passing accuracy would be much more important despite the distance. In addition, according to Masahiro et al. (2017), the 95% confidence ellipse pitching distribution was dependent on the pitching form. In this study, it would be tested whether similar location distribution occurs in volleyball passing.

METHODS: Subjects were 11 male volleyball players (height: 175.8 ± 6.4 cm, age: 20.2 ± 1.7 years old, experience: 8.2 ± 2.9 years) who have played volleyball more than 3 years. They passed the ball for 3, 5, 7, 9, and 11 m targets in front of them by forearm pass. All trials were 20 times for each distance. The ball trajectories of passes around the target area were captured as ball landing points with 3D DLT method. For the coordinate axes, the Y-axis was the passing direction, the X-axis was the vertical axis in Y-axis in the horizontal plane, and the Z-axis for the vertical direction. The landing points were defined at the lowest points. Comparison of the spread of variance across different passing distances was calculated by paired one-way

RESULTS: The distribution tended to increase as the passing distance increased. However, there was no significant difference ($p = 0.999$) between 3m (0.49 ± 0.04 m) and 5m (0.53 ± 0.03 m). The mean point of the ball landing was getting shorter (subject side) as the distance increased. Although the distribution of each axis (X and Y-axis), the Y-axis was significantly greater than the X-axis in 3m ($p < 0.001$), 5m ($p = 0.004$), and 7m ($p = 0,003$) trials, there was no significant difference between X and Y-axis in 9m and 11m trials.

CONCLUSION: There was no significant difference in the distribution between 3m and 5m trials. In volleyball, players usually practice for 5-6 m for the warming-up training. The 5m passing would be the most practiced distance in volleyball. In addition, the mean landing locations tended to shorten as the pass distance increased. In a real game of volleyball, the first touch passes the ball to the net direction, so it causes the point lost that the passing distance is getting too long. Players likely tended to shorten their passes to avoid them hitting the net. The Y-axis distribution of the pass location was not higher than that of the X-axis in the 9 and 11 m trials. Generally, the movement error spread the point of the movement direction. However, in volleyball forearm pass, the characteristics were not observed. From these results, volleyball players acquire unique control programs for passing the ball in specific game situations.

THE EFFECTS OF 12-WK DANCE-MOVEMENT THERAPY ON THE FUNCTIONAL CAPACITY AND SARCOPENIA PARAMETERS IN OLDER ADULTS

HOLA, V.

FACULTY OF PHYSICAL EDUCATION AND SPORT

INTRODUCTION: Exercise in older adults is essential for health because it preserves and maintains muscle mass and strength, which leads to improved functional capacity (1). Recent evidence (2,3) suggests that a very potent and enjoyable type of exercise for older adults is dancing because it can significantly improve many aspects of functional fitness as well as cognition. This study investigated the effects of 12-wk of dance-movement therapy (DMT), according to Laban and his students (4), on the physical capacity and sarcopenia parameters in older adults. Chosen DMT works with the functional connection of the whole musculoskeletal system (the coordination of movement) in conjunction with the emotional experience to perceive bodily signals.

METHODS: 29 healthy older individuals aged 65≥years (training group n=14, and control group n=15, sex and aged-matched) underwent 2 x wk for 12-wk a DMT for 60 mins.

Body composition - skeletal muscle mass (SMM) was measured by bioelectrical impedance (BIA) (InBody 720, Biospace Co., Ltd., Seoul, Korea), maximal upper - handgrip (HG) and lower body isometric (MVIC) strength by dynamometry (TKK5401; Takei Scientific Instruments Co., Ltd., Niigata, Japan and Humac NORM, CSMi, Stoughton, MA, respectively). Functional capacity was tested by gait speed and chair stand test. Ultrasound index of the loss of muscle mass associated

with sarcopenia (USI) and pennation angle (PA) were calculated using muscle architecture measured on the right vastus lateralis at 65% distal length (5) by ultrasound (Mindray M5).

RESULTS: By the end of the DMT, SMM, HG, MVIC, gait speed and chair stand test did not change significantly. However, USI significantly decreased in the DMT group and increased in the control group (absolute change difference of 0.40 vs -0.8). PA also significantly increased in the DMT group and decreased in the control group (absolute change difference of 0.40 vs – 0.71).

CONCLUSION: The present findings show that 12-wk of DMT does not affect functional capacity in healthy older people. However, DMT positively affects muscle architecture parameters, specifically USI, suggesting a protective effect on age-related sarcopenia.

SYNTHETIC FEATHER VS WATERFOWL FEATHER SHUTTLECOCKS: DIFFERENCES IN MECHANICAL PROPERTIES, 3D FLIGHT KINEMATICS IN A SIMULATED SMASH AND ACCURACY OF SMASHES PERFORMED BY HIGHLY TRAINED SHUTTLERS

LEE, M.1, TAN, K.1, GOH, W.1, BOEY, D.1, OZAKI, H.2, HIROTAKA, N.2

1. SINGAPORE SPORT INSTITUTE 2. JAPAN INSTITUTE OF SPORTS SCIENCES

INTRODUCTION: The Badminton World Federation announced plans to transit from the traditional waterfowl feather shuttlecocks (WFS) to synthetic feather shuttlecocks (SFS) for long-term sustainability reasons in January 2020. This change in shuttlecock build could affect its flight characteristics and game play. We compared 10 competition-standard Mizuno SFS versus 10 Li Ning WFS in terms of mechanical properties, discrete and continuous variables associated with 3D flight kinematics during a robot-simulated smash, and percentage of shots landing in a demarcated scoring zone during a smash by highly trained shuttlers.

METHODS: The weights, skirt diameters, lengths, and centre of mass (COM) positions were compared between 10 SFS and 10 WFS to identify differences related to mechanical properties. A three-dimensional opto-reflective motion capture system captured the flight of 10 SFS vs 10 WFS during a simulated smash by a robot under the same settings. Flight duration, peak velocity, average velocity, lateral displacement, and front-back displacement were compared between both shuttlecock types. One-dimensional statistical parametric mapping (SPM) was used to differentiate the flight characteristics between the SFS and WFS. The accuracy of 20 smashes of each shuttlecock type to land in a demarcated zone performed by 20 well-trained shuttlers were compared. All comparisons were made using two-tailed independent t-tests.

RESULTS: The SFS was on average lighter (5.20 ± 0.05 vs 5.29 ± 0.07 g), shorter (88.83 ± 0.29 vs 90.69 ± 0.40 mm) and had a more anteriorly positioned relative COM (30.67 ± 0.57 vs 31.90 ± 0.50 mm) compared with the WFS. The SFS recorded shorter flight durations (1.05 ± 0.01 vs 1.07 ± 0.02 s), higher average peak velocities (45.44 ± 0.58 vs 44.46 ± 1.03 ms-1), higher average velocities (10.72 ± 0.12 vs 10.10 ± 0.14 ms-1) and landed further down the court (11.42 ± 0.10 vs 11.02 ± 0.14 m) for the simulated smash with the robot. SPM analysis revealed significant differences in front-back displacement between the SFS vs WFS from 15% of normalized flight time with no differences in lateral and vertical displacements. Players were more accurate smashing the WFS (62.00 ± 18.24 %) compared with SFS (48.00 ± 25.26 %).

CONCLUSION: Although lighter, the SFS recorded longer flight durations and higher peak and average velocities during the robot-simulated smash compared with the WFS, possibly be due to a lower drag coefficient caused by greater skirt deformation. The faster speeds during the robot-simulated smashes of the SFS versus WFS could mean that shuttlers may find it more difficult to defend against offensive smashes using the SFS. The advantage of a faster smash of the SFS could be offset by less accurate positioning of smashes compared with WFS as identified in this study. Taken together, the higher velocities and different flight trajectories of the SFS compared with WFS would require shuttlers to adapt technically and physiologically.

CP-SH12 Imagery and psychological skill training

AN EXPLORATION OF DIET AND MENTAL COPING STRATEGIES DURING THE ULTRA TOUR MONTE ROSA: A CASE STUDY

MAHON, E.A., JACKMAN, P.C., WHITEHEAD, A.E.

LIVERPOOL JOHN MOORES UNIVERSITY

Introduction: As ultra-endurance events become more popular, investigations into the characteristics of what makes a successful ultra-athlete are growing. The importance of nutrition and coping have been identified as key factors in successful performance. However, the interplay between diet and mental coping strategies is yet to be investigated in an in-depth case study during an ultra-running event. Furthermore, overcoming stressful situations and employing relevant coping strategies is important in providing practical implications for future athletes engaging in these events. Therefore, this research aims to use Lazarus and Folkman's (1984) transactional model of stress and coping as a lens to examine how the above factors come into play within ultra-running performance.

Methods: An experienced ultra-marathoner took part in this qualitative case study. The researchers took an interpretivist approach to data analysis, with a view that data is not to be generalised, instead to provide one person's detailed account of their experience during the 100-mile Ultra Tour Monte Rosa. A pre-event interview (-5 days) was performed cover-

ing the participant's background, race overview, preparation, perceived challenges, coping strategies and nutrition plan. To capture thought processes and dietary intake during the event a GoPro was attached to the runner, who was instructed to Think Aloud (TA) and verbalise thoughts, where possible, throughout the event. GPS and heart rate data was also collected. A post-race interview (+3 days) provided a chronological account, evaluated performance, and explored experience and strategy use. Both interviews and TA data were transcribed verbatim. A timeline of dietary intake, stressors and coping responses over the duration of the race (87 miles completed) was compiled.

Results: The main stressors were nutrition, terrain, environment, physical, social and performance. Various coping strategies (problem, emotion and avoidance-focused) were adopted at different time points. During the initial stages of the race problem-focused coping was employed more frequently, which focused on the monitoring of internal physiology and fuelling. However, as the race progressed problem-focused coping reduced, and emotion-focused coping became more common. Insufficient fuelling was identified as a critical factor that may have impacted upon coping strategies and ultimately led to race withdrawal.

Discussion: These results provide detailed insight into the experiences of an ultra-runner, presenting unique data regarding how nutritional intake may affect psychological responses to stressful situations. Further research investigating the link between fuelling and coping in ultra-endurance events is needed to support the literature assessing diet and physiological response.

THE EFFECT OF A SIX WEEKS AO PLUS MI COMBINED INTERVENTION ON GOLF PUTTING ACCURACY: A PILOT, SINGLE-BLINDED,RANDOMIZED STUDY

ZHANG, Y.

SHANGHAI UNIVERSITY OF SPORT

The effect of a six weeks AO plus MI combined intervention on golf putting accuracy: A pilot, single-blinded,randomized study

Yuqi Zhang.

Shanghai University of Sport, Shanghai, China

INTRODUCTION: Both action observation (AO) and motor imagery (MI) have been shown to have similar cognitive and neural information processing processes to actual movement execution [1], and they have been shown to have a significant role in improving motor skill learning and accuracy. A study has found that after six weeks of AO+MI intervention training, the target aiming performance of the AO+MI group was significantly higher than that of the AO or MO group alone [2]and that the combination of the two could reveal a relationship between the subjects behavioral mental processes and the actual execution of the putting stroke. Therefore, the aim of this study was to assess the effect of a six-week AO+MI intervention on the accuracy of putting in beginner college golf.

METHODS: Sixteen college beginner golfers participated as subjects and were randomly divided into a control group (n=8, 22±1.60) and an AO+MI group (n=8, 22±1.25). All subjects completed a Vividness of Movement Imagery Questionnaire (VMIQ-2) to exclude the effect of individual differences in verbal ability on the results. The experimental group underwent a six-week AO+MI psychological intervention training, twice a week for 40 minutes per intervention. After six weeks, a putting experiment was conducted in which subjects in each group made 10 putts at a distance of 3 meters. The AO+MI group would watch a 3-minute intervention script before putting it, while the control group did not have any other interventions. The vertical and horizontal distances of the ball from the hole cup, ball speed, deviation, and putting angle were measured after each putt. Paired-sample t-tests were used to detect differences in means for each indicator. A statistical level of $p<0.05$ was accepted. All data are expressed as mean ± SEM.

RESULTS: There were no individual differences in the clarity of external visual imagery, internal visual imagery or kinesthetic imagery of the subjects measured pre-experimentally. After the experiment, the hole-in-one rate was 27.5% and 10% for the AO+MI and control groups, respectively. Significant differences were found in putter speed ($P=0.041$) and vertical distance ($P<0.01$). The vertical distance was 19.92±22.66 and 56.87±47.95 for the AO+MI and control groups, respectively. horizontal distance ($P=0.267$), left-right deviation ($P=0.527$), and putter angle values ($P=0.709$) were not significantly No significant differences.

CONCLUSION: The novel finding of this pilot work was that the six-week AO+MI intervention improved the accuracy of beginner golf putters. The subjects achieved positive results by observing the correct putting stroke while repeating the simulation internally, ensuring the ball rolled towards the target cup at a reasonable ball speed based on perceived putting distance and reducing the horizontal and vertical distance between the final landing point and the cup. In summary, the use of AO+MI interventions in golf putting training sessions is clearly effective in improving putting accuracy for beginners, however, it is unclear if this affects the putting accuracy and swing performance of the actual game for beginners.

Abstract

Introduction

Holmes and Collins (2001) proposed functional equivalence from a neuroscience perspective. They also argued that imagery execution and movement will bring out the same neuro mechanism that leads to benefits for sport performance. In this study, we aimed to apply different delivery intervention methods to investigate the effects of regular (RI), progressive (PI), and retrogressive (RETI) PETTLEP imagery patterns (Fazel et al., 2018) to jump-shot performance, state anxiety, and self-confidence of basketball players.

Methods

Participants were recruited from 4 high-school basketball teams of Division II league. They were randomly assigned to a RI group, PI group, RETI group or a control group. Three intervention groups were implemented by following the 7 elements of the PETTLEP model. The intervention was delivered three times a week for 4-weeks, a total 12 imagery training sessions.

Discussion

The results showed: (1) PI and RETI significantly improved performance of running jump shooting, (2) RI and PI significantly reduced players' state anxiety, (3) RI and PI significantly improved players' self-confidence. To sum up, different imagery training patterns are beneficial to efficient learning for young athletes under certain circumstances that will improve sport performance, self-confidence, and reduce state anxiety levels. However, we recommend further exploration of the efficiency of different imagery intervention patterns among diverse age levels and sports. Lastly, in order to strengthen the effectiveness of imagery training, practitioners are suggested to provide different imagery patterns to match different skill development stages of athletes.

Key words: Functional equivalence, Regular Imagery, Progressive Imagery, Retrogressive Imagery, High school Basketball

THE EFFECT OF PSYCHOLOGICAL SKILLS TRAINING ON PERFORMANCE OF COMPETITIVE ATHLETES: A SYSTEMATIC REVIEW AND META-ANALYSIS

ZHANG, X.1, WANG, H.N.1,2, LUO, P.2,3

1 UNIVERSITY OF CALGARY, 2 BEIJING SPORT UNIVERSITY

INTRODUCTION

Sport psychology interventions have been empirically examined during the past several decades, with the objective of improving performance and quality of athletes' experience through cognitive behavioural changes [1]. Although psychological skills training (PST) as the primary intervention conducted in various programs has been widely adopted in the field of sport psychology interventions [2,3], some authors claim there is the effectiveness of PST in modifying internal states to be related to athletic performance but limited on the enhancement of athletic performance [4,5] . The aim of the present study was to examine the effect of PST on performance of competitive athletes.

METHODS

A structured literature search was conducted in three online databases (PsychoINFO, SPORTDiscus, and Web of Science). Studies were included if they were randomized controlled trials (RCTs) that compared an PST as an intervention with a control, in current or former competitive athletes.

RESULTS

Of 3080 articles identified, a total of four studies met the inclusion criteria. The pooled result showed no significant difference between PST and performance (SMD=-0.14 with 95% CI from -0.33 to 0.05) within competitive sport. In addition, the heterogeneity of the interventions was moderate (I2=46%).

CONCLUSION

PST improved several performance outcomes in various sports. These studies should emphasis intervention fidelity within competitive sport. Given the moderate degree of evidence, high-quality, adequately powered trials are needed in the future.

DEVELOPMENT OF AN INNOVATIVE VIRTUAL REALITY TRAINING SYSTEM AND ITS EFFECT ON MENTAL TRAINING IN GYMNASTS

SATO, Y., FUKAMI, M., ENDO, K., MIZUSHIMA, K., NISHIKAWA, D., TAKAYOSE, M., KOSHIZAWA, R.

NIHON UNIVERSITY

INTRODUCTION

Research on the use of virtual reality (VR) for mental training in athletes is increasing. VR can simulate situations that athletes may not usually experience, including unusual competition scenarios and environments such as stadiums the athletes have not visited before. We have been developing an innovative VR training system (iVRTS) and have used it for mental training to enhance athlete performance. Users wear a head-mounted display (HMD) and can move freely in a VR environment constructed based on an actual stadium. However, it is unclear whether the iVRTS is effective for mental training, such as performing breathing techniques while experiencing a simulated stressful situation. Therefore, this study aimed to assess the effectiveness of iVRTS for mental training by analysing biometric information.

METHODS

Participants were 20 male gymnasts (mean age ± standard deviation: 19.41 ± 0.91 years) who had competed at the national level. Participants were assigned to the VR group or the control group. Both groups had five mental training sessions over a 4-week period (Fukami, 2019). Each session comprised two 5-min breathing activities. In the first, participants stood with their eyes opened and breathed normally. In the second, they continued to stand while performing a breathing technique and were allowed to look around while turning around; the VR group, who wore a HMD (Vive, HTC) during the second activity, viewed a VR environment of an actual gymnastics stadium filmed using a 360-degree camera (QooCam 8K, KanDao) during a competition, whereas the control group saw only the gymnasium where they train. To determine the effect of the experience on mental training, salivary amylase (SOMA Cube Reader, YKC) and mental sweating (eVu TPS, MP Japan) were measured. To examine the iVRTS effect, measurements were compared between the first and final sessions (Times 1 and 2, respectively). The Kolmogorov–Smirnov test was performed to assess the distribution of the data, and the Wilcoxon-signed rank test and Mann–Whitney U test were performed to compare the data between the VR group and the control group and between Times 1 and 2.

RESULTS

There was a significant difference in the salivary amylase results between Times 1 and 2 in the VR group, but no significant differences were found in mental sweating between Times 1 and 2 or between the groups.

CONCLUSION

These results indicate that mental training using iVRTS reduces the stress response, suggesting its potential to contribute to improved psychological skills in athletes. Because salivary amylase is associated with both the sympathetic and parasympathetic nervous systems, breathing techniques performed while using the iVRTS might be useful for acquiring relaxation skills.

AN INVESTIGATION OF THE IMAGERY ASPECTS OF BLIND SOCCER PLAYERS WITH VISUAL IMPAIRMENT: TOWARDS PERFORMANCE IMPROVEMENT

MOMOSE, Y.
TOKOHA UNIVERSITY

Introduction

The theoretical basis for the effectiveness of motor imagery has been based on the neuromuscular theory (Jacobson, 1931), which states that skill improvement can be expected by imaging of vividness, controllability, and internal imagery (Mahoney & Avenir, 1977; Munford & Hall, 1985). However, a meta-analysis of imagery training showed a success rate of only half % (Murphy, 1994; Simonsmeier, et.al.,2021), and the methodology still needs to be reviewed. In addition, the examination of the imagery aspects of visually impaired players is still in its exploratory stage, and generalized findings have not yet been submitted. In the meantime, evaluation criteria for cognitive imagery strategies that are indispensable for blind soccer (Momose, 2023). Therefore, the purpose of this study was to investigation of image aspects by blind soccer players with visual impairment. This study will provide suggestions for improving the performance skills of blind soccer players.

Methods

Participants included 32 Japanese blind football players (sex: 23 males, 7 females/skill levels: 8 international, 10 national, 2 regional, 12 never participated/ vision class: 11 totally blind, 14 low vision/time: 19 congenital, 12 acquired). The scales used were (1) the Questionnaire upon Mental Imagery (QMI: visual, auditory, tactile, kinesthetic, gustatory, olfactory, and organic senses, 5-point scale), (2) Test of Visual Imagery Control; Visual Impairment Person Version (TVIC-V, 3-point scale) , (3) Movement Imagery Questionnaire-Revised; Japanese Version (JMIQ-R: internal, external, 7-point scale), (4) Evaluation Scale of Movement Imagery; Blind Soccer version(ESMI-BS: overlooking, venue, sound, subject, 7-point scale).

Results

As a result, by skill level, ANOVA analysis on the ESMI-BS for overlooking imagery ($F(3)=3.247$, $p<.05$) and venue imagery ($F(3)=3.327$, $p<.05$). Significant differences were also found by congenital or acquired on the QMI for visual imagery ($t(22.150)=2.208$, $p<.05$), and by blind or low vision on the ESMI-BS for venue imagery ($t(27.769)=-2.233$, $p<.05$) and sound imagery ($t(22.102)=-2.318$, $p<.05$). Moreover, the correlation analysis showed that the ESMI-BS overlooking imagery ($r=.427$, $p<.05$) and venue imagery ($r=.550$, $p<.05$) were significantly related to the TVIC-V scores.

Discussion

The results suggest that was inferred that the skill to easily visually imaged the venue (pitch and lines) and the game situation from a birds-eye view is required to improve the skills of blind soccer players. But controllability is required to easily image these venue and birds-eye images, was not related to vividness. Moreover, congenitally blind athletes may have difficulty imaging related to visual information (Momose and Ito, 2016). It was considered that guidance should be provided based on these results to improve performance.

EFFECTS OF EYE MOVEMENT AND INTEREST ON MEMORY OF ADVERTISEMENTS DURING SPORTS BROADCASTS

ISOGAI, H.
KYUSHU SANGYO UNIVERSITY

Introduction

Because of the high viewership of TV broadcasts of mega-events such as the soccer World Cup, many companies present advertisements, but it is not clear how viewers perceive these corporate advertisements. It would be important to investigate to what extent the advertisements are seen and remembered. One scientific approach to this is eye tracking, a technique based on eye gaze measurement [1]. It is also conceivable that emotions such as interest in the sport being watched may influence memory. The purpose of this study was to clarify the influence of advertisements on memory by analyzing viewers eye movement, eye placement, and interest in baseball during a live professional baseball game.

Methods

The subjects were 20 college students (18 males and 2 females, mean age 19.65 ± 0.79) with no baseball experience. An eye tracker, EMR-ACTUS (Nac Image Technology), was used as the eye tracking device. Subjects were seated 2.0 meters away from the monitor, and a video was played after confirming that eye gaze could be measured. After the video was shown, subjects were asked to describe the advertisements they remembered and the reasons why they remembered them. The video was edited from a televised video of the first game of the Japan Series, an official game of the Nippon Professional Baseball (NPB), and lasted 180 seconds, from the pitcher in the set position before pitching to the catcher catching the ball after pitching. The ads were from 13 companies (6 billboard ads and 7 digital ads), and eye movement and gazing time were measured.

RESULTS

To see the overall trend of gazing time, we measured the gazing time and obtained the percentages. The results showed that 94.82% of the gazing time was placed on the pitcher, catcher, batter, etc. The percentage of gazing time for adver-

tisements was only 5.18%. To examine the relationship between gazing time and ad memory, we compared gazing time for the no ad memory group (n=8; 0/13 companies) and the many memory group (n=6; 3/13 or more companies). The results showed significant differences for both billboard ($F=5.83$, $p<0.05$) and digital ($F=4.84$, $p<0.05$) advertisements, indicating that the majority memory group had a longer gazing time.

To examine the relationship between interest in professional baseball and memory for advertisements, we asked participants to rate their interest in professional baseball on a five-point scale and examined the relationship with the number of ads they remembered. The results showed that those who were not interested in professional baseball tended to remember more advertisements, while those who were interested in professional baseball tended to remember fewer advertisements.

Conclusion

The results of this study showed that those who remembered more advertisements spent more time gazing at them and were less interested in professional baseball. Gaze movement and interest were found to be involved in the memory of sports scenes.

THE EFFECTIVENESS OF HEAT PREPARATION AND ALLEVIATION STRATEGIES FOR COGNITIVE PERFORMANCE: A SYSTEMATIC REVIEW

BARGH, M.J.1, WILLIAMS, E.L.2, DONNAN, K.J.3

<1> UNIVERSITY OF LINCOLN, <2> LEEDS BECKETT UNIVERSITY, <3> UNIVERSITY OF HULL

Introduction

A range of occupational and performance contexts (e.g., military personnel operations, emergency services, sport) require the critical maintenance of cognitive performance in environmentally challenging environments. Several reviews exist which evaluate the effectiveness of heat preparation strategies to facilitate physical performance however, to date, no review has explored the usefulness of heat preparation strategies for cognitive performance. Therefore, this systematic review aimed to evaluate a range of interventions for the maintenance of cognitive performance, during or following active or passive heat exposure.

Methods

This systematic review was undertaken in accordance with the Preferred Reporting Items for Systematic Reviews and Meta-Analysis (PRISMA) guidelines. After systematically searching six electronic databases and undertaking manual searches from August 2021 to October 2022, 40 studies published since 2000 were included in the review.

Results

Of the 40 articles included, 5 examined heat acclimation/acclimatisation, 13 included a hydration strategies, 18 included cooling methods, 6 include a supplementation/mouth rinse intervention, and 2 involved psychological or "other" strategies. Interventions were subsequently categorised into chronic (i.e., acclimation/acclimatisation) and acute strategies (i.e., hydration, cooling, supplementation, psychological). The results indicate that medium-term consecutive heat acclimation may mitigate some cognitive deficits under heat stress, although heat acclimation effectiveness could be influenced by age. Furthermore, pre-cooling appears the most effective cooling method for maintaining cognitive performance under heat stress, although results were somewhat ambiguous. The hydration literature showed that the most effective hydration strategies were those which individualised electrolyte fortified fluid volumes to match for sweat loss. Limited research exploring psychological interventions indicates that motivational self-talk could be facilitative for maintaining cognitive skills following exercise in hot conditions.

Discussion

These findings can be used to help inform strategies for maintaining critical cognitive and decision-making skills in hot environments. The effectiveness of well-known physical heat preparation strategies for cognitive performance is conflicting, due in part, to the sparseness of research, and differences in methods implemented. Most studies included in this review explored an acute strategy, with a lack of existing research exploring the effectiveness of widely used chronic heat-based preparation strategies (i.e., acclimation and acclimatisation strategies) and psychological strategies for the maintenance of cognitive performance.

PHYSICAL EXERCISE INFLUENCES ATTENTIONAL ORIENTATION TOWARDS EMOTIONAL STIMULI

MANSOURI, N., COUTTÉ, A., DRU, V., BAYLE, D.

LICAE LAB, PARIS NANTERRE UNIVERSITY

INTRODUCTION: Physical performance depends on perceived exertion and pain. Attention is generally preferentially directed towards particular stimuli in the environment, such as information related to potential danger. This involuntary preferential allocation of attention would allow for an adapted response. Studies have shown that patients suffering from chronic pain have an enhanced attentional bias towards pain related stimuli (word, picture or face). Similarly, this bias is also demonstrated in participants suffering from acute pain or receiving experimentally induced pain.

Since intense physical effort can be perceived as painful, to first see how exertion influences perceptions, we were interested in physical effort as a potential source of attentional bias. Does physical effort influence attentional orientation to-

wards emotional stimuli, and in particular towards stimuli representing pain, as it does for pathological or experimental pain?

METHODS: In order to provide a more accurate measure of attention, we recorded eye movements while participants (N = 37) performed a dot-probe task. The latter consisted of the simultaneous presentation of two facial expressions (pain-neutral or neutral-neutral), one on the left and the other on the right of the screen, for 700 ms, followed by the appearance of a target at the location of one of the two stimuli. Participants were asked to freely move the eyes during the presentation of stimuli, and to manually respond as quickly as possible by pressing the mouse button corresponding to the target location. Participants first completed the task at rest, then they had to complete the task by performing the wall sit test, then once more at rest.

RESULTS: Eye-tracking data showed that the percentage of first fixations was higher for pain faces at rest (52% for pain vs 48% for neutral) and higher for neutral faces during effort (52% for neutral vs 48% for pain). Fixation time was higher for pain faces at rest (202ms vs 188ms for neutral) and higher for neutral face during effort (197ms vs 184ms for pain). Overall, physical effort leads to avoidance of pain related stimuli, contrary to pathological or experimental pain.

CONCLUSION: These findings lead to new issues. Is it an avoidance of pain faces or an attraction to neutral faces? If there had been happy faces, would there have been an attraction to them?

Since these attentional biases are complex phenomena depending on many factors, future studies are needed to characterize more precisely the extent to which physical effort could influence attentional orientation. Then, see if manipulating attention could lead to a decrease in perceived exertion, and thus improve physical performance. We are currently conducting new studies to answer these new questions.

ACCURACY OF A NEW SETUP FOR MEASURING MECHANICAL VARIABLES DURING RUNNING SPRINTS USING THE 'SIMPLE METHOD'

SOUSA, F.A.B., LIMA, T.S., RODRIGUES, N.A., MARINHO, A.H., DA SILVA, D.G., FONSECA, F.S., ARAUJO, G.G.

UNIVERSITY OF ALAGOAS

INTRODUCTION: Kinetic variables are often challenging to measure during sprint running. Recently, a simplified method to estimate kinetic parameters and force and velocity relationship (FxV) during running was proposed [1]. This method can be applied using an iPhone app (MySprint) with a resolution of 240 fps and presents high accuracy [2]. This study aims to test the concurrent validity of another set up to use the simple method in sprints with lower resolution smartphones (30 fps), broadening the access to this kind of tool for sprint training.

METHODS: Seven university track and field athletes (3m, 4f) underwent six 30-meter sprints. Sprints were filmed by an iPhone (iPhone 11 Pro Max - 240fps) positioned 16-m apart and 1-m above the track and by an android smartphone (30 fps) positioned on the stands, 25-m apart and 6.6-m above the track. Parallax was analogically accounted for to use MySprint [2], and digitally for the low fps smartphone using a pc app (Dvideow[3]). Dvideow calibration used pairs of markers positioned 1.22m apart, at each 2.5m until 10m and each 5m until 30m, to apply DLT and posterior 2D frame-by-frame reconstruction [3]. The low fps position data was interpolated (spline, 1000Hz). Split times were extracted for MySprint and Dvideow, and a spreadsheet [4,5] was used as reference to calculate F0, V0, Pmax and RF by the time-shift method, as well as maximum (max) and mean (me) modeled force (Fh), velocity (Vh) and power (Ph). The level of agreement between devices was tested by the ICC(2,1) (mean values), with a significance level of $p<0.05$. The coefficient of variation (CV) [6] measured the relative magnitude of error.

RESULTS: All studied variables presented ICCs higher than 0.96, except for F0 (ICC=0.84, 95%CI 0.32-0.97, p=0.005) and maximum modeled force (ICC=0.84, 95%CI 0.33-0.97, p=0.004). CVs were typically low for most variables (depicted as CV[95%CI] V0=1.9%[1.6-2.7%]; Pmax=5.5%[4.3-7.5%]; RF=2.9%[2.3 – 4.0%]; maxVh=1.1%[0.9-1.6%]; meVh=1.0%[0.8-1.4%]; maxPh=5.5%[4.4-7.6%]; mdPh=2.1%[1.7-2.9%]), but not for F0 (7.2%[5.7-9.9%]) and maxFh (7.1%[5.6-9.8%]). Descriptive statistics were close to the ones seen in the literature for this kind of athletes (DVIDEOW: F0=7.53±1.04 N·kg-1; V0=8.61±0.95 m·s-1; Pmax=16.26±3.25 W·kg-1; RF=44±4% MySprint: F0=6.88±0.83 N·kg-1; V0=8.65±0.89 m·s-1; Pmax=14.98±3.03 W·kg-1; RF= 3±3%).

CONCLUSION: The studied setup results in relatively low error for parameters of the FxV relationship when compared to a higher FPS and using MySprint. The most troubling error to consider are for F0 and maxFh. Future studies should focus on improving the setup.

ISOKINETIC DATA RELATED TO RATE OF FORCE DEVELOPMENT IS BETTER CORRELATED TO ACCELERATION SPRINT PERFORMANCE THAN PEAK TORQUE.

BERTOCHI, G.F.A., PUGGINA, E.F.

UNIVERSITY OF SÃO PAULO

INTRODUCTION: Isokinetic tests are commonly used for strength assessment in athletes. Previous data support a relationship with knee strength and sprint acceleration performance [1], although not unanimous [2]. However, due to velocity component of sprint performance, is to be expected that isokinetic data associated with rapid force capacity would be better related with acceleration sprint performance (0-40 m) when compared to peak torque data. Therefore, the aim of this study was to investigate the association between isokinetic data associated with rapid force capacity or peak torque and acceleration sprint performance, and compare with traditional repetition maximum (RM) test.

METHODS: Seven national level male sprinters (age: 24.14±6.64) completed a 40-m sprint (mean: 5.35±0.19), 6 RM strength test and knee extension and flexion for 5 and 30 repetitions at 90°/sec and 180°/sec on an isokinetic dynamometer. Isokinetic assessment was tested for peak torque, average peak torque, torque at 0.18 seconds and time to peak torque. Measurements involved one testing day of 6 RM and isokinetic data, and a second testing day of three 40-m sprint trials. Photocells were positioned on every 10-m from the start, the best sprint trial for each participant was used. RM tests were conducted for squat and stiff exercises and were analyzed as absolute load lifted and relative load lifted to body weight. Pearson's correlation test was used to assess the association between data. Correlations were classified as trivial, (<0.1), small (0.1 – 0.29), moderate (0.3 – 0.49), large (0.5 – 0.69), very large (0.7 – 0.89) and almost perfect (0.9 – 0.99) (3). Significance was set at $p \leq 0.05$.

RESULTS: Very large correlations were found between 10 to 20-m sprint time with time to peak torque at 90º for extension for right and left leg (r= 0.772 and 0.875, respectively; $p < 0.05$). Very large correlations were found between 20 to 30-m sprint time with time to peak torque at 90º and 180º for extension, both for left leg (r= 0.789 and 0.822, respectively; $p < 0.05$) and with 6 RM stiff absolute load (r= -0.865; $p < 0.05$). Very large correlations were found between 30 to 40-m sprint time with time to peak torque at 90º and 180º for extension, both for left leg (r= 0.755 to 0.783; $p < 0.05$), average peak torque at 180 for flexion for right leg (r= 0.764; $p < 0.05$), 6 RM relative stiff load (r= -0.878; $p < 0.05$) and almost perfect correlations with 6 RM squat relative load (r= -0,954; $p < 0.05$).

CONCLUSION: Time to peak torque, average peak torque and 6 RM strength test were associated with sprint time. However, time to peak torque was consistently correlated with sprint time across a larger split range (10 to 40-m), differently from average peak torque (30 to 40-m) indicating a more reliable isokinetic data to assess sprint performance. Compared to isokinetic data, 6 RM presented larger correlation but only in (20 to 40-m split).

EFFECT OF DIFFERENT STARTING TECHNIQUES ON SPRINT SPEED AND LOWER EXTREMITY MUSCLE ACTIVATION FOR 50 M SPRINT

HUANG, B.X., HSU, T.M., NAI, H.F., LIN, J.Z.

NATIONAL TAIWAN UNIVERSITY OF SPORT

INTRODUCTION: The block start position has long been regarded the best starting method for sprints. From the block start, the runner can more quickly enter the optimal running mode than from a standing start and achieve a faster start speed in the shortest time [1]. However, in recent years, the three-point start has been used in the 4*100 m relay, where those running second to fourth legs can choose to start in a standing or three-point starting position. Most of the studies have compared the differences in sprint performance between block and standing starts, but the three-point start has rarely been considered. Examining the process of sprinting is limited during field experiments, as effectively analyzing the muscle activation mode during each phase is challenging. Therefore, the purpose of this study was to explore the instant step point and lower extremity muscle activation of different starting techniques for 50 m sprinting.

METHODS: We recruited 16 college athletics sprinters. The participants performed a maximum-effort sprint of 50 meters with block, three-point, and standing starts, and three sprints were performed. We used Optojump and 5 Witty to record the real-time sprint step and time parameters. Used 8 Noraxon wireless EMG sensors to record the signals. The action phase was considered as: the crouched "set" position; 200 ms after the starting gun fire; the 1, 3, 5, 9, and maximum speed steps. The phase divided into pre-landing, initial contact, stance, and recovery. The statistical method used was One-way repeated measures ANOVA.

RESULTS: In the first 10 m sprint time and speed, and the results show that the block start was significantly faster than the three-point and standing start; the three-point start was also significantly faster than the standing start. In the lower extremity muscle activation section, the results show that the MGAS and SOL activation was significantly lower with the block start than with the three-point start.

CONCLUSION: The sprint time and speed were the fastest in the first 10 m of the block start, and the sprint time of the three-point start was faster than that of the standing start. Therefore, both the block start or three-point start can produce faster acceleration. In terms of muscle activation in the lower extremity, the activation of MGAS and SOL in the block start was significantly lower than that in the three-point start. However, the action patterns of the two were similar, and the three-point start does not provide the starting pedal to supports the ankle joint, so the MGAS and SOL provide more iso-

metric work in the "set" position. We found that the block start produced better sports performance in key indicators such as, sprint time, and speed. The overall movement performance produced with the three-point start was better than that with the standing start. The findings suggest that in the future, during start technique training, the three-point start can be used instead of standing starts.

DIFFERENCES IN HAMSTRING MUSCLE ACTIVATION DURING MAXIMAL AND SUB-MAXIMAL SPRINTS

KNIEWASSER, C., MASON, J., ZECH, A.

FRIEDRICH-SCHILLER-UNIVERSITÄT JENA: FRIEDRICH-SCHILLER-UNIVERSITAT JENA

INTRODUCTION: Hamstring injuries are prevalent across all football codes. While recommended prevention measures include one to two sprint bouts at 95% of maximum speed per week (1) there is only limited knowledge about the hamstring muscle activation during sprinting. Existing studies were performed on a treadmill or analyzed a limited number of steps (2) leading to questions regarding the generalizability of findings to real sprinting situations. This study aims to evaluate the hamstring muscle activation during complete 40-meter sprint trials at maximal and submaximal speeds (80% and 90%).

METHODS: 10 sport students (5 male, age: 23.3 ± 2.4 years) performed multiple 40-meter sprints with maximum speed (27.66 km/h ± 2.68 km/h), 90% (25.27 km/h ± 2.90 km/h) and 80% of maximum speed (22.13 km/h ± 2.81 km/h) on an indoor multisport court. For all trials electromyographic (EMG) activity of the biceps femoris long head (BFlh) and semitendinosus (ST) muscles were recorded with a wireless sEMG sensor (Ultium, Noraxon USA Inc., Arizona). Peak and average activation of the dominant leg over all step cycles were analysed using MyoResearch Software (Noraxon USA Inc., Arizona). A repeated measures ANOVA was used to compare the peak and average EMG activity of the different trials.

RESULTS: In both submaximal sprint conditions, the average BFlh EMG activity was significantly lower compared to the maximum sprint (76.3% ± 10.2% at 90% maximum speed, $p < .001$ and 70.5% ± 13.5% at 80% maximum speed, $p < .001$). Peak BFlh EMG activity was also significantly lower during submaximal conditions with 85.3% ± 13.1% ($p = 0.040$) at 90% maximum speed and 83.9% ± 23.4% at 80% maximum speed ($p = 0.037$). No significant differences were observed between the two submaximal conditions. The average ST EMG activity was lower in both submaximal conditions compared to the maximum sprint trial, with 79.1% ± 8.4% for 90% maximum speed ($p < .001$) and 71.3% ± 17.2% for 80% maximum speed ($p < .001$). There were no significant differences in ST EMG activity between the submaximal conditions. No significant difference was found for Peak ST EMG activity.

CONCLUSION: Conclusion: Submaximal sprinting considerably reduces hamstring muscle activity compared to a maximal sprint and may therefore provide an insufficient stimulus for hamstring injury prevention.

EFFECT OF FORCE VELOCITY AND POWER-BASED TRAINING ON SPRINT PERFORMANCE: A PRELIMINARY STUDY

CHARENTUS, A.1, FORNASIER-SANTOS, C.1, LE MOAN, D.1, GIROUX, C.1, GUILHEM, G.1, MORIN, J.B.2, SLAWINSKI, J.1

INSEP 1, UNIVERSITÉ SAINT-ETIENNE 2

INTRODUCTION: Force-velocity relationship computed during a sprint-acceleration represents the ability of athletes to specifically apply high amounts of force in the horizontal direction. In this way, it is directly linked with sprint acceleration and overall performance (Morin et al., 2012). One goal of sprint training is to move this relationship to the right (stronger, faster and more powerful). One method used to do that is resisted sprint training (Cahill et al., 2019). While studies focus their resisted sprint training (RST) program mainly on the power zone (Lahti et al., 2020), this study aimed to evaluate the effect of a training program based on all 3 zones (speed-strength, power, strength-speed) on sprint performance and force-velocity profile.

METHODS: Seven students in sport science, were split into two groups: power-oriented training (POW) and force-power-velocity oriented training (FPV), with loads based on the decrement of maximal velocity (%Vdec). Both groups performed eight sessions of resisted sprint training over three weeks. Every session was performed in the power zone (50% Vdec) for POW, while FPV performed a same duration resisted sprint training, alternating between speed-strength (25%Vdec) power (50%Vdec), and strength-speed (75%Vdec) zones. Before (Pre-) and after (7 days after the end of the program; Post-) the training period, a force-velocity test was implemented (Fornasier-Santos et al., 2022). The velocity time curve was recorded with a linear motorized encoder (1080 Motion; 333 Hz, Lidingö, Sweden). Performance was evaluated as the 40-m time. The model proposed by Samozino et al. (2016) was used to calculate the theoretical force (F0), velocity (V0) and maximal power (Pmax). Mean, percentages of differences and Cohen's d (ES) were computed on the main variables to compare effect of training.

RESULTS: One week after the last training session, 40-m time did not significantly decrease in both groups (POW: -0.33%, ES = 0.04 vs. FPV: +0.17%, ES = 0.02). Similar results were found for both groups for Pmax (POW: +0.70%, ES = 0.03 vs. FPV:

+0.99%, ES = 0.06), F0 (POW: +2.48%, ES = 0.17 vs. FPV: -0.14%, ES = 0.01), V0 (POW: +0.13%, ES = 0.01 vs. FPV+1.09%, ES = 0.12) and Vmax (POW: +0.39%, ES = 0.04 vs. FPV: + 1.49%, ES = 0.19).

CONCLUSION: Eight sessions of RST based on power or force-power-velocity do not seem enough to improve force components of FVP. A larger number of athletes should be included to improve the analysis and a larger delay after the last training session could lead to observing greater adaptations due to more recovery time after this significant sprint overload.

EFFECT OF HIGH-INTENSITY INTERVAL TRAINING AND REPEATED SPRINT TRAINING IN HYPOXIA ON PERFORMANCE IN FEMALE SPRINTERS

KASAI, N.1, GOTO, K.2

1AICHI SHUKUTOKU UNIVERSITY; 2RITSUMEIKAN UNIVERSITY

INTRODUCTION: High-intensity interval training in hypoxia has been used widely by several type of athletes. Recently, the effect of repeated sprint training in hypoxia caused further increases in sprint performance with augmented anaerobic energy supply [1, 2]. However, the influence of combined high-intensity interval training and repeated sprint training in hypoxia on performance has not been fully evaluated in female sprinters. Therefore, the purpose of the present study was to determine the effect of combination of high-intensity interval training and repeated sprint training in hypoxia on performance among competitive female sprinters.

METHODS: Eight sprinters (height; 161.6 ± 1.1 cm, body weight; 55.9 ± 1.6 kg) performed sprint training under hypoxic conditions [fraction of inspired oxygen (FiO2): 14.5%, a simulated altitude of 3,000m] twice per week for the first half of two week once per week for the latter half of two week (total training sessions: 6). The training consisted of four types of test [10-s maximal sprint, repeated sprint (5 × 7-s sprints), 30-s submaximal sprint following 10-s maximal sprint, and high-intensity interval exercise (5-10 × 60-s submaximal sprints)]. Before and after the training period, repeated sprint ability (5 × 7-s sprints) and 60-s sprint ability tests were conducted. Respiratory samples were collected to evaluate oxygen uptake (VO2), carbon dioxide production (VCO2), ventilation volume (VE), and respiratory exchange ratio (RER) during 60-s sprint ability test. Blood lactate concentrations were determined before exercise, immediately after exercise, and 3, 5 and 7 min after exercise. Moreover, time-course changes in peak and mean power output were evaluated.

RESULTS: In the repeated sprint ability test, mean power output significantly increased compared with before training ($P < 0.01$, ES = 0.74). There was a significant main effect of time ($P < 0.01$, ES = 0.90) for blood lactate concentration, but no significant difference after the training period was observed ($P = 0.07$, ES = 0.45). Mean power output during 60-s sprint ability test was significantly increased compared with before training ($P = 0.04$, ES = 0.52). Post-exercise blood lactate concentrations did not differ significantly after the training period ($P = 0.43$, ES = 0.16).

CONCLUSION: Combined high-intensity interval training and repeated sprint training in hypoxia caused further increase anaerobic performance without affecting post-exercise blood lactate concentration.

EFFECTS OF ASSISTED NORDIC HAMSTRING EXERCISE ON STRENGTH, RANGE OF MOTION, MUSCLE SORENESS AND PERCEIVED EXERTION: A PILOT STUDY

CALLIS, L.J., BAXTER, B.A., KAY, A.D.

UNIVERSITY OF NORTHAMPTON

INTRODUCTION: While the Nordic Hamstring Exercise (NHE) is used to increase hamstring eccentric strength and range of motion (ROM) to reduce hamstring strain incidence [1], poor adherence has been reported due to high exercise intensity and perceived muscle soreness [2]. However, the use of elastic resistance bands during the NHE may reduce loading to alleviate symptoms of muscle soreness. Therefore, the aim of this study was to examine the efficacy of assisted NHE to improve hamstring strength and ROM, whilst assessing perceptual measures (muscle soreness and exertion [RPE]).

METHODS: Twenty-nine university team sport athletes ([mean±SD] 21.1±2.1y) took part in an 8-week training programme twice per week, progressing from two sets of three NHE repetitions in week 1 to four sets of four in week 8. Athletes were stratified based upon NHE strength and body mass, and then assigned to a group that performed NHE (UNASSIST n=12) or NHE assisted with an elastic resistance band (ASSIST n=17). RPE was reported immediately after performing NHE with muscle soreness reported at 24 and 48 hr post-training. Hamstring strength (NHE peak force and isometric force measured at 0, 30, and 60° knee flexion [0°=full extension]) and ROM were measured pre- and post-intervention. Twenty-five athletes (UNASSIST n=10; ASSIST n=15) were included in the analyses of perceptual measures during the initial four weeks, however due to attrition unrelated to the programme, 13 athletes (UNASSIST n=6; ASSIST n=7) were included in post-intervention muscle function assessments.

RESULTS: During the initial week, UNASSIST reported significantly (P<0.05) greater muscle soreness than ASSIST at 24 (5±2 vs. 3±1) and 48 hr (4±2 vs. 2±2) post-exercise; hereafter no between-group differences were reported. No between-group differences were revealed for RPE. Post-training, significant increases in isometric strength (0° knee flexion = 25.1±23.4%, d=0.95; 30° knee flexion = 26.5±32%, d=0.85) and ROM (9.8±3.9°, d=2.53) were detected within ASSIST, with non-significant increases in NHE strength (8.8±11.1%, d=0.80) and isometric strength at 60° knee flexion (14.3±20.4%, d=0.62). Within UNASSIST, a significant increase in ROM (7.8±8.3°, d=0.95) was detected with non-significant increases in NHE strength (10.2±20.8%, d=0.48), isometric strength at 0° (18.3 ± 20.2%, d=0.92), 30° (13.0±13.9%, d=1.01), and 60° (13.5±27.8%, d=0.36) of knee flexion.

CONCLUSION: These preliminary data indicate that assisted NHE can elicit improvements in hamstring muscle strength and ROM, despite a lower exercise intensity. The reduced intensity may allow unaccustomed individuals to be eased into a NHE training programme via reduced perceptions of muscle soreness, whilst still benefiting from positive adaptations. However, further research using a larger sample size is needed to confirm these findings.

DOES MID-COOLING WITH ICE SLURRY INGESTION IN A HOT ENVIRONMENT IMPROVE INTERMITTENT SPRINT PERFORMANCE IN FEMALES PLAYING TEAM SPORTS?

IWATA, R.1, MIZUSHIMA, R.1, MOMMA, R.1, TAKAHASHI, Y.2, HAYASHI, N.3, MURAOKA, I.3

1: JAPAN INSTITUTE OF SPORTS SCIENCES, 2: THE UNIVERSITY OF TOKYO, 3: WASEDA UNIVERSITY

INTRODUCTION: Effects of ice slurry ingestion on exercise performance in females have remained unclear. Then, we have compared the effects of ice slurry ingestion on exercise performance to examine the sex differences. Our previous studies showed that there was no difference between sexes for body temperature in the pre-cooling condition (1), while the post-cooling condition promoted a decrease in body temperature only in females (2). Thus, we hypothesized that cooling the body with ice slurry in females would be more effective than males when the body temperature elevates. The present study examined the effects of mid-cooling with ice slurry ingestion on thermoregulation during exercise, in particular intermittent sprint performance after a certain amount of time has elapsed in females playing team sports.

METHODS: Subjects were 11 females college students (age 20.6 ± 1.1 years, height 160.2 ± 5.4 cm, body mass 56.4 ± 6.3 kg) who played team sports. The intermittent sprint test consisted of two sets of intermittent sprint exercises separated by a 15-minute half rest in 32°C, 60% relative humidity. Each half was divided into 10 x 2-minute blocks consisting of a 4 second sprint, 100 seconds of active recovery, and 20 seconds of passive recovery. The subjects ingested 5.0 g/kg of either ice slurry at -1 ◦C (ICE) or control water at 20 ◦C (CON) during 15-minute half rest. Measurements included rectal temperature (Tre), mean skin temperature (Tsk), perceived measurements (Thermal sensation; TS, Thermal comfort; TC), peak power output (PPO), mean power output (MPO), and whole body sweat loss (WBSL).

RESULTS: Changes in Tre, Tsk, TS and TC were significantly lower in the ICE trials compared to the CON trials ($p < 0.05$). Although statistical analysis with two-way ANOVA showed no interaction effect on exercise performance, statistical analysis with magnitude-based inference method showed a partial " likely positive" effect solely on mean power output in the second half for MPO. There no differences in PPO and WBSL.

CONCLUSION: Mid-cooling with ice slurry ingestion in female may reduce the increase in body temperature in the intermittent sprint performance after a certain amount of time has elapsed, and improve exercise performance, albeit only slightly.

IS THE VENTILATORY THRESHOLD A GOOD SURROGATE FOR MAXIMAL LACTATE STEADY STATE?

LACROIX, S., GHACHEM, A., BOULAY, P.

UNIVERSITÉ DE SHERBROOKE

INTRODUCTION: Maximal lactate steady state (MLSS) is defined as the highest workload that can be maintained for a longer period without continued blood lactate (BL) accumulation and considered to be the best method to establish anaerobic threshold (AT). However, determination of MLSS requires a series of steady state exercise tests which are considered time consuming and tiring. Thus, the aim of this study was to determine if threshold analyses from gas exchanges

obtained during an incremental maximal exercise test (IMET) to volitional fatigue can; 1) be a good surrogate for MLSS testing and, 2) determine which gas exchange threshold coincide with MLSS.

METHODS: This research included 16 trained cyclists (14 males, 2 females; 26.1±5.2 years; 73.3±6.9 kg). The IMET and MLSS were done on separate visits. During the IMET, maximal power output (PO) and oxygen uptake (VO2max) were established using a metabolic cart with mixing chamber (Cosmed, Italy). PO and heart rate (HR) were determined at both the ventilatory threshold (VT), as defined by V slope method [1] and an increase in VE/VO2 [2], and at the respiratory compensation point (RCP), as defined by an increase in VE/VCO2 [2]. The IMET started at 100 watts with 20 watts/min for males and started at 70 watts with 15 watts/min increments for females until each participant attained volitional fatigue. MLSS was established using 30 minutes steady state exercise starting at about 20% below the identified VT and BL was measured (Lactate Plus, USA) every five minutes between the 10th and 30th minute. The test was terminated once BL concentration increased by more than 1 mmol/L between the first and last measurement [3]. Data were analyzed using repeated measures Anova with adjustment of Bonferroni.

RESULTS: VO2max was 62.2 ±6.3 mL/min/kg with a peak PO of 392±65 watts. VT was identified at 47.03±6.8 ml/min/kg (75% max) with a mean PO of 281±54 watts (72% max) and a mean HR of 155±15 bpm (84% max). MLSS was established at a PO of 270±50 watts (69% max) and a HR of 164±10 bpm (88 % max) with a BL concentration of 3.7±0.9 mmol/L. There was no significant difference between methods (both p>0,05) for mean PO (11.6±15.2 watts) and HR (8.75±10.6 bpm). However, PO (361±64 watts; 92% of max; p=0.0004) and HR (175±10 bpm, 95% of max; p=0.027) at the RCP were significantly higher than those identified during MLSS.

CONCLUSION: Our results show that the VT can be used as a good surrogate for MLSS testing and to establish the AT in endurance trained cyclists. Mean differences in PO (4.4%) and HR (5.8%) between both methods were minimal and non-significant. On the opposite, PO (32.7%; p<0.01) and HR (7.3% p=) data at the RCP were significantly higher (32.7% p<0.01 and 7.3% p=0.027) and does not support previous studies suggesting this parameter as an appropriate indicator of AT or to be equivalent to MLSS.

DOES COUNTERMOVEMENT JUMP CAN BE USED TO EXAMINE PEAK POWER OUTPUT AND ACCELERATION PERFORMANCE IN SPRINT TRACK CYCLING?

MICHALIK, K., MROCZEK, D.

WROCLAW UNIVERSITY OF HEALTH AND SPORT SCIENCES

INTRODUCTION: Peak power output (PPO) of lower limbs is one of the crucial factors used to determine sporting performance during maximal athletic tasks such as sprint cycling (1). Especially, acceleration phase demands a high rate of power production, expressed relative to body weight (2). Different sport specific or non-specific tests are performed to assess ability of lower limbs to generate PPO. One of them is countermovement jump (CMJ) which has been widely used to indirectly quantify their mechanical power output capability (3). But, lack of evidence between potential correlation with acceleration performance in cycling. Thus, the main goal of this study was to examine the relationship of peak power output calculated from CMJ and acceleration performance in sprint track cyclists.

METHODS: Fourteen men sprint track cyclists: age 23.6 ± 3.3 (years), height 177.4 ± 4.5 (cm), weight 87.1 ± 6.5 (kg), percentage of body fat 11.8 ± 3.2 (%) (minimum 5 years of training experience). They performed during one training session after 15 minutes warm-up: 1) three countermovement jumps using OptoJump (MicroGate, Bolzano, Italy), 2) peak power output test lasted 6 seconds on the cycle ergometer with maximal load (Wattbike Ltd, Nottingham, UK), 3) three maximal accelerations from the standing start at a distance of 1/4 lap (62.5m) (gear ratio 3.33) with electronic timekeeping system based on dual-beam photocells (Witty System, Microgate, Italy). PPO from CMJ was calculated using the Sayers et al. equation (4). Also, Pearson's linear correlation coefficient was calculated.

RESULTS: Best time of 62.5m was strongly correlated with PPO obtained in the cycle ergometer: r = -0.73 (p<0.01) and PPO per kilogram body weight r = -0.80 (p<0.01), average power r = -0.78 (p<0.01) and relative average power r = -0.86 (p<0.001). Additionally, the acceleration sprint performance was strongly related to CMJ height r = -0.87 (p<0.001), PPO calculated from CMJ r = -0.72 (p<0.01) and PPO from CMJ per body weight r = -0.85 (p<0.001).

CONCLUSION: Our results indicate that CMJ height and calculated power parameters can be useful indicators of training control in sprint track cycling.

ESTIMATION OF LACTATE THRESHOLD USING TIME-INVARIANT AND TIME-VARYING PARAMETER MODELS BASED ON HEART RATE AND POWER DATA

STESSENS, L., AERTS, J.M.

KU LEUVEN

INTRODUCTION: The anaerobic threshold is an important marker in endurance sports used to identify training zones and monitor training progress. The determination of the anaerobic threshold requires expensive equipment, invasive sampling and a visit to a specialized facility. Therefore, regular monitoring of the anaerobic threshold is inaccessible to a large population of cyclists, even among the elite.

Mathematical modelling might form a suitable method for continuous monitoring of performance, especially in combination with wearable technology. In cycling, the heart rate, power and cadence are already continuously measured and monitored during training and competition, making them particularly suitable for integration in a modelling technique. This study attempts to estimate the anaerobic threshold with linear time-invariant and linear time-varying models based on the heart rate, power and cadence.

METHODS: 11 amateur, trained cyclists (6 male, 5 female) participated in this study. They performed an incremental cycling test on a Lode Excalibur ergometer in laboratory conditions to determine the maximal oxygen consumption (VO2max), ventilatory thresholds (VT) and second lactate threshold (LT). The workload increased with 40 watts every 3 minutes. The heart rate was measured with a 12-lead electrocardiogram (ECG). Lactate samples were taken at the end of each step and analyzed with the EKF Biosen Lactate Analyzer. Modelling and analysis was performed with the CAPTAIN toolbox in Matlab R2021b. The anaerobic threshold was estimated with both time-invariant parameter (TIP) models and time-variant parameter (TVP) models. The results were compared with the actual LT identified from the incremental step test.

RESULTS: Calculation of the LT with time-invariant parameter (TIP) models was performed with an average error of 11%. For 5 out of 11 participants, the estimated LT was approximated with an error smaller than 10 watts. The time-variant parameter (TVP) models performed with an average error of 4%. For 9 out of 11 participants, the LT was estimated with an error smaller than 10 watts. The better performance of the time-variant parameters was attributed to their adaptability and their ability to capture a highly varying signal such as the heart rate better.

CONCLUSION: Modelling techniques based on the heart rate and power output approximate the LT with a decent accuracy, with time-varying parameter models performing better than time-invariant models. Our results are interesting to the ECSS community since they propose an alternative to the current gold-standard of testing that might enable at regular monitoring of the anaerobic threshold. Given the widespread popularity of heart rate, power and cadence sensors in the cycling population, this modelling approach could The modelling approach based on wearable-captured heart rate, power and cadence data might even be applied in the field. Future work needs to focus on verifying the technique in a bigger population and adapting it to the field.

THE COMPARISON OF FOAM ROLLING FORCE ON LOWER EXTREMITY MUSCLES BETWEEN YOUNG AND MIDDLE-AGED MEN AFTER ECCENTRIC CONTRACTION

WEN, H.J., WANG, P.K.

TZU-CHI UNIVERSITY, HUALIEN TZU-CHI HOSPITAL

INTRODUCTION: A foam roller (FR) is a popular toolkit for muscle recovery after delayed onset muscle soreness (DOMS) due to eccentric contraction training because of its convenience, portability, and cheapness for active people and athletes. Most studies instructed participants to place "as much body mass as tolerable" on the FR at all times. A major problem of the FR-related study is the lack of biomechanical load, especially in different muscles after the delayed onset of muscle soreness for consecutive 3 days is still unknown. Purpose: The aim of this study was to understand the FR force in different muscles in the lower extremity after delayed onset muscle soreness for consecutive 3 days.

METHODS: Twenty healthy men with regular exercise (= 5 times/ week exercise) were recruited as participants. All participants receive the DOMS-induced protocol by a dynamometer (Biodex System 4 Pro) in the non-dominant leg (DL). After that, the participant was instructed to the FR recovery program on the force plate for 20 to 30 min, targeting the major muscle groups of the anterior (quadriceps), lateral (iliotibial band), posterior (hamstrings), and medial aspect (adductors) of the thigh, along with the gluteal muscles on both the right and left legs for two 60-s bouts each for total 20 min, 2 sets for 60 s (Macdonald et al. 2014; Pearcey et al. 2015). After completing 1 set of 5 muscles (hamstrings, abductor, quadriceps, adductor, and calf muscle), repeat one set in DL. After completing 2 sets in DL, switch to non-DL for the same protocol. Participants accept the FR protocol for consecutive 3 days (0, 24h, and 48h), and relative vertical ground reaction forces measured during foam rolling for the thigh were recorded and analyzed.

RESULTS: The FR-force in non-DL was significantly greater than that in DL (29.93 ± 5.16 kg vs. 28.90 ± 5.76 kg, $p = 0.030$). The main effects of FR-force between 5 muscle groups [$F(1,18) = 6.45$, $p = .021$, $?p2 = 0.26$] were significant. The FR-force in the Calf muscle (23.56 ± 7.48 kg) was significantly smaller than that in the hamstring (34.92 ± 7.71 kg, $p < 0.001$), abduction (33.56 ± 6.79kg, $p < 0.001$), and Quadriceps (32.16 ± 7.67kg, $p < 0.001$), respectively. The FR-force in the adduction muscle (22.86 ± 8.01kg) was significantly smaller than that in the hamstring (34.92 ± 7.71 kg, $p < 0.001$), abduction (33.56± 6.79kg, $p < 0.001$), and quadriceps (32.16 ± 7.67kg, $p < 0.001$), respectively. There was no age effect (young or middle-aged men), and time effect (days 1, 2, and 3) in FR-force.

CONCLUSION: The FR-force influenced muscles in the lower extremity after delayed onset muscle soreness. The FR-force might be higher in the leg with muscle soreness condition and determined by body posture. The results may provide

coaches and athletes with post-exercise muscle recovery applications. The study was supported by the Ministry of Science and Technology (MOST109-2410-H-320-003) and Hualien Tzu Chi Medical Center (TCRD109-75).

HOT WATER IMMERSION TO BOOST MUSCLE RECOVERY IN ATHLETES: A MATTER OF HEAT DOSE?

SAUTILLET, B.1, MILLET, G.P.2, AHMAÏDI, S.1, COSTALAT, G.1

1FACULTY OF SPORT SCIENCES, APERE LABORATORY, UR 3300, UNIVERSITY OF PICARDIE JULES VERNE, AMIENS, FRANCE. 2 INSTITUTE OF SPORT SCIENCES, UNIVERSITY OF LAUSANNE, LAUSANNE, SWITZERLAND

INTRODUCTION: Athletes who require rapid recovery between bouts of damaging exercise should implement evidence-based recovery strategies. Hot water immersion (HWI) has shown promising results to promote muscle recovery [1], despite limited data on the optimal heat dose [2]. The objective of this study was to compare the responses of two exogenous heat strains (40°C, HWI40 and 41°C, HWI41) on core body temperature and key functional markers of muscle recovery following exercise-induced muscle damage (EIMD). We hypothesized that both modalities would increase core body temperature, with HWI41 but not HWI40 attenuating EIMD-induced decline in muscle strength.

METHODS: Twenty-eight athletes underwent a customized EIMD protocol by means of an isokinetic dynamometer, immediately followed by one of the following recovery interventions: HWI40, HWI41, or 36°C (CON36). Markers of endogenous heat strain such as gastrointestinal temperature, thermal impulse (area under the curve > 38.5°C), physiological strain index and heart rate were tracked throughout HWI. Finally, functional markers of quadriceps muscle recovery [peak concentric torque (Tpeak), late-phase rate of force development (RFD100-200)] were assessed before EIMD (pre-), 24 hours (post-24h), and 48 hours (post-48h) after EIMD.

RESULTS: By the end of immersion, HWI41 induced a more pronounced increase in gastrointestinal temperature than HWI40 (38.8 ± 0.1 vs. 38.0 ± 0.6°C, $p<0.001$). Thermal impulse only increased during HWI41 (14.9 ± 8.72 °.min, $p<0.05$). The physiological strain index was significantly higher during HWI41 compared to HWI40 (5.93 ± 0.96 vs. 3.81 ± 1.19 AU, $p<0.05$). HWI41 but not HWI40 mitigated the decline in RFD100-200 at post-24h (-7.1 ± 31.8%; $p = 0.63$) and Tpeak at post-48h (-3.1 ± 4.3%, $p = 1$).

CONCLUSION: A single session of HWI41, rather than CON36 or HWI40, provided the required endogenous heat strain to mitigate the decline in muscle strength following mild exercise-induced muscle damage. Heat-based protocols should be designed to achieve a sustained core body temperature (~ 25 minutes) above 38.5°C when muscle recovery is of primary importance.

COMPARISON OF TWO DIFFERENT WAYS OF ACTIVE RECOVERY AFTER A MAXIMAL 500M IN HUNGARIAN YOUNG KAYAKERS.

TRÁJER, E.1,2, KATONA, P.1,2, KOVÁTS, T.1,2

1 HUNGARIAN UNIVERSITY OF SPORTS SCIENCE; 2 KATALIN KOVÁCS NATIONAL CANOE SPORTS ACADEMY

INTRODUCTION: Efficient lactate clearance after maximal exercise is a key in competition. Athletes in canoe sprint reach high lactate values, therefore, an effective lactate clearance method is fundamental to restore homeostasis. Active recovery has been indicated more effective in blood lactate clearance than passive recovery (1,2). However, there are differences in the efficiency of the active recovery whether using the same or different muscles from those which are mainly used during the specific sport activity (3). The aim of this study was to compare the effectiveness of active recovery on water and on cycle ergometer.

METHODS: Fourty-one (21 boys; 17 girls; 16±1 ys) well-trained kayakers (part of the national team of the Olympic Hopes 2022) performed a maximal 500meter on flat water. Participants were randomly divided into 3 groups (A,B,C). A: active recovery by kayaking on water. B: active recovery on cycle ergometer (Precor Spinner Ride, Spinning Hungary). C: control group, passive recovery. Athletes in A and B group had previously performed a step test to determine their individual maximal lactate clearance heart rate zone. The recovery phase lasted 20 minutes and athletes of A and B group had to remain in their individually determined heart rate zone. Heart rate was continuously monitored during and after the race (HRmax, HR5', HR10', HR15', HR20') (Garmin HRM-Dual). Blood lactate was measured after the race (Lamax) (Lactate Scout, EKF Diagnostics, Germany) and during the recovery in every 5 minutes (La5', La10', La15', La20'). After a normality test, one-way ANOVA or Friedman test were used to detect changes between the different recovery methods. Significancy was set at $p<0.05$.

RESULTS: There were no significant differences between the maximal lactate and maximal heart rate values in the three groups (A:11.93±1.86, B:11.95±1.76, C:11.52±2.21 mmol/L and A: 189±6, B:183±24, C:190±5 bpm/min, $p>0.05$). There were significant differences during the recovery in the lactate values between the kayak and passive groups (A vs C: La5': 7.85 vs 10.21, La10': 5.52 vs 8.99, La15': 4.01 vs 7.40, La20: 3.40 vs 6.31 mmol/L) ($p<0.05$). At the end of the recovery, we also found significant differences between the cycling and the passive group (La20': 4.27 vs 6.31 mmo/L). The average heart rate during the recovery was the highest on water, the lowest in the passive group and in between on the cycle ergometer.

CONCLUSION: According to the results of the study, the on-water kayaking is more effective to eliminate the blood lactate than the use of cycle ergometer. However, individual differences in the efficiency of lactate elimination were observed in each group.

NON-LINEAR HEART RATE VARIABILITY AS A NONINVASIVE BIOMARKER TO ASSESS THE PHYSIOLOGICAL STATUS OF TRIATHLETES DURING SIMULATED WARM-UP BOUTS

SCHAFFARCZYK, M.1, ROGERS, B.2, REER, R.3, GRONWALD, T.1

1MSH MEDICAL SCHOOL HAMBURG; 2UNIVERSITY OF CENTRAL FLORIDA; 3UNIVERSITY OF HAMBURG

INTRODUCTION: The non-linear index alpha 1 of Detrended Fluctuation Analysis (DFA a1) of heart rate variability (HRV), has revealed potential as a marker of fatigue during endurance exercise. This report is an initial exploration of the ability of DFA a1 to assess the physiological status of triathletes as a surrogate marker for "readiness to train" while performing simulated warm-up sessions the day after two different exercise sessions.

METHODS: After the recruitment of 11 triathletes from a local triathlon club, the first ventilatory threshold (VT1) was determined during a baseline assessment. During the four other laboratory visits, triathletes were instructed to perform 10-min of cycling at 90% of VT1 (simulating a warm-up bout) before (PRE) and within 36 h after (POST) light and heavy running exercise. The effects of the performed exercise sessions were verified by means of the recorded RR intervals for DFA a1 analysis along with neuromuscular testing. Besides common statistical methods, magnitude-based inferences (MBI) were utilized to assess the changes in true score and thus also the practical relevance of the magnitude.

RESULTS: The heavy exercise session induced a significant higher rating of perceived exertion as opposed to the light exercise session ($p < 0.001$, $d = 0.89$). In terms of MBIs, PRE versus POST comparisons revealed a significant reduced DFA a1 with large effect size after the heavy exercise session ($p = 0.001$, $d = - 1.44$) and a 99% chance that this negative change was clinically relevant.

CONCLUSION: Observation of the DFA a1 to power relationship during simulated warm-up bouts seems to represent a valuable measure to depict physiological status and guide athletes in their training as an easy-to-apply monitoring procedure. The inter-individual differences observed indicate the need for a regular assessment including individual data history and statistical references for identification of response. Further data are necessary to confirm the results in a larger and more homogeneous population.

THE COMPETITIVE SPORT MENTALITY AND THE MENTALITY OF INDIVIDUAL ATHLETES AS REVEALED THROUGH JUNGIAN-ORIENTED COUNSELING

NAKAGOMI, S., AKIBA, S.

UNIVERSITY OF TSUKUBA AND KOKUSHIKAN UNIVERSITY

Introduction

Jungian psychology provides specific concepts such as "self," "individuation," "wholeness," "shadow," and "persona," etc. which guide the psychotherapeutic approach. One of the manifestations of this is the importance of "images" and "symbols," and expressive methods such as dream analysis, sandplay technique and drawing methods are often used in psychotherapy. Furthermore, we do not understand episodes narrated by clients causally (causality), but rather from the point of view of their meaning (teleology) by paying attention to their synchronicity or constellation.

Purpose

The purpose of his study was to identify the psychological characteristics (mentality) of both competitive sports in general and in individual athletes as revealed through sports counseling oriented to Jungian psychology.

Method

The authors analyzed material derived from the psychotherapeutic cases that they have reported at various occasions (articles, books, case conferences, etc.) and the findings of others who have taken similar therapeutic approaches. Factors related to both types of mentality were extracted which at the same time were unique, significant and highly common.

Result and Discussion

Analysis of the case reports resulted in the identification of the following characteristics: 1) A balance (wholeness) between adaptation to reality (performance enhancement) and individualization (personality development) is a key psychological issue in psychotherapy, and a strong bias toward adaptation to reality in their athletic history experienced up to that point may be problematic. 2) Many of their narratives are related to the "body" in terms of movement and performance, and through these narratives (unconscious, symbolic), the athlete addresses his/her own psychological issues, and thus the narratives about the "body" serve as a "window" into the therapeutic relationship between the athlete and the therapist to approach through which the athletes inner experience. 3) The experience of the athletic situation and the expectations of those around them add to the formation of a specific persona (e.g., sport-only identification) that serves as a background for psychological problem and which makes the athlete reluctant to tackle psycho-developmental tasks (self-reliance, ego

identity, and subjectivity) that give rise to psychological problems. These mentalities can also replace common therapeutic cues and issues in psychotherapy of athletes, regardless of differences in therapeutic approaches.

IMPLEMENTATION OF THE SPECIFIC TRAINING OF EXECUTIVE FUNCTIONS IN FOOTBALL (STEFF) AMONG LOWER DIVISION FEMALE PLAYERS: A PILOT STUDY

FILGUEIRAS-GONCALVES, A.

UNIVERSITY OF GLOUCESTERSHIRE

Introduction

Evidence from the past two decades associate executive functioning with sport expertise, especially in football. This collective knowledge showed that inhibition and working memory tend to have higher association to defending and goal-scoring skills, whereas cognitive flexibility tends to be strongly linked to assists and dribble skills. While there is not enough evidence to support nor deny the effectiveness of computerized or face-to-face cognitive training to improve in-game decision-making, findings have suggested that these practices constitute far transfer which do not influence performance, whereas the inclusion of these tasks in technical training sessions enables near transfer of these skills. This pilot study aims to implement and test the effects of a training protocol that taps onto executive functions.

Methods

We drew eight pre-training sessions of 10 minutes each to be used before the main training session. The club's roster of 28 players, participated of the protocol four times a week, throughout a one-month pre-season period. Executive functions were assessed by standardized measures and in-game decision-making was assessed by the Decision-making coding instrument from Romeas et al. (2016). We collected the data before and after the intervention, and a 60-day follow-up.

Results

Repeated-measures ANOVA retrieved significant improvement in working memory ($p<.05$), cognitive flexibility ($p<.01$) and decision-making ($p<.001$), but no statistical difference for inhibition ($p=.12$). Bonferroni's post-hoc analyses revealed significance for working memory and cognitive flexibility between pre- and post-intervention ($p<.05$), but non-significant results between post-intervention and follow-up ($p=.21$ and $p=.37$, respectively). Decision-making yielded statistically different results between both time frames ($p<.05$).

Discussion

We investigated whether a protocol would be able to produce changes on cognition and decision-making among female football athletes. STEFF potentially influenced working memory and cognitive flexibility which points out to a possible far-back transferability, from the sport environment to the pencil-and-paper test. However, decision-making kept increasing which might be influenced by confound variables. Because it was a pilot study, and to comply with the club's conditions, we decided not to constitute a control group, which means that our results might be influenced by time or by technical training, which are likely to help the improvement of decision-making as well. Nevertheless, our findings are partially supported by previous literature and STEFF seems a promising new set of short training sessions that could be adopted within a pre-season plan to improve cognitive outcomes and decision-making among footballers.

"IS IT REALISTIC?": THE EXPERIENCES OF ELITE FEMALE ATHLETES CONSIDERING PARENTHOOD

MCHUGH, T., RAY, L., NESDOLY, A., THORNTON, J.S., KHURANA, R., DAVENPORT, M.H.

UNIVERSITY OF ALBERTA

The gender inequities experienced by pregnant and parenting elite athletes have been documented by the media and in sport research. However, the experiences of elite female athletes considering parenthood are underrepresented. Various sporting bodies, including the International Olympic Committee, have called for more research in this often-overlooked group. Such research is necessary for the development of evidence-informed policies and practices to support athletes during pre-conception, pregnancy, and while parenting. The purpose of this study was to describe the experiences of elite female athletes considering parenthood. Participants included 10 North American elite female athletes (ages 29-36 years) who are considering parenthood in the next five years. Nine of the ten athletes had previously competed at one or more Olympic Games. Using a qualitative description study design, participants engaged in one-on-one semi-structured interviews. Interviews were audio-recorded, transcribed verbatim, and analyzed using a process of content analysis. Participant experiences of considering parenthood are represented by five main themes: (a) Calls for essential mandates and leadership; the lack of National-level sport policies and practices supporting pregnant and parenting athletes was described as a major barrier to becoming mother-athletes, (b) "How do your support yourself?"; concerns regarding limited financial and social support for athlete-parents were expressed, (c) Concern about body changes; physiological and psychological changes that result from pregnancy were noted as a concern, (d) Age inequities; participants described

barriers experienced from societal notions that as athletes reach a certain age they will (or should) leave sport to become mothers, and (e) Being proactive about reproductive health; participants identified the need for early and comprehensive education about reproductive health. Grounded in the experiences of elite athletes, these findings provide necessary evidence to inform the development of sport policies and practices that support gender equity and participation of girls and women across all levels of sport.

"WE'RE NOT THE SAME": A COMPOSITE VIGNETTE ON PREGNANCY AND MOTHERHOOD FOR ELITE ATHLETE MOTHERS IN AND OUT OF FUNDING PROGRAMMES

MASSEY, K., WHITEHEAD, A.

LIVERPOOL JOHN MOORES UNIVERSITY - COPPERAS HILL

28th Annual ECSS Congress France/Paris, July 4-7 2023

"We're not the same": A composite vignette on pregnancy and motherhood for elite athlete mothers in and out of funding programmes

Massey, K.L, & Whitehead, A.E

Liverpool John Moores University

Introduction

Today, pregnancy is often viewed as a temporary phase allowing a break from the physical and mental pressures of high-performance sport rather than career closure. Yet, obtaining the elite athlete mother identity is not without struggle. A cultural shift sees sporting organisations developing contracts and policies to support the success of the post-partum return. Although there is much research on elite athlete mothers within professional contracts or in receipt of funding it has yet to explore how experiences differ between elite athlete mothers with and without these financial agreements. The present study aims to provide insight into the disparity between support of elite athletes with and without National Governing Body funding in hopes of informing future policy, provisions and practices for those elite athlete mothers who fall short of funding.

Method

This study took on a qualitative approach, creating composite vignettes using extracts from the raw data of a published study containing three semi-structured interviews exploring pregnancy and postpartum experiences of a funded Paralympian and an unfunded Olympian. Bengtsson's (2016) 4-stage content analysis was used to find disparities between the two elite athlete mothers. Stage 1 involved reading and rereading transcripts. Stage 2 removed extraneous data. Stage 3 the first author coded quotations and consulted the wider research team to group codes into topics. In stage 4 quotes were used to construct an initial composite vignette involving a conversation between the participants. Using member reflections, a co-constructed composite vignette was created.

Results

A co-constructed composite vignette involving a discussion between two elite athlete mothers, one receiving funding and the other not was presented. Topics such as views on sport as a hobby or job, competition and qualification and the relationship with the NGB highlight distinctions between being an elite athlete mother in and outside of funding structures. Further topics highlight the dichotomy of sport vs motherhood, discriminatory policies and gender of performance directors.

Discussion

This current study highlights disparity between elite athlete mothers in and outside of funding structures. Results indicate the need for further change within policy, provision and practice to encompass athlete mothers who meet the definition of elite but not the requirements for funding. Simple improvements in competition and training opportunities and in NGB communication may enhance the experiences of unfunded elite athlete mothers.

GROUP INTERVIEWS ON MENSTRUATION WITH FEMALE AESTHETIC SPORTS COLLEGE ATHLETES —BASED ON THE FRAMEWORK OF HEALTH PROMOTION—

YAMANAKA, Y., TSUTIYA, H.

1. OSAKA SANGYO UNIVERSITY 2. OSAKA UNIVERSITY OF HEALTH AND SPORTS SCIENCES

Introduction

The Female Athletes Triad (FAT) is a typical health issue of female athletes. The risk of FAT is higher in aesthetics and weight class competitions (Torstveit and Sundgot-Borgen, 2005). Recent studies on FAT have focused on menstruation. Several studies have investigated the effects of the menstrual cycle on athletes' condition and performance. However, only a few studies have investigated how athletes feel about menstruation. The understanding of menstruation is increasing in sports and society. The increased interest and social changes are likely to impact female athletes.

Purpose

This study aimed to identify knowledge and attitudes about menstruation among female college athletes competing in gymnastics, an aesthetic sport considered high risk for FAT.

Method

The author conducted semi-structured interviews in groups of two to four students, with 14 female gymnastics club members (mean age 19.3 years). The interviews lasted approximately one hour and inquired about students' attitudes and coping with menstruation. We classified the data based on the content and examined them from the perspectives of personal and environmental factors based on the health promotion framework.

Results

We classified personal factors into three facilitating factors: "worries about menstruation," "correct knowledge about menstruation," and "coping behavior during menstruation," and an inhibiting factor, "wrong perception of menstruation. We also classified environmental factors into three inhibiting categories: "spread of false knowledge within the club," "transmission of false knowledge from family members," and "restrictions by family members." Based on the health promotion framework, the results indicated that many personal factors are moving in the direction of promoting health behaviors for correct menstruation, while environmental factors are inhibiting at the micro-level.

Discussion

The results of this study indicated that many personal factors promoted resolving problems related to menstruation, suggesting that athletes might try to engage in correct health behaviors regarding menstruation from the perspective of health promotion. On the other hand, environmental factors provided by familiar figures such as family members and teammates were the only factors that inhibited menstruation-related proper health behavior.

Recently, social interest in menstruation among women, including female athletes, and knowledge of menstruation-related diseases are increasing. Conventional obstetrics and gynecology clinics are now called "ladies' clinics" or "outpatient clinics for female athletes," suggesting that macro-level environmental factors promote understanding menstruation and correct health behaviors. However, micro-level environmental factors, such as family and teammates, might inhibit female athletes attempts at conducting appropriate menstruation-related health behaviors.

ASSESSMENT OF COMPLAINT MECHANISMS FOR INTERPERSONAL VIOLENCE: WHAT CAN SPORT SETTINGS LEARN FROM RESEARCH-BASED RECOMMENDATIONS?

RADZISZEWSKI, S.1, PARENT, S.1, ST-PIERRE, E.1, DAIGNAULT, I.V.2, HÉBERT, M.3, BARIL, K.4

1 UNIVERSITÉ LAVAL, 2 UNIVERSITÉ DE MONTRÉAL, 3 UNIVERSITÉ DU QUÉBEC À MONTRÉAL, 4 UNIVERSITÉ DU QUÉBEC EN OUTAOUAIS

Sport represents a context associated with a host of physical and psychological benefits, yet the sport environment can sometimes be characterized by interpersonal violence (IV). Research has shown that experiencing IV in sport can lead to anxiety, depression, and eventually dropping out of sport. To ensure access to a safe sporting environment, it is essential that people confronted with IV, whether themselves or as witnesses, feel safe and informed as to how to report their experience. While research is sparse on this subject, results indicate that reporting rates remain particularly low. Studies have highlighted the lack of formal, independent complaint mechanisms as one of the most significant barriers to reporting IV in sport and seeking help. There is, however, a growing interest by athletes, decision-makers, and researchers in implementing well-defined mechanisms. To do so, it is essential to identify the key practices that could help in this endeavor. This communication will present the results of a rapid review that aimed to document the recommendations issued from the evaluation of IV complaint mechanisms. The rapid review was conducted following the guidelines provided by the Cochrane Rapid Review Interim Guidance (Garrity et al., 2021). Given the recency of these efforts in the sport domain, any mechanism for receiving complaints pertaining to IV were included. The initial search through the databases (PubMed, PsycInfo, ProQuest Dissertation and Thesis Open, SportDiscus, Human Resources Abstracts, and Sociology Abstracts) yielded 306 references, and two members of the research team then screened to assess for eligibility. A total of 35 references published from 2012 to 2022 were identified, and they covered mechanisms mainly targeting IV in general (any type) or sexual violence more specifically. Complaint mechanisms varied in scope and as a function of the setting considered, including work, university, military, and medical settings. Our review identified recommendations spanning four broad categories: 1) Institutional accountability (e.g., public transparency regarding the process and the results, collaborative efforts between stakeholders); 2) Awareness and accessibility of the complaint mechanism (e.g., targeted educational workshops, regular promotion); 3) Adapted process (e.g., ensuring anonymity and protection, providing timely response and regular feedback); and 4) Ongoing evaluation strategies (e.g., continuous monitoring and adjustments). Findings from this rapid review will inform current efforts to develop and implement formal and independent complaint mechanisms in the sport domain. The synthesis of recommendations from various research disciplines and types of mechanisms offers a comprehensive portrait of best practices currently implemented. Strategies to adapt and integrate such recommendations within an independent complaint mechanism in the sport context will be discussed.

THE ASSOCIATION BETWEEN SPORTS SELF-IMAGE AND SPORTS PERFORMANCE IN COLLEGIATE ATHLETES: A MIXED METHODS STUDY

LEWIS, J., KHANAL, S., ENRIQUEZ, M., GAMBOA, B., OTTEN, M.P.

CALIFORNIA STATE UNIVERSITY, NORTHRIDGE

INTRODUCTION

This paper conceptualizes self-image as a novel measure in the sports performance world as it pertains to an athlete's perception of themselves with an emphasis placed on their body and appearance both on and off the field. Strengthening one's self-image may make a player stronger and more effective in their performance–and carry on with them throughout their life, not just in their respective sport.

METHODS

This study investigates the association between sports self-image and sports performance amongst collegiate athletes using a mixed methods approach. 40 Division 1 collegiate athletes participated in the study and were given two open-ended qualitative questions: 1) "Are you conscious of your body image or appearance while you are playing your sport?" and 2) "Does how you feel about your body-image or appearance affect your performance on the court or field?" Afterwards, self-image was assessed using the Body Self-Image Questionnaire (BSIQ) and sports performance was assessed using the Athlete Sports Performance Survey (ASPS).

RESULTS

The qualitative data suggests that self-image and its subsequent effect on performance varies by sport. Beach volleyball players expressed feeling highly conscious of their body self-image while playing in small, tight uniforms while they are in direct comparison to their competition across the net. Women's water polo players described their ability to experience flow while playing, but once they stepped out of the water, they felt self-conscious about their bodies. Men's basketball players suggested that their self-image was important to them; many expressed wanting to look good in order to feel good and play well. Co-ed track and field explained that they struggled with feeling confident while wearing their tight-fitting uniforms all the time. Women's tennis suggested that it became hard to maintain a high body self-image when always being compared to other players. Quantitative analyses await a second round of data collection (in progress) that will allow for a longitudinal assessment of the relationship between self-image and performance across two time points, three months apart.

CONCLUSION

We found that most of the elite athletes are conscious of their body self-image, especially while they were not performing. However, once it was gametime, many were able to reach a flow state and block out the excess noise. Overall, the qualitative data suggests that most athletes struggle with their body self-image regardless of gender, age, sport, and performance. Research that explicitly details the importance of enhancing a player's self-image illuminates the critical role that coaches play. Moreover, the research can teach athletes at critical ages to appreciate their bodies.

PARALLEL MULTIPLE MEDIATION EFFECT OF PHYSICAL EDUCATION MAJORS STUDENTS'S COLLEGE LIFE ADAPTATION ON THE RELATIONSHIP BETWEEN PHYSICAL SELF-EFFICACY AND CAREER PREPARATION BEHAVIOR

YANG, E.S., LEE, Y.E.

KOREA NATIONAL SPORT UNIVERSITY, KOREA NATIONAL SPORT UNIVERSITY

This study attempted to verify the multiple mediating effect of college life adaptation in the relationship between Physical Education Majors Students's physical self-efficacy and career preparation behavior. The study targeted 229 students of University in Korea. The survey tools used the physical self-efficacy (Rycman, Robbins, Thornton & Cantrell, 1982), college life adaptation (Baker & Siryk, 1989), and career preparation behavior (Kim, 1997) scales. Physical self-efficacy consists of perceived physical confidence(PPC) and physical self-expression confidence(PSEC), and college life adaptation consists of academic adaptation(AA), social adaptation(SA), emotional adaptation(EA), physical adaptation(PA), and attachment to college(AC). Career preparation behavior consists of career exploration(CE), information gathering(IG), and occupational experience(OE). All scales consist of a 5-point Likert scale. The collected data were analyzed through SPSS 21.0 and PROCESS macro (v.3.3) model 4 to verify the parallel multi-mediatied effect, and the mediatied effect was further verified through Bootstrapping. Results show that, Firstly, PPC was found to have a significant effect on AA(β=.186, p<.01), SA(β=.267, p<.001), EA(β=.284, p<.001), PA(β=.178, p<.01), IA(β=.177, p<.01), and PSEC was found to have a significant effect on SA(β=.238, p<.001), EA(β=.331, p<.001), PA(β=.286, p<.001), AC(β=.235, p<.001). Secondly, AA was found to have a significant effect on CE(β=.244, p<.001), IG(β=.623, p<.001), OE(β=.788, p<.001), and SA was found to have a significant

effect on CE(β=.255, p<.001) and OE(β=.149, p<.01). Third, the relationship between PPC and CE was mediated by AA(95% CI=.011~111) and SA(95% CI=.083~.292). Fourth, the relationship between PPC and IG was mediated by AA(95% CI=.034~.179). Fifth, the relationship between PPC and OE was mediated by AA(95% CI=.044~.245) and SA(95% CI=.013~.070). Sixth, the relationship between PSEC and IG was mediated by SA(95% CI=.017~.132). Seventh, the relationship between PSEC and IG was mediated by SA(95% CI=.017~132) and AC(95% CI=.007~.076). Eighth, the relationship between PSEC and OE was mediated by SA(95% CI=.014~.114).

THE IMPACT OF PE, SPORT AND PA FOR SOCIAL INCLUSION IN ROMANIAN SCHOOLS

RADMANN, A.

NORWEGIAN SCHOOL OF SPORT SCIENCES

The impact of PE, Sport and PA for social inclusion in Romanian schools

Introduction

The project is a collaboration between National University for Physical Education and Sports (UNEFS), Romania and Norwegian School of Sport Sciences (NSSS) with several researchers from both countries participating.

The study represents a thorough assessment of Romanian pupils (aged 10-15 years) accessibility to physical and motor activities and the way PE, PA and sports activities can play a role in facilitating a context of sustainable social integration for students with different challenges or with specific vulnerabilities.

Method

2,600 pupils and 760 teachers who work directly with the pupils participated in the study. The study involved three types of correlated surveys: questionnaire survey; structured interviews and focus groups interviews. The sociological survey involved the application of 2,600 questionnaires to the main target group (pupils with vulnerabilities). At the level of the secondary target group (teachers), 760 semi-structured interviews were applied and 16 focus groups were organized where a total of 131 teachers participated.

Results

One conclusion is that Physical education and sports class has an impact in terms of increasing the inclusion of pupils and strengthening the solidarity between pupils.

Results from the survey also show that PE, PA and sport improve relationships, favor cooperation between people from different social categories or who have different physical or psycho-emotional conditions. The study showed that PE, PA and sport can constitute a social integration solution for pupils from disadvantaged environments, and it can offer children with unfavorable conditions participation in the activities

Discussion

The project was organized based on two general research goals:

1. analyze and discuss the ways PE, sports activities and PA can be used to reduce the social exclusion of pupils with vulnerabilities.

2. analyze and discuss if PE, sports activities and PA can be used as a strategy to fight absenteeism from school.

The project has so far resulted in several publications and now a new public policy is to be drawn up to strengthen PE and PA in Romanias schools.

THE EFFECT OF A 10-WEEK PHYSICALLY ACTIVE LEARNING INTERVENTION: FOCUS ON 10-YEAR OLD PUPILS DEVELOPMENT IN MATHEMATICS

BOGNÁR, J., KERTÉSZ, T., SZAKÁLY, ZS.

ESZTERHÁZY KÁROLY CATHOLIC UNIVERSITY

Introduction

Regular physical activity has been proven to have a positive impact on executive functions and cognitive performance in youth. Physically active learning (PAL) with active student engagement in classroom-based lessons can effectively contribute to both the development and outcomes in academic learning and specifically, in mathematics. The use of innovative tools and their associated methods to support movement-based development in primary school mathematics is considered an area with limited research. Hence, the aim of this study is to demonstrate the effectiveness of an innovative sports tool and its associated motor coordination methods in the learning of mathematics in lower primary school pupils.

Methods

The sample of this study consisted of 4th-grade pupils from a primary school in a county town. One experimental group (EG, n=28, Mage=9,81±0,35) and one control group (CG, n=27, Mage=9,98±0,39) took part in the study. An innovative

ladder was utilized to support the teaching-learning process in mathematics during the 10-week program for EG. The total time spent using the tool for EG was 80-90 minutes per week depending on the main tasks. The teaching of mathematics of the two groups was exactly the same as related to content and process. The effectiveness of the program was assessed by completing 4 tasks of algebra and 2 tasks of geometry worksheets for both groups. Besides, 2 classroom teachers and 2 leaders of the school were interviewed to understand the experiences and impact of intervention in the school on a larger scale.

Results

The EG demonstrated significant improvements in 2 tasks of algebra, 1 task of geometry variables, and also in the overall scores. However, no statistically significant difference was found between the pre-and post-test for CG. Repeated ANOVA analysis yielded significant differences in the overall factor for group, time, and variables (F= 3.965; p= 0.00066). The in-depth interviews supported the effectiveness of the innovative sport system, not only on pupils' cognitive but also on emotional and social development. Teachers and leaders believed that the ladder was clearly developmental because it was able to provide opportunities for differentiation and to develop learning in a complex way through playful activities, while at the same time providing pupils with optimal peer and teacher support.

Discussion

Based on the present study, it can be affirmed that 15 minutes of non-traditional classroom exercise per day for 10 weeks resulted in a significant improvement in academic achievement in algebra and geometry tasks for lower primary school students. Furthermore, the program increased the levels of activity and attention and with that, pupil behavior and concentration. It is recommended to future studies to further explore PAL in different types of interventions and content areas and also include cognitive, affective, and social aspects.

OVER-TIME CHANGE IN INTERNALIZING PROBLEMS IN CHILDREN WITH DEVELOPMENTAL COORDINATION DISORDER: A TWO-YEAR FOLLOW-UP STUDY

LI, Y.C., WU, S.K.

CHINA MEDICAL UNIVERSITY

Introduction: Preschool children with developmental coordination disorder (DCD) are characterized by poor motor coordination which has been found to be associated with an increased risk for internalizing problems, such as anxiety or depression. However, due to a lack of longitudinal research, our understanding is limited towards the over-time change in mental health in young children, specifically within the Asian context. Therefore, this two-year study was to investigate the over-time difference in internalizing problems between preschool children with and without DCD.

Methods: One hundred and twenty-three preschool children aged between 4 and 6 years participated in this study at baseline. The Movement Assessment Battery for Children – Second edition was administered to assess their motor coordination, whereas the Child Behavior Checklist was completed by their parents to report internalizing problems. Preschool children who scored at or below the 16th percentile were further confirmed whether they met the DSM-V diagnostic criteria for DCD (n=23, 13 boys and 6 girls). All participants were asked to receive the re-assessment of internalizing problems one year later. However, only 92 children (17 DCD and 75 typical development (TD)) returned in the second year. Generalized estimating equations was used to evaluate the main effects of group (DCD vs. TD) and time (first vs. second year) and the interaction of group by time on internalizing problems, while controlling for sex and age.

Results: In Model 1 with group and time as predictors, there was a significant time effect on internalizing problems (p = .02) and a marginally significant group effect (p = .07). When adding sex and age as covariates, the time effect became non-significant, and the group effect became statistically significant (p = .04). Nevertheless, after the group by time interaction was further added, no any significant effect was found.

Conclusion: While controlling for sex and age, children with DCD may consistently have more internalizing problems during early childhood, compared to their TD peers. However, a non-significant group by time interaction indicates that these problems may not deteriorate over a two-year period. A longer follow-up duration is recommended to better understand the long-term development in children with DCD.

HOW DO PARENT ATTITUDES TOWARDS PHYSICAL ACTIVITIES INFLUENCE CHILD EXERCISE BEHAVIOR?

SHIMIZU, Y., MIYAZAKI, M.

INTERNATIONAL CHRISTIAN UNIVERSITY, J.F. OBERLIN UNIVERSITY

INTRODUCTION: The physical activity level of Japanese children has been steeply decreasing in the last decades. This study examines the hypothetical psychological model concerning how parent attitudes towards exercise and physical activities influence their childs exercise behavior.

METHODS: The subjects included 600 Japanese elementary school pupils (male: 292, female: 308, mean age=10.06, SD=0.863) and their parents (mother: 300, father: 300, mean age: 45.05, SD=5.51) who voluntarily answered a questionnaire composed of items concerning parent attitudes towards physical activities, child attitudes towards physical activities and child exercise amount. Positive Exercise Attitudes Scale (PEAS), Negative Exercise Attitudes Scale (NEAS), and Child Exercise Amount Scale (CEAS) have shown acceptable reliabilities and structural validities in previous studies, and Child Positive Exercise Attitude Scale (CPEAS), Child Negative Exercise Attitude Scale (CNEAS) were developed in this study. Exploratory factor analyses, confirmatory factor analyses, and reliability analyses were conducted to develop the CPEAS and CNEAS, and covariance structure analyses were conducted to confirm the acceptability of the hypothetical model and the relationship among subscale factors.

RESULTS: We hypothesized that parents attitudes towards physical activities would impact their childs attitudes towards exercise, influencing their behavior. The analysis showed that our hypothetical model (with the subscales of PEAS and NEAS as independent variables, CEAS as dependent variables, and CPEAS and CNEAS as mediators) yielded acceptable fit indices (GFI: 0.992, AGFI: 0.956, CFI: 0.980, RMSEA: 0.072). Parent positive attitudes had direct effects on positive child attitudes (β: 0.30, $p < 0.001$) and no significant impact on negative child attitudes(β: -0.02, n.s.), while parent negative attitudes had direct effects on negative child attitudes (β: 0.30, $p < 0.001$) and relatively small negative effects on their positive attitudes (β: -0.14, $p < 0.001$). Child exercise amount was found under more influence their positive attitudes (β: 0.43, $p < 0.001$) than their negative attitudes (β: -0.13, $p < 0.001$).

DISCUSSION:

The results indicate that the hypothetical model can be used to design programs to increase childrens exercise amount. Targeting parent attitudes towards exercise, such as providing parents with information on health and physical activities and making exercise opportunities available in the community, potentially change their childs attitudes towards physical activities and exercise level and frequency. Further research is needed to assess what interventions are effective for parents with school children.

PARENTS' EXPECTATIONS THAT FACILITATE CORPORAL PUNISHMENT BY COACHES

UENO, K.

KAGAWA UNIVERSITY

Introduction

Human Rights Watch (2020) published a report entitled "I was hit so many times I can't count: Abuse of child athletes in Japan." After the death of a student who suffered corporal punishment at the hands of a teacher-coach in 2012, corporal punishment by coaches garnered significant attention; however, it remains a serious issue. Ueno (2021) cited "The Fraud Triangle" (Albrecht, 2014), which explains the factors leading to fraud, and examined the situations in which coaches resort to corporal punishment. Ueno also showed that the expectations or pressures from parents of players perceived by coaches facilitate corporal punishment. Consequently, this study aimed to clarify the type of parents' expectations that facilitate corporal punishment by coaches.

Methods

Among 299 coaches participating in a coach training course, 136 coaches of children up to high school participated in this study's survey. These participants were certified as coaches by the Japan Sport Association, and coached various sports, including track and field, sailing, and boxing. This survey was conducted to investigate coaches' experiences with corporal punishment (violence, verbal abuse, coercion, excessive training, or sexual harassment) within the past five years and the expectations and the pressures (winning, proprieties, enjoyment, teamwork and cooperation, technique and physical strength, and hard work ethics) perceived by them from parents of players.

Results

The percentage of coaches who facilitated corporal punishment in five years decreased compared to that stated by Ueno (2021). The results of a multiple regression analysis showed that the parents' expectation of teaching "proprieties" had a positive effect on coercion.

Discussion

Various initiatives are implemented for the elimination of corporal punishment in coaching. Nonetheless, these results show that coaching that relies on corporal punishment is still being carried out. The background of persistent corporal punishment, despite its strong disapproval, appears to involve parents who in certain situations facilitate corporal punishment because they expect that the sports instruction will result in various outcomes such as winning and personality development. The results of this study suggest that corporal punishment issues should not be solely attributed to the respective coach, but also study the contexts (especially stakeholders such as parents) in which it is carried out.

EFFECTS OF ACUTE EXERCISE AT DIFFERENT VOLUME-MATCHED LOADS ON EXECUTIVE FUNCTION IN OLDER ADULTS

CHEN, F.T.1, WANG, C.C.2, CHANG, Y.K.2

1. DEPARTMENT OF SPORTS MEDICINE, CHINA MEDICAL UNIVERSITY, 2. DEPARTMENT OF PHYSICAL EDUCATION AND SPORT SCIENCES, NATIONAL TAIWAN NORMAL UNIVERSITY.

The benefit of acute exercise on executive function (EF) has been observed in an increasing number of studies; however, the effect varies depending on exercise-related variables (e.g., intensity, duration). The dose relationship between acute exercise and EF was ensured by combining exercise intensity and duration (e.g., volume). The present study investigated the effects of acute exercise with different volume-matched loads on the planning dimension of EF in older adults. A total of 40 healthy participants between the ages of 55 and 70 were recruited for the study. Reading control condition and three exercise volume-matched conditions were included in the counterbalanced and repeated-measure experimental design: 1) acute exercise at a moderate intensity for a 30-min duration (M-30); 2) higher intensity exercise for 16 minutes (H-16); and 3) lower intensity exercise for 40 minutes (L-40). After each condition, we examined the Tower of London (TOL) task. Acute exercise, regardless of exercise conditions, led to greater move-related scores (i.e., total correct scores, total move scores) and time-related scores (i.e., total executive time, total problem-solving time), excluding violation-related TOL task scores, as compared to the reading control condition. Regardless of the exercise volume loads involved, these findings suggest a selective benefit in terms of TOL performance following a single bout of exercise.

EFFECT OF PARENTAL INVOLVEMENT AMONG HUNGARIAN YOUNG HANDBALL PLAYERS

KOVÁCS, K.1, TAKACS, J.2, NOVAK, A.1, JUHASZ, I.3, KOVACS, K.4

1. EÖTVÖS LÓRÁND UNIVERSITY 2 SEMMELWEIS UNIVERSITY, 3 HUNGARIAN HANDBALL FEDERATION 4 HUNGARIAN UNIVERSITY OF SPORT SCIENCE

Aims and background: As elsewhere, the dropout rate of young athletes is high in Hungary, which also affects handball. The reasons for dropping out are complex, however parental support is critical to succeed or continue after failure or injury. Unfortunately, excessive parental pressure might cause negative effects on childrens psychosocial outcomes in sports. Studies also show that the childs involvement in sports could cause stress for most parents. We mapped the Hungarian youth handball players' parental involvement and the stress factors related to their childs sports. Methods: Using convenience sampling, 1,196 parents (Mage= 44; SD = 4.62) completed the online questionnaire. In addition to the psychological scales (PISQ-H, PSSS), demographic and sports-related questions were included. At least 1 child (Mage= 13.66; SD = 1.69) of each respondent played handball weekly. Results: Results of the independent samples t-test and one-way ANOVA test indicate that fathers scored lower on Praise and Understanding than mothers. Parents of children in the sampling stage showed a higher level of Directive Behavior and lower level of stress as compared to parents of those at either the specializing or the investment stage. Parents of children with previous sports injuries reported higher stress also. Parental stress showed low but significant positive partial correlations with parental pressure. Discussion: The intensity of parental stress and parental behaviour might be influenced by the childs stages of sports development. Parental involvement could decrease while parental stress increases over time.

PREDICTING ONE REPETITION MAXIMUM FROM THE LOAD VELOCITY RELATIONSHIP IN LOWER EXTREMITY RESISTANCE EXERCISES

KRISTIANSEN, M.1, PEDERSEN, S.R.1, JENSEN, J.G.1, FAARUP, M.1, JAKOBSEN, R.T.1, JOLAS, E.2,3,4, ANDERSEN, M.S.2,3, SIMONSEN, M.B.2,3

AALBORG UNIVERSITY

INTRODUCTION: Previous research has shown that the one repetition maximum (1RM) in dynamic resistance exercises can be accurately predicted using the load-velocity relationship. There is, however, a lack of studies investigating the ability to predict 1RM in single-joint exercises in both untrained and trained participants. Therefore, the present study aimed to investigate the concurrent validity of an estimated 1RM from the load-velocity relationship compared to a measured 1RM in ten lower extremity resistance exercises.

METHODS: Twenty-two healthy adults participated in the study. Each participant attended three sessions separated by at least 48 hours. The first session was a familiarization session allowing the participants to familiarize themselves with the ten exercises and estimate their approximate 1RM for each exercise. In the second session, knee flexion, hip flexion, hip adduction, ankle dorsiflexion, and seated ankle plantar flexion were tested. In the third session standing ankle plantar flexion, knee extension, hip extension, hip abduction, and leg press was tested. The order of the exercises was randomized for each participant. In each exercise, three repetitions were performed at 20%, 40%, and 60% and one repetition was performed at 80% and 100% of the approximate 1RM load. If the participants surpassed the approximate 1RM, the

load was increased until failure. Mean velocity during the concentric phase at was computed using data from a linear transducer on all repetitions. Simple linear regressions (i.e., one for each participant and each exercise) with mean velocity as a function of load were constructed using all submaximal loads to predict 1RM. Bland-Altman plots were created to evaluate concurrent validity between measured and predicted 1RM in each exercise.

RESULTS: The coefficient of determination (R2), standard error of the estimate (SEE), and Bland-Altman mean bias (BIAS) were as follows for all exercises. Ankle dorsi flexion (R2 = 0.68±0.31, SEE = 0.014±0.010, BIAS = 1.95), Seated ankle plantar flexion (R2 = 0.73±0.25, SEE = 0.029±0.020, BIAS = 1.23), Standing ankle plantar flexion (R2 = 0.69±0.35, SEE = 0.021±0.016, BIAS = 4.34), hip abduction (R2 = 0.61±0.42, SEE = 0.055±0.027, BIAS = 0.68), hip adduction (R2 = 0.45±0.47, SEE = 0.066±0.043, BIAS = 1.04), hip extension (R2 = 0.56±0.36, SEE = 0.078±0.048, BIAS = 0.25), hip flexion (R2 = 0.61±0.37, SEE = 0.075±0.039, BIAS = 0.19), knee extension (R2 = 0.72±0.23, SEE = 0.097±0.035, BIAS = 1.27), knee flexion (R2 = 0.47±0.43, SEE = 0.075±0.042, BIAS = 0.20), and leg press (R2 = 0.69±0.21, SEE = 0.035±0.018, BIAS = 5.16).

CONCLUSION: The coefficient of determination was lower, and the standard error of the estimate larger than previous studies reported. Although BIAS between measured and predicted 1RM was low, the limits of agreement were very wide. As such, predicting the 1RM in lower extremity resistance exercises from the load-velocity relationship is not considered to exhibit high concurrent validity.

INTER-INDIVIDUAL VARIABILITY IN ENDURANCE CAPACITY IN JUMPING: A SUPPORT TO FORCE-VELOCITY-ENDURANCE PROFILES

RIVIÈRE, J.R.1,2, PEYROT, N.2, CROSS, M.R.3, MESSONNIER, L.A.1, SAMOZINO, P.1

(1) UNIVERSITÉ SAVOIE MONT BLANC, LIBM, EA 7424, F-73000, CHAMBÉRY, FRANCE; (2) LE MANS UNIVERSITÉ, MIP - EA4334, LE MANS, FRANCE; (3) AUCKLAND UNIVERSITY OF TECHNOLOGY, SPRINZ, AUCKLAND, NEW ZEALAND

INTRODUCTION: Maintaining power over a series of repetitions (i.e., endurance) is key in daily physical and sporting activities. Endurance depends on exercise intensity, often quantified via power output: the higher the power output, the lower the endurance. Across individuals, some display better endurance at high power outputs, while others present better endurance at lower ones, highlighting distinct individual power-endurance profiles. Recently, endurance in jumping has been shown to also depend on the force-velocity (Fv) condition in which power is produced: at matched absolute or relative power, lower force-higher velocity conditions increased endurance [1]. However, it was undetermined whether an individual exhibiting the best endurance in high force-low velocity condition would remain so in low force-high velocity condition. Such inter-individual variability, supporting the existence of distinct individual force-velocity-endurance (FvE) profiles, is yet to be explored. Knowledge of these profiles may enhance testing and training individualization [2]. Our aims were to test the inter-individual variability in endurance across Fv conditions and to assess individuals' FvE profile.

METHODS: 14 participants performed repeated squat jumps tests during which endurance was quantified by the maximum repetitions until exhaustion. Tests were conducted in 10 force-velocity-power (FvP) conditions over 6 sessions (≥48h rest), including 3 at matched relative power output to assess FvE profile (slope of the maximum repetitions-F-v conditions relationship).

RESULTS: Correlations (absolute values of r) of endurance between FvP conditions ranged from 0.019 to 0.76, with 9 correlations being significant over 45 tested ($p<.05$). At the matched relative power output, some individuals displayed one of the best endurance in the highest force-lowest velocity condition, while others displayed one of the best endurance in the lowest force-highest velocity condition. This inter-individual variability was interpreted as force-oriented and velocity-oriented FvE profiles, respectively (FvE profiles ranged from -0.05 to -1.6, with between-individual coefficient of variation ~60%). For instance, two individuals showed similar endurance in the moderate force-moderate velocity condition (~1.5% of difference), but the one with a force-oriented FvE profile (slope: -0.2) had better endurance in the highest force-lowest velocity condition (~34% of difference), and the one with a velocity-oriented FvE profile (slope: -1.6) had better endurance in the lowest force-highest velocity condition (~57% of difference).

CONCLUSION: Endurance evaluation in a single Fv condition provides a limited view of endurance capacity in jumping, partly due to inter-individual variability in FvE profile. This profile can be approached by assessing endurance in multiple Fv conditions, and is notably of interest when facing distinct Fv conditions within the same activity.

DIFFERENCES IN LOAD-VELOCITY AND LOAD-POWER RELATIONSHIP BETWEEN MALES AND FEMALES

DELLO STRITTO, E., ROMAGNOLI, R., PIACENTINI, M.F.

UNIVERSITY OF ROME FORO ITALICO

INTRODUCTION: Velocity based training (VBT) is an objective autoregulation method, that uses barbell velocity to manage and quantify resistance training sessions. The minimum velocity threshold (MVT) represents the lowest velocity at which an exercise can be performed1. Evidence suggests how MVT may be different based on sex2 and excercise performed1 . The aim of the present study was to investigate sex differences in the load-velocity and load-power relationship during back squat exercise, with the hypothesis that males and females would show different profiles.

METHODS: Thirty males (age: 28 years±6.4; body weight:80kg±11.99; height: 179cm±6.70; 6.9 years of experience±3.7; 1RM/BW:1.60±0.30) and twenty-seven females (age: 24.2 years±3.45; body weight: 57.11kg±5.1; height: 164cm±4.50; 4.29

years of experience±3.7; 1RM/BW:1.54±0.28) performed an incremental 1RM test on the back squat. Barbell velocity was registered with a linear position transducer (LPT) (Vitruve; SPEED4LIFTS S.L). Load-velocity and load-power profiles of all subjects were analyzed and prediction equations were created for all subjects using a second-degree polynomial. Velocity and power output values were compared from 10% to 100%1RM in 5% increments performing indipendent t-tests. Power output was normalized for body weight during analysis.

RESULTS: Both velocity and power output were significantly different between males and females at each load including MVT (males: 0,30±0,06 m·s-1; females 0,25±0,04 m·s-1) ($p<0.05$). Males and females achieved peak power output at the same percentage of load (60% 1RM). In addition, general prediction equations were developed for both males and females, showing an excellent degree of fit for the load velocity relationship (males $R2=0.95$; females $R2=0.93$). While a poor fit was found for the general load-power equation (males $R2=0.52$; females $R2=0.36$).

CONCLUSION: ales showed higher velocities at each load, including MVT and higher power outputs at each load, both as absolute value or normalized by body weight. Both males and females achieved the peak power output at the same percentage of 1RM. The good fit of the general equation with individual data for the load-velocity relationship suggests that general equations may be used to prescribe VBT training still acknowledging their limitations.

INFLUENCE OF SEX AND STRENGTH DIFFERENCES ON THE LOAD-VELOCITY RELATIONSHIP OF THE SMITH-MACHINE BACK SQUAT

FITAS, A., SANTOS, P., GOMES, M., PEZARAT-CORREIA, P., MENDONÇA, G.V.

UNIVERSITY OF LISBON FACULTY OF HUMAN KINETICS

INTRODUCTION: There is general agreement that movement velocity is strongly related with relative load in response to several multi-joint resistance exercises ($R^2 > 0.95$) [1] . However, the inclusion of female participants in the load-velocity relationship analysis is quite recent [2,3,4,5,6]. Additionally, despite there is some evidence that the load-velocity relationship is stable regardless of the individual strength levels, this is not a universal finding [1,7]. For instance, past research has shown that, besides differing between sexes, the load-velocity relationship varies as a function of muscle strength [3,8]. Therefore, different levels of muscle strength between males and females may confound sex comparisons in the load-velocity relationship. Unfortunately, this possible confounding factor has not yet been examined for the smith machine back squat, a variation of the back squat exercise that better accounts for technical flaws or horizontal displacements of the bar. We aimed at determining whether the load-velocity relationship of the Smith machine concentric-back squat differs between sexes and persons with different levels of strength.

METHODS: Thirty-two participants (16 males: 23.3±3.8 and 16 females: 26.1±2.7 years) were included. All participants underwent a familizarization session. Load and mean concentric velocity (MCV) were obtained individually during an incremental test (30-90% one-repetition maximum – 1RM) with a previously validated Chronojump linear position transducer, which sampled the bar's velocity at a frequency of 1000 Hz (Chronojump, Barcelona, Spain) coupled to the Smith machine.

RESULTS: We obtained strong linear relationships between the individual MCV and relative load ($R^2>0.95$). Overall, relatively strong persons reached faster MCVs throughout the full range of relative loads (effect size [ES]: 0.48–0.93), except at 1RM. We also obtained steeper slopes and higher velocity intercepts (y intercepts) in relatively strong participants (ES: 0.05 and 0.83, respectively; $p<0.01$). Finally, we found that males attained steeper load-velocity relationships (ES favoring relatively strong and weak males: 2.8 and 1.4, respectively) and higher velocity intercepts (ES favoring relatively strong and weak males: 2.0 and 1.0, respectively) than females ($p<0.0001$).

CONCLUSION: The novel finding of this study is that MCV can be used to estimate relative load on the Smith machine concentric-back squat in males and females with different levels of muscle strength, however, the load-velocity relationship is affected by muscle strength and sex. Therefore, the extraction of individual load-velocity relationships is advisable instead of computing group estimations.

THE INFLUENCE OF MAXIMAL ISOMETRIC STRENGTH ON COUNTERMOVEMENT JUMP PERFORMANCE AND STRATEGY

SANGARI, D., BAYNE, H., CRONIN, J.

UNIVERSITY OF PRETORIA

INTRODUCTION: Countermovement jump (CMJ) performance provides valuable information regarding neuromuscular status and lower body power. Jump strategy, the movement of an athlete's centre of mass (COM) reflected by the vertical ground reaction force-time series generated during the CMJ, influences jump performance. Previous investigators (1, 2) have suggested that peak ground reaction force occurring at or soon after the moment of transition between the eccentric and concentric phase is required for a biomechanically efficient jump as it would maximise the effects of the stretch-

shorten cycle (SSC). The jump strategy required to generate early time to peak force (TPF) is described as having greater unweighting of the COM during the eccentric phase. However, this strategy is likely associated with high neuromuscular demands and some athletes may not have the required strength to effectively decelerate their COM and transfer the benefits of the SSC to concentric performance. Therefore, the aim of this study was to determine the influence of maximal isometric strength on jump strategy and CMJ performance.

METHODS: A total of 104 males (mean ± SD height: 1.80 ± 0.08 m; mass: 84.7 ± 16.5 kg; age: 21.6 ± 3.0 yr) from various sports volunteered and provided informed consent to participate in this study, which was approved by the institution's ethics committee. Each participant performed three CMJs and three isometric squat tests (ISQ) on a dual force platform (JM6090-06, Bertec, USA) and data was collected using Forcedecks (Vald Performance, Australia). Two groups were created using the group mean relative isometric force as a threshold, separating participants into strong (≥ 32.7 N.kg-1) and weak (< 32.7 N.kg-1) groups. An independent t-test and Cohen's d effect size were used to determine the effect of maximal strength on CMJ performance, TPF and eccentric phase jump strategy variables.

RESULTS: The strong group had greater jump height (43.7 ± 6.6 vs 39.8 ± 6.9 cm, $p < 0.05$, ES = 0.58) and modified reactive strength index (0.60 ± 0.13 vs 0.52 ± 0.1 AU, $p < 0.05$, ES = 0.68) compared to the weak group. All jump strategy variables were significantly ($p < 0.05$) different as strong males demonstrated lower minimum eccentric force (-7.13 ± 1.86 vs -6.14 ± 2.17 N.kg-1, ES = 0.49), greater eccentric velocity (-1.38 ± 0.26 vs -1.20 ± 0.28 m.s-1, ES = 0.66), countermovement depth (-35.3 ± 6.6 vs -32.6 ± 6.3 cm, ES = 0.42), force at zero velocity (16.1 ± 3.5 vs 13.9 ± 3.2 N.kg-1, ES = 0.68) and earlier TPF (14.3 ± 24.5 vs 26.7 ± 30.1 %, ES = 0.45) compared to the weak group.

CONCLUSION: Stronger athletes demonstrated better CMJ performance, earlier TPF, and kinematic and kinetic features reflecting a more efficient eccentric phase. It may be suggested that athletes require a certain level of strength before adopting such a jump strategy to enhance vertical force production during the CMJ.

COUNTER MOVEMENT JUMP WITH ARM SWING PRODUCES MORE CONSISTENT FORCE CURVE PERFORMANCES THAN COUNTER MOVEMENT JUMP WITHOUT ARM SWING

KOLLIAS, A.1, CHALITSIOS, C.1,2, NIKODELIS, T.2

1KINVENT; 2ARISTOTLE UNIVERSITY OF THESSALONIKI

INTRODUCTION: Vertical ground reaction force curves during a countermovement (CMJ) can vary in shape between subjects (e.g., non-modal, unimodal, or bimodal). Thus, athletes adopt different movement strategies that may be dependent on performance related factors [1] (i.e. biological or task constraints). Studies based solely on discrete values may mask such factors [2]. On the contrary, analysing curve profiles may reveal different performance subgroups. Although previous studies exist applying clustering analysis to CMJ (vGRF data), no investigations were found for applying this type of analysis to CMJ with an arm swing, a type of jump that enhances performance. Our hypothesis was that there would be a differentiating effect of arm swing during CMJ that could be captured with subgroup analysis.

METHODS: Three hundred and thirty-two male adult high-level athletes from various sports, performed a series of CMJ and CMJ with arm swing (CMJas) on a 1D force platform. From those tests, only the best were kept for further analysis. Hierarchical cluster analysis (Ward's method) was used to extract common kinetic patterns from 1-D curves. Each curve was interpolated to a length equal to 101 points. For the hierarchical algorithm, pairwise distances were calculated using Euclidean distance. The assessment of the derived clusters' quality was conducted by calculating the cophenetic correlation coefficient between the hierarchical cluster tree and the pairwise distances. The optimal number of cluster selection was determined using the gap statistic [3].

RESULTS: Hierarchical cluster analysis revealed three distinct subgroups for the CMJ force-time curves. The cophenetic correlation coefficient for the three dendrograms was above 0,7. The sizes of those clusters were 117, 145, and 37 curves, respectively. The subgroups revealed three shapes: a bimodal with the peak ~60% of the jump duration, a bimodal with the peak at ~90% of the jump duration, and a unimodal shape with a single peak at ~80% of the jump duration. For the CMJas force-time curves, the gap statistic suggested a single cluster with a bi-modal shape with an early peak at ~65% of jump duration and a higher one later at ~90% of jump duration.

CONCLUSION: These results suggested that CMJas - vGRF shapes were more consistent with similar kinetic patterns among participants, whereas, in line with previous research, CMJ has more variability in terms of vGRF patterns. These findings also support the efficacy of clustering techniques to analyze force time curves and search for similar subgroups in the population. Further research is needed to identify the mechanical properties of momentum transfer from the arms that dictate a single performance pattern in the CMJas.

USING MOBILE APPLICATIONS TO EASILY AND RELIABLY CAPTURE PERFORMANCE FATIGABILITY DURING FUNCTIONAL EXERCISE TEST: PRELIMINARY EVIDENCE

SOURON, R.1,2, GRUET, M.1

1> NANTES UNIVERSITÉ, MOVEMENT - INTERACTIONS - PERFORMANCE, MIP, UR 4334, F-44000 NANTES, FRANCE 2> UNIVERSITÉ DE TOULON, LABORATOIRE IAPS (N°201723207F), TOULON, FRANCE

INTRODUCTION: Performance fatigability refers to objective changes in a performance indicator during and/or after a physical task (1). This measure can inform on overall physical abilities and could help coaches or clinician to manage their athletes or patients. The common protocols used to evaluate performance fatigability require expensive and cumbersome equipment thus limiting their use in daily life settings (e.g. home, sport clubs). Further, implementing the systematic assessment of performance fatigability in some widely used field tests (e.g. one minute sit-to-stand test, STS1min) could help in overcoming their drawback of being self-paced, with the test performance (i.e. number of repetitions for the STS1min) potentially influenced by pacing strategies. We aimed to overcome these issues dealing with the evaluation of performance fatigability in two different studies.

METHODS: A first study aimed to create a test that could easily capture performance fatigability and assess its test-retest reliability. We asked participants to perform the isometric wall squat exercise during successive stages of incremental duration. Participants performed two squat jumps and two sit-to-stand (from a chair) exercises at the end of each stage. We used MyJump (2) and Sit to Stand (3) mobile applications to assess performance fatigability through the kinetics of changes in squat jump height (SJh) and sit-to-stand time (STSt), respectively.

In a second study, we aimed to determine if the STS1min could induce a significant and reliable level of performance fatigability, as assessed by the pre-post decline in STSt measured with the Sit to Stand mobile application (3). In both projects, participants (young healthy adults, study 1: N = 16; study 2: N = 24) performed the test in two separate days.

RESULTS: The new test we developed in the first study was able to induce progressive levels of performance fatigability, reaching at exhaustion a decrease of 22±11% in SJh, and an increase of 31±13% in STSt. Changes in both fatigability indicators were highly reliable (e.g. CV of 4.8% and ICC of 0.88 for SJh recorded at isotime).

In the second study, we observed a significant pre-post decrease of 8±6% in STSt after the STS1min. Changes in this fatigability indicator was associated with a good relative test-retest reliability (ICC of 0.86).

CONCLUSION: We proposed through these two studies new, low cost, and easy to implement alternatives to assess performance fatigability in an ecological fashion. The use of various fatigability indicators is a tremendous advantage to be considered with very distinct populations, e.g. athletes, patients. One important next step will be the establishment of reference values in a wide range of age groups, ensuring optimal interpretation in specific populations.

RELATIONSHIP BETWEEN CHANGE OF DIRECTION ABILITY AND LOWER-LIMB STRENGTH AND POWER MEASURES IN JUNIOR FEMALE RUGBY LEAGUE ATHLETES

DASCOMBE, B., FLANNERY, L., COMPTON, H.R., SECOMB, J.

UNIVERSITY OF NEWCASTLE

INTRODUCTION: Research has demonstrated that change of direction (COD) ability is dependent upon factors such as anthropometry, technique, linear sprinting speed and leg muscle qualities (1). However, almost all COD research has been limited to male athletes that have been reported to possess different physical capacities and COD abilities to female athletes (2). Therefore, this study aimed to determine the relationships between COD ability and lower-limb strength and power measures in junior female rugby league athletes.

METHODS: Semi-elite junior female rugby league athletes (n=27, 17.5±0.5 yr; 1.7±0.5 m; 71.5±13.0 kg) were recruited for the study. Athletes underwent countermovement and squat jump testing using a linear position transducer (Gymaware, Fusion Sport, Australia) (3) The isometric mid-thigh pull (IMTP) was performed on a custom rig and measured using portable force plates (ForceDecks, VALD, Australia) (4). 10m linear sprint speed was assessed through a 40m sprint using electronic timing gates (Fusion Sport, Australia), from which 10m sprint momentum was calculated (2). COD ability was assessed bilaterally through the 505-test using electronic timing gates from which COD deficit was calculated (5). Repeat efforts were provided with adequate recovery provided. Descriptive statistics were calculated, and a multiple stepwise linear regression used to determine the strength of the relationships between COD ability and lower-limb strength and power measures.

RESULTS: The 505-time (mean ± SD) between left (2.44±0.12 s) and right (2.23±0.13 s) sides was similar and therefore, the mean 505-time (2.44±0.12s) was used for further analysis. The mean COD deficit was 0.46±0.08s. The (absolute; [relative]) power measures for the CMJ (2810±500 W; [39.7±0.5.4 W.kgBM-1), SJ (2748±477 W; [38.8±5.2 W.kgBM-1) and IMTP (1940±283 N; [2.8±0.4 N.kgBM-1). Lastly, the 10m sprint time was 1.98±0.09 s, equating to a 10m sprint momentum of 361±61 kg.m.s-1. The statistical model demonstrated good fit ($F(2,24)=39.181$, $p<0.001$, $R2=0.766$) with COD ability, despite including only body mass (ß=0.006 [0.004-0.009; $p<0.001$) and 10m sprint momentum (ß=0.028 [0.020-0.036; $p<0.001$).

CONCLUSION: The results demonstrate that only body mass and sprint momentum demonstrated a relationship with COD ability in junior female rugby league players. The data demonstrate that female athletes with higher body masses and subsequently higher sprint momentum tended to possess poorer COD abilities. Interestingly, no measure of lower-limb strength or power demonstrated a significant relationship and hence was not included in the multiple regression model related to COD ability. Future research should continue to explore how the physical capacities of female athletes relate to COD ability to inform future training practices of team-sport athletes.

OPEN TRAP BAR, A VALID MODALITY FOR ASSESSMENT OF POWER, AND FORCE-VELOCITY PROFILE IN WEIGHTLIFTERS' SQUAT JUMPS.

LANTERI, T., MORIN, J.B., YAGODKIN, K., CORCELLE, B., BROUSSAL-DERVAL, A., PIPONNIER, E.

CÔTE DAZUR UNIVERSITY

INTRODUCTION: Power and force-velocity profile can be easily assessed through ballistic movements, such as squat jump (1). However, these tests may not be specific to certain disciplines like weightlifting and may pose an additional risk when heavy loads are used. In a recent study, authors (2) compared the data obtained from squat jumps with a hexagonal bar, using both a strength platform and the Samozino method. They found that the results were highly valid for calculating force-velocity profile parameters. However, no comparison has been made with a conventional weight bar (CWB) in back squat, which is more traditionally modality. Therefore, the aim of this study was to determine the validity of an open trap bar (OTB) during squat jump to assess vertical force-velocity profile parameters, in comparison to bask squat jumps with CWB, i.e., the reference modality.

METHODS: Seventeen weightlifters (10 males and 7 females; age: 22.4 ± 2.7 years; height: 1.72 ± 0.35 m; body mass: 66.35 ± 11.56 kg; 2 to 3 training sessions by week) participated in this study. They performed four vertical jumps with different additional load (0%, 25%, 50% and 75% of their body mass) in back squat jump with CWB and squat jump with OTB. All force-velocity profile output variables (theorical maximal force, F0; theorical maximal velocity, V0; maximal power, PMAX; slope of force-velocity profile, SF-v and force-velocity imbalance; F-vIMB) were calculated using system mass, push-off distance, and jump height. Validity of OTB was determined by comparing the results of the OTB to those obtained with the CWB, using Pearson correlation, coefficients of variation and bias.

RESULTS: Nearly perfect correlations ($r > 0.90$; $P < 0.001$) were observed between force-velocity profile outputs obtained using CWB and OTB for all calculated variables (F0, V0, PMAX, SF-v and F-vIMB). The results showed bias values and narrow 95% confidence interval for maximal jump height (-0.01 m [-0.05–0.03]), F0 (79.7 N [-147–306]), V0 (0.04 m·s-1 [-0.33–0.42]) and PMAX (30.8 W [-243–181]).

CONCLUSION: Squat jumping with an OTB is a valid alternative to back squat jumping with a CWB for assessing the force-velocity profile parameters. Jumping with the OTB is more specific to certain disciplines, such as weightlifting, and may allow using heavier loads for testing. Indeed, the independence between the trunk and load likely leads to a more forward position of the center of mass, which is more specific to weightlifting.

CUSTOM-MADE BADMINTON-SPECIFIC FITNESS TEST DISCRIMINATES COMPETITIVE LEVEL OF PLAYERS

ANDO, R.1, NAKASHIMA, H.1, KAMEDA, M.1, INABA, Y.1, NAKAMURA, M.1, SUITA, M.2, IIZUKA, T.3, HOSHIKAWA, Y.4, OZAKI, H.1

1. JAPAN INSTITUTE OF SPORTS SCIENCES, 2. UNIVERSITY OF TSUKUBA, 3. NIPPON BADMINTON ASSOCIATION, 4. JAPAN WOMENS COLLEGE OF PHYSICAL EDUCATION

INTRODUCTION: Badminton is an intensive sport and demands both aerobic and anaerobic capacities (Phomsoupha and Laffaye, 2015). Many lunge steps are performed with unequal loads on each side of the legs in the game. Therefore, conventional tests consisted of cyclic and symmetrical exercises (e.g., running, pedalling) may not evaluate the physical fitness of badminton players. We have found that the anaerobic power test on a bike or the lactate curve test by running could not discriminate the physical fitness between international and national levels (unpublished data). Therefore, we developed a novel badminton-specific fitness test and examined if that could discriminate the competitive level of players.

METHODS: Ten collegiate women competitive badminton players participated in the study. Five of them earned a podium of the Japanese intercollegiate tournament (highly-trained), while the others were unable to participate (trained). The participants performed the badminton-specific test on a court. They reacted quickly with badminton-specific movements to sensors located at four corners of the court from the center. The direction was pseudo-randomly selected by software and displayed on a monitor located on the opposite court. They reacted eight times at specific intervals (depending on the stage, described below), which were repeated six sets with a rest of 20 seconds in each stage. There were three stages in the test and exercise intensity was increased by shortening the intervals between each reaction, such as 1.2, 1.0, and 0.8 seconds for stage 1, stage 2, and stage 3, respectively. The time from the displayed direction to reaching the sensors (reach time) were averaged in each stage. Blood lactate accumulation (BLa) was measured from finger tips between

stages (rest of 75 seconds). The effect size (r) was calculated to compare averaged reach time and BLa between competitive levels. The value of r was interpreted as 0.10 < r ≤ 0.30 for small effect, 0.30 < r ≤ 0.50 for medium effect, and 0.50 < r for large effect.

RESULTS: Reach times were shorter in highly-trained than in trained with medium or large effect sizes (stage 1: 1.56 ± 0.03 s vs 1.62 ± 0.03 s, r = 0.50; stage 2: 1.56 ± 0.03 s vs 1.63 ± 0.08 s, r = 0.36; stage 3: 1.55 ± 0.03 s vs 1.63 ± 0.06 s, r = 0.69). BLa were lower in highly-trained than in trained with medium effect size (stage 1: 2.9 ± 0.2 mM vs 5.1 ± 2.5 mM, r = 0.50; stage 2: 3.8 ± 0.7 mM vs 6.0 ± 3.3 mM, r = 0.46; stage 3: 5.8 ± 2.0 mM vs 7.6 ± 3.5 mM, r = 0.33).

CONCLUSION: As there were no differences in the lactate curve test by running between highly-trained and trained in the present study (unpublished data), it is suggested that the badminton-specific fitness test can discriminate the competitive level of players. It is possible that elite players move quickly and economically in badminton-specific steps.

CP-AP23 Endurance Testing

DETERMINATION OF RUNNING CRITICAL POWER AND W´ THROUGH TWO-TIME TRIALS

JAÉN-CARRILLO, D., GARCÍA-PINILLOS, F., RUIZ-ALEJO, S.A., PÉREZ-CASTILLA, A., ÑANCUPIL-ANDRADE, A.A.

UNIVERSITÄT INNSBRUCK

INTRODUCTION: The power-duration curve (PDC) enables the identification of critical power (CP), which represents the maximal work rate at which the metabolic stability is sustainable, and the work capacity over CP (W´), referring to determining the time to exhaustion (TTE) at the severe intensity domain. CP shows a strong correlation and non-significant differences with the work rate associated with the respiratory compensation point. W´ can accurately estimate the TTE at the severe domain.

Although the CP concept determines that PDC should be constructed with four to five-time trials, the linearity of the work-time (CPwork) and power-1/time (CP1/time) relationship along such intensity enables the use of two-time trials. Thus, this study aims to determine the level of agreement of CP and W´ values obtained from different two-time trial combinations with the ones derived from five-time trials using the linear CP models.

METHODS: Fifteen highly trained athletes participated in the study. PDC was defined through five-time trials (i.e., 3, 4, 5, 10, 20 min) during a three-week training period. CP and W´ were defined through the CPwork and CP1/time using five and different two-time trial combinations.

After a warm-up, athletes began the time trial under the instruction of completing the longest distance possible. The five-time trials were performed on a 400 m track at a self-selected pace. To determine mean absolute running power (in W) for each trial, a Stryd running power meter was attached to the laces of the right shoe of the participants. The reference values for CP and W´ were derived from five-time trials and also obtained from the different two-time trial combinations. The level of agreement (LoA) was examined using systematic bias, coefficient of determination and standard error of the estimate obtained from linear regression analysis, and intraclass correlation coefficients using a two-way mixed model for absolute agreement. An acceptable LoA was considered when the following criteria were met: low bias and SEE (CP: < 14 W [corresponding to ± 5%mean CP]; W´: < 2.0 kJ [corresponding to ± 10% mean W´]), R2 > 0.90, and ICC > 0.81. Statistical significance was set at P ≤ 0.05.

RESULTS: 7 min between the short and long-time trial was required to obtain a valid two-point combination. The 3-10 min was the shortest valid combination for CPwork (Bias: 9.2 [4.3 to 14] W; SEE: 9.0 W; ICC: 0.99 [0.87 to 0.99]; R2: 0.98) and CP1/time (Bias: 3.3 [-0.2 to 6.9] W; SEE: 6.4 W; ICC: 0.99 [0.99 to 1.00]; R2: 0.99). For W´, validity criteria was not met for any two-time trial combination.

CONCLUSION: CP parameter can be accurately estimated from two-time trials. For both CP linear models, the 3-10 minutes was the shortest valid combination, while the 3-20, 4-20 and 5-20 min showed the greatest LoA with CP derived from five-time trials. The W´ presented a high SEE in both CP linear models when using the five-time trials. Thus, none of the two-time-trial combinations reach an acceptable level of accuracy

REVISITING THE VALIDITY OF THE MAXIMAL AEROBIC POWER CONCEPT: THE MECHANICAL WORKRATE AT VO2MAX IS AN ARRAY, NOT A VARIABLE.

SABATER-PASTOR, F.1, IANNETTA, D.2, TOWNSEND, N.3, MURIAS, J.M.4

1-UNIVERSITÉ PERPIGNAN VIA DOMITIA, 2.-UNIVERSITY OF UTAH, 3-HAMAD BIN KHALIFA UNIVERSITY, 4-UNIVERSITY OF CALGARY

INTRODUCTION: The terms "maximal aerobic power" (MAP) and "velocity at maximal O2 uptake (VO2max)" are conceptually similar and extensively used in the exercise sciences. There are multiple definitions for MAP, including: a) the lowest power output (PO) that elicits VO2max during an incremental test, b) the peak power in said test (PPO), and c) the PO esti-

mated from extrapolation of the submaximal VO2 vs PO linear regression. Each definition disregards the dissociation between VO2 and PO during incremental testing compared to constant work rate exercise and assumes a unique PO corresponding to VO2max i.e. MAP is a variable. However, it is well documented that activities performed within the severe exercise intensity domain should elicit VO2max if enough time is provided for the full expression of the VO2 slow component. The aim of this study was to test the hypothesis that a range of POs at or below PPO would elicit VO2max and therefore, that MAP should be conceptualized as an array , not a variable.

METHODS: Eight recreationally active individuals performed a ramp incremental test (30 W/min) and 3-4 time to task failure (TTF) trials at PO ranging from 70 to 100% of ramp test PPO (nb: one participant did not complete a TTF at 90% PPO). Breath-by-breath VO2 was recorded during all trials and converted to 20 s moving averages. VO2max was taken as the maximal value recorded during the ramp test, and VO2peak was taken as the highest recorded during each TTF trial. VO2max and VO2peak for each TTF trial were compared using a paired-samples T-test, in addition to Bland-Altman analyses. VO2peak for each TTF was also compared individually to VO2max, assuming a threshold of <100 mL/min to be considered equivalent.

RESULTS: Group mean VO2max was 3.81 ± 0.64 L/min. Participants reached a VO2 within 100 mL of VO2max at 94.4±3.2% of PPO during the incremental test, which occurred 10-70 s before task failure. VO2peak during the TTF trials was not significantly different (p>0.05) to VO2max at 70% PPO (3.69±0.69 L/min, N=8), 80% PPO (3.90±0.71 L/min, N=8), 90% PPO (3.79±0.66 L/min, N=7) and 100% PPO (3.73±0.65 L/min, N=8) . Bland-Altman mean bias was 112 (95% CI -260–485) mL/min, -96 (-435–242) mL/min, -91 (-222.6–203) mL/min, and 74 (-244–391) mL/min for the 70, 80, 90 and 100% PPO TTF trials. Duration of TTF was 752±352 s, 334±75 s, 194±51 s and 129±27 s at 70%, 80%, 90% and 100% PPO, respectively. Six, 7, 5, and 6 participants achieved a VO2peak within 100 mL/min at 70, 80, 90, and 100% PPO, respectively.

CONCLUSION: During constant workrate exercise to task failure in the severe intensity domain, VO2max was elicited across a range of PO, which extended beneath the lowest PO at which VO2max occurred during an incremental test. These results confirm that MAP is an array and therefore, the validity of the MAP concept should be revisited, as there is not a unique PO associated with VO2max.

MECHANICAL POWER OUTPUT AT 4 MMOL/L BLOOD LACTATE OF ELITE JUNIOR ROWERS IS ASSOCIATED WITH LONG-TERM CAREER ATTAINMENT

WINKERT, K.1, TREFF, G.2, STEINACKER, J.M.1

1 UNIVERSITY OF ULM, 2 PARACELSUS MEDICAL UNIVERSITY SALZBURG

INTRODUCTION: It is well established that successful rowers exhibit larger anthropometrical characteristics and higher laboratory-based performance than their less successful peers. While talent identification programs in juniors typically include performance and anthropometric variables, their effect on long-term career attainment has not been sufficiently examined. Similar to a previous study focusing on anthropometrics [1], we aimed to assess the effect of laboratory-based performance outcomes on long-term career attainment in elite junior rowers.

METHODS: Retrospectively, 976 junior German national team rowers (female n=427) from 1992-2018 were grouped according to their highest progressive career level, being U19-, U23-, Senior World Championships (WCh), or Olympic Games (OG). We analyzed differences in absolute (P4) and allometrically scaled (P4-index=P4/(body mass +15)^(2/3)) power output at 4 mmol/L blood lactate (5-6x4min step test) and tested their effect on long-term career attainment. Therefore, a one-way ANOVA with post-hoc test (Bonferroni correction) and proportional odds model (POD) with odds ratio (OR) analysis was applied.

RESULTS: Distribution for those female and male rowers reaching the U19-level as highest progressive career level was 53.4% (P4 231 ±18 W, P4-index 11.8 ±0.8 W/(kg+15)^(2/3) and 52.8% (322 ±24 W, 14.9 ±1.0 W/(kg+15)^(2/3), reaching U23-level: 26.9% (235 +18 W, 12.1 +0.9 W/(kg+15)^(2/3) and 29.9% (337 ±27 W, 15.4 ±1.2 W/(kg+15)^(2/3), reaching WCh-level10.1% (239 ±18, 12.3 ±0.9 W/(kg+15)^(2/3) and 7.1% (344 ±26 W, 15.6 ±1.0 W/(kg+15)^(2/3), reaching OG-level 9.6% (247 ±18 W, 12.7 ±0.9 W/(kg+15)^(2/3) and 10.2% (353 ±30 W, 16.0 ±1.2 W/(kg+15)^(2/3), respectively. We calculated significant medium to large effects for P4 ($F(3,426) = 9.504$, $p<.001$, $\eta2 = 0.063$ and $F(3,548) = 31.937$, $p<.001$, $\eta2 = 0.150$) and P4-index ($F(3,426) = 16.320$, $p<.001$, $\eta2 = 0.104$ and $F(3,548) = 24.201$, $p< .001$, $\eta2 = 0.118$) among female and male progression levels. Further, both P4 (OR=1.024, p<0.001 and 1.029, p<0.001) and P4-index (OR=1.983, p<0.001 and 1.872, p<0.001) had significant effects on career attainment in females and males.

CONCLUSION: Our findings suggest that higher P4 and P4-index within a group of adolescent elite junior rowers are associated with long-term career progression in international elite rowing. Importantly, in females the allometrically scaled P4-index had larger effects compared to unscaled P4. Our data set may be used as thresholds associated with career success. However, as maturation to the elite senior level is inherently multi-dimensional, laboratory-based performance outcomes like P4 must not be exclusively used for talent identification. Rather, a holistic approach including at least anthropometric, physical, skill, and mental variables should be applied.

AGE-RELATED DIFFERENCES IN BLOOD LACTATE ACCUMULATION AND MAXIMAL BLOOD LACTATE CONCENTRATION IN RECREATIONAL ENDURANCE ATHLETES

KAMP, L., HANAKAM, F., FERRAUTI, A.

RUHR UNIVERSITY BOCHUM

INTRODUCTION: In endurance performance diagnostics, training zones are usually defined based on individual blood lactate curves, which are influenced by maximum blood lactate concentration (Lamax). As there is a decline in Type-II muscle fibres with high capacity to produce lactate with ageing, a change in lactate production in skeletal muscles might occur. Therefore, the study aims to investigate whether age has an impact on blood lactate accumulation as well as maximal blood lactate concentration. For this purpose, a retrospective observational approach was implemented using endurance performance diagnostic data of the last decade.

METHODS: A cohort of recreational endurance athletes (n = 264) was drawn from a larger database (n = 2040) who completed a multistage incremental endurance test until exhaustion on either treadmill or cycling ergometer and met the following inclusion criteria: integrity of data, stage duration (3 or 5 min) and maximal exhaustion (RPE > 16). In all subjects, blood lactate samples were taken during a 30-second break after each stage. Statistical data analysis was divided into three approaches. First, a sample of subjects at High-Performance Age (HPA, n = 70; 45 male and 25 female, 24.6 ± 3.3 years) was matched pairwise to athletes at Master´s Age (MA, n = 70; 45 male and 25 female, 55.5 ± 5.5 years) on sex, type of test and stage duration. Descriptive statistics were used to compare Lamax between the two age groups. Second, averaged blood lactate curves in the groups were evaluated graphically to assess the practical relevance of differences in Lamax. Third, several mixed regression models with age, sex and type of test as predictors and random effects for individuals using the full sample were conducted. The models were compared by the goodness of fit (Akaike and Bayesian information criteria).

RESULTS: Lamax was higher in the High-Performance Age group (10.76 ± 2.34 mmol·l-1) than in the Master´s Age group (7.85 ± 2.25 mmol·l-1 ; $p < .001$). Regression analysis predicts lower Lamax with increasing age. However, the age-related effect on Lamax was lower than the difference between the groups HPA and MA (1,20 mmol·l-1). Average blood lactate curve analysis showed overall lower blood lactate concentration (La) in MA. The exponential rise of La (increase in the curve´s tangent angle) is higher in HPA group resulting in higher Lamax.

CONCLUSION: An age-related decline in Lamax and a difference in blood lactate accumulation within incremental performance testings was observed. This suggests a lower rate of lactate production in Master Athletes. Possible reasons may be an age-related or training induced decline in Type-II muscle fibres or a higher aerobic capacity of Master Athletes. In practical terms, training zones may be adjusted to average lower La in Master´s to prescribe targeted training. Further, exercise at high-intensities in Master´s may reduce age-related effects. However, whether it should be aimed for higher La is depending on training objectives.

PATTERN OF THE HEART RATE PERFORMANCE CURVE IN MAXIMAL GRADED TREADMILL RUNNING FROM 1100 HEALTHY 18-65 YEARS OLD MEN AND WOMEN: THE 4 HAIE STUDY

BIRNBAUMER, P.1, DOSTAL, T.2, CIPRYAN, L.2, HOFMANN, P.1

<1> UNIVERSITY OF GRAZ; <2> THE UNIVERSITY OF OSTRAVA

INTRODUCTION: Heart rate performance curve (HRPC) in maximal incremental cycle ergometer exercise has been shown to be neither linear nor uniform (1) and three different patterns (downward, linear and inverse) have been prescribed with some main implications for exercise prescription. A downward deflection was the most frequent and was suggested the regular version (2). However, no detailed data for running exercise are available yet. This study therefore investigated the deflection of the HRPC in maximal graded treadmill tests (GXT) from the 4 HAIE study (3). We hypothesized a similar distribution of HRPC patterns as in the cycle ergometer results (4) and comparable dependence on sex, performance and age.

METHODS: Additional to maximal values, the first and second ventilatory thresholds as well as the degree and the direction of the HRPC deflection (kHR) were determined from 1100 active (60%) and sedentary (40%) subjects (489 women) GXTs with diagnostic software (Vienna CPX Tool) by applying linear regression analyses. HRPC deflection was categorized as downward ($kHR < -0.1$), linear ($-0.1 \leq kHR \leq 0.1$) or inverse ($kHR > 0.1$) curves. Four (even split) age- and two (median split) performance-groups were used to investigate the effects of age and performance on the distribution of regular (downward) and non-regular (linear + inverse) HR curves for male and female subjects.

RESULTS: Men (age: 36.8 ± 11.9 yrs, BMI: 25.0 ± 3.3 kg.m-2, VO2max: 46.4 ± 9.4 ml.min-1.kg-1) and women (age: 36.2 ± 11.9 yrs, BMI: 23.3 ± 3.7 kg.m-2, VO2max: 37.4 ± 7.8 ml.min-1.kg-1) presented 556 / 449 (91% / 92%) regular downward deflecting, 10 / 8 (2% / 2%) linear and 45 / 32 (7% /6 %) inverse HRPC´s. Chi-squared analysis revealed a significantly higher number of non-regular HRPC´s in the low-performance group and with increasing age. Binary logistic regression revealed that the odds ratio (OR) to show a non-regular HRPC is significantly affected by maximum running speed (OR = 0.840, 95% CI = 0.754 - 0.936, p = 0.002) and age (OR = 1.042, 95% C I= 1.020 - 1.064, $p < 0.001$) but not sex.

CONCLUSION: Like in cycle ergometer exercise, three different patterns for the HRPC were identified from the maximal incremental treadmill exercise with the highest frequency of regular downward deflecting curves but no differences between males and females. Older participants and participants with a lower performance level had a higher probability to show a non-regular linear or inverse curve which needs to be considered for exercise prescription.

SELF-REPORTED VAS SUBSTITUTING RPE TO EVALUATE EXERCISE LOAD IN AN INCREMENTAL RUNNING TEST

BIAN, C., ROELANDS, B., WEI, J., LI, Y.

SHANGHAI UNIVERSITY OF SPORT; VRIJE UNIVERSITEIT BRUSSEL

INTRODUCTION: Incremental exercise tests identify the dynamic relationship between external load and integrated physiological systems. Although a combination of the rate of perceived exertion (RPE, using the Borgs 6-20 scale) and physiological parameters (e.g., blood lactate, BLa) contributes to load quantification during incremental running tests, finely-marked intensity zones and previous values of RPE might interfere next self-assessment, amplifying the inconsistency between subjective and objective values in continuous use. it might correlate more to accumulative load (refered to BLa concentration profile). One way to circumvent the interference of previous values is by using a visual analogue scale (VAS) on which the subjects have to indicate their feeling of fatigue using a slider which is reset every time, it might correlate more to accumulative load (refered to BLa concentration profile).

METHODS: Eighteen healthy trained (398.8 ± 102.4 km/month) male long-distance runners (21.5±2.0 yr; 178.6±5.0 cm; 70.3±6.0 kg) were recruited. They performed a 2-phase incremental running test to exhaustion on the treadmill with +1% slope. Each runner had a 5-min familiarization and standardized warm-up 3 min prior to the test. The first phase of the test consisted of 5 constant velocity stages, and the second phase was a continuous progressive run until exhaustion. The initial velocity was 7 km/h for 5 min and it increased 2 km/h after each stage in first phase, while a 1 min interval between each stage was set for negative recovery and blood sampling. The continuous stage started at 15.5 km/h and increased 0.5 km/h per minute until exhaustion. Verbal encouragement and performance feedback were given for motivation every minute. Immediately before and after the test, immediately after every stage, a 20 μL earlobe capillary blood sample was collected for BLa concentration profile. During 10-s blood sampling, RPE and VAS were utilized in a random sequence with a 5-s interval to evaluate perceived load as subjective fatigue.

RESULTS: Before exhaustion, Pearsons correlation (n=107) showed a stronger relationship of BLa-VAS ($r=0.90$, $p<0.001$) than BLa-RPE ($r=0.87$, $p<0.001$), although both were strong. Optimal results of regression indicated that RPE increased more as a linear ($y=0.38x+6.83$, $R^2 = 0.84$), while VAS ($y=-0.002x^3+0.122x^2+0.45x+9.04$, $R^2 = 0.77$) changed in parallel with the BLa profile ($y=-0.0006x^3+0.036x^2-0.29x+1.87$, $R^2 = 0.70$) as a typical curve relationship. The average subjective feeling of exhaustion reflected on the RPE was 19, which corresponded to 87 AU on the VAS.

CONCLUSION: Based on the current incremental exercise test we conclude that the VAS had a stronger correlation with the BLa profile, closer matching the load accumulation than RPE did. This indicates it might be more suitable for measuring acute training load. Further integration of the VAS in training monitoring and quantification can be considered.

AGE AND GENDER SPECIFIC EVALUATION OF TWO DIFFERENT ENDURANCE TESTS IN TENNIS – HIT & TURN TENNIS TEST AND YO-YO INTERMITTENT RECOVERY TEST

WIECZOREK, V., VOLK, N.R., FERRAUTI, A.

RUHR UNIVERSITY BOCHUM

INTRODUCTION: The aim of the present study was to compare the validity of two different endurance field tests for elite junior tennis players based on the correlations between the main performance outcomes and the national ranking position as well as on the comparison of the characteristics of age and gender specific performance.

METHODS: 378 nationally ranked junior male (m) and female (f) tennis players of different age groups (U12, U14 & U16) completed the Hit & Turn Tennis Test (HTT) [1] and the Yo-Yo Intermittent Recovery Test Level 1 (YY) [2] under similar standardized conditions. 50 players completed both tests, separated by six months. Test results are described by the total distance covered as well as by VO2max (estimated by equations [1],[2]) and HRmax. Tennis performance is defined by the age and gender specific position on the national ranking list. Correlations are calculated by Pearson's correlation coefficient (r) and means were analysed using one-way ANOVA and t-test (95% confidence intervals).

RESULTS: Total distance covered significantly correlated between both tests ($r=0.68$, $p<.001$) and increased significantly with age in males and females during both tests with males reaching a significantly higher test performance than females (HTT: m=2137±378m; f=1827±343m; p=.004 and YY: m=1268±430m; f=885±276m; p<.001). Estimated VO2max ($r=0.64$, $p<.001$) and HRmax ($r=0.56$, $p<.001$) were correlated as well between both tests with similar values in HRmax but significantly different values for VO2max (e.g., HTTm14: 60.7±4.0 vs. YYm14: 47.7±3.0 ml/min/kg). Low to moderate correlations were found between the total distance covered and the official ranking position in both tests for almost each group (HTT vs. YY in m12: r=-0.26 vs. r=-0.11; f12: r=-0.29 vs. r=-0.27; m14: r=-0.12 vs. r=-0.39; f14: r=-0.22 vs. r=-0.27; m16: r=0.15 vs. r=-0.10; f16: r=-0.60 vs. r=0.03). A strong and significant correlation between endurance performance and ranking was only found for f16 during HTT ($r=-0.60$, $p=.003$).

CONCLUSION: Both, HTT and YY can monitor the age and gender dependent endurance performance development and lead to a similar maximum cardiorespiratory exhaustion (HRhtt: 200±7; HRyy: 200±8 bpm). Inconsistent VO2max values for YY demonstrate that indirect equation might underestimate the actual VO2max for junior age groups. The difference can be explained using different equations for the estimated VO2max for each gender and age group during the HTT.

Differences in the test specific external load can explain the correlation for the U16 group with other physiological parameters become more relevant during adolescence in male and female. Regarding the validity of both tests for tennis specific endurance performance no clear distinction can be made since the correlations of both tests to the ranking position remains low to moderate. Tennis specific endurance (HTT) might be more important for the overall tennis performance in older female junior players.

THE SAME PHYSIOLOGICAL VARIABLES WERE RELATED TO MIDDLE DISTANCE PERFORMANCE IN RUNNING AND IN DOUBLE POLING

GJERLØW, L.

UNIVERSITY OF SOUTH-EASTERN NORWAY

INTRODUCTION: There has already been established a relationship between middle distance performance and maximal aerobic speed (MAS; 1) and maximal anaerobic speed (MANS; 2). Equivocal findings have been reported regarding the impact of anaerobic capacity measured as either maximal accumulated oxygen deficit (MAOD) or time to exhaustion (TTE) at a supra-maximal intensity related to MAS (3,4). The purpose of the present study was to compare the impact of MAS, MANS, TTE and MAOD on 800 m time trial performance in running and in double poling in a ski ergometer.

METHODS: 55 healthy active adults (37 running and 18 double poling) participated in the present study. In running, maximal oxygen consumption (VO2max), oxygen cost of running (Cr), time performance at 100 m (100TT) and 800 m (800TT), and TTE at 130 % of MAS were measured. In double poling, the participants were tested for peak oxygen uptake (VO2peak), oxygen cost of double poling (CDP) and 100TT, 800TT and TTE at 130 % of MAP in a Concept 2 Ski Ergometer. MAS was calculated as VO2max/Cr in running and as VO2peak/CDP, presented as maximal aerobic power (MAP), in double poling. MANS and maximal anaerobic power (MANP) were calculated from the 100TT performance in running and double poling.

RESULTS: Both MAP and MANP in double poling ($r = -0.936$ and -0.922, respectively, $p < 0.01$) and the relationship between 0.8 MAS + 0.2 MANS in running ($r = -0.836$, $p < 0.01$) correlated strongly with 800TT. Neither in double poling nor running, did TTE correlate with 800TT. There was no correlation between MAOD and 800TT in double poling.

CONCLUSION: The findings in this study shows that 800TT is determined by MAS/MAP and MANS/MANP in both running and ski ergometer double poling. Anaerobic capacity measured as either 130 % MAS/MAP or MAOD do not seem to be a determining factor for middle distance performance.

A VERIFICATION PHASE ADDS LITTLE VALUE TO THE DETERMINATION OF MAXIMUM OXYGEN UPTAKE IN TRAINED YOUNG ADULTS

BRUGGISSER, F.1, NIEMEYER, M.2, SCHOCH, R.1, SCHMIDT-TRUCKSÄSS, A.1, KNAIER, R.1

UNIVERSITY BASEL <1>, PHILIPPS-UNIVERSITY MARBURG <2>

INTRODUCTION: The main objective of this study was to investigate if performing a supra- or submaximal constant exercise test to exhaustion, termed verification phase, following an incremental exercise test provides additional value in the determination of the true maximum oxygen uptake (VO2max).

METHODS: Seventeen males and fourteen females performed two incremental exercise tests to maximal voluntary exertion. Immediately after both exercise tests, a verification phase was performed, with the load in one verification phase being 95% and in the other 105% of the previously achieved maximum workload. The duration of the recovery phase prior to the verification phase lasted until capillary blood lactate concentration was ≤ 3 mmol/L. If a VO2 plateau occurred during the incremental test the following verification phase was termed as no added value, since true VO2max was already determined. If no VO2 plateau occurred and the verification VO2 was < 97%, between 97-103%, or > 103% of the highest VO2 achieved in the incremental test, no added value, uncertain added value, and certain added value was attributed to the verification phase, respectively.

RESULTS: Participants mean VO2peak was 60 ± 8 mL/kg/min. Overall, in 50% of the 62 incremental tests performed, a VO2 plateau occurred, providing no additional added value from the subsequent verification phase. Of the remaining 31 tests where no VO2 plateau occurred, no added value, uncertain added value, and certain added value were obtained in

the 95% verification phase in 35%, 65%, and 0%. Considering the 105% verification phase, the values were 64%, 36%, and 0%, respectively.

CONCLUSION: Because of an additional physical strain, particular time expenditure, and no certain added value in any case, the benefit of conducting a verification phase is questionable.

STUDY OF THE PSYCHOLOGICAL PROCESS DURING THE ANTERIOR CRUCIATE LIGAMENT INJURY USING THE TRAJECTORY EQUIFINALITY APPROACH (TEA)

YAMAKAWA, R., SAKAUE, Y., YAMAURA, K., OKADA, S., SHIOZAWA, N.

RITSUMEIKAN UNIVERSITY

Introduction

Anterior cruciate ligament (ACL) injuries are severe, potentially life-altering injuries for athletes. While the importance of ACL injury prevention has been emphasized, the incidence of ACL injuries has remained the same; internal and external factors leading to ACL injuries have been classified and reported, but the psychological processes of athletes who sustain ACL injuries need to be better understood. In this study, we focused on the process of ACL injury in athletes and attempted to typify the psychological approach by comparing multiple experiences.

Methods

Semi-structured interviews were conducted with six patients (2 males and 4 females) who underwent ACL reconstruction from April 2020 to March 2022. The analysis method used was the Trajectory Equifinality Approach （T EA）

Results

In games and practices where ACL injuries were sustained, athletes who were highly motivated by their sport affected their psychological state during competition as their condition on the day of the injury and their athletic performance were affected by the competitive situation. The process of ACL injury was shown to be a result of changes in concentration due to the expression of emotions of wanting to win the game and win the match against the opponent and choosing to make decisions such as modifying the play or making a decision to play.

Discussion

A possible factor in athletes selection of injury-risk behaviors is that changes in their psychological states during competition may contribute to their obsession with winning.

The psychological states of the study subjects changed significantly during the competition compared to before, suggesting that the psychological state during the competition may vary depending on ones performance in the contest and the competitive situation. Furthermore, changes in a psychological state may contribute to the obsession with winning. The subjects in the present study played sports with a strong will to win and improve their skills. Athletes with these personality traits strongly desire to fully demonstrate their athletic performance and gain an advantage in the battle. In other words, the athletes athletic performance status and the competitive situation significantly distort the athletes subjective view. As a result, the athletes psychological state during competition may change, creating a desire to take advantage of the game and a strong desire not to lose the match, thus demanding a higher level of athletic performance from themself.

Thus, the change in psychological state fosters a focus on winning, which may induce behaviors that are more demanding than the athletes own body can tolerate and may put the athlete at risk for injury.

To prevent serious sports injuries such as ACL, it may be necessary to examine biomechanical and medical aspects from an interdisciplinary perspective, including behavioral science.

THE EFFECTS OF EXERCISE AND SPORT SCIENCE OBJECTIVE STRUCTURED CLINICAL EXAMINATION ON STUDENTS' STRESS RESPONSE AND ACADEMIC ACHIEVEMENT.

BURGOS-POSTIGO, S., FERNÁNDEZ-ELÍAS, V.E., BUSTAMANTE-SÁNCHEZ, Á., RAMÍREZ-ADRADOS, A., MARTÍNEZ-PASCUAL, B., GONZÁLEZ-DE-RAMOS, C., FERNÁNDEZ-MARTÍNEZ, S., CLEMENTE-SUAREZ, V.J.

UNIVERSIDAD EUROPEA DE MADRID

Introduction

The objective structured clinical examination (OSCE) is a method for assessing clinical competencies and skills widely used in health careers (e.g. medicine, physiotherapy). The use of OSCE to assess competencies in social sciences students is not usual and there is a need to research its convenience. The aim of this study was to analyze the autonomic stress response of Exercise and Sport Sciences Degree (ESS) students in their OSCE..

Methods

We analyzed, in 88 undergraduate students (72 men and 16 women; 24.5±3.5 years old; 23.5±3.0 Kg·m-2), the autonomic stress response, cortical arousal, subjective distress perception, and the expected academic achievement before and after the OSCE.

Results

All the heart rate variability results showed that the ESS students had an anticipatory stress response before the OSCE that decreased after it (HRmin: 6.7%; HRmax: 9.0%; HRmed: 10.4%; RMSSD: 32.0%; PNN50: 66.3%; LF/HF: 20.3%; LF: 7.7%; HF: 28.7%; SD1: 32.7; SD2: 20.5; all $p<0.05$). Also, the cortical arousal was significantly higher before the OSCE than after it (2%; $p<0.05$). However, the subjective stress perception was significantly greater after the OSCE (20%; $p<0.05$). And the expected academic achievement was also lower after the OSCE (7.3±1.0 vs 7.0±1.0 over 10, respectively; $p<0.05$), and both higher than the actual academic achievement (6.2±0.9 over 10).

Conclusion

Therefore, OSCE methodology triggered and anticipatory anxiety response while their competency's perception is not affected before the examination, and it decreased autonomic stress and cortical arousal responses in ESS students. However, the subjective distress perception increased, and the expected academic achievement decreased after the OSCE.

RELATIONSHIPS BETWEEN PSYCHOLOGICAL RESILIENCE AND COMPETITIVE LEVEL IN JUDO

RODRIGUEZ-ROMO, G., BLANCO-GARCÍA, C., GARRIDO-MUÑOZ, M., GARCÍA-MERINO, S., ACEBES-SÁNCHEZ, J.
UNIVERSIDAD POLITÉCNICA DE MADRID , UNIVERSIDAD FRANCISCO DE VITORIA

INTRODUCTION

Numerous researchers and professionals have been interested in the role of psychological resilience in competitive sports and its relationship with sports performance. In this sense, various studies confirm a positive relationship between high levels of resilience and optimal sports performance. Could resilience be a psychological quality among athletes who reach a high competitive level? The purpose of this study was to assess the possible association between the competitive level in Judo and psychological resilience, both in men and women.

METHODS

The sample consisted of 703 Judo practitioners. Men (n = 469, 66.7%) and women (n = 234, 33.3%) were 40.32 ± 14.09 and 31.42 ± 10.97 years old, respectively. We assessed psychological resilience with the 10-item Connor-Davidson Resilience Scale (10-item CD-RISC; Campbell-Sills & Stein, 2007), with a score range from 0 to 40. Higher scores indicate greater resilience levels. The judokas were classified into two groups based on their competitive level: TOP level [when all or some of the following inclusion criteria were met: (i) form or have formed part of the national junior or senior Judo team; (ii) be or have been recognized as a High Level Athlete (HLA) and/or High Performance Athlete (HPA) by the competent official bodies; (iii) occupy or have occupied the top 70 positions in the world junior or senior Judo ranking in their corresponding weight category] and non-TOP level (none of the three criteria were met).

RESULTS

TOP level judokas (n = 194, 27.6%) reported significantly higher levels of resilience than non-TOP level judokas (34.25 + 4.13 vs. 32.58 + 5.08, respectively, $p< .001$). Since both groups were significantly different in other variables under study (gender, age, age of initiation in the practice of Judo, years practicing Judo, weekly hours of practice and years competing), an ANCOVA was carried out for men and another for women, introducing these variables as covariates. Both in men [$F (1,469) = 5.04$; $p = .025$; eta squared = .011], as in women [$F (1,234) = 12.45$; $p = .001$; eta squared = .052], the differences in resilience scores between TOP and non-TOP level judokas were confirmed.

DISCUSSION

The results shows that being or having been a judoka at a highly competitive level (TOP level judoka) is related to higher levels of resilience in men and women. Although the effect size is small in both cases, it seems that this relationship is more robust in the case of women. From a practical point of view, these results seem to indicate that specific work on resilient qualities could contribute to reaching a highly competitive level in Judo, especially in women.

THE IMPACT OF WAR-INDUCED STRESS ON THE HEALTH AND PHYSICAL ACTIVITY OF UKRAINIANS

VOROBIOVA, A.1,2, SCHILLING, R.1

1 UNIVERSITY OF BASEL, SWITZERLAND; 2 NATIONAL UNIVERSITY OF UKRAINE ON PHYSICAL EDUCATION AND SPORT, UKRAINE

Introduction. The full-scale invasion of russia into Ukraine on 24th of February 2022 has changed the lives of millions. Some of these people decided to stay at home, some decided to move to the calmer regions of Ukraine or abroad, and all of them have stress. In our research project we examine the impact of war-induced stress on the health and physical activity of Ukrainians and how they have been changed in comparison with their level before the full-scale invasion of russia into Ukraine.

Methods. We have applied an online questionnaire for Ukrainian adults including the Patient Health Questionnaire (PHQ-9), the Visual Analogue Scale for Pain (VAS), the Insomnia Severity Index (ISI), the Saltin-Grimby Physical Activity Level Scale (SGPALS), and Self-perceived fitness (10-score scale). The survey started in February 2023. Preliminary data includes 93 participants, who at the moment of survey were in Ukraine (n=77) or abroad (n=16), aged 17-67 years ($\bar{x}$=36,9, SD = 11,4), 93,1% female and 6,9% male.

Results. The health level of Ukrainians has decreased in various outcomes from the time before 24th of February 2022 to the time of the survey. According to VAS 49,5% of Ukrainians have moderate or severe back pain, 36,6% head pain, 35,5% pain in arms or legs, and 23,7% stomach pain. Most Ukrainians reported to have sleeping problems (62,4%), while 42,1% of respondents showed moderate or severe insomnia symptoms based on the ISI. Chronic diseases increased by 18,3%, panic attacks by 17,6%, headaches by 15,1%, back pain by 14,0%, increased blood pressure by 8,6% and frequent respiratory diseases by 7,5%.

Interestingly, the level of physical activity of Ukrainians has increased. The number of physically inactive persons or with light physical activity decreased by 17,2%, and 7,5% of respondents began to engage in intensive training. On average, Ukrainians rate their fitness level lower (5,5 points) than before the full-scale invasion into Ukraine (6,2 points).

Conclusions. Our data showed tremendous impact on the health levels of Ukrainians compared to before the full-scale invasion of russia into Ukraine. The survey showed a high exacerbation of chronic diseases, panic attacks, headache and back pain. Close to half of the respondents showed moderate to severe symptoms of insomnia. This research project is still ongoing. Data collection will proceed June 2023. Further statistical analyses on the effects of stress experiences on health outcomes, and stress-buffering effects of physical activity will be presented based on a considerably larger sample size.

THE EFFECTS OF MENTAL STRESS ON SWIMMERS' PERFORMANCE AND PSYCHOPHYSIOLOGICAL VARIABLES

WELP, U.

FEDERAL UNIVERSITY OF RIO DE JANEIRO

INTRODUCTION: Chronic stress is defined as a state of threatened homeostasis in which affective, physiological, biochemical and cognitive changes could lead to many diseases. Yet, acute stress represents the body's reaction to a current situation and can be specifically negative during an activity that requires working memory and decision-making. Following that, some studies demonstrate cognitive exertion (e.g., arithmetic tasks) has a negative effect on subsequent physical performances [1] possibly by the modulation of the autonomic nervous system [2] and others psychophysiological variables [3]. We hypothesized that a mental stress task would be associated with lower performance in a swimming test. Moreover, the perceived exertion would increase as the focus becomes more associative and the affect gets negative.

METHODS: Five randomized competitive swimmers (15±0,44y) participated in a mental stress (ME) and control condition (CON) before a swimming test. In ME, athletes performed continuous arithmetic tasks for 15 min. In CON, they sat quietly with eyes opened for 15 min. A 200 m maximal swimming test analysis was performed and stroke length, stroke rate, and stroke index from each split were individually analyzed. Ratings of perceived exertion, heart rate variability, attentional focus, and affect (arousal and valence) were collected before the warm-up (M1), after the warm-up (M2), after ME or CON (M3), after the swimming test (M4) and 20 min after the test (M5). A two-way ANOVA was used to determine the effects of condition (ME and CON) and time (M1, M2, M3, M4) for all dependent variables. A t-test was used to compare the 200 m time from both conditions.

RESULTS: There was a significant condition x time interaction for arousal ($p=0.02$) and a main effect for time ($p<0.05$), but not for condition ($p=0.38$). There was no significant condition x time interaction for affective valence, attentional focus, or perceived effort ($p>0.05$). However, there was a main effect for time for focus ($p=0.04$) and perceived effort ($p<0.05$). Besides, there was no significant condition x time interaction for 50 m splits times, HF and LF/HF ratio ($p>0.05$) or main effect for condition ($p>0.05$), but there was a main effect for time for 50 m splits time ($p=0.01$). There was a significant interaction between condition x time for LF ($p<0.05$), but no main effect for condition or time for LF ($p>0.05$). In addition, the t-test revealed significant interactions between both conditions ($p<0.05$).

CONCLUSION: As hypothesized, athletes decreased performance when swimming after a mental stress task. Besides exercise, mental stress pre-exercise also modulated athlete's responses by increasing arousal, perceived exertion, and sympathetic activity, also focus became more associative. Therefore, the athletes were 1,842 s slower in the ME. For future reference, it would be interesting to investigate whether coping strategies can interact with these results.

PHYSICAL BEHAVIOR PROFILES IN PHYSICAL EDUCATION TEACHERS: DO PROFILES DIFFER IN RECOVERY EXPERIENCES?

VON HAAREN-MACK, B., HAUFSCHILD, M., PELS, F.

KARLSRUHE INSTITUTE OF TECHNOLOGY

28th ECSS Congress Pars/France, July 4-7 2023

Physical Behavior Profiles in Physical Education Teachers: Do Profiles Differ in Recovery Experiences?

von Haaren-Mack,B.1, Haufschild, M.2, Pels, F.2

1Karlsruhe Institute of Technology, 2German Sport University Cologne

Introduction

Teaching physical education (PE) is a high stress profession requiring substantial physical and mental resources. To prevent ill-health, recovery after work is highly important. Previous studies showed positive relations between physical behavior during leisure time and recovery experiences. However, they applied self-report measures, assessed physical activity only and did not address PE teachers. Therefore, the present study aimed to investigate the association between physical behavior and recovery experiences in PE teachers, using a holistic approach and objective measures for physical behavior.

Methods

Forty-five PE teachers were recruited as a subsample in the context of the "Schulsport 2030" project (BMBF). Physical behavior was continuously measured for one week using accelerometers and then classified into four physical behavior intensity categories (i.e., sedentary, light, moderate, vigorous). Recovery experiences (detachment, relaxation, control, mastery) were assessed with the Recovery Experiences Questionnaire (Sonnentag & Fritz, 2007). To identify physical behavior profiles, hierarchical cluster analysis was used.

Results

Based on the cluster analysis, PE teachers were classified into two distinct profiles based on their physical behavior. The "active profile" was characterized by significantly higher proportions of moderate ($t(43) = 3.29$, $p = .002$, $d = 0.98$) and vigorous ($t(43) = 9.54$, $p < .001$, $d = 2.85$), but not light ($t(43) = -0.14$, $p = .890$, $d = -0.04$) activity and lower proportions of sedentary behavior compared to the "less active" profile. In addition, only the "active profile" achieved the physical activity guidelines of the WHO (Bull et al., 2020). When comparing recovery experiences between the activity profiles, PE teachers within the "active profile" showed significantly higher values in mastery experience ($d = 0.66$, $p = .032$), control ($d = 0.72$, $p = .02$) and the overall recovery experiences score ($d = 0.79$, $p = .011$) compared to the "less active" profile.

Discussion

For recovery experiences, a more "active profile" with less sedentary behavior and more moderate and vigorous physical activity is favorable against a "less active profile". As practical implications, the results suggest to integrate recovery strategies in teacher training programs and highlight moderate to vigorous physical activity as a successful strategy to buffer the detrimental effects of stress.

OPEN GOALS PRODUCE MORE ENJOYABLE EXPERIENCES AND EQUIVALENT LEVELS OF PHYSICAL ACTIVITY WHEN COMPARED TO SMART GOALS FOR INSUFFICIENTLY ACTIVE ADULTS

HAWKINS, R., SWANN, C., JACKMAN, P.C.

UNIVERSITY OF LINCOLN

Introduction

Goal setting is one of the most frequently employed behaviour-change techniques in physical activity (PA). When employing goal setting, it is common practice in PA to promote the use of specific goals, which are commonly implemented as "SMART" goals in practice (i.e., specific, measurable, achievable, realistic, and time-bound goals). However, recent evidence from lab-based walking studies has indicated that open goals (e.g., "see how active you can be") could be a promising alternative to SMART goals for increasing PA and producing adaptive psychological outcomes. This study aimed to examine the effects of open goals and SMART goals on PA and psychological outcomes over one week in active and insufficiently active individuals.

Methods

A three-arm, randomised controlled-trial design was employed. Active (n = 30) and insufficiently active (n = 31) participants were randomly assigned to one of three experimental groups: (1) SMART; (2) open; or (3) control. Participants took part in a baseline week, followed by an experimental week, in which participants recorded daily information regarding their physical activities and responded to a range of psychological measures. Data were analysed using three-way mixed-model ANCOVAs.

Results

Open and SMART goals had no significant effect on PA compared to the control condition, and no differences were found between active and insufficiently active participants. However, insufficiently active participants reported significantly greater enjoyment (compared to SMART), perceptions of performance (compared to SMART and control) and perceptions of confidence (compared to the SMART and control), whereas active participants reported significantly greater levels of enjoyment in the SMART condition and the control condition compared to the open goal condition.

Discussion

This study offers the first insights into the effects of open and SMART goals outside lab-based walking tests and has several important findings. First, findings in the current study were consistent with meta-analytic evidence demonstrating that non-specific goals are as effective as specific goals for the purpose of increasing levels of PA. Second, the study provided further evidence that open goals produce more positive psychological outcomes (enjoyment, perceived performance, and confidence) when compared to SMART goals for insufficiently active adults but extends existing evidence by demonstrating such positive psychological outcomes over an extended period of time, and in more ecologically valid PA settings. Third, the study supports existing evidence which has indicated that active adults, with prior experiences in PA, may experience adaptive psychological outcomes when pursuing SMART goals compared to open goals. This research therefore extends understanding of open and SMART goals in PA and provides further evidence that open goals may be a potentially advantageous alternative goal type for insufficiently active adults.

EXPRESSIVE PSYCHOLOGY OF DEOPBAEGI DANCE

BAEK, H.

KOREA NATIONAL SPORT UNIVERSITY

Introduction

The Deotbaegi Dance is a dance of the Gyeongsang-do region of Korea. This dance is heavy and is based on folk rituals. 'Deotbaegi' refers to the Gyeongsang-do-style Madangnori dance, and in particular, the Daegu region's Deotbaegi dance is a clunky and dynamic dance that expresses the excitement of Koreans well. In deotbaegi, 'deot' means 'to add' or 'to get rid of' and has the meaning of 'mask' or 'mask'. Also, baegi has the meaning of baekda or veda. This study intends to infer the expressive psychology of the deopbaegi dance movement that includes the meaning of such a dance.

Methods

As for the research method, literature study through prior research and field study for dance motion analysis, that is, dancing motions were recorded and analyzed on video, and then oral interviews were conducted with the dancers. Oral is the process of recording personal memories and contents verbally. And by analyzing the video footage taken from the field, the expressive psychology of the deopbaegi dance was inferred.

Results and discussion

First, most of the movements of the deopbaegi dance are bending the knees and exhausting them tightly. It expresses the shamanistic psychology of taking bad energy and pushing it away. This shamanistic psychology is based on Korean exorcism, and the action itself symbolizes the meaning of getting sick. Therefore, it refers to the psychology that means to get rid of what is out of place.

Second, it symbolically expresses the actions that are performed while working in the fields. In other words, it symbolically expresses the action of digging the ground, the action of holding a colander on the head, and the action of sowing seeds in the field. The meaning of these fields should be understood as a place of agriculture, 'a place where food was produced'. Therefore, it is said that they danced a dance related to farming to soothe the tiredness of farmers who were working in the fields.

Third, the dance moves are not a stereotyped dance that is aesthetically well structured, but improvisation, expressing the heart of the dancer from time to time. In other words, it expresses improvisation, such as a 'makchum', in which you dance according to the music. Therefore, this dance is not a dance choreographed by someone, but an impromptu dance that is not tied to a special format when people have a desire to dance.

Fourth, like Madangnori, where everyone gathers and plays happily, the excitement of Koreans is expressed in dance movements. In Korea, everyone dances together when they are excited even after doing difficult and arduous work. In particular, it gives people energy to go back to their daily lives by raising the excitement of peoples minds through the fast beat of music and solving their dissatisfaction through that excitement.

THE RELATIONSHIP BETWEEN MOTIVATIONAL REGULATIONS AND PHYSICAL ACTIVITY LEVELS DURING PHYSICALLY ACTIVE LESSONS AMONG 6TH AND 8TH GRADE ADOLESCENTS.

REINBOTH, M.S.1, JOHANSEN, J.M.1, MANDELID, M.B.1,2, TJOMSLAND, H.E.2, THURSTON, M.3, RESALAND, G.K.2, BRATLAND-SANDA, S.1

UNIVERSITY OF SOUTH-EASTERN NORWAY

The relationship between motivational regulations and physical activity levels during physically active lessons among 6th and 8th grade adolescents.

Reinboth, MS.[1]., Johansen, J-M.1, Mandelid, MB.1,2, Tjomsland, HE 2, Thurston, M.3, Resaland, GK.2, Bratland-Sanda, S.1

INTRODUCTION

Physically active lessons (PAL), the combination of physical activity (PA) and academic content, has shown to be a promising way of increasing children's PA levels as well as academic-related outcomes without reducing academic time (Daly-Smith, et al., 2021). Less is known about how pupils' motivational regulation relates to the PA executed during PAL. Based on self-determination theory (Ryan & Deci, 2017), this study aimed to examine the relationship between motivational regulations for PA and the objectively measured PA levels during PAL among early adolescent pupils.

METHODS

Thirty-seven pupils were recruited from the 6th and 8th grades. PA levels were measured by Actigraph triaxial accelerometers, worn by the pupils only during lectures that consisted of a scheduled PAL. Data were collected during 25 PAL sessions within six months throughout the schoolyear. All PA data were analyzed in 1-sec epochs. Evenson cut-off points were used to define minutes of sedentary time, light, moderate and vigorous PA. Motivational regulations were assessed using a Norwegian version of the BREQ-2.

RESULTS

A significant positive correlation was found between intrinsic motivation and vigorous PA ($p < 0.01$) whereas amotivation was significantly negatively correlated with vigorous PA ($p < 0.05$) during PAL. A positive significant correlation was found between amotivation and sedentary behaviour ($p < 0.05$). Linear regression analysis showed that intrinsic motivation was a positive significant predictor of vigorous PA (Total $R^2=0.28$, $\beta=0.49$, $p < 0.05$).

DISCUSSION

Pupils who were intrinsically motivated were more likely to be more active during PAL. In contrast, this relationship was reversed for pupils who were amotivated. This may be of practical importance for some activities (e.g., competitive relays) or where pupils are allowed to choose the activity level to solve a PAL activity. Consequently, amotivated pupils may choose to be less active, whereas intrinsically motivated pupils may dominate activities and show high PA levels. The motivational regulations of the pupils may therefore be a key factor for teachers to consider when planning PAL.

TESTING MEASUREMENT INVARIANCE OF MOTIVATIONAL PROFILES IN SPORT AND PHYSICAL EDUCATION CONTEXT

HARBICHOVÁ, I., RUSNÁKOVÁ, K., SCHEIER, L., KOMARC, M.

CHARLES UNIVERSITY, FACULTY OF PHYSICAL EDUCATION AND SPORT

Introduction

The importance of a multidimensional conceptualization of motivation in sport and Physical Education (PE) proposed by the Self-Determination Theory (Deci & Ryan, 2000) has been supported by a large body of empirical evidence. Recently there was an increased interest in using person-centered analytical approach to examine sport motivational profiles, which reflect the simultaneous presence and interactions of multiple motivations within the same individual. Although a measurement invariance (e.g., scalar invariance) of the extracted profiles constitutes an important methodological prerequisite of valid between-profile comparisons in outcomes, this prerequisite was never empirically tested in previous studies.

Method

The Czech version of the Sport motivation scale (Komarc et al., 2020) was used to measure different types of motivational regulations (intrinsic, identified, introjected, external, amotivation) in a sample of N=456 undergraduate students. The optimal number of profiles was determined using the Latent Profile Analysis (LPA), a model-based clustering method. Invariance tests based on gender, competitive level and type of sport (individual vs. team) were then conducted using a multi-group analysis framework.

Results

The model fit indices and parameters for different LPA models supported existence of 4 distinct latent motivational profiles in our sample. The largest latent profile (Moderately autonomous) consisted of 51.5% participants, who reported the highest levels of intrinsic motivation compared to other profiles. Participants in the smallest profile (Highly amotivated, 7.5%) on the other hand, reported extremely high levels of amotivation. Multigroup LPA supported configural invariance (number of profiles is the same) for all 3 grouping variables. Further analyses have indicated that a partial metric invariance is a plausible hypothesis after removing equality constrains on several latent profile indicators.

Discussion

Consisted with our expectations and previous research using the LPA modeling framework, we identified four distinct sport motivation profiles. Evidence of partial metric invariance for the extracted profiles provides a sound basis for assessing between-profile differences in motivational outcomes, which are of a great interest for coaches and sport psychologists. Future studies are however warranted in order to replicate our findings and/or expand available evidence about invariance in other contexts (e.g., PE) and for other important grouping variables such as age, experience with sport participation, or culture.

MEDIATION EFFECT OF BASIC PSYCHOLOGICAL NEEDS IN THE RELATIONSHIP BETWEEN LEADER'S AUTONOMY SUPPORT AND COLLEGE LIFE ADAPTATION IN STUDENT-ATHLETES

KIM, Y., LEE, Y.

KOREA NATIONAL SPORT UNIVERSITY, KOREA NATIONAL SPORT UNIVERSITY

Introduction

This study attempts to verify the mediating effect of basic psychological needs in the relationship between autonomy support of leaders recognized by university athletes and their adaptation to college life.

Methods

In this study, data were collected from 227 athletes attending K University in Seoul, Korea. The survey tools used the leaders autonomy support (Deci, 2000), basic psychological needs (Deci & Ryan, 2001), and college life adaptation (Baker & Siryk, 1989) scales. Leader's autonomy support(LAS) is composed of a single factor, and basic psychological needs are composed of autonomy, relationship, and competence. college life adaptation consists of academic adaptation(AA), social adaptation(SA), emotional adaptation(EA), physical adaptation(PA), and attachment to college(AC). All scales consist of the Likert 5-point scale. The collected data were analyzed through SPSS 23.0 and PROCESS macro (v.3.3) model 4, and the mediating effect was verified through Bootstrapping.

Results and discussion

First, it was found that the LAS had a significant effect on autonomy(β=.424, p<.001), competence(β=.499, p<.001), relationship(β=.501, p<.001), and AA(β=-.162, p<.05). Second, autonomy was found to have a significant effect on AA(β=.424, p<.001), EA(β=.670, p<.001), PA(β=.409, p<.001), and AC (β=.444, p<.001), and competence was found to have a significant effect on AA (β=.424, p<.001) and PA (β=.409, p<.01). In addition, it was found that relationships had a significant effect on SA (β=.475, p<.001) and AC (β=.174, p<.05). Third, it was found that autonomy (95% CI=.095~.254) and competence (95% CI=.083~.292) had a mediating effect in the relationship between LAS and AC. Fourth, it was found that the relationship (95% CI=.150~.361) had a mediating effect in the relationship between LAS and SA. Fifth, it was found that autonomy (95% CI=.202~.430) had a mediating effect in the relationship between LAS and EA. Sixth, autonomy (95% CI=.107~.258) and competence (95% CI=.025~.205) were found to have a mediating effect in the relationship between LAS and PA. Seventh, it was found that autonomy (95% CI=.092~.237) and relationship (95% CI=.013~.149) had a mediating effect in the relationship between LAS and AC.

THE EFFECTS OF EMPOWERING AND DISEMPOWERING MOTIVATIONAL CLIMATE ON SELF DETERMINATION THEORY, FUN, AND BOREDOM AMONG STUDENT IN PHYSICAL EDUCATION CLASSES

DONG FANG, J.D., TSAI, S.H., LIN, M.S.
SOOCHOW UNIVERSITY

Introduction: Teachers can guide students motivational experiences through a variety of guiding teaching methods (Braithwaite et al, 2011). Previous studies have found that in the perspective of socio-psychology individuals' behaviors and attitude play an important role in the activity, In recent years, Duda and colleagues (2016) combined previous studies of achievement goal theory and self-determination theory, and proposed empowering and disempowering, expanding the scope of previous climate measurements. The main purpose of this study was to investigate the potential motivational processes of positive and negative effects of empowerment and disempowerment climate toward self-determination theory and the relationship it has with the behaviors of fun and boredom in the context of physical education.

Method: This study retrieved 550 questionnaires from universities that attended physical education course in universities and after the elimination of invalid questionnaires, a total of 449 valid questionnaires was used . The hypotheses were estimated using one-way ANOVAs and linear regression for the path hypothesis.

Results: The basic descriptive analysis of students were 240 male and 259 female. The linear regression analysis revealed a significant amount which explained variance on empowering and disempowering with ($r = -0.615^{**}$, $p < 0.01$) and the relationship of empowering and competence, autonomy and relatedness ($r = 0.445^{**}$; $r = 0.622^{**}$; $r = 0.561^{**}$, $p < 0.01$) and a negative relationship of disempowering toward competence autonomy and relatedness ($r = -0.168^{**}$, $r = -0.376^{**}$, $r= -0.300^{**}$, $p < 0.01$). Furthermore, SDT had a positive relationship on fun ($r = 0.617^{**}$; $r = 0.672^{**}$; $r = 0.562^{**}$, $p < 0.01$), and a negative effect on boredom ($r = -0.489^{**}$;$r = -0.584^{**}$;$r = -0.464^{**}$, $p < 0.01$). R square= 0.515 the explanatory power for predicting fun on behalf of all other variables in the model with a F value of 0.5.

Discussion: In this study, the physical education class was further explored to elucidate the different potential motivational processes that explain the positive and negative effects of an empowering and disempowering climate. Students grow stronger and rely most on teachers when they seek to create a learning environment that meets their three basic psychological needs such as, autonomy (e.g., students feel psychologically free to participate positively in decision making), competence (e.g., students feel competent), and relatedness (e.g., students feel a sense of connection and belonging with their classmates or with their teachers). Therefore, three basic psychological needs produce mediating effects between empowerment and disempowering motivational climate and basic psychological needs of fun, boredom.

THE ASSOCIATIONS BETWEEN PERCEIVED EMPOWERING AND DISEMPOWERING MOTIVATIONAL CLIMATE, COACH-RELATIONSHIP, SATISFACTION, AND DROPOUT INTENTION AMONG ATHLETES

TSAI, S.H., LIN, M.S., WU, H.F.
SOOCHOW UNIVERSITY

Introduction: The behavior of coaches in sports settings has been extensively studied in relation to athletes motivations and feelings and reactions to the sports they participate in. Duda (2013) an empowering motivational climate framework as a theoretical basis for predicting and explaining achievement performance, motor motivation, and related behaviors. Previous studies have suggested that climate reduces basic psychological needs, making motivation less autonomous, participation of activity less motivated, making individuals more prone to physical burnout or anxiety (Bartholomew, et al., 2011). Furthermore, in situations like sport team training, the coach and the athlete are the primary interaction which may affects the athletes decision to continue to participate in the sport and can even have an effect on individual and team performance (Jowett & Ntoumanis, 2004). The purpose of this study was to extend the applicability of Empowering and Disempowering Motivational Climate, Coach-Relationship, Satisfaction, and Dropout Intention Among Athletes.

Method: A total of 308 high school athletes were surveyed using a questionnaire. With the use of (Empowering and Disempowering Motivational Climate Questionnaire ; EDMCQ-C) scale (Jowett & Ntoumanis, 2004) and (Coach-Athlete Relationship Questionnaire, CART-Q) with back forward translation to Chinese questionnaire including sport motivation scale with Pearsons product difference correlation was used to understand the relevant situations, multivariate stepwise regression was used to analyze and the predicted the relationship, and the mediation effect was verified using the bootstrap method.

Results: This study found that player empowerment climate was positively correlated with intamacy, commitment, complementarity, and satisfaction of coach-player relationship; ($r = .61$, $r = .64$, $r = .60$, $r = .57$, $r = .53$; $p < .001$) on the contrary, Disempowering climate was negatively correlated with intimacy, commitment, complementarity and satisfaction of coach-player relationship empowerment climate was significantly negatively correlated with disempowerment climate and dropout intention ($r = -.39, -.35$; $p < .001$).

Discussion: The results showed that when players perceived that the coach was shaping an empowering climate, there were higher levels of intimacy, commitment, and complementarity in the coach-player relationship, and higher levels of satisfaction development; conversely, when players perceived that the coach was disempowering climate and lower levels of commitment in the coach-player relationship, this resulted in dropout intentions. This finding is consistent with previous studies (Olympiou, Jowett, & Duda, 2008; Duda et al., 2014) .

BORN TO BE PROUD OR LEARNED TO BE PROUD: ANALYSES OF ASSOCIATIONS OF PRIDE WITH PERSONAL DETERMINANTS AND CAUSAL ATTRIBUTION STYLES

LEISTERER, S., WINKLER, E.
LEIPZIG UNIVERSITY

The social emotion pride appears to be closely associated with performance in sport. However, pride can be divided into the more functional emotion pride and the more dysfunctional emotion hubris (Tracy & Robins, 2007). The semantic differentiation between pride as a positive experience of success and hubris as a positive emotion regarding a striving for dominance shows parallels to the descriptions of the implicit motives for achievement and power (Wegner, 2020). Moreover, pride is more likely to be associated with an internal-variable attribution style and hubris with an internal-stable attribution style. Attribution styles, however, correlate with the motive components of hope and fear (Schüler & Elbe, 2020). Since pride can be considered a functional emotion, especially for sports (Sabiston et al., 2020), the goal of enabling athletes to better regulate pride and hubris arises. Attention should be paid to individual determinants–personality traits and individual factors (Kobylińska & Kusev, 2020). For this purpose, it seems necessary to identify associations between the emotions pride and hubris with individual implicit motives, attributional styles, and motivational components. In an ongoing cross-sectional survey with currently N = 11 recreational athletes (ten of them female, one male), pride, implicit motives, motive components, and attributional styles will be assessed using the Pride Scale (Tracy & Robins, 2007), the Picture Story Exercise (Winter, 1994), the Multi-Motive Grid (Schmalt et al., 2000), and the Attributional Scale Questionnaire (Peterson et al., 1982) to explore the associations between pride and pride with individual determinants using bivariate Pearson correlation analyses. Initial results show exclusively negative correlations for pride with the motive components fear of failure (r = -.78, p = .008, CI95%[-.94; -.26]) and fear of loss of control (r = -.70, p = .035, CI95%[-.93; -.03]). In contrast, correlations of pride with hope for success (r = .75, p = .020, CI95%[.12; .94]), hope for control (r = .86, p = .003, CI95%[.41; . 97]), internal-variable causal attribution (r = -.76, p = .017, CI95%[-.94; -.16]), and the implicit motives of power (r = .76, p = .017, CI95%[.15; .94]) and achievement (r = .81, p = .009, CI95%[.26; .95]). More pride is found to be associated with lower fear components of both the implicit power and achievement motives. More pride is associated with stronger expressions of the implicit motives and their hope components, as well as less internal-variable causal attribution. Accordingly, future studies should increasingly discuss the function of motive components in influencing pride and hubris as well as the conditional relationship between an internal-variable causal attribution and hubris.

NEED TO BELONG AND EXERCISE PARTICIPATION OF COMMUNITY-DWELLING ELDERLY FROM TAIWAN

WU, H.J., LIAO, C.M.
NATIONAL TAIWAN SPORT UNIVERSITY

ntroduction

Need to belong is one of the basic psychological needs of human and individuals are motivated to engage what satisfy this need (1;2). According to our previous work on adults, people who were high in need to belong seldom engaged in solitary activities and tented to have lower level of self-esteem. For the elderly, physical activities not only help to maintain their health but also provide a context in which need to belong can be satisfied through interpersonal interactions. In this study, we attempted to extend the understanding of physical activity participation of the elderly by investigating the relationship between levels of need to belong and exercise participation as well as possible gender differences.

Method

One hundred and ten community-dwelling elderly from Taiwan without physical and mental disabilities participated in this survey. Questionnaire consisted of demographic, need to belong scale, Rosenberg self-esteem scale, self-reported exercise behavior and exercise status preference.

Result

Three underaged participants (under 65) and 7 multivariate outliers were deleted from the sample during data screening. There were 30 males and 70 females in the sample, aged 65-94 (M= 74.09, SD= 5.74). All of the participants were capable of independent mobility, 64% of them exercised almost every day and 51% of them usually exercised with others; 14% of participants disliked exercise alone, and only 5% of them disliked exercise with others. The Pearson product-moment correlations showed that need to belong (M = 28.29, SD = 5.06) was positively related to preference for exercising with others (r = .22, p = .031) and was correlated negatively to self-esteem (M = 38.03, SD = 3.92) (r = -.34, p < .001), however, was not related to the frequency of exercise participation. In addition, t-test showed that female (M= 29.00, SD= 4.62) had a higher level of need to belong than male (M= 26.63, SD= 5.70) (t = 2.19, p = .031).

Conclusions

It was encouraging to find that, in this sample, the majority of the community-dwell elderly exercised regularly. Need to belong seemed not associated with the frequency of exercise participation, however, the elderly who were high in need to belong did showed a preference for group exercise. This study also showed that senior women had higher level of need to belong than senior men. This might provide a possible answer to the question why community-based exercise groups usually attracted more female than male. Finally, people who were high in need to belong tended to have lower self-esteem. It seems necessary to pay more attention to this issue.

Introduction : From 2019 to 2022, the sporting environment of the entire international community has changed significantly as a result of major public safety events.The development of the entire sports industry has been largely static because of the epidemic, but on the contrary, home-based sports have risen rapidly and peoples attitudes towards sports have changed a lot.The initiative of peoples fitness becomes stronger, almost all on-line and off-line go out, the national health demand is increasing.Peoples health awareness has improved significantly compared to the past, and more attention has been paid to health, and the number of people exercising at home has increased significantly.As Koreans exercise using YouTube home training videos, more and more people are interested in their health.In particular, the number of views on home training videos has increased by more than 40% since the pandemic began in earnest (YouTube Data, 2020).According to a survey of Chinese nationals, 27.2% of the Chinese people value healthy exercise habits more during the epidemic, 23.8% learn more home-based fitness skills and 21.1% have more stable exercise habits(2020年大众运动健康报告，2020).Health awareness and awareness of home training in China and South Korea have improved significantly compared to before the outbreak. Objectives : If dangerous situations end and peoples needs are not constrained, will home-based fitness continue?Will we do better than we do now when dangerous situations come again?This is a topic worthy of discussion and reflection.Only by reflecting on the past can we look forward to the future.Therefore, it is necessary to analyze the change characteristics of urban residents home-building behavior and make theoretical exploration. Methods : This study takes urban residents as the object of investigation and Shangqiu City, Henan Province, China as the regional scope.A total of 1000 questionnaires were distributed, 912 valid questionnaires were issued .Reliability 0.881 and validity 0.946.With demographic characteristics as the background variable, home fitness environment as the independent variable, sports demand as the medium variable and sustainable behavior as the dependent variable.To explore the sustainability of home-building behavior of urban residents in the course of outbreak and after epidemic by using ERG theory.After the end of the epidemic, peoples behavior is not compulsory, so how the peoples fitness behavior will change and whether home-based fitness behavior will continue. Result & Discussion : The results show that when the survival needs are met, the home environment has a positive impact on the sustainability of home-building behavior of urban residents.When the interrelationship and growth needs are suppressed, the home environment has positive and negative effects on the sustainability of home fitness behaviors of urban residents due to different ages and occupations. Conclusion : YouTube Data(2000). KR, Mar 15 ~ Sep 30, 2020 vs. Jan 1 ~ Mar 14, 2020.

ROAD TO PARIS 2024: FORCE- VELOCITY PROFILE IN SPEED CLIMBERS

MUÑOZ DE LA CRUZ, V., RODRIGO-CARRANZA, V., GONZALEZ-RAVE, J.M.

UNIVERSITY OF CASTILLA-LA MANCHA - TOLEDO CAMPUS: UNIVERSIDAD DE CASTILLA-LA MANCHA

INTRODUCTION: Speed climbing will be a new discipline at the next Olympic games in Paris 2024 within sport climbing along with bouldering and lead climbing. Physical requirements of speed climbing are different from the other modalities, especially due to the short event time (WR men=5" & WR women=6.53"). Previous studies indicate that speed climbing requires higher level of strength and power (1,2). These parameters have been measured through the F-V profile previously in different type of climbers (3). However, there are no known results evaluating at different speed climbing performance to determine whether this is a determining factor between levels. The purpose of this study was to evaluate the F-V profile on different speed climbers' ability (national vs international). We hypothesized that international climbers may have a different F-V profile to national level climbers.

METHODS: A total of 26 speed climbers participated in this study divided into two groups (International level n=9 and national level n=17). The participants performed pull ups and squat incremental tests in the same day in a non-competitive period where velocities performed with different loads were collected using a lineal encoder to obtain the F-V profile variables (F0, V0, Pmax and FV slope) in addition to the repetition maximum value (1RM).

RESULTS: We found significant differences in F0 and 1RM in pull-ups ($p<0.05$) between level groups after performing a two-way ANOVA. However, we found no significant differences between groups in any of the variables obtained from the squat F-V profile. After performing a Pearson correlation, we found significant ($p<0.05$) and strong correlations between running time and 1RM (pull-ups and squat) and F0 and FV slope in pull-ups.

CONCLUSION: Climbers with better climbing performance showed a higher F0 despite no difference in peak power, therefore strength training in national climbers should be focused on improving the F0 (i.e., lifting heavy weights rather than ballistic movements with light weights (4)). Moreover, there was significant correlation between performance (time) and squat 1RM, but without significant differences between groups, so it does not appear to be an indicator of speed climbing performance.

INTRODUCTION: Training scheduling cannot be separated from what happens in competition. Understanding the demands of competition allows training content to be better adapted and individualised [1]. In this sense, computer is a great tool to achieve this. It allows us to collect information as faithfully as possible while being non-intrusive [2]. The objective of this work is to determine the tactical demands by weight category and then to model the duration of the fight according to the style of wrestling.

METHODS: Computer vision has made it possible to build the dataset made up of 5280 fights since 2019 automatically annotated with the point score, the associated time as well as the name, the competition round, the weight category and the wrestling style. The non-parametric Kaplan-Meier estimator was applied to estimate the time remaining before the end of the bout. The Cox proportional hazards model estimates the duration of the fight by taking into account independent covariates.

RESULTS: The log-rank test confirms a significant difference between the duration of the fights of women (women wrestling) and men (freestyle (32.74 ; p$<$0.005) and greco-roman wrestling (26.49 ; p$<$0.005)). On the other hand, the Cox proportional hazards model gives us the information that the duration of the fight increases as the competition progresses with a significant difference between the preliminary and final rounds for each style (GR : 87.11, FS : 39.42, WW : 8.62 ; p$<$0.005).

CONCLUSION: These preliminary results make it possible to lay the foundations of competitive expectations in Olympic wrestling. They can provide benchmarks for coaches to use during training or for athletes to achieve. Further work will focus on adding qualitative variables to improve the various results.

PHYSIOLOGICAL DEVELOPMENT OF JUNIOR WINDSURFERS TO PREPARE FOR THE CHANGE OF OLYMPIC RACE CLASS FROM RS:X TO IQFOIL

CHAN, Y.Y., TAI, C.H.

HONG KONG SPORTS INSTITUTE

INTRODUCTION: In November 2019, the World Sailing Council has approved Starboard iQFoil to replace RS:X as the windsurfing equipment for Olympic Games from Paris 2024 [1]. After this decision was made, competitive windsurfing around the world has gradually transit their program to iQFoil focus, with the first iQFoil Senior and Youth World Championships being held in 2021. One of the main differences between iQFoil and RS:X is that iQFoil have foil instead of fin under the board which allow a faster speed in the same wind conditions [2]. Coaches and athletes have therefore applied different training strategies to adopt the changes. The aim of this study was to investigate the difference in physiological development for junior windsurfers in preparing to race in iQFoil class when comparing with the RS:X class.

METHODS: Athletes from Hong Kong Junior Windsurfing National Team participated in fitness testing batteries twice a year, which included height and weight measurement, 20-meter shuttle run to estimate VO2max and 1-minute modified pull up. iQFoil group consist of 17 athletes (age 14.9±0.8), whom at least participate in 1 fitness test in year 2018-19 as pre-test, and also year 2021-22 as post-test for pairwise comparison. These athletes transfer from training with RS:X to iQFoil right after the announcement of equipment change in 2019. RS:X group consist of 15 athletes with similar age (age

16.0±1.8) whom at least participate in 1 fitness test in year 2015-17 as pre-test, and also year 2018-19 as post-test for pair-wise comparison. These athletes trained with RS:X equipment throughout the whole study period. Repeated measures ANOVA was used to detect changes of pre and post-test, effect sizes expressed as partial eta-squared (n2). Significance was set at $p<0.05$.

RESULTS: Both iQFoil (Pre-test: 59.1±8.2 kg; Post-test: 67.3±10 kg)(p=0.00, n2=0.66) and RS:X (Pre-test: 63.0±5.9 kg; Post-test: 65.4±6. 2kg)(p=0.00, n2=0.32) groups has significant increase in body weight, with the effect in iQFoil group was twice as strong as the RS:X group. RS:X group has significant improvement in VO2max (Pre-test: 49.9±6.9 ml/kg/min; Post-test: 53.5±5.8 ml/kg/min)(p=0.00, n2=0.19), but not for iQFoil group (Pre-test: 51.5±5.7 ml/kg/min; Post-test: 51.5±5.7 ml/kg/min)(p=0.98, n2=0.00). iQFoil group has significant improvement (Pre-test: 27.4±7.3; Post-test: 41.1±7)(p=0.00, n2=0.59) in 1-min modified pull up but not for RS:X group (Pre-test: 31.8±8.3; Post-test 29.2±6.1) (p=0.39, n2=0.02).

CONCLUSION: The results suggest that the physiological development of junior windsurfers have been changed, since iQFoil replaced RS:X to be the official racing equipment for Olympics. Athletes training for iQFoil has more significant increase in body mass, and significant increase in 1-min modified pull up. Athletes training for RS:X, on the other hand, has significant increase in VO2max. However, it is still unclear if these changes affect performance with difference equipment.

CLUSTERING TECHNICAL APPROACHES OF WORLD CLASS POLE VAULTERS

CASSIRAME, J., EUSTACHE, E., SANCHEZ, H., CZINGON, H., HOMO, S., FRÈRE, J.

1UNIVERSITY OF FRANCHE–COMTE, C3S–UR 4660, BESANÇON, FRANCE 2EA 7507, LPMS, 51100 REIMS, FRANCE 3MTRAINING, R&D DIVISION, 25480 ECOLE VALENTIN, FRANCE

4 University of Neuchâtel, institut de statistique, Switzerland

5 French Athletics Federation, Paris, France

6 University Grenoble Alpes, GIPSA-Lab, 38000 Grenoble, France

INTRODUCTION: Pole vault performance has been mainly biomechanically investigated to point out performance determinants [1]. Several key parameters were highlighted such as speed, grip, size of athletes or take-off (TK) angle. From this, many coaches and scientists published studies describing ideal technical approaches of pole vaulting for performance [2]. Today, observations of top vaulters raise questions about the classical technical model that is well-documented. The goal of this study was to identify potential technical profiles using actual measurements taken during official competitions and to examine these profiles from athlete's characteristics and mechanical perspective.

METHODS: Data were collected during more than 80 official competitions with same experimental setup. Best jump from 98 men with personal best between 5.10 and 6.21 m were analyzed. Spatiotemporal parameters and horizontal speed were collected during the run-up using Optojump Next system (Microgate, Italy) synchronized with radar gun (Applied Concept, USA). Kinematic (pole bending) and dynamic (mechanical energy gain) analyses were done by means of 2-dimensional video analysis on sagittal plan (100 Hz, Panasonic HC-V770, Japan). Pole vaulters were divided into an optimal number of non-overlapping subgroups using the k-means clustering method based on two technical parameters allowing identification of technical styles independent of morphology or level: TK angle and Under (horizontal distance between TK foot and upper hand).

RESULTS: K-means method pointed out 4 clusters with distinct behaviors. Cluster 1 (C1) was composed of athletes with high to moderate Under with higher TK angle (over 12.5 °). C2 was composed of athletes with lower Under-values and higher TK angle. C3 included athletes with high to moderate Under and lower TK angle. Finally, athletes of C4 had low Under-values with the lowest TK angle. C4 was composed with smaller athletes, running with the smallest contact time, and an increased the last stride while others tended to reduce this one. C4 athletes performed with higher TK distance and produced the biggest pole bending ratio. C2 athletes performed with stiffer pole, higher grip distance and produced the smallest pole bending. C1 and C3 produced their performance using smaller grip and TK distance than another clusters. We did not identify any differences in speed or energy gain between clusters.

CONCLUSION: This study pointed out that different pole vault styles can be highlighted at world class level based on technical parameters. We observed that each cluster produces performances with similar speed and energy net gain level as input but had various behaviors when interacting with the pole (TK phase, pole bending and trajectory). Therefore, it is of interest to describe more accurately these technical approaches for teaching this discipline and improving coaching process.

KNEE INJURIES IN SPORT CLIMBING: A SYSTEMATIC REVIEW

GINSZT, M.1, SAITO, M.2, ZYSKO, A.1, KIKUCHI, N.2

1 MEDICAL UNIVERSITY OF LUBLIN, POLAND; 2 NIPPON SPORT SCIENCE UNIVERSITY, TOKYO, JAPAN

INTRODUCTION: Previous research in sport climbing was dominated by studies focusing on climbing-specific upper extremity injuries, especially finger injuries. No last systematic review has examined the prevalence of knee injuries in sports climbers. Our objective was to establish the prevalence and risk factors for knee injuries resulting from sport climbing activity in both professional and recreational athletes.

METHODS: A systematic review was conducted to determine the injury rate and risk factors for knee injury from a biomechanical point of view during sport climbing. The literature search was performed from January 2000 to January 2023 in the PubMed (Medline) and Scopus databases. The following keywords were used: injury AND sport climbing OR rock climbing, OR lead climbing OR bouldering OR speed climbing. Original, peer-reviewed, full-text articles published in scientific journals in the English language were included. Papers in non-climbers, mountain climbers, papers concerning climbing intervention in climbers and non-climbers, review articles, conference papers, case studies, animal studies, studies published in other languages, and studies with incomplete statistics data were excluded. Reference lists of review articles were reviewed for additional relevant articles. The following descriptive data were extracted from studies: study type, cohort, and knee injury information (structure and mechanism). The Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) statement and checklist were used to guide this systematic review.

RESULTS: A total of 849 studies were retrieved from this research. Finally, 13 studies were selected after the full-text review. 339 knee injuries were found in the analyzed studies, accounting for 1-18.9% of all climbing-related injuries. The most common injury was to the meniscus. Most knee injuries result from falls, overtraining or traumatic mechanisms of injury, e.g., heel hook, high step, or drop knee techniques.

CONCLUSION: The growing sport climbing popularity is associated with a higher incidence of knee injuries. Specific climbing-related training of the knee stabilizers for improved joint control and stretching techniques may reduce the risk of a knee injury during falls and climbing-specific knee techniques.

PERFORMANCE DETERMINANTS IN JUNIOR- AND ELITE-LEVEL AIR-RIFLE ATHLETES

SPANCKEN, S.1, HOFFMANN, M.1, STEIN, T.1

KARLSRUHE INSTITUTE OF TECHNOLOGY

INTRODUCTION: Sport shooting is an accuracy and precision sport, in which multifactorial processes occur simultaneously and sequentially, requiring many factors to be controlled at once [1]. Especially in air-rifle shooting, previous studies examined various factors and their influence on shooting performance [1]. So far, the influence of different factors in one comprehensive model has only been examined across technical factors [2]. Therefore, the aim of this study was to identify the role of technical, coordinative, physiological and psychological factors that best predict shooting performance of both junior-level and elite-level air-rifle athletes.

METHODS: Federal squad athletes of the German Shooting Federation participated in the study (n = 18 junior- and n = 18 elite-level athletes). Participants performed a simulated air-rifle competition of 60 shots according to the ISSF regularities. Based on a systematic review [1], the following performance factors were assessed during shooting: the aim point trajectory of the weapon via SCATT (technique), postural balance in ML- and AP-direction via a 3D force plate, as well as muscle activity and heart rate via EMG (coordination). Before the competition started, athletes completed a questionnaire on their current psychological well-being. On two other consecutive days, athletes performed a steps-test, a computer-based diagnostic instrument to measure shooters' coordination and concentration. Further, maximum isometric strength of the trunk and thigh muscles were tested using a force measuring chair. Athletes also performed a laboratory-based incremental endurance test on a treadmill to assess endurance capacities (both physiology). Principle component analysis was used to form orthogonal linear combinations for each test variables. Stepwise multiple regression analysis (MRA) with principle components (PC, PCs with the highest explained variance from each test were used for MRA) were used to test for variance explained in shooting score.

RESULTS: Shooting results differed between skill levels (617,8 ± 4,6 vs. 621,3 ± 5,5 rings). MRA revealed four factors to be relevant for junior-level athletes: PC1: holding ability and cleanness of triggering (β = 1,58), PC2: maximum strength of leg abduction muscles (β = - 2,71), PC3: COP sway in AP-direction (β = - 2,05) and PC4: reaction and anticipation (β = 2,12). These variables accounted for 76,9 % of variance in shot score, whereas PC1 provided the highest contribution (technique). Four factors were relevant in elite-level athletes: PC1: concentration (β = 2,14), PC2: holding ability (β = 2,28), PC3: heart rate (β = - 2,94), PC4: COP-sway in AP-direction (β = - 3,08). These variables accounted for 86,8 % of variance in shot score.

CONCLUSION: The results show that, depending on the skill level, a different combination of technical, coordinative, physiological and psychological factors is important for achieving a high shot score in air-rifle shooting.

THE INTERPLAY OF BIOMECHANICS AND BODY COMPOSITION IN KAYAK SPRINT PERFORMANCE: AN EXPLORATIVE STUDY

KLITGAARD, K.1, DE ZEE, M., KRISTIANSEN, M.

AALBORG UNIVERSITY

INTRODUCTION: Sprint kayaking is a dynamic sport that requires a combination of strength, power, and endurance. Sprint performance in kayaking is influenced by various physiological and biomechanical factors [1], including body composition, muscle strength, stroke rate, stroke force and paddling technique [2]. There is, however, still a lack of knowledge on how the interplay of different factors impact performance [3]. This study aims to fill this gap by conducting a comprehensive evaluation of kayak sprint performance by examining multiple biomechanical and physiological variables simultaneously

METHODS: 13 highly trained male kayakers (Age 22.92 ± 6.25 years, body weight 84.80 kg ± 7.29, height 1.80 ± 0.44 m) were recruited. The following variables were recorded during a 100 m all out on-water test: paddle force (E-kayak, AP-

Lab), footrest force, kayak velocity. Furthermore, 1 repetition maximum in bench press, bench pull, pull up and a specific kayak strength test measured on a custom-made single arm machine (SAM) were tested. Body compositions were measured using a DEXA scanner (GE Lunar iDXA).

RESULTS: The results from on water showed: 100m sprint time: 20.32 ± 0.74s. Paddle mean stroke force: 280.34 ± 67.95 N, paddle peak force: 563.28 ± 69.82 N, footrest mean stroke force: 288.45 ± 105.99 kg, footrest peak force: 588.45 ± 210.38 kg. The results from the strength tests were: Bench press: 113.46 ± 12.39 kg, bench pull: 104.65 ± 8.25 kg, pull ups 39.80 kg ± 10.12 kg, SAM: 63.07 ± 13.09 kg.. The results from DEXA scan showed: body fat percentage: 18.59 ± 3.97 %, lean body mass: 66.15 ± 5.78 kg

CONCLUSION: This study aimed to comprehensively evaluate kayak sprint performance by examining multiple biomechanical and body composition variables simultaneously. The kayakers in the study demonstrated similarities in levels of paddle and footrest force compared to the literature [4], along with high levels of lean body mass and moderately body fat percentages, not as low the ones found in the literature [1]. The results of the study showed that kayak sprint performance is influenced by a combination of different factors, including muscle strength, stroke force, and body composition. These findings suggest that to improve kayak sprint performance, athletes should focus on developing their strength and optimizing their body composition to a certain degree. The interplay between the biomechanical variables should be investigated further.

RELIABILITY OF THE MAXIMAL LACTATE ACCUMULATIONS RATE (VLAMAX) IN SUB-ELITE ROWERS

BROCKHERDE, J., HELD, S., RAPPELT, L., DONATH, L.

GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: During a 2000-meter rowing race, rowers mostly depend on their aerobic energy metabolism, but also rely to a certain amount on their anaerobic capacities including lactate accumulation. While most performance diagnostics in competitive rowing aim to evaluate the aerobic capacity, diagnostics determining anaerobic capacities are uncommon and rarely used. One promising parameter is the maximum lactate accumulation rate (VLamax), which indicates anaerobic capacities. While positive results in other sports are already investigated, including running and cycling, studies based on rowing are missing, but crucial within sport specific performance testing. Thus, this study aims the verification of reliability of VLamax in rowing. Positive results might expand performance diagnostics in rowing and therefore optimise training plans and sport performance.

METHODS: In a between day design with repeated measurements, seventeen competitive male (n=9) and female (n=8) rowers (age: 19.8 ± 5.3 years, height: 176.7 ± 7.8 cm, and weight: 70.8 ± 8.7 kg, VO2max: 54 ±13 ml/min/kg) were asked to undergo a 20-seconds all-out sprint on the Concept 2 rowing ergometer. Those two different measurement days were separated by 5-10 days. VLamax, peak lactate concentration, time to lactate peak and mean rowing power were measured.

RESULTS: Good to excellent intraclass correlation coefficients (ICC), low standard error of measurement (SEM), and acceptable level of agreements (LoA) for VLamax (ICC = 0.85; SEM = 0.02 mmol/Ls; LoA ≤0.09 mmol/Ls), peak lactate (ICC = 0.88; SEM = 0.3 mmol/L; LoA ≤1.4 mmol/l), time to lactate peak (ICC = 0.92; SEM = 0.1 min; LoA ≤0.5 min), and mean rowing power (ICC = 0.98; SEM = 3 min; LoA ≤39W) were observed. In addition, VLamax was highly correlated ($r = 0.96$; $p \leq 0.001$) to the rowing power.

CONCLUSION: Those results verify a good reliability of measuring VLamax and sprint performance parameters including lactate peak concentration, time to peak lactate and mean rowing power using this sport-specific sprint test protocol in rowing. These findings affiliate with earlier research in cycling and running with similar high reliability markers. In conclusion, determination of VLamax can be used as a reliable tool in rowing to identify anaerobic capacities and thresholds. In addition, correlations between VLamax and rowing power indicated a promising parameter of anaerobic lactic power testing. Therefore it can expand the performance diagnostics in rowing and help optimising training plans and performance.

FLYING HIGH: THE INFLUENCE OF A SIX-WEEK RESISTANCE TRAINING PROGRAMME ON ELITE TRAMPOLINE ATHLETE PERFORMANCE

HOWATSON, G.1, DYAS, N.1,2,3, YOUNG, B.2,3, GREEN, D.2, MATTHEW, E.2, THOMAS, K.1

<1> NORTHUMBRIA UNIVERSITY; <2> ENGLISH INSTITUTE OF SPORT; <3> BRITISH GYMNASTICS

INTRODUCTION: There are few data on training interventions in elite athletes, particularly in gymnasts. In trampoline gymnastics, the ability to attain and maintain high time of flight (ToF) is an important component in competition for two reasons: 1) it is directly scored, and 2) it allows gymnasts to perform routines at greater heights and potentially execute more

complex skills. The purpose of the study was to investigate the effects of a 6-week isometric training programme on time of flight (ToF) in highly trained gymnasts.

METHODS: Fourteen national level trampoline athletes (10 females, 4 males, age = 15 ± 2 years; mass = 55.0 ± 8.2 kg; stature = 163.7 ± 6.5 cm) volunteered to participate. In a parallel group design, athletes were allocated to either an intervention; INT (6 weeks of maximal isometric strength training incorporated into normal training) or control; CON (normal training) group. The INT consisted of 3-5 sets of 5 repetitions of maximal isometric contractions at 3 joint angles (150, 120 degree knee joint angle and plantar flexion at full knee extension) twice per week. Participants performed a battery of tests consisting of counter movement jump (CMJ), isometric squat (ISO at 150 and 120 degrees knee flexion; 180 degrees being full extension), and 20-max trampoline (20-max) test before and after the intervention.

RESULTS: There was a significant interaction where the INT group increased ToF in the 20-max test by 2.8% compared to a 0.2% increase in CON (P = 0.021). Only isometric strength at 150 degrees changed differently between groups, where the INT group increased by 27% vs 5% in the CON (P = 0.02). No other changes were observed in CMJ.

CONCLUSION: The improvements in ToF highlight the applicability of joint-specific isometric training to enhance a fundamental performance index (maximal ToF) for highly trained trampoline athletes. This simple, but effective intervention, illustrates the translation of strength training to a sport-specific performance index.

INTRA- AND INTER-DAY RELIABILITY OF INERTIAL LOADS WITH CLUSTER SETS WHEN PERFORMED DURING A QUARTER SQUAT ON A FLYWHEEL DEVICE

RYAN, S., BYRNE, P., BROWNE, D., MOODY, J., CAMPILLO, R.

SOUTH EAST TECHNOLOGICAL UNIVERSITY CARLOW

INTRODUCTION: Flywheel iso-inertial training (FIT) has become increasingly popular as a training modality. To date, only one study has examined the reliability of the flywheel quarter-squat (Sabido et al., 2018). The aims of this study were to i) estimate the intra- and inter-day reliability of mean concentric (CON) and eccentric (ECC) power at different inertial loads during a flywheel quarter-squat using a cluster set approach; and ii) to determine the acute effect of internal and external attentional focus on mean power when performing the flywheel quarter squat.

METHODS: Twelve collegiate field sport athletes attended four cluster-set testing sessions separated by 7 days. Sessions consisted of 4 sets of 15 repetitions of a quarter- squat flywheel exercise with varying moments of inertial (0.025, 0.050, 0.075 and 0.100 kg·m2) in an ascending or descending order (Sabido et al., 2018). The cluster set protocol consisted of 5 repetition clusters, including "momentum repetitions" (3 x 5+5+5). Mean concentric (CON) power output, mean eccentric (ECC) power output, and ECC overload were recorded for both internal and external attentional focus groups

RESULTS: Mean power output showed lighter inertial loads (0.025 kg·m2) produced greater CON force. Alternatively, heavier inertial loads (0.050, 0.075 and 0.100 kg·m2) produce greater ECC force and subsequently, greater ECC overload. The external instructional group attained familiarisation (outcome stability) after two flywheel sessions (ES = 0.03 – 0.15) with little volatility between performance measures (CV% = 3. 39 – 9. 22). In contrast, the internal group had a significant difference between day-2 and day-3 using the 0.075 kg·m2 load (p = 0.017). In addition, the internal group saw large differences in mean power output between all inertial loads from day-2 to day-3 (ES = 0.59 – 1.25).

CONCLUSION: Familiarisation proceedings underpin the efficiency of flywheel iso-inertial training (FIT). This study offers an alternative cluster-set approach to familiarisation for FIT, in addition to examining the impact specific coaching instructional cues in FIT. Both instructional groups reported positive performance measures, albeit the external group reached stability at an earlier stage. In addition, the cluster approach as a mode of flywheel training showed no significant drop-offs in performance.

EFFECTS OF LOW-INTENSITY TORQUE-MATCHED ISOMETRIC TRAINING AT LONG AND SHORT MUSCLE LENGTHS OF THE HAMSTRINGS ON MUSCLE STRENGTH AND HYPERTROPHY

NAKAO, S.1,2, IKEZOE, T.1,2, TANIGUCHI, M.2, MOTOMURA, Y.2,3, HIRONO, T.2,4, NOJIRI, S.2, HAYASHI, R.2, TANAKA, H.5, ICHIHASHI, N.2

1 KANSAI MEDICAL UNIVERSITY; 2 KYOTO UNIVERSITY; 3 KOBAYASHI ORTHOPAEDIC CLINIC; 4 CHUKYO UNIVERSITY; 5 KYOTO UNIVERSITY HOSPITAL

INTRODUCTION: Utilizing passive muscle tension at muscle-lengthened position may be useful to induce muscle hypertrophy for those who cannot or do not like to exert high intensity contractions such as older people and patients. The total torque at the joint generated during isometric contraction is divided into active torque generated by voluntary contraction and passive torque generated by stretching the muscle. In terms of training effects, the amount of active torque exerted during training is often focused; however, as previous animal studies have reported an increase in muscle volume or the rate of protein synthesis after passive muscle stretching, it is possible that the passive torque, as well as the active torque, would contribute to hypertrophy. This study aimed to investigate the effects of low-intensity isometric training with

matched total torque at long (LL) and short muscle lengths (SL) of the hamstrings on muscle hypertrophy and strengthening.

METHODS: Thirty participants (16 males and 14 females, 25.2 ± 3.4 years) were randomly assigned either to LL or SL group, in which trained at 30° or 90° of knee flexion, respectively. They performed isometric knee flexion training (30% of maximal voluntary contraction (MVC) × 5 s × 20 repetitions × 5 sets × 3 times/week × 8 weeks). The cross-sectional areas (CSAs) of the hamstrings were assessed before and after 8 weeks by scanning transverse panoramic images at the proximal 1/3, 1/2, and 2/3 points of the ischial tuberosity to the lateral epicondyle (proximal, intermediate, and distal hamstrings, respectively). The MVC torques at 30° and 90° of knee flexion were measured before and after the training period. The active torque was calculated by subtracting the passive torque at rest from the total torque during training.

RESULTS: Twenty-eight participants (14 males and 14 females) completed the program. The active torque was significantly lower in the LL group than in the SL group ($p<0.01$), whereas there was no between-group difference in total torque during training. For the CSA of the proximal, intermediate, and distal hamstrings and the MVC torque at 30° knee flexion, a split-plot analysis of variance showed no significant time × group interaction; however, it did show a significant main effect of time ($p<0.05$), indicating a significant increase after training intervention. As for the MVC torque at 90° knee flexion, there was a significant time × group interaction ($p<0.05$) and a significant simple main effect of time in both the LL ($p<0.01$; Cohen's d effect size [ES]=0.36) and SL ($p<0.01$; ES=0.64) groups, which indicated a greater increase in the SL group than the LL group.

CONCLUSION: Low-intensity isometric training at LL can induce hypertrophy, even in cases where the active torque production is lower than that at SL. Muscle strength increased after both LL and SL training; whereas SL training may be more effective for increasing MVC at SL position (90° of knee flexion).

THE EFFECTS OF COLD-WATER TRAINING ON GRIP STRENGTH AND PERCEIVED COMPETENCE AMONG STUDENTS

LITLESKARE, S., SOLBAKKEN, T., PETTERSEN, S., SIGURJONSSON, T.

INLAND NORWAY UNIVERSITY OF APPLIED SCIENCES

INTRODUCTION: Cold-water training is becoming more prevalent in physical education programs. However, little is known about how students perceive and respond to these training regimes, or the physiological responses and associated risks of typical cold-water training regimes. And if these responses are evenly distributed among students.

METHODS: This study aimed to investigate the student's perceptions prior to cold-water training and their perceived competence after. The effects of short duration cold-water immersion on grip strength were assessed as well. Participants performed 2-4 minutes of cold-water immersion in a lake and performed activities such as treading water, swimming short distances, and floating. Assessments of students' fears, worries (7-point Likert-scale, 1 being most worried/fearful), and grip strength were assessed before and after immersion, while perceived competence (4 items, 7-point Likert scale, 1 being most competent) was assessed after immersion.

RESULTS: The results showed that most participants were not worried prior to cold-water immersion (Mdn = 5, IQR = 4-6), but some heterogeneity was observed. The fears experienced during immersion was even less pronounced (Mdn = 7, IQR = 6.75-7). The 50% strongest participants experienced a mean reduction in grip strength following cold-water immersion of -5.4 kg (-8.1 %; $p < 0.001$), while the 50% weakest participants did not (-0.7 kg, -2.3 %; $p = 0.604$). Perceived competence after cold-water training was considered high (Mdn = 2, IQR = 1.3-3.9).

CONCLUSION: These findings suggest that some students are worried prior to cold-water training, but also that these worries largely dissipate during cold-water immersion. The results also show that even short duration immersion can lead to reductions in grip strength, but only among participants with high baseline grip strength. This reduction in grip strength may increase the risk of drowning accidents or other dangerous situations during cold-water training and accidental cold-water immersion for these individuals. Students generally perceive themselves as competent after a non-comprehensive cold-water training regime.

EFFECTS OF IMPROVEMENT IN TAKEOFF MOTION ON LOWER LIMB STRETCH-SHORTENING CYCLE ABILITY

ZUSHI, A.1, ZUSHI, K.2, YOSHIDA, T.1

1: JAPAN INSTITUTE OF SPORTS SCIENCES 2: SHIGA UNIVERSITY

INTRODUCTION: The stretch-shortening cycle (SSC) ability of the lower limb is important in several sports and evaluated using the and SSC ability is evaluated using the rebound jump (RJ) test. In addition to the RJ index, which is the jump height divided by the contact time, an evaluation focusing on the kinetic variables of the three lower-limb joints has been proposed for the RJ test. In contract, it is difficult to calculate the kinematic variables of the three lower limb joints in real-time coaching. Therefore, investigating effective takeoff motions is imperative. Furthermore, knee joint flexion movement prior to landing on a jump influences performance variables and lower limb extension force. However, the effect of improved takeoff motion on RJ performance and lower limb force exertion remains unclear. Thus, we aimed to investigate the effect of improvements in RJ takeoff motion on performance variables, three lower limb joint kinematics and kinetics.

METHODS: Twenty-one female university athletes (training group:11, control group:10) performed the RJ test before and after training. Performance variables (jump height, contact time, and RJ index), kinetics (torque and power), and kinematics (joint angle and amount of flexion) of the three lower limb joints (ankle, knee, and hip) were calculated. The training group received training for eight weeks (two days/week) based on previous studies: i) Jumping on a 10-cm platform and stopping with the knees flexed. ii) Jumping onto the platform and then jumping up. iii) Jumping off the platform and then

jumping up. In the first week, all participants performed only task i). After mastering tasks i) and ii), they performed tasks iii). Two-factor analysis of variance (pre-post × between-groups condition) and effect size was performed to test for differences in each group ($P < 0.05$).

RESULTS: In the training group, the RJ index significantly increased, while the contact time significantly shortened and knee flexion angle significantly decreased. In addition, the ankle joint power significantly increased in the training group. Negative knee joint power significantly increased in both groups, whereas, the eccentric torque showed an increasing trend (medium effect) only in the training group.

CONCLUSION: It is thought that the takeoff motion training inhibited the knee flexion, indicating that the lower limb was no longer more flex against gravity may have positively affected takeoff and increased the RJ index. Moreover, negative knee joint power and eccentric torque were exerted in the eccentric phase of takeoff to counteract the lowering of the center of gravity. The training group was able to exert greater eccentric torque by acquiring a movement that inhibited negative knee flexion. Therefore, landing motion training enables the lower limbs to effectively receive the landing impact, which may improve the power exertion ability at the ankle and knee joints during takeoff and the SSC ability of the lower limbs

DOES POST-ACTIVATION POTENTIATION AFFECT AGILITY PERFORMANCE?

DOCHERTY, C.

UNIVERSITY OF STRATHCLYDE

INTRODUCTION: Agility is widely accepted as being critical to sporting success, particularly in team invasion sports such as football, basketball, rugby and hockey. Agility, unlike planned change of direction speed, is a rapid whole-body movement with a change of velocity or direction in response to a stimulus. It is a complex motor skill that is made up of cognitive, physical and technical factors. However, the relative importance of each factor is understudied. Post-activation potentiation (PAP) is a phenomenon within muscle contractile history which can acutely enhance short-duration athletic physical performance. PAP has been harnessed to improve vertical jump height, straight sprint speed and planned change of direction speed. The aim of this study was to investigate the effect of PAP on agility performance.

METHODS: Sixteen participants (nmale= 10, nfemale=6) completed three days of testing, each starting with a standardised dynamic warm up. Day 1 for all participants consisted of 3RM back squat testing and Speedlight agility Y-test familiarisation. On day 2 and day 3 participants either completed a PAP or control preloading conditioning activity (CA) followed by agility testing. at set time intervals of 4, 8-, 12-, 16- and 20-minutes post CA. The PAP CA consisted of performing the 3RM back squat that was calculated on day 1, the control CA consisted of three body weight squats. There was a minimum of 48 hours between testing days.

RESULTS: Agility performance was quantified as the total time to complete the agility Y-test. A Friedman two-way ANOVA showed a non-significant ($p>0.05$) effect of preloading condition on agility performance. A Mann-Whitney U test showed that the test direction (left or right) and the time elapsed between pre-load stimulus and agility testing had a non-significant ($p>0.05$) effect on agility test time. Overall, there was no potentiated effect evidenced in this study.

CONCLUSION: The results of this study indicate that completing 3RM back squats prior to agility testing causes no potentiation in agility Y-test performance. The prior CA also showed no detrimental effect to Y-test performance. For practitioners, this suggests that it may be feasible to complete both strength testing and agility testing within the same testing session, without the prior impacting the latter. However, more research is needed to confirm this.

Though not tested, researcher observations during testing found that some participants seemed to be pre-empting the direction of the light stimulus based on their previous runs. Future research should include more than two agility directions to avoid this issue. Further agility research should include cognitive and biomechanical outcome measures as agility is multifaceted.

RESPONDERS AND NON-RESPONDERS TO ECCENTRIC CYCLING TRAINING IN MUSCLE SIZE AND PERFORMANCE MEASURES

MAVROPALIAS, G., NETHERTON, A., BLAZEVICH, A., NOSAKA, K.

EDITH COWAN UNIVERSITY, MURDOCH UNIVERSITY, AUSTRALIA

INTRODUCTION: Eccentric cycling training has been reported to increase muscle mass and function at low efforts [1], but the optimal protocols for eccentric cycling training are yet to be established. Previous studies prescribed eccentric cycling based on heart rate, oxygen consumption, or perceived effort [1-3]. However, a protocol based on maximal power may better standardize mechanical stimulus to the muscle. We investigated the effects of 8-week eccentric cycling training with incremental increases in power on several outcome measures to test the hypothesis that the protocol would significantly increase muscle mass, strength, and other performance measures.

METHODS: A total of 15 healthy men (24.3±4.8 y; body mass 84.1±19.0 kg; height 178±7.4 cm) underwent 3 training sessions a week for 8 weeks. Participants performed 10-s maximal concentric cycling, and 33% of its average power output was used for the intensity of the first 3 sessions. The intensity increased by 10% every 6 sessions to 40% in week 8 (7-10 min per session). Outcome measures included whole-body (WBLM) and lower-limb lean mass (LLLM) by DEXA, vastus lateralis cross-sectional area (CSA) and thickness (MT), knee extensor maximal voluntary isometric contraction (MVIC) torque, cycling-specific performance (peak and average concentric cycling power, braking strength), and squat and counter-movement jump height.

RESULTS: Significant improvement (9.2-26.2%) in cycling-specific performance was evident from pre- to post-training, but MVIC torque and jump heights did not change (P>0.05). Large inter-participant variability was observed for changes in WBLM, LLLM, CSA, and MT such that 8 participants had increases in WBLM (3.4±2.6%) and LLLM (4.3±3.0%), but 7 participants had no changes or decreases (WBLM: -1.3±1.3%; LLLM:-0.9±4.2%). This was also found for CSA and MT. No significant differences between LLLM responders and non-responders were found for average total work (107±21 vs 111±19 kJ) or cycling intensity (207±40 vs 216±36 W) of 24 sessions. The only significant predictor for muscle hypertrophy was the perceived effort (0-10 scale) during cycling (R=0.9; P=0.03). Participants who reported higher efforts in sessions 19-24 (6.8±0.8) showed no changes or decreases in WBLM, LLLM, CSA, and MT, but those who reported lower efforts (5.5±0.8) showed increases. However, the effort did not predict the changes in other measures.

CONCLUSION: The training protocol did not increase MVIC torque and jump height, and muscle hypertrophy was induced in 8 participants only, although all participants showed increases in peak and average cycling power. It should be noted that muscle hypertrophy was induced in the participants whose perceived efforts in the training were lower. Optimal prescription and progression of eccentric cycling training require further investigation.

BOTH CONTRAST AND CONSTANT INERTIAL FLYWHEEL LOADING IMPROVES JUMP PERFORMANCE, THROUGH ENHANCED MUSCLE CONTRACTILE MECHANICS.

SELVAMOORTHY, R., HUNTER, A.M., DONALD, N., MACGREGOR, L.J.

UNIVERSITY OF STIRLING

INTRODUCTION: Acute flywheel priming strategies have positively impacted sports performance across multiple sports (1). Certain sports, such as swimming, have at least 20 minutes of waiting before athletes compete which can be sub-optimal for individuals, as most priming-related mechanisms tend to occur between 3-9 minutes post-exercise cessation. However, flywheel-based priming evidence is limited regarding priming time decay and underlying mechanisms (3). Therefore, our study aims to investigate acute neuromuscular changes to constant and contrast load flywheel squats on jump performance and residual effects lasting up to 24 minutes.

METHODS: Very strong males (n = 10, height = 178.7 ± 3.8 cm, body mass= 86.2 ± 9 kg, relative strength in the barbell back squat = 2.1 ± 0.6 kg/kg) completed two flywheel squat loading conditions. The constant load condition involved using medium inertia for three sets of 6 repetitions. While the contrast load condition involved three sets of 4 repetitions at high inertia followed by 4 repetitions at low inertia. Each set was separated by 3 minutes of rest. Tensiomyography (TMG) assessment of the participant's right leg vastus lateralis and rectus femoris were taken after every set and at 4 minutes post-exercise cessation, followed by a measurement every 4 minutes until 24 minutes. TMG variables used for analyses were muscle displacement (Dm, units: mm) and normalised response speed (Vrn, units: mm/s/mm). TMG assessments were followed by countermovement jumps recorded on a force plate, and the variables used were jump height (cm) and peak power (W).

RESULTS: There was an increase in Vrn of the rectus femoris across time in both flywheel loading conditions (P<0.01), while Dm was altered only in the contrast condition (P<0.01). In the vastus lateralis, only the contrast loading condition saw an increase in Vrn (P < 0.05). Additionally, there was an increase in jump height in both loading conditions (P<0.05), but no changes in peak power (P>0.05).

CONCLUSION: The increases in jump performance indicate that either of the loading conditions can be valuable for improving acute performance in very strong individuals. This initial work also explains underlying mechanisms of performance enhancement, based on changes in muscle contractile mechanics.

SPORTS SCHOOLS AND THE CREATION OF CHAMPIONS: FOLLOWING 10 FEMALE HANDBALLERS FOR A DECADE

KRISTIANSEN, E., STENSRUD, T.

UNIVERSITY OF SOUTH-EASTERN NORWAY

The number of secondary sport schools and high schools in Norway is increasing and presumably resulting in earlier sport specializing and increased training volume among the young athletes. How do the athletes respond to the total load? The sport school system can be a valuable resource to develop for young aspiring athletes, in particular in national sport such as handball in Norway, but extra pressure is also put on young athletes that chase an Olympic dream.

Methodology

This qualitative multidisciplinary study, a combination of psychology, physiology and management, followed a group of 10 female student-athletes from the age of 13 to 23 to closely monitor their physical and mental development as well as their understandings of ups and downs at a sport school in Norway. The handballers also provided us with physical data so we could monitor their physical and psychological development. Thematic analysis was used for the complete data material, several measures was taken to protect the athlete's anonymity in addition to ensure trustworthiness by prolonged engagement, reflexivity and discussion of results with participants and collegues.

Results

When we first started following them at age 13, the importance of sleep, growth and stage of puberty needs to be taken into consideration in the total workload. However, parental support, support from teachers/trainers at school and rest are mentioned as main coping mechanisms that contribute to effective coping. Evidence of competition-related stressors, organizational stressors (sport and school balance) and personal stressors (social life and sport balance, lack of sleep and severe injuries) was recurring themes in the annual interviews with the handballers. After ten years, only three were playing at the elite level. They had also taken part in the injury preventive program, they had stamina, and they always had a good relationship with their coach. However, all three had gone through serious long-lasting injuries, and their return to sport provided interesting information. This is necessary as talking about pain in the context of handball, where players are expected to be tough and push through pain, was hard.

Discussion

It is important to be aware that young athletes need time to adapt to a high workload, high expectations and the huge demands of elite sport. Together this will create a constant 'need' to cope with new and different sources of strain. After a decade, importance of the coach-athlete relationships, emerged as a parallel narrative to that of injuries. Being seen was the common denominator for healthy and sustainable development among our participants. We would recommend teaching athletes in contact sports to talk about pain and injuries in order to protect them. This is vital to preventing them from developing long-term and career-ending injuries. To conclude, miscommunication or lack of communication and not feeling seen when they struggled where the reason why half of them ended their career prematurely.

LEARNING BASKETBALL TACTICS BY IMAGINATION: INVESTIGATING THE EFFECTS OF TIME OF TESTING AND EXPERTISE LEVEL

MGUIDICH, H.1, ZOUDJI, B.1, KHACHAREM, A.1,2

1 LARSH - LABORATOIRE DE RECHERCHE SOCIÉTÉS & HUMANITÉS, UNIVERSITÉ POLYTECHNIQUE HAUTS-DE-FRANCE, VALENCIENNES, FRANCE. 2 UFR SESS-STAPS, PARIS-EAST CRÉTEIL UNIVERSITY, CRÉTEIL, FRANCE

Introduction

To better communicate tactical instructions in basketball training sessions, coaches verbally present tactical instructions to the players so that they know their role and position on the field. However, due to the complexity and interplay of the game elements, verbal instructions are not always an effective method. Therefore, asking players to imagine while listening to the tactical instructions could be a possible solution to avoid this problem and optimize tactical learning (Khacharem et al., 2020). Thus, the aim of the present study was to examine the effect of imagination on the learning of basketball tactics and to determine whether this effect remains stable over time and in players with different levels of expertise.

Methods

Eighty participants (40 basketball experts and 40 novices) participated in this study and were recruited based on their previous experience with basketball. The learning material consisted of audio recordings on the development of an offensive tactical system. The test consisted of two phases: immediate and delayed. Participants were assigned to one of two conditions, in which they were instructed to either listen and learn the material ("N-I": "No imagination") or listen and imagine the learning material ("I": "Imagination"). Immediately afterward, they rated their mental effort and drew the game system they had learned on a sheet of paper. After one week, they were instructed to draw the same learned material.

Results

In the immediate phase, novices showed lower recall scores and higher investment of cognitive load in the "I" condition compared to the "N-I" condition. However, experts showed higher recall score and lower cognitive load in the "I" condition compared to the "N-I" condition. In the delayed phase, novices and experts benefited more from the "I" condition by achieving higher recall score compared to the "N-I" condition.

Discussion

The findings revealed that for novices in the immediate phase, imagining while listening is not an effective teaching method. Based on cognitive load theory, asking learners who lack of prior knowledge to imagine could overload their working memory and this might result in several mistakes in initial learning. However, in the delayed phase, imagining and investing more cognitive load led to more traces of learning material over time which is explained by the desirable difficulties. For experts, the integration of information in long term memory is easier to them and this is due to their prior knowledge, therefore imagining resulted in retaining more traces of the game elements in the short and long term. Results suggest that coaches need to consider players level of expertise when using imagination.

RELATIONSHIP BETWEEN COACH-RATED PERFORMANCE, PHYSICAL FITNESS, SKILL PERFORMANCE, AND MENTAL SKILLS IN YOUTH SOCCER PLAYERS

TSENG, P.H., HSIEH, W.L., TUNG, P.C., MOREAU, D., KAO, S.C., WANG, C.H.
NATIONAL CHENG KUNG UNIVERSITY

Introduction

Coach-rated player performance has been considered as an important performance indicator in youth soccer. However, soccer is a multifaceted sport and various technical, physical, and mental skills can contribute to overall performance and development in the context of youth sport. Accordingly, this study sought to investigate the link between coach-rated performance and various factors such as physical fitness, technical skills, executive function, and creative thinking in youth soccer players.

Methods

This study included 28 elite youth soccer players aged 9-11 years. They were administered a battery of tests including standing long jump, 20-m sprint, Illinois agility test, motor coordination test, and aerobic capacity to measure physical fitness, Illinois agility dribble test to measure soccer technical skill, Dimensional Change Card Sort task to measure executive function, and Alternative Uses Test to measure creative thinking. The players performance was rated by three certified coaches from the Asian Football Confederation based on eight soccer-specific skills: ball control in dribbling, passing and trapping, duel tackles, rapidity of actions, finding appropriate solutions under pressure, taking relevant decisions situationally, and studying group/team plays. The relationship between these variables was analyzed using the Pearson product-moment correlation coefficient, controlling for age, body mass index, and socioeconomic status.

Results

Our results showed that coach-rated performance was significantly correlated with all physical fitness [standing long jump ($r = .51$, $p = .011$), 20-m sprint ($r = -.48$, $p = .017$), Illinois agility test ($r = -.59$, $p = .003$), motor coordination test ($r = -.88$, $p < .001$), and aerobic capacity ($r = .74$, $p < .001$)] and soccer technical skill tests [Illinois agility dribble test ($r = -.59$, $p = .002$)]. In addition, fluency ($r = .42$, $p = .046$) and flexibility ($r = -.52$, $p = .009$) indicators of the creative thinking test were correlated with coach-rated performance, but originality was not ($r = .24$, $p = .25$). However, executive function performance was not correlated with coach-rated performance ($r = -.17$, $p = .44$).

Discussion

Our findings suggested that coaches and talent development professionals should consider the importance of physical fitness, technical ability, and creative thinking when evaluating and developing elite youth soccer players. Furthermore, these findings highlight the need for a multidimensional approach to assessing player performance, as coach ratings may not always align with measures of mental skills such as cognitive function. Further research is needed to validate these findings in youth soccer players at different levels of competition.

TACTICAL LEXICAL KNOWLEDGE OF SOCCER BY AGE 15 AND 18

ACOUMAMBO, D.
LARSH – INSA - UNIVERSITÉ POLYTECHNIQUE HAUT-DE-FRANCE

Introduction

According to the theory of the development of lexical knowledge (Lieury & Lorant, 2013), the lexicon is built progressively over the course of life through different stages and experiences. The objective of this study is to measure the effect of age on the size of the football tactical lexicon.

Method

We tested 164 participants: 82 soccers, aged 15 (U-15) with 10 years of practice and 82 soccers aged 18 (U-18) with 10 years of practice. Both groups are elite soccer in their category. The test consists of answering a selfassessment

questionnaire on the degree of lexical knowledge (Deplus S, Grégoire J, Van Broeck N, 2013). The task is to indicate the degree of familiarity and frequency of use in relation to 40 tactical words in football: 1 (I have never heard); 2 (I have already heard, but don't know what it means); 3 (I often hear but don't know what

it means); 4 (I know) and 5 (I know and practice it on the field).

Analyse and results

A t student test was used. The analysis plan includes a VI: Age (U-15 and U-18). The significance level (α) has been set to 0.05. The main results show a significant effect of age ($t = -9$ $df = 162$; $p < .001$). In addition, the results show intersections of word nucleus between groups but also words that appear in one category and not in the other and vice versa.

Discussion and conclusion

Our results: (i) confirm the effect of age on players' lexical knowledge. U-18 soccers know more tactical words than U-15 soccer. (ii) The most important and original result reveals that soccers lexical knowledge does not appear in a linear manner as in a conventional scheme but is random. These results suggest that lexical knowledge is influenced by other fac-

tors. (iii) Finally, these results show that none of the categories reach a knowledge of all the words. Our study suggests that practical coaches work on the lexical knowledge of tactical words to optimize the understanding and performance of players on the field.

DIFFERENCES IN DYNAVISION D2 COGNITIVE AND MOTOR SKILLS ASSESSMENTS AMONG VOLLEYBALL REFEREE LEVELS

ABU ALIM, M.

YARMOUK UNIVERSITY

INTRODUCTION: Sport refereeing demands attention, accuracy, and fast response to ensure the fairness and quality of sporting competitions. Assessing and training referees cognitive and motor skills using convenient training programs and equipment is essential. Dynavision D2 assessments have been proven to be validated and expedient. The study aimed to assess Jordanian Volleyball Referees Cognitive and Motor function using Dynavision D2 tests among three official Volleyball Refereeing levels (Provincial, National, and International).

METHODS: Data collection was obtained throw Dynavision D2 assessments of performance accuracy, cognitive, and reaction time for 30 Jordanian officials registered volleyball referees grouped (n=10) depending on Volleyball Refereeing levels (Provincial age (26.2±4years), National age (37.7±3.2years), and international age (M= 38.3±7years)) for each level included 10 participants. OneWay -ANOVA and linear regressions between referee levels and selected Dynavision D2 tests were completed.

RESULTS: There were statistically significant differences between the refereeing levels performance of the selected Dynavision D2 tests. The Provincial level group achieved better reaction times, and no significant differences were found between the national and international levels. The international referee level showed higher accuracy and attention focus than the other groups.

CONCLUSION: Training referees cognitive skills could be as essential as physical training. In contrast, the contusions assessments can provide crucial data that enhance the skills and capabilities of volleyball referees.

THE IMPACT OF GAME SCORE AND PITCHER HANDEDNESS ON BATTING DECISIONS IN BASEBALL PLAYERS

CHEN, Y.H.1, CHEN, Y.L.1, KING, J.T.2

1 NATIONAL TAIWAN SPORT UNIVERSITY; 2 NATIONAL YANG MING CHIAO TUNG UNIVERSITY

Skilled players outperform their less skilled counterparts in the action anticipation ability thanks to their higher proficiency in detecting the crucial advance kinematic information of the observed action. Recent studies showed that contextual information also has an impact. Specifically, the impact of game score remains unclear. Moreover, the left (L)-handers have shown advantages in sports. However, the understanding of the cognitive and neural underpinning remains limited. Hence, the aim of this study was to investigate the effect of contextual information, particularly the game score, on anticipating the batting decision to a pitch thrown by a L- and right (R)-handed pitcher, respectively, in baseball batters, using electroencephalography (EEG). We recruited 27 male collegiate skilled batters (SBs) and 29 controls. Participant was either presented with the information of game score (far-ahead and even/slightly-ahead or slightly-behind [Even]) or not, and then the video of a L- or R-handed pitcher throwing a pitch (strike vs. ball). While viewing the video, participant had to predict his batting decision to the observed pitch. After all the trials within one condition were performed, they had to indicate their confidence as well as stress level across their responses within the given condition. Separate four-way (2 groups x 2 pitcher handedness x 2 pitch results x 3 game score conditions) mixed-model ANOVAs were used for accuracy and event related potential (ERP: N1 and P3) data analyses. Results revealed that SBs had higher rate of swinging decision for R-handed pitcher than for the L-handed one, no matter at strikes or balls, whereas controls only showed this tendency at balls. Both groups showed higher self-rated stress level when the score was Even compared to the other two score conditions. The average N1 ERP across occipital sites (O1, Oz, and O2) was significantly higher when participants viewed the pitching videos preceded with the score information compared to videos without preceding score information. The average N1 ERP across same sites was higher for L-handed pitcher than the R-handed one. On the contrary, the average P3 ERP at parietal regions (P3, Pz, and P4) was higher for the R-handed pitcher than the L-handed one. Our behavioral results indicated that both baseball players and individuals with limited baseball-playing experiences were influenced by the contextual information of game score, and the greater N1 ERP might be related to the greater attention allocated to observing the pitching videos in such conditions. Our participants were less tended to swing at the pitches thrown by the L-handed pitcher than those thrown by the right-handed one. The lower N1 at occipital regions and then the greater P3 at parietal regions might be associated with the greater attention induced but less attention selected to the L-handed pitcher than the R-handed pitcher due to lower familiarity.

GROWTH MINDSET BELIEFS AND PERCEPTIONS IN ELITE YOUTH SOCCER PLAYERS

BEST, M.
THE MINDSET ASSESSMENT PROJECT

Introduction

In the realm of education, Dweck and her colleagues have found that students with growth mindsets are more likely to engage in their studies, invest effort, persevere for longer periods through more challenges, be more self-motivated, and achieve greater academic success (Dweck, 2007). However, very little has been done to study the relationship between growth mindset and performance in sport. Instead, much of the research on the construct has dealt with the relationship between growth mindset and other psychological constructs. Our study seeks to address these deficits.

Methods

The study measured players' own growth mindset beliefs (e.g., reverse score of "I have a certain degree of soccer ability and I cant really do much to change it") and players' perceptions of their teammates', and coaches' growth mindset beliefs about players' soccer abilities (e.g., reverse score of "My teammates/coaches seem to believe that I have a certain amount of ability and I cant do much to change it") in a sample of over 5,000 elite youth soccer players between the ages of 13 and 19. Given the lack of previous research on the role of growth mindset in sport performance, we used validated measures from education research and adapted them to the context of elite youth soccer.

Results

We first demonstrated the validity and reliability evidence of the four scales to establish them as legitimate measures of the construct. Descriptive analyses then revealed players' perceptions of their teammates' and coaches' growth mindset are more correlated with key performance outcomes (e.g., goals scored among attackers) than players self-reported growth mindset. Similarly, we found that when players are "unsure" about their coaches' and teammates' growth mindsets, they tend to report lower growth mindset beliefs themselves. We also explored the interactions between player growth mindset and perceptions of coaches' and teammates' growth mindset using linear multiple regression. Attacking players with more of a growth mindset especially benefited from perceiving their coaches and teammates to have a growth mindset about them, as they tended to score more goals than their peers. Interestingly, when attacking players with more of a growth mindset reported that their coaches and teammates did not have a growth mindset about them, they tended to score fewer goals.

Discussion

Our data highlight the importance of player perceptions of their teammates and coaches, which can provide insight into how we can better support players to succeed in the future. Following these findings, we recommend implementing growth mindset interventions with players and coaches to examine effects on growth mindset beliefs and performance outcomes in future studies. Assessing changes in players' mindsets over time, more proximal performance outcomes, and physiological markers in tandem would propel forward our understanding of psychological factors and their impact on performance.

PSYCHOLOGICAL RISK FACTORS OF A FIRST HAMSTRING STRAIN INJURY IN SOCCER: A QUALITATIVE STUDY

BAIZE, D., D'ARRIPE-LONGUEVILLE, F., PIPONNIER, E., MÉRIAUX-SCOFFIER, S.
UNIVERSITÉ CÔTE DAZUR

INTRODUCTION: The Hamstring Strain Injury (HSI) is one of the most burdensome injuries in amateur and professional soccer teams. Numerous HSI risk factors have been identified, but few studies have considered the psychological risk factors. Although several theoretical models of sports injury psychology have been developed, they have not yet been applied to the context of HSI in soccer. The objective of this study was to determine the psychological risk factors of a first HSI in competitive males' soccer players.

METHODS: In this qualitative study, we conducted semi-directive interviews with ten male competitive soccer players (age=19.8±2.6 years) who had sustained their first HSI within the past 6 years. The interview guide was based on the comprehensive model of injury causation of Barh & Krosshaug (2005). We investigated the dispositional, contextual and situational factors of the soccer players before their first HSI. Interviews were led by the same researcher who ensured the confidentiality of the data. Interviews were verbatim transcribed, coded line-by-line and first deductively organized into the guide's main categories by two of the authors, ensuring trustworthiness. Next, using an inductive approach, all authors triangulated the data and brought out new subcategories.

RESULTS: Participants had common dispositional psychological risk factors, including at-risk personality traits (e.g., perfectionism, external health locus of control), an obsessive passion for soccer with competitive motivational goals, strong athletic identity, poor health literacy, and maladaptive health-related behaviors. They were exposed to a controlling coaching context with a fear of negative staff evaluation, and had recently undergone injuries or life stressors. When injured, all athletes were in positive psychological states. They faced different situational factors (e.g., match, training overload), experienced positive or negative physical states, and were highly engaged in the activity (e.g., sprint).

CONCLUSION: These results helped to specify the comprehensive model of Barh & Krosshaug (2005) in the context of HSI in soccer, while providing a broader identification of psychological risk factors. From a preventive perspective, results suggest the need to moderate the controlling coaching style and thus lower the fear of negative staff evaluations, enhance the players' health literacy, and build their autonomy.

CRICKET COACHES PERSPECTIVES ON PROVIDING AUGMENTED FEEDBACK TO THEIR PLAYERS

TISSERA, K.1, ORTH, D.1, HUYNH, M.2, BENSON, A.1

1. SWINBURNE UNIVERSITY OF TECHNOLOGY, MELBOURNE, AUSTRALIA; 2. LA TROBE UNIVERSITY, MELBOURNE, AUSTRALIA

INTRODUCTION: Coaches play an important role in developing skilled athletes. In sports like cricket, augmented feedback has traditionally been conceptualised as a tool coaches can modify to elicit learning and development [1]. However, little is known about how and why coaches choose to provide augmented feedback in cricket and how they operationalise this [2]. This study explored cricket coaches conceptualisation of feedback, and their underpinning knowledge and reasoning.

METHODS: An online questionnaire (Qualtrics) consisted of closed and open-ended questions, exploring demographic/coaching experience and attributes of feedback (role, content and provision). Closed-responses were analysed exploring associations (frequencies, chi-square with adjusted alpha) or differences (Mann-Whitney U) between two coaching groups (lower-level vs higher-level cricket players); identified following silhouette and k-mode cluster analysis. Thematic analysis [3] examined open-ended questions to explore coaches understanding and provision (how and why) of feedback.

RESULTS: 134 coaches (94% male, 6% female) aged 18-69 years from 12 countries responded to the questionnaire; 86% with coaching accreditation and 55% with over 10 years experience. Results were explored for two coaching groups; those coaching at lower-level (mostly community cricket; Group 1 (Gp1), n=84, 63%) and at higher-level (mostly sub/elite; Group 2 (Gp2), n=50, 37%). There were significant differences between the two groups; Gp2 were more credentialed and experienced. Additionally, they reported greater self-efficacy around feedback, albeit with a small effect size ($p=<0.001$, $r=0.29$). No significant association existed for how coaches provided feedback. Thematic analyses identified both similar ideas, and different pedagogical approaches [4] to feedback by each group. Emerging themes about the role of feedback were: (i) benefits (improving skilled behaviour) and (ii) disadvantages (inhibiting learning/performance); with comments on the role of feedback in encouraging cognitive reflection (Gp1) vs active search for movement solutions (Gp2). Coaches reported providing group feedback for consistent messaging (Gp1) and to enable emergent group discussion/ideas (Gp2). Further, coaches used technology to 'highlight deficiencies and errors' (Gp1) and 'explore and adapt technique to improve outcomes and strategy' (Gp2).

CONCLUSION: The current study provides insights into cricket coaches conceptualisation of augmented feedback, and reasons underpinning choices. Findings depict the complexity of feedback within cricket coach-athlete systems; with coaching groups sharing both similar notions to feedback, and different pedagogical approaches to providing feedback. Results contribute to the limited cricket feedback research [2] and may also assist with identifying effective use of feedback and technology use as part of coach education.

EFFECTS OF LONG-TERM RUNNING ON BRAIN STRUCTURE AND FUNCTION IN COLLEGE STUDENTS: A 2-YEAR FOLLOW-UP STUDY

KEYING, Z.1,2, DONG, Z.2, CHUNMEI, C.2

1 DEPARTMENT OF PHYSICAL EDUCATION, SOUTHEAST UNIVERSITY, NANJING, CHINA; 2 DIVISION OF SPORTS SCIENCE AND PHYSICAL EDUCATION, TSINGHUA UNIVERSITY, BEIJING, CHINA

Introduction

Existing studies have documented differences in brain structure and function in endurance exercise participants. However, there is still a lack of conclusive evidence on whether this difference is due to nature or training. This study adopted a long-term follow-up research paradigm to investigate the changes in brain structure and functional activity before and after 2-year endurance training.

Methods

A group of 16 college students was included in this study. Eight subjects (22.5 ± 3.1 years old) were recruited from the college Marathon club. They experienced a systematic running training year of 2.6 ± 1.6 years. The other eight subjects (18.1 ± 0.3 years old) were healthy college students without any systematic running training. All subjects were right-handed and had no history of neurological disorders. Two fMRI tests were performed before and after the follow-up using a Philips 3.0T Trio scanner with a standard 32-channel head coil. Structural T1-weighted images and blood oxygen level-dependent (BOLD) data were acquired. Subjects were told to relax without thinking about anything and remain awake with their eyes closed. Voxel-based morphometry (VBM) was used to calculate gray matter volume(GMV). The fractional amplitude of low-frequency fluctuation (fALFF) and degree centrality(DC) was used to evaluate the intensity of regional spontaneous brain activity and network connection, respectively. Age was included as a covariate. Paired-sample t-tests were used to compare the changes in brain structure (GMV) and function (fALFF and DC) during two years(RESTplus).

Results

(1) In a follow-up questionnaire two years later, participants in the running group reported that they had basically completed endurance training in the past two years with a weekly exercise frequency over 3 sessions and 1 to 1.5 hours in each session. While the control group reported no systematic long-distance running or endurance training over the two years.

(2) In the running group, GMV was significantly increased in the bilateral prefrontal brain regions, bilateral medial frontal lobes, right insula, right putamen, and right fronto-parieto-occipitotemporal regions and decreased in the bilateral posterior cerebellum. Meanwhile, DC was significantly increased in the right temporal lobe and bilateral dorsolateral prefrontal lobe and decreased in the left thalamus. The fALFF of the right precentral gyrus was significantly increased ($p < 0.001$, FWE corrected).

(3) In contrast, no significant changes were found in brain structure or function in the control group ($p < 0.001$, FWE corrected).

Conclusion

2-years of running can improve the structure and function of runners brain regions related to episodic memory, spatial attention, motor regulation, motor execution, rhythm coordination, and sensorimotor integration. The current results may provide new insights into the neuroplasticity induced by exercise.

EFFECTS OF COMBINED PHYSICAL AND COGNITIVE TRAINING ON EXECUTIVE FUNCTION OF ADOLESCENT SHOOTING ATHLETES: A FUNCTIONAL NEAR-INFRARED SPECTROSCOPY STUDY

XIANG, M.Q., LI, G.R., HU, M.

GUANGZHOU SPORT UNIVERSITY

Individual executive function improvement through physical and cognitive training is a research hotspot in physical education and cognitive science. However, few studies have evaluated whether combined physical and cognitive training (CPCT) has greater benefits for executive function performance and cerebral oxygenation in adolescent athletes than cognitive training alone. This study randomly assigned 33 adolescent shooting athletes to a CPCT (n = 17) or computerized cognitive training (CCT, n = 16) group and compared their executive function after six weeks of training. All subjects were assessed using the 2-back, task-switching, and Stroop tests before and after training. The prefrontal cortex oxygenated hemoglobin (Oxy-Hb) activation level was monitored while executing the three tasks using functional near-infrared spectroscopy. Our results showed that the CPCT and CCT groups similarly improved their updating function as indicated by the 2-back task accuracy. The CPCT group significantly improved the switching function in the task-switching test accuracy, while the CCT group did not. However, both groups did not improve in behavioral performance as indicated by the inhibition function in the Stroop task. Cerebral oxygenation, indicated by the oxy-Hb activation level in the frontal pole area of the prefrontal lobe, significantly improved in the CPCT group during the three cognitive tasks, whereas the CCT group showed no change. These findings indicated that CPCT endowed greater advantages in task-switching in the behavioral performance of the executive function than CCT. Moreover, CPCT was superior to CCT in increasing task-efficient cerebral oxygenation during activation of the prefrontal cortex in adolescent shooting athletes.

RELATIONSHIP BETWEEN THE RESTING-STATE EEG BRAIN OSCILLATIONS AND ARCHERY SHOOTING PERFORMANCE

HUANG, C.C.1, KING, J.T.2, KUO, C.W.1, LIN, Y.1, LIN, T.C.1, CHEN, S.Y.1, KUO, W.J.2, CHEN, Y.H.1

1 NATIONAL TAIWAN SPORT UNIVERSITY; 2 NATIONAL YANG MING CHIAO TUNG UNIVERSITY

INTRODUCTION: Resting state before exercise has been shown to reflect sporting performance in previous studies (1,2,3). However, such evidence was mostly based on data collected from one single resting state session, either with eyes open or closed, correlated with the following sporting performance. To overcome these limitations, the current study recorded the resting-state electroencephalography (EEG) at multiple sessions in both eyes open and closed conditions in a longitudinal design, and investigated the relationship with the following archery shooting performance in one skilled archer.

METHODS: We recruited a collegiate archer who has seven years of archery shooting experience and was currently active in competitions. In each experiment, the resting-state EEG activity, with eyes opened and closed for three minutes respectively, was recorded with a 32-channel EEG system (Brain products LiveAmp) with 250 Hz sampling rate. Next, the participant was asked to shoot 12 rounds of 6 arrows at a 122-cm target face at 70 m. 6 experiments were performed. Standard preprocessing and removal of noise identified using independent component analysis (ICA) was performed with eeglab (v2021.0). Then, the mean power density in each frequency band (delta, theta, alpha, beta, and gamma) in frontal (Fz), central (Cz), parietal (Pz), and occipital sites (Oz) was computed. Pearson correlation coefficient was used to examine the relation between the power density in each frequency band in the four sites with the mean (M) and standard deviation (SD) of the shooting scores across the six experiments. The level of significance was set at $\alpha = .05$.

RESULTS: For eyes-open states, a positive ($r=.814$, $p<.05$) and a negative correlation ($r=-.814$, $p<.05$) was found in the power of the alpha band at Oz with the M and SD of scores, respectively. Whereas the delta power at Pz was negatively correlated with the M of scores ($r=-.825$, $p<.05$). For eyes-closed state, gamma power at the Fz ($r=.827$, $p<.05$) and Oz ($r=.820$, $p<.05$) was positively correlated with the M of scores.

CONCLUSION: Generally, our results were in agreement with the notion that pre-performance resting state brain oscillations could reflect the latter sporting performance. However, resting state EEG with eyes open and closed might reveal different brain oscillations from specific bands at specific brain regions correlated with the shooting performance. Whether resting state EEG with eyes open or closed might need to be considered when correlating the performance in different sport types.

BIGOREXIA AND CONFRONTATION WITH SOCIALLY PROMOTED AESTHETIC IDEALS

GIORDANO, F., CORTIS, C., CASTELLANI, L., FUSCO, A., SALADINO, V., VERRASTRO, V.

UNIVERSITÀ DEGLI STUDI DI CASSINO E DEL LAZIO MERIDIONALE

ABSTRACT

Introduction: Bigorexia is characterized by an obsession with the appearance of one's body, fear of not having enough muscles, and the urgent need to exercise excessively. This discomfort affects the individuals mental and physical health and damages his or her relationship with sports and physical activity. The research aims to describe possible individual and environmental elements that may promote the development of bigorexia and exercise addiction, with the intent to identify the prevalence of this distress among young individuals.

Materials and Methods: The research involved a group of 1662 male individuals aged 18-30 years. Questionnaires were administered online and then analyzed using research software. The test battery included the following questionnaires:

- Sociocultural Attitudes Towards Appearance Questionnaire: an instrument consisting of 22 items that assesses thin and muscular-ideal internalization as well as appearance-related pressures from peers, family, and media by distinguishing between pressures to achieve socially promoted aesthetic standards and internalization of such ideals. It comprises five subscales: Internalization: Thin/Low Body Fat; Internalization: Muscular/Athletic; Pressures: Family; Pressures: Media; Pressures: Peers. Items are rated on a 5-point Likert scale ranging from 1 (definitely disagree) to 5 (definitely agree)

- Muscle Dysmorphic Disorder Inventory: consisting of 13 items, a total score and three subscales: Measurement Concern (5 items, range 5-25), Outward Appearance Intolerance (4 items, range 4-20), and Functional Deterioration (4 items, range 4-20).

Descriptive statistics and frequency of occurrence were calculated.

Results: Data analysis shows that participants' body image is not predominant: for 16.1% looking athletic is important, for 13.8% not at all. As for thinking about appearing muscular, 10.6% think about it often, while 24.4% never think about it. 26.4% do not spend much time on activities that make them look athletic, while 12% put a lot of effort into it. Concerning the perception of being under pressure in their daily lives regarding improving their physical appearance, 68.6% do not feel this pressure from their family, while 4.2% feel it importantly. 17% perceive peer pressure in contrast to 5%. Finally, 45.1% do not feel any pressure from the media while 2.5% feel it significantly.

Conclusions: The research highlights that approximately 10-12% of the analyzed sample shows to possess predictive aspects of bigorexia and exercise addiction which are determined by a number of interacting individual and environmental factors. Among these factors, the study shows that a prominent role is played by the individuals confrontation with the aesthetic ideals that the family, social and media context proposes or shows appreciation for.

A NEW EEG NEUROFEEDBACK TRAINING APPROACH IN SPORTS: THE EFFECTS FUNCTION-SPECIFIC INSTRUCTION OF EEG AND MOTOR SKILL PERFORMANCE

WANG, K.P.1, ELBANNA, H.1,2, THIEMER, F.1, SCHACK, T.1

1.BIELEFELD UNIVERSITY, 2. MANSOURA UNIVERSITY, EGYPT

INTRODUCTION: Neurofeedback training is a technique used to train brain activity using real-time feedback. The results of traditional electroencephalography (EEG) neurofeedback training (NFT) protocols for changing EEG activity and improving sports performance have been inconclusive. These traditional approaches mainly rely on nonfunctional directed verbal instructions. This means that traditional training does not provide participants with a specific strategy (i.e., how to regulate a certain brain region) for change their mental state. However, a new approach to EEG NFT, namely the function-specific instruction (FSI) approach, may provide an more effective way to change EEG activity and impact sports performance. The FSI approach is based on the idea that the verbal instructions that consider the meaning of the brainwave function in the target region and the EEG power magnitude can induce mental states. To test the effectiveness of the FSI approach, we replicated Wang et al., 2022's study which partially failed to show a significant relationship between changes in Mu power activity that has been associated with motor control and golf putting performance in the traditional approach.

METHODS: To do so, thirty novice golfers were randomly assigned to either the traditional increased Mu rhythm approach group (T), increased Mu rhythm FSI group (FSI), or sham group (S). In addition, we used EEG-NFT to manipulate Mu rhythm during a golf putting task (complex visuomotor skill).

RESULTS: We mainly found that only the FSI group showed a slightly increased Mu rhythm and decreased motor performance after training.

CONCLUSION: We suggest that the function-specific instructional approach may be more effective in guiding participants to change their state of mind in EEG-NFT.

ANALYZING THE WATER POLO EGGBEATER: RELIABILITY AND VALIDITY OF A NOVEL APPROACH

CLÉMENT, J.1,2, LANOÉ, E.2,3, CROTEAU, F.2,4

1 ÉCOLE DE TECHNOLOGIE SUPÉRIEURE, CANADA ; 2 INSTITUT NATIONAL DU SPORT DU QUÉBEC, CANADA; 3 GRENOBLE INP – UNIVERSITÉ GRENOBLE-ALPES, FRANCE ; 4 MCGILL UNIVERSITY, CANADA;

INTRODUCTION: Water polo players benefit from greater odds of scoring a goal when positioned directly in front of the net (1). Therefore, the abilities to gain tactical positions in front of the net and to defend invading teams from doing so are key performance factors in this sport. These abilities require a strong capacity to push against their opponent's resistance (2). This project aimed at evaluating the reliability and validity of a water-based strength test.

METHODS: 14 elite female and 19 sub-elite male Canadian water polo players participated in this study. Data were collected during regular training sessions using a force gauge (DFS II R-ND, Ametek, 100Hz) to instrument a weight stack resistance by the pool. After a warm-up, female and male participants executed two pushing tasks (based on the team average 1RM): one four-second push task (80lbs and 140lbs) and one ten-second (120lbs and 180lbs) push task. The tests were repeated, in reverse order, one week later in a subset of 12 female and 15 male players. Performance parameters were defined using a Python script. Variables included overall mean force, mean peak and stroke forces, mean stroke duration and variability, number of strokes, total impulse, loss of force index, and time to first peak. Test-retest reliability was assessed using intra-class correlations (ICC3,1). Comparisons between elite female and sub-elite male players were explored with student t-tests and Wilcoxon tests to evaluate validity (normality evaluated with Shapiro-Wilk tests). Effect size (ES) with Hedge's g describes the size of the group differences.

RESULTS: For the four-second task, the reliability findings were very high for the mean force, mean peak force, and total impulse (ICC 0.92-0.95, $p<0.01$). Time to first peak was the only non-significant variable, with an ICC of 0.03 [95% CI 0.00-0.41]. For the ten-second task, the reliability findings were high for mean force, mean peak force, mean stroke force, total impulse and loss of force index (ICC 0.74-0.89, $p<0.01$). All variables were significantly correlated in this ten-second task. Group comparisons for the four-second task showed significantly greater values in elite females for mean force ($p<0.01$, ES=1.794), mean peak force ($p<0.01$, ES=1.161) and total impulse ($p<0.01$, ES=1.597). Group comparisons for the ten-second task showed significantly greater values for elite females for mean force ($p<0.01$, ES=0.948), mean peak force ($p=0.05$, ES=0.747), and total impulse ($p<0.01$, ES=1.066).

CONCLUSION: These preliminary findings show that the test-retest reliability of the main variables explored were either highly or very highly related. However, a larger sample size will be necessary to confirm the importance of variables related to stroke assessments and time to first peak. The ten-second task alone may be sufficient to inform coaches about athlete performances.

THE CURRENT COACHING PRACTICES IN THE FEMALE GAELIC FIELD SPORT OF CAMOGIE

CONNORS, P., EARLS, D., BROWNE, D., RANKIN, P., FITZPATRICK, P.

SOUTH EAST TECHNOLOGICAL UNIVERSITY CARLOW

INTRODUCTION: Camogie is a Gaelic female field sport, akin to hurling. Camogie research is growing, with physical characteristics, and locomotive demand research now available. No research currently exists on camogie coaching practices, however. This research aimed to address this and add to the body of literature on female athletes, with a lack of female sports science research currently available [1].

METHODS: 33 camogie coaches from elite developmental and adult squads completed an online survey on their current session sequencing, session design, and monitoring practices, across pre and peak season. Coaches reported on their use of specific training components such as drills, small-sided games, and training matches across the season, as well as their use of objective measures to monitor their players and training practices.

RESULTS: Camogie coaches seem to sequence their sessions using a traditional drill-to-game approach. Coaches reported primarily using training form activities in pre-season, moving towards playing form activities in peak season. A reduction in both drills and running from pre (41.21%) to peak season (27.27%), and an increase in training matches from 22.58% to 32.58%, may explain the shift from training to playing form across a season. Despite this, a similar percentage of small-sided games were reportedly used in pre (21.21%) and peak (25.45%) season. 5 coaches reported using objective measures to monitor their players and training practices.

CONCLUSION: Coaches reported using traditional session sequencing in preparing their players. Furthermore, coaches reported a shift to more game-specific training in peak season compared to pre-season, due to a reduction in drills and running, while increasing their use of training matches. The use of small-sided games across a season may be an area for further research. Coach education programmes may look to develop current camogie coaching practices to utilise more game-specific methods throughout the season, given training matches and small-sided games equal or surpass the relative camogie match-play running demands [2]. Objective measures would seem to be scarcely used in elite camogie at present. Future research may look to investigate the lack of monitoring practices in camogie.

TEST-RETEST RELIABILITY OF POWER, PINCH, AND TRIPOD GRIP STRENGTH IN BASEBALL PLAYERS

PARK, W., LEE, D.H., CHEON, H.U., HONG, K.

CHUNG-ANG UNIVERSITY, BAEMYEONG HIGH SCHOOL

INTRODUCTION: Grip strength is paramount for baseball players to grip and pinch the ball; therefore, current grip-type assessments must be more comprehensive. This study evaluated different handgrip strength test-retest reliabilities utilizing a dynamometer to smartphone apparatus.

METHODS: We selected sixty secondary (middle and high schools) and college student baseball players 12-22 years of age as participants. A dynamometer and smartphone application evaluated power, pinch, and tripod grip strengths. Overall grip strength measurements slightly decreased across all tests and increased alongside academic grade level.

RESULTS: Tests 1 and 2 demonstrated good-to-excellent retest reliability for the three grip strength positions by calculating their intraclass correlation coefficients or ICCs (middle school power grip: 0.917 [0.644-0.973]; collegiate pinch grip: 0.920 [0.770-0.970]; high school tripod grip: 0.929 [0.728-0.976]). Furthermore, we verified moderate reliability regarding the other grip strengths (middle school tripod grip, Tests 1 and 2: 0.779 [0.428-0.914]; collegiate power grip, Tests 2 and 3: 0.738 [0.360-0.895]).

CONCLUSION: We confirmed these grip strength tests as reliable measurements for childhood to adulthood baseball players with an acceptable margin of error. Thus, these handgrip strengths are sufficient normative values for helping discipline and rehabilitate baseball players and other athletes.

RELATIONSHIP BETWEEN PROTEIN INTAKE RECORDS AND PHYSICAL COMPOSITION AND PHYSICAL STRENGTH IN JAPANESE HIGH SCHOOL BASEBALL PLAYERS

KUNIYOSHI, H.

JAPAN WOMEN COLLEGE OF PHYSICAL EDUCATION GRADUAT SCHOOL

INTRODUCTION: High school athletes and their families have few opportunities to acquire knowledge about nutrition, and their understanding of the importance of diet is insufficient. In particular, students who are part of high school baseball teams in Japan bring lunch from home or purchase it. Students and their parents may be interested in protein intake but may not be aware of its correlation to physical fitness and the importance of simultaneously consuming carbohydrates with it. This study aimed to examine changes in physical fitness and body composition through records of protein intake by students during the training period prior to the district qualifiers.

METHODS: The participants were 16 high school boys who belonged to baseball teams at the district tournament level. Measurements were taken in January before the season and in June during the season. Body weight, body fat percentage, fat mass, lean mass, and muscle mass were measured using TBF-310 (Tanita). In the physical strength evaluation, grip strength (Takei), back muscle strength (Takei), vertical jump (DKH), and medicine ball back throw (MB) were considered indicators of muscle strength. In terms of dietary education, lectures on carbohydrates were given from April to June, and we asked participants to record the frequency of their intake of main dishes as a guideline for protein intake. They were divided into groups that were recorded (RG, n=8) and those that were not (NRG, n=8). Statistical differences were determined using two-way factorial analysis of variance. Differences were considered statistically significant at $p<0.05$.

RESULTS: In terms of body composition, lean mass did not differ. However, a significant difference was detected in body weight and fat mass. The body weight and fat mass of the RG were considerably higher than those of the NRG (weight: $p=0.039$, fat mass: $p=0.019$). Body weight (63.0±8.3kg, $p=0.022$) and fat mass (8.7±3.8kg, $p<0.001$) were substantially lower in June than in January. In contrast, lean mass (54.4±5.1 kg) was considerably higher in June than in January. Physical fitness was assessed using MB values, and the RG showed significantly higher values than the NRG ($p=0.025$). Re-

gardless of whether it was recorded, grip strength (41.5±8.5kg, p<0.001), back muscle strength (138.8±30.5kg, p=0.020), and vertical jump values (42.0±4.6cm, p=0.015) were substantially higher in June than in January.

CONCLUSION: Male baseball team players lost weight and fat mass. In addition, their lean mass and physical strength improved prior to the district qualifiers, regardless of whether they recorded the frequency of the intake of main dishes, which was a guideline for protein intake. Those who kept records gained more weight and fat mass and had higher values in MB; hence, it was inferred that body weight was related to MB. Overall, the recording did not affect physical fitness improvement.

SAME, SAME OR DIFFERENT? ANALYSIS OF COMPLEX SPORT PROFILES IN BASKETBALL, ROWING AND TENNIS.

TRITTENBACH, S.1, HOFFMANN, A.1, TEUNISSEN, J.W.2,3, PION, J.2,3

1 INSTITUTE FOR APPLIED TRAINING SCIENCE; 2 HAN UNIVERSITY OF APPLIED SCIENCES; 3 GHENT UNIVERSITY

INTRODUCTION: What are the similarities between the various sports disciplines? And where do they differ more specifically? Within an international project aiming to determine similarities and differences between sports, highly qualified coaches were surveyed. The questionnaire aims to draw up sport profiles and for this purpose the Differentiated Model of Giftedness and Talent [1] was used as a guide. The research question is twofold and focuses on the differences between the three sports on the one hand, and on the other hand whether there are differences in required skills/abilities of youth athletes to develop successfully and characteristics of elite athletes.

METHODS: Using the online survey "I need 2.0" (based on "I need 1.0" and Flemish Sports Compass [2,3]) via Qualtrics XM, highly qualified coaches (A-License, Diploma, International License) rated 88 total items within 8 categories. They were asked either how important each item is for youth athletes to successfully develop towards a potential elite senior level athlete (Y) or for elite athletes to successfully perform at international level (E).

In total 127 complete surveys (44 basketball (Y: 30, E: 14), 55 rowing (Y: 25, E: 30) and 28 tennis (Y: 17, E: 11)) were collected. Data were analyzed using a MANOVA with the two factors sports and context (Y) or (E) in SPSS 23 for each category.

RESULTS: The results show that the three sports differ within each category ($p < .05$; Partial η^2 .371 - .891). Regarding the factor context, profiles for „youth" and „elite" only differ within the two categories anthropometrics and physical condition ($p<0.05$ and Partial η^2 .151 - .154). There is a significant interaction effect sports*context within the category intellectual abilities ($p<0.05$; Partial η^2.098).

CONCLUSION: The analyses show that the profiles of the three sports show differences and similarities. The results of the tests of the between-subjects effects and the post-hoc-tests are logical in terms of content and prove the face validity of the sport profiles. The three sports represent different sport families, in the next step of the project, comparisons of sports within a sport family will be made.

The identified differences between youth and elite for physical condition may be due to the high trainability of the characteristics. The fact that, except for anthropometry, there are no differences between the profiles in all other categories may also mean that the sensitivity of the method is not high enough for this question. The results are only a partial result of an extensive analysis of the sport profiles, further analyses will follow.

Clarifying differences and specificities of sports can help practitioners to give sport orientations. Similarities could be the starting point to design a broad and versatile development of junior athletes and eventually a tool for talent transfer programs.

THE EFFECTS OF AGE AND TRAINING PRESCRIPTION ON THE ACUTE RESPONSES TO TRAINING IN YOUNG ITALIAN RUGBY UNION PLAYERS

SPINABELLI, S., NIGRO, F., MARCORA, S.M.

ALMA MATER STUDIORUM UNIVERSITY OF BOLOGNA

INTRODUCTION: Questionnaires and scales are often used to monitor training loads and training effects in elite sports (1). The purpose of the present research was to understand the moderating effect of age on the internal training load and acute responses to two different training prescriptions in young high-level rugby union players.

METHODS: Acute responses to High Intensity Training (HI) and Low Intensity Training (LI) in 3 groups (U15 n=8, U17 n=10 and U19 n=9) of young Italian rugby players have been measured. HI training consisted of breakdown and wrestling activity alternating with aerobic power exercise, with small-sided games at the end. LI training consisted entirely of small-sided games with non-contact for technical and tactical objectives. Both the training prescriptions were 90 minutes total, warm-up and cool down included. The 2 workouts were part of the normal weekly training routine. The present research was done by strictly applying the procedures of an ecological experimental design. The following validated questionnaires were used to monitor the acute training effects: Foster's CR10 modified Rating of Perceived Effort scale (RPE) (2), Total Quality Recovery scale (TQR), Main and Grove (MG) questionnaire that monitors training distress in athletes, Fatigue (FAT) and Fatigability (FAB) scales. Repeated measure analysis of variance (2x3 ANOVA) was used to analyze RPE, FAT and FAB with respect to Age and Training type, while a 2x2x3 mixed ANOVA was used for MG and TQR questionnaires to further analyze the interactions of Time, Age and Training type. All post hoc analyses were performed following the Bonferroni correction procedure, setting the significance at a p value <0.05.

RESULTS: Only a significant Training type by Age by Time interaction for the Sleep Disturbances subscales was found. Perceived effort was significant for age by training type interaction. Follow up tests revealed that the U17 group was statistically different for both conditions, while in the U19 group was just near to the threshold. The main effect of training type was statistically significant for the FAB scale. Only in post training conditions we found significant main effects of Training type and Age for the Physical Symptoms subscale.

CONCLUSION: The RPE and FAB scales are most sensitive to acute effects of training load for group U17 and U19, while under the age of 15 these scales do not seem to provide valid ratings of session RPE. With the possible exception of the Physical Symptoms subscale of the MG questionnaire, TQR and the other MG subscales are not sensitive to acute differences in training load. Although some instruments have proven to be more sensitive and valid than others, the Training Monitoring strategy used in the present research represents a valid approach to control training sessions acute effects in young rugby union teams.

COMPARISON OF THREE "ACUTE:CHRONIC" WORKLOAD RATIO METHODS TO MONITOR PROFESSIONAL RUGBY UNION PLAYERS' WORKLOAD AS A FUNCTION OF POSITIONS DURING PRE-SEASON PERIOD

REN, X., BOISBLUCHE, S., DEMY, M., DING, S., PRIOUX, J.

ÉCOLE NORMALE SUPÉRIEURE DE RENNES

INTRODUCTION: The quantification of workload (WL) is based primarily on forwards and backs in rugby union (RU)1, necessitating a more refined division to clarify the function of each position. In addition, as a common method of analyzing data in team sports2, no scientific research has reported to quantify the variability of all acute chronic workload ratio (ACWR) models in pre-season training for RU. Therefore, this paper aims (i) to investigate the differences in external workload (EWL) of players at five positions after eight weeks, (ii) to compare the variations in ACWR for players at various positions, as well as (iii) to analyze the substitutability of the three ACWR approaches in professional RU players.

METHODS: Fifty-seven professional RU players (25.07±4.82 years old) participated in 8-week pre-season training. They were divided into 5 groups : Tight 5 (T5), third-row (3R), number 9 (N9), center, third line defence (3L) . During training sessions, ETL was monitored using wearable 10-Hz GPS (Vector X7, Catapult Sports®, Melbourne, Australia) to characterize WLs by total distance (TD), player load (PL), the number of accelerations and decelerations (ACC+DECnum > ± 2.5 m/s²), the number of accelerations (ACCnum >2.5 m/s²), acceleration distance (AD > 2 m/s²), high-speed running (HSR >15 km/h), very high-speed running (VHSR >21 km/h), sprint running (SR >25 km/h) distance. Coupled/uncoupled rolling average and exponentially weighted moving averages was used to calculate ACWR. Statistical assessments were one-way and multi-way analysis of variance with Tukeys multiple comparisons test.

RESULTS: Throughout the pre-season, the WL of the 3L was always higher than T5 on ACC+DECnum, ACCnum, AD, HSR, VHSR and SR ($P < 0.001$). For both TD and PL value, the group of number 9 was the highest and significantly greater than that of forwards (T5 and 3R, $P < 0.001$). When quantifying PL, AD and HSR, the three approaches for estimating ACWR are interchangeable. Furthermore, no matter what calculating method was utilized, the ACWR of the center of the backs had the maximum value.

CONCLUSION: Tracking differences in positional WLs during pre-season allows coaches and training staff to evaluate player preparedness and organize future training sessions more individualized. In addition, ACWR is still a reliable and effective tool for evaluating WL, it is sufficient to use one of the three methods in some cases.

GPS AND SUBJECTIVE DATA DO NOT CORRELATE WITH MUSCLE DAMAGE ASSESSED BY BLOOD CREATINE KINASE LEVEL FOLLOWING INTERNATIONAL WOMENS RUGBY UNION GAME

IMBERT, S., DELAITRE, R., DAUSSIN, F.N.

UNIVERSITÉ DE LILLE

INTRODUCTION: Rugby is an intermittent, high-intensity contact and running sport that causes muscle damage. Biological markers such as creatine kinase are currently used to adapt the training protocols and follow the recovery of athletes after a game. However, the evolution of biological markers follows specific kinetics which peaks up to 48h after the game and delays the choice of the recovery protocol. Therefore, developing new strategies to identify earlier exercise-induced muscle damage would be interesting. With the development of current technologies, a multitude of data is available from the field, such as GPS or subjective questionnaires. The study aimed to identify whether GPS parameters and/or subjective questionnaires will reflect muscle damage values determine using biological assessment.

METHODS: Twenty-six french womens rugby union players (mean age: 26.1 ± 3.4 years, mean body mass: 75.5 ± 11.6 kg, mean height: 172± 6.9 cm) were monitored using GPS during five matches of the Rugby World Cup in October 2022. Questionnaires and CPK were monitored 36 hours after the match. Only players who played at least 50 minutes of the match were included in the study. At the end of each match, 11 GPS parameters were studied: playing time, total distance, percent walking, maximal aerobic speed percent activity, number of accelerations and decelerations, high-intensity dis-

tance, very high-intensity distance, sprint distance, and maximum speed. A video analysis allowed us to quantification 13 high-intensity rugby action parameters: total number of high-intensity actions and number per minute, number of jumps and lifts, first, second and third row pushes, number of mauls, number of times carrying the ball, number of offensive and defensive rucks, number of tackles, tackle assists and accelerations in the game. The rate of perceived exertion (RPE) was measured using Borg Scale modified by Foster.

RESULTS: Sixty-nine data were recorded for comparison. The mean CPK post 36h of the match was 350±273 UI/L and a delta of 308±250 UI/L compared to basal values was measured. Among the 35 parameters, only two parameters, tackle and activity, were correlated with CPK level but the relations were characterized by low coefficients of determination (<0.1).

CONCLUSION: The physical strain of a rugby match induces muscle damage. These results suggest that GPS data and subjective surveys do not reflect muscle damage and, on a larger scale, tools to investigate fatigue in international female rugby players. Further study with other time point measurements of CPK kinetic and other biological parameters needs to be investigated to determine whether there are of interest.

THE AUTONOMIC NERVOUS SYSTEM RECOVERY AFTER EXERCISE IS DIFFERENTLY AFFECTED BY INCREMENTAL VS. ALL-OUT TESTS

LOPES STORNIOLO, J., MARIA MARCHESE, S., ESPOSTI, R., CAVALLARI, P.

UNIVERSITÀ DEGLI STUDI DI MILANO

INTRODUCTION: By investigating steady-state exercises at different percentages of maximal aerobic power, it has been reported that the time required for the autonomic nervous system to recover grows with exercise intensity (Michael et al., 2017; doi: 10.3389/fphys.2017.00301). However, little is known about this recovery after exhausting protocols in which the load changes over time, nor is it clear whether training to a specific aspect of the exercise (e.g., power vs. endurance) may differently contribute to the autonomic recovery. Therefore, we aimed to compare incremental and all-out exercises, starting with a population of athletes mainly trained for power output.

METHODS: ECG was recorded in fourteen semi-professional rugby players (male Italian League, second and third divisions) who accomplished two tests on the cycle ergometer, randomized and separated by at least 72 h. One was an incremental test (INC) requiring a regular load increase of 30 W every minute till exhaustion; the other was an all-out effort (AOU) against the subject's maximal cycling load. Tests were preceded by a 10 min resting period and followed by a 10 min recovery period. In the last 5 min of each period, the sympathovagal balance was assessed by measuring HRV power in the low (LF) and high-frequency (HF) bands, together with the mean value of heart rate (HR). Moreover, the post-exercise exponential decay of HR was evaluated to calculate the time constant Tau.

RESULTS: A treatment x exercise ANOVA confirmed that HR increased after both exercises, but to a larger extent for INC than AOU (+35% and +24%, respectively; interaction $p = 0.007$). In parallel, a paired t-test indicated a longer Tau after INC than after AOU (109.8 vs. 65.7 sec; $p = 0.002$). From the sympathovagal balance standpoint, the ratio LF/HF (in log units) increased similarly after both protocols (about +13%; exercise $p = 0.013$; no interaction).

CONCLUSION: The higher HR value and the longer Tau observed after INC suggest that this exercise is more stressful for the autonomic nervous system. However, the parallel increase in log LF/HF after both tests suggests that INC and AOU induced similar changes in both the sympathetic drive and the vagal tone. The different response to INC vs. AOU exercise might be due to the higher external work exerted in the former test (about 90 vs.21 kJ). Indeed, despite the significantly lower peak power (on average 306 W in INC vs. 927 W in AOU), the INC protocol had a longer duration than AOU (563 vs. 23 sec). A second possibility is that this difference may stem from the training program, which mainly targeted power output in rugby players. It will be of interest to complete these results with those obtained in endurance-trained athletes.

EFFECTS OF 5-WEEK SOCCER TRAINING ON THE AEROBIC PERFORMANCE OF ELITE WOMEN SOCCER PLAYERS

RODRIGUES-FERREIRA, M.A.1,2, VENCESBRITO, A.1,2, CYNARSKI, W.3,4, CASTRO, M.A.5,6

1ESDRM-IPS, PORTUGAL 2CIEQV, PORTUGAL 3IMACSSS, POLAND 4UNIVERSITY OF RZESZOW, POLAND 5ESSLEI-IPL, PORTUGAL 6UNIVERSITY OF COIMBRA, PORTUGAL

INTRODUCTION: Pre-season changes in the physical performance of elite women soccer players are scarce. So, the aim of the study was to evaluate the effects of 5-weeks of specific soccer training (4-6 sessions/week), during the preparatory period, on the aerobic performance of elite women soccer players.

METHODS: The sample was composed by 24 elite women soccer players with an average of 22 years of age. It was applied the Yo-Yo intermittent recovery level 1 test for the evaluation of aerobic performance. A paired sample t-test was used to compare differences between pre and post preparatory period. The level of significance was established at $p \leq 0.05$.

RESULTS: After 5-week specific soccer training the women soccer players significantly improved the Yo-Yo intermittent recovery level 1 test performance ($p<0.001$; $\Delta\% = 23.3$).

CONCLUSION: It was recently demonstrated that it is possible to develop aerobic and power abilities of elite women soccer players during 8-weeks of pre-season using an equalized ratio of soccer training and strength-power training schedules (Kobal et al., 2021). The same authors found an improvement of 28,5% in aerobic performance in the Yo-Yo intermittent recovery level 1 test. An improvement in Yo-Yo intermittent recovery level 1 test performance was also observed in U12-U16s pre-post season (Emmonds et al., 2020). It can be concluded that 5-weeks of specific soccer training allowed a significant increase in the aerobic performance of elite women soccer players. Future studies should analyze seasonal changes in the neuro-muscular performance of elite soccer players.

INTERRELATIONS BETWEEN AEROBIC CAPACITY AND ANAEROBIC POWER IN SOCCER PLAYERS UNDER 17 YEARS

PETSEVA, Y., MANCHEV, A., PENCHEVA, N.

SOUTH WEST UNIVERSITY

INTRODUCTION: The high pace and intensity of the soccer and the long distance (over 10 km per game), require a specific adaptation of soccer players to both aerobic and anaerobic energy expenditure [1,2]. On the other hand the aerobic and anaerobic capabilities have ontogenetic differences [3]. This study aimed to investigate: -whether the adolescent players with higher aerobic capacity (AC) have lower anaerobic power (AnP); and -to evaluate the age related differences in both types of performance.

METHODS: Adolescent male soccer players (n=16), in two age groups (14 years-G14,n=7; 15-16 years -G15-16, n=9), participated. For assessing of the AC a maximal test to exhaustion was used on a treadmill (HP Cosmos). AnP was evaluated by Wingate Anaerobic Test (WAnT) on a cycle ergometer (Monark 828 E) to determine Peak power (PP), Average Power (AP), and Relative Total Work (RTW). Data were analyzed with Descriptive statistics, Mann-Whitney U test and Pearson coefficient ($p<0.05$), using Prism (ver. 3.2).

RESULTS: The values of VO2max (ml/min.kg-1) reveal high AC (59.3±4.3 for G14; 59.2±2.6 for G15-16) for all players, with no significant differences between age groups for the metabolic, ventilator and cardiovascular parameters. The indices of AnP: relative PP, AP and RTW were higher ($p<.05$) for the players from G15-16 (9.6±.9W/kg, 450±83W and 210±16J/kg, respectively) compared with G14 (8.3±.6W/kg, 352±32W and 181±12J/kg, respectively). Furthermore for all participants, a moderate correlations were established between age and PP ($r=.57$, $p=.022$), as well as between AP and RTW ($r=.50$, $p=.047$ and $r=.50$, $p=.046$ respectively). No relationships were found between VO2max and any anaerobic variables investigated. However, very high positive correlations were established in G15-16 between peak VO2/HR, an aerobic parameter, with PP ($r=.92$; $p=.0005$), AP ($r=.96$; $p<.0001$) and RTW ($r=.96$; $p=.0001$). The only negative correlations observed, were for HRmax with relative AP and RTW ($r=-.62$; $p=.03$ and $r=-.62$; $p=.03$, respectively) in G15-16 and with relative PP and relative AP ($r=-.72$; $p=.03$ and $r=-.67$; $p=.04$, respectively) in G14.

CONCLUSION: The high AC of tested soccer players was not associated with low anaerobic performance. The increase in AnP, between 14 to 15-16-years old soccer players is significant, as opposite to AP. The strong correlations between peak VO2/HR and parameters of WAnT designate that: -a higher AnP does not indicate a greater anaerobic capacity; and -the WAnT is not a proper approach for assessing the interrelations between aerobic and anaerobic energy expenditure. Negative relationships of HRmax with parameters of WAnT probably could be a sign for anaerobic capacity.

THE EFFECT OF SPECIFIC HIIT TRAINING WITH AN INTENSITY BETWEEN THE ANAEROBIC THRESHOLD AND THE PSYCHOMOTOR FATIGUE THRESHOLD ON THE PHYSIOLOGICAL PARAMETERS OF YOUNG SOCCER PLAYERS

CHMURA, P., CHMURA, J., CHODOR, W., DROZDZOWSKI, A., ROKITA, A., KONEFAL, M.

WROCLAW UNIVERSITY OF HEALTH AND SPORT SCIENCES

INTRODUCTION: Effective HIIT training requires determining the individual intensity that optimally stimulates the development of exercise capacity [1]. To achieve this, it is necessary to determine the minimum intensity at the anaerobic threshold (TAN) and the maximum intensity at the psychomotor fatigue threshold (PFT) [2,3]. The aim of the study was to assess the effect of specific HIIT training, performed between the TAN and the TPF on the physiological parameters of young soccer players. In addition, the aim of the study was to determine whether in 4x4 games on a 25x35 m pitch, the tested players exceed the anaerobic threshold and are able to achieve TPF intensity.

METHODS: Fourteen young U-17 soccer players from a professional sports club competing in the second Polish league took part in the study. Physical activity of all field players was analyzed. Goalkeepers were excluded from the analysis due to the specificity of the effort. The project consisted of four stages of research: first, an exercise test with increasing load was applied in the laboratory, second six 3-minute 4 x 4 games were played with goalkeepers and with a break between games lasting 3 minutes, third of the experiment was to perform an additional program of three specific HIIT exercises twice a week on Tuesday and Thursday in a training microcycle lasted 4 weeks, fourth repeated first stage - an exercise test with increasing load, performed on a running treadmill in the laboratory. Lactate (LA) was analyzed to determine the anaerobic threshold, choice reaction time (CRT) to determine the psychomotor fatigue threshold and selected physiologi-

cal parameters. External loads were determined using GPS (Catapult Sports, Melbourne, Australia). Repeated-measures ANOVA was used to compare mean values for the examined variables.

RESULTS: It was found that after 4 weeks of specific HIIT training significantly increased VO2 and running speed on TAN and TPF and HR on TAN. The tested players realized 4x4 games on a 25x35 m pitch exceed the intensity of effort on TAN, but do not reach the intensity on TPF.

CONCLUSION: The proposed specific HIIT training, carried out between the anaerobic threshold and the psychomotor threshold of fatigue, consisting of three exercises, each subsequent one generating greater intensity, greater variability of the stimulus and longer duration, is a practical proposal that effectively increases the exercise capacity of football players.

ACUTE FATIGUE EFFECTS OF SOCCER TRAINING SESSION IN YOUNG PLAYERS: ANALYSIS OF THE FUNCTIONAL PERFORMANCE

MANGINI, A.1,2, GIRAUD, D.2,3, MACCHI, R.4, POMPORTES, L.1, GALANTINE, P.5, NICOL, C.1, BERTIN, D.1,2, HAYS, A.2

1AIX-MARSEILLE UNIV, CNRS, ISM, MARSEILLE, FRANCE; 2AIX-MARSEILLE UNIV, HIPE HUMAN-LAB, MARSEILLE, FRANCE; 3AIX-MARSEILLE UNIV, CNRS, IUSTI, MARSEILLE, FRANCE; 4INSEP, SEP-EA 7370, PARIS, FRANCE; 5UNIVERSITY OF TOULON

INTRODUCTION: Soccer training includes efforts performed at different intensities leading to physiological and neuromuscular fatigue and a decline in physical performance (1). Young players are reported as a group with more variable and specific risk factors than older players (2). Considering the additional increased risk of injuries towards the end of the match (3), this study examined the acute fatigue effects of a soccer training session in young players.

METHODS: Eighteen male soccer players (15.6 ± 1.7 yrs) from a training center performed a test protocol immediately before and 8 min after a common soccer training of 75 min. Each test session included capillary blood samples (HCO3-, Lactate, pH), subjective ratings of muscle soreness and fatigue perception (Visual Analogue Scale). Three functional tests were performed at maximal intensity: a drop Jump (DJ), a 30 m sprint and a horizontal force-velocity (HF-V) test under four resistive conditions. Using 2 force platforms, unilateral and bilateral values of force, velocity and power were calculated (4). The mechanical Force-Velocity-Power profile was also computed (5). To test the training effect, a linear mixed model was used. The Kmean method was applied to the first two dimensions of the PCA analysis based on the DJ and H-FV changes. Only bilateral data are presented.

RESULTS: After training, blood markers and increased subjective sensations revealed significant fatigue effects. Sprint time increased (2±1 %, $p<0.001$, d=0.32) and velocity at take-off in DJ decreased (-8±9 %, $p<0.001$, d = 1.46). In DJ, mean push-off velocity and power also decreased (-9±9 %, p = 0.04, d = 0.42 and -6±16 %, $p<0.05$, d = 0.23, respectively). No change was found in the HF-V test. However, the clustering analysis revealed two opposite fatigue profiles (n = 9 for each). In the first cluster, velocity decreased in both tests (DJ: Vpush-off = -12±10 %; $p<0.001$, d = 1.44; H-FV: V0 = -23±9 %; $p<0.001$, d = 1.03) while force increased in the H-FV (F0 = 18±12 %; $p<0.001$, d = 0.72). In the second cluster, force decreased in both tests (DJ: Fpush-off/BW = -6±5 %; $p<0.01$; d = 0.86; H-FV: F0 = -13±6 %; $p<0.001$, d = 0.91) while velocity increased in the H-FV (V0 = 44±17 %; $p<0.001$, d = 2.5).

CONCLUSION: The training-induced fatigue was reflected by a combination of blood marker changes, muscle soreness and perceived subjective fatigue. The battery of tests was of interest as the combination of the H-FV and DJ tests revealed 2 opposite profiles of functional loss in young soccer players. This battery is considered as a useful non-invasive tool for the coach and medical staff to individually adapt the recovery and/or the training process, in an attempt to potentially reduce the risk of injury.

MANIPULATING TRAINING LOAD 48 HOURS AFTER A MATCH: EFFECTS ON RECOVERY RESPONSES IN ELITE YOUTH SOCCER PLAYERS

FRANCESCHI, A.1,2, ROBINSON, M.A.2, OWENS, D.2, BROWNLEE, T.3, CONNOLLY, D.1,4, FERRARI BRAVO, D.1, ENRIGHT, K.2

1 JUVENTUS FOOTBALL CLUB, TORINO, ITA; 2 LIVERPOOL JOHN MOORES UNIVERSITY, LIVERPOOL, UK; 3 UNIVERSITY OF BIRMINGHAM, BIRMINGHAM, UK; 4 UNIVERSITY OF TECHNOLOGY SYDNEY, SYDNEY, AUS

INTRODUCTION: Manipulation of training load represents the starting point in any recovery strategy to increase or decrease fatigue over the microcycle [1]. Soccer match-play has the highest load of the week and 48 hours after a match youth players are not fully recovered [2]. It is therefore important that early in the microcycle, training-based interventions favour both regeneration and exposure to optimize youth player development. However, no information exists on the effect of modifying soccer-specific training load on recovery responses. This study investigated two training load-based recovery interventions following a match, and observed recovery responses up to 72 hours post-match in elite youth soccer players.

METHODS: Thirty-three elite youth soccer players (under-16: n = 15; under-15: n = 18) from an Italian Serie A team completed an 80-minute match (MD) and were assessed before (baseline) and after (+0.5h, + 48h, +72h) the match. Countermovement jump (CMJ), isometric posterior-chain (IPC) and muscle soreness (VAS) were used as neuromuscular and perceptual recovery indicators. Using a parallel group design, on the second day after the match (MD+2) participants were randomly assigned to either a complete training (CT: 105min session) or a reduced training group (RT: 75min session). Training and match loads were quantified using global positioning systems, heart rate sensors and RPE. For each squad, differences between training groups at MD and MD+2 were analysed using an independent t-test and Hedge's g effect size (g). Differences between training groups and time points were analysed using a two-way mixed (group x time) ANOVA for each recovery measure, with Bonferroni post-hoc correction.

RESULTS: Verification of the intervention showed that both groups were exposed to similar match demands ($p > 0.05$; g: trivial to small) and that the CT group had significantly greater training loads on MD+2 compared to RT ($p < 0.05$; g: moderate to very large). There was a significant interaction (group x time) effect on CMJ, IPC and VAS in the under-16, while in the under-15 a significant interaction effect was only observed in IPC ($p < 0.05$). CMJ, IPC and VAS significantly declined at +0.5h ($p < 0.05$), recovering at +48h after the match. Following the training load interventions, at +72h CT showed significant decrements in CMJ and IPC compared to +48h in under-16 players ($p < 0.05$), while no significant changes were observed in under-15 players between +48 and +72h ($p > 0.05$).

CONCLUSION: Neuromuscular and perceptual status declined immediately after the match, recovering to baseline levels at 48 hours. A complete training session, characterized by higher training loads on MD+2, may negatively influence neuromuscular recovery at 72 hours. Modifications of training load early in the microcycle may be applied as a strategy to promote the desired recovery and acute training effects in elite youth soccer players.

CORRELATION ANALYSIS OF EXPLOSIVE POWER AND SPECIAL PHYSICAL FITNESS IN ELITE WOMENS SOCCER PLAYERS

CHEN, L.Y., LU, K.H., HUANG, B.X., TANG, C., LIN, J.Z.

NATIONAL TAIWAN UNIVERSITY OF SPORT

INTRODUCTION: Football is a comprehensive sport that requires basic physical fitness. The lower limbs are used to generate the strength needed to quickly achieve sprints and change in direction [1]. The explosive power of the lower body is a necessary core ability. From a strength and conditioning perspective, explosive power is an important ability that contributes to various aspects of physical fitness. Researchers have often used vertical jump height as one of the indicators of maximum explosive power. [2] However, the relationship between maximum explosive power and the special ability output of women players in football has not yet been studied. As such, our purpose in this study was to explore the correlation between explosive power and the physical fitness of outstanding women football players.

METHODS: We recruited 20 college womens elite football players as voluntary participants. All experimental participants fully warmed up after the various test procedures were explained to them. We recorded body composition measurements, and the participants performed vertical jump, standing long jump, 505, pro agility, Illinois, 10 m sprint, 40 m sprint, 300 yard shuttle, and yo-yo tests. The experimental equipment included: Inbody 370s, Opto jump, Witty, starting pistol. We used SPSS 20.0 for Pearson product difference correlation analysis.

RESULTS: The results show a significantly positive correlation between vertical jump and standing long jump, showed a significant positive correlation between vertical jump and standing long jump ($r = 0.694$; $P = 0.001$) and significantly negative correlation between the 10 meter sprint, ($r = -0.629$; $P = 0.003$),40 meter sprint ($r = -0.547$; $P = 0.013$),pro agility ($r = -0.527$; $P = 0.017$) ,300 yard shuttle test ($r = -0.397$; $P = 0.083$)

CONCLUSION: The results of the correlation analysis show that the vertical jump was significantly positively correlated with the standing long jump, followed by the 10 meter sprint, 40 meter sprint, pro agility, and 300 yard sprint. The vertical jump is a short-term explosive power output movement and requires explosive power. In the 300 yard turn-back test, the participant must turn back every 25 yards; explosive movements are also required for the direction change. Therefore, the contribution of explosive power is also related to anaerobic ability during the return run test. Our findings demonstrate that explosive power affects athletic sprint performance, agility, and anaerobic capacity. The results of this study can be used as a guideline of vertical jump height as an indicator of specific sports performance and to help players and coaches more effectively and purposefully monitor training results.

THE INDEPENDENT EFFECTS OF MENSTRUAL CYCLE PHASE, MATCH LOCATION, MATCH RESULT AND THE QUALITY OF OPPOSITION ON SELF-REPORTED WELLBEING IN PROFESSIONAL FEMALE SOCCER PLAYERS: A SQUAD CASE STUDY

HANSELL, E., ABBOTT, W., CLIFFORD, T.

LOUGHBOROUGH UNIVERSITY

INTRODUCTION: Poor subjective wellbeing is associated with injury, illness, and decreased performance in team-sport players. Previous studies show that in male soccer players, situational match variables (such as match location, opposition quality, and match result) influence self-reported wellbeing, independent of training load. These situational match

factors have not been investigated in female soccer players; in addition, no study has examined the effects of menstrual cycle phase on wellbeing. Therefore, the aim of this study was to assess the effects of match location, opposition quality, match result, and menstrual cycle phase, on self-reported wellbeing before and after professional female soccer matches across a season.

METHODS: Twenty-two professional female soccer players (25±5 years) from a squad in the Women's Super League in England self-reported their muscle soreness, sleep, stress, mood, and fatigue on a 1 (positive) to 5 (negative) Likert scale on the morning of match day (MD), and the subsequent three days (referred to as MD+1, MD+2, MD+3, respectively). Twenty-six matches in total were used for the analyses. Internal and external load (assessed by 1-10 rating of perceived exertion [RPE], and total distance covered via GPS), match location, match result, opposition quality (determined by final league-table position) and menstrual cycle phase were recorded for each match. Linear mixed models were used to examine for match-day x variable interactions (statistical significance was $P<0.05$; effect sizes were Hedge's g).

RESULTS: Situational match factors and menstrual cycle phase had no influence on the distance covered during matches or RPE ($P>0.05$). After away matches, sleep was rated ~60% worse on MD+1 ($P<0.001$; g=1.59) and ~29% worse on MD+2 ($P=0.005$; g=0.98). Stress and mood were >28% worse after playing against top vs. middle and bottom table opposition at MD+1 ($P\leq0.047$; g=0.8-0.94); likely because they lost most of these matches, which worsened stress and mood compared to winning and drawing at MD+1 ($P\leq0.001$; g=0.20-2.95) and MD+2 ($P\leq0.017$; g=1.42-1.77). Soreness, sleep and fatigue were most affected at MD+1 during menstruation (2.6-3.2); stress and mood were most affected during ovulation (~2.8); however, menstrual cycle phase (menstruation, follicular, ovulation, luteal) had no significant influence on post-match wellbeing ($P<0.05$).

CONCLUSION: In professional female soccer players, menstrual cycle phase did not influence wellbeing, but subjective sleep quality was impaired after away matches and losing matches negatively affected stress and mood. Coaches and sports science practitioners should be aware of, and take into consideration, the potentially negative effects of playing away from home and losing matches on self-reported wellbeing and consider strategies to mitigate the impact of these variables.

EFFECTS OF 3D MULTIPLE OBJECT TRACKING TRAINING ON FRONTAL EEG'S IN PROFESSIONAL SOCCER PLAYERS

SAITO, Y.1, ISOGAI, H.2, NATSUME, K.1

1 KYUSHU INSTITUTE OF TECHNOLOGY ; 2 KYUSHU SANGYO UNIVERSITY

INTRODUCTION: In sports, physical training is essential to achieve the optimal performance. However, cognitive ability is also an important factor. In the case of professional athletes who already possess a high degree of physical competence, advantages in perceptual and cognitive abilities can become key superiority .

A method to improve the cognitive abilities of the brain is a 3D multiple-object tracking (3D-MOT) task. NeuroTrackerX (NTX; Neuro Tracker Inc, Canada) has been used for the task. It is performed on a PC the trainee's having 3D glasses. There are some previous studies indicating that 3D-MOT training could improve attention, working memory, and visual information processing speed, accelerate the processing speed, and also producing quantitative changes in the resting-state EEG of the university students [1]. We conducted the study on four professional soccer players currently active in the Japanese League. We measured EEG at the frontal region of the brain with their eyes open after training using NTX . As a result, theta rhythm power at mid-frontal region (Fmθ) showed a significant increase [2]. In this study, we studied whether θ rhythms changed at the other frontal regions after 3D-MOT task of the Japanese League athletes.

METHODS: Thirteen J-League players with the age of 23.7 ± 1.1 (mean ± SD) years, and the measurements were performed during the J-League season. NTX was used for evaluating the ability of 3D-MOT and training. The training period was about two months. Before and after the training, the cognitive tasks of trail-making test (TMT)-A, and B, and 1-back test were performed. At the same day EEG was measured with the subjects' eyes open for 15 seconds after the NTX task. It was measured at the frontal F3, Fz, and F4. Average power values of θ, α, β, and γ waves were calculated using MATLAB R2020b (Mathworks Inc, USA). In the statistical test, paired student's t-test was performed.

RESULTS: There was a significant increase in NTX scores by the training ($p < .001$). The increased rate of the score significantly positively correlated with the number of training sessions and (Pearson correlation coefficient $r = 0.57$; $p = .04$). The score of TMT-A, and B significantly increased after the training (A; $p = .004$, B; $p = .03$, respectively). θ powers at F3, Fz, and F4 significantly increased after the training (F3; $p < .001$, Fz; $p < .001$, and F4; $p = .02$).

CONCLUSION: NTX scores increased with the training accompanying with the significant increase in the scores of TMT-A, B. The results suggest that NTX training will improve the working memory ability in the professional soccer players.

θ rhythms not only at mid-frontal region, but also at the right and left frontal regions significantly increased after the training. Frontal θ rhythm is related to the working memory function. The result suggests that NTX training influences working memory ability throughout the increase in the θ rhythm at the frontal lobe.

VALIDITY AND RELIABILITY OF A NEW WEARABLE CHEST-STRAP DEVICE TO MEASURE RESPIRATORY FREQUENCY IN ELITE SOCCER ATHLETES

DI PACO, A., BONILLA, D.A., PERROTTA, R., CANONICO, R., CIONE, E., CANNATARO, R.
CASA DI CURA SAN ROSSORE

INTRODUCTION: The assessment of the respiratory frequency (fR) has practical importance in monitoring training progress in competitive athletes, especially during exercise. This study aimed to validate a new wearable chest-strap (wCS) device to measure fR against ergospirometry as a criterion device in healthy adults. The gold standard for performance evaluation remains the cardiopulmonary exercise test. However, it remains a test that cannot be applied in daily training practice

METHODS: A total of 26 elite professional soccer players (23.6±4.8 years; 180,6±5.7 cm; 77.2±5.4 kg) from three Italian Serie A League teams participated in this cross-sectional study. The sample included attackers, midfielders, and defenders. All participants were free of injuries at the time of testing. Participants were equipped with a heart rate sensor (Polar H10, Polar, Kempele, Finland); they wore a face breathing mask connected with a fast-responding gas analyzer (Vyntus Vyaire medical, Chicago, ILL, USA). In addition, they wore a wCS equipped with sensors to read HR and RF and with the newly designed device that tests breath frequency and heart rate, i.e., a belt strap (similar to Polar or Garmin) made of elastic and inelastic materials, and with two internal electrodes, to check the heart rate and with a strain gauge sensor, only with resistive functions, that is used to record the breathing act; it is mechanically and electrically connected, through four snap contacts to a device; hardware cyclically reads the analogic signals created by the internal sensors of the belt and transmit them, after an appropriate collecting filtering to a remote station. The subject underwent an incremental symptom-limited exercise test wearing gas analyzer and chest band simultaneously

RESULTS: A total of 16529 comparisons were performed after collecting data in the maximal incremental exercise test. No significant differences were found for both methods (P<0.05). Correlation among devices was statistically significant and very large (r [95% CI]: 0.970 [0.970, 0.971], P<0.01; aR2 [95% CI]: 0.942 [0.942, 0.943], P<0.01). Similarly, a high concordance was found (ρc [95% CI]: 0.970 [0.969, 0.971], bias correction factor: 0.999). However, the VyntusTM CPX, as a standard criterion, showed moderate agreement with wCS after Bland-Altman analysis (bias [95% lower to the upper limit of agreement]; % agree: 0.170 [-4.582 to 4.923]; 69.9%). A strong association between measurements (rrm [95% CI]: 0.960 [0.959, 0.961]), a high absolute agreement between methods (ICC [95% CI]: 0.970 [0.970, 0.971]), and a high inter-rater reliability (rF: 0.947) was found

CONCLUSION: The new wCS device is an in-field valid and reliable method to evaluate fR compared to a breath-by-breath gas exchange analyzer. The statistical parameters analyzed show a high correlation between the two methods. We are already testing the device in a larger sample. Notwithstanding, caution is advised if methods are used interchangeably while further validation occur

CP-SH19 Cognition

MULTI-DOMAIN ASSESSMENTS OF COGNITIVE FUNCTIONS IN ELITE ATHLETES ACCORDING TO THEIR SPORT TYPE AND SEX: PRELIMINARY RESULTS

ROMEAS, T.1,2, VONA, M.3, DESLAURIERS, J.1, LECLERC, S.1,4, DE GUISE, É.3
1. INSTITUT NATIONAL DU SPORT DU QUÉBEC, 2. SCHOOL OF OPTOMETRY, UNIVERSITÉ DE MONTRÉAL, 3. DEPARTMENT OF PSYCHOLOGY, UNIVERSITÉ DE MONTRÉAL, 4. DEPARTMENT OF FAMILY MEDICINE, UNIVERSITÉ DE MONTRÉAL

Cognition is crucial for high performance sports. Consistent evidence has demonstrated that cognitive abilities, in particular executive functions (EF), are superior in experts. These studies have been recently challenged for the magnitude of their effect, contradictory evidence towards a superior development of EF in experts, and their rapid endorsement of cognitive evaluation for talent identification. Similarly, considering that different sports require variable cognitive demands, cognitive performance between sports has been explored with inconsistent findings, which can be mostly attributed to poor classification. Lastly, there is a general lack of female representation and assessments of multi-domains of cognitive functions in the literature. Therefore, the objectives of this study were to compare multiple domains of cognitive functions: 1) between a homogenous sample of expert athletes and representative norms; and 2) between sport types and sex.

Two hundred and thirty athletes (F=124, M=106; mean age 21.35 ± 3.8 years) classified as elite level (Tier 4) from a national sport institute were divided across three sport categories (team [n=91], precision-skill dependent [n=63], speed-strength [n=76]) according to a clear classification framework. Athletes were tested on a validated computerized neuropsychological test battery (Vienna Test System, Schuhfried) during pre-season by a sport neuropsychologist in standardized conditions. Six multi-domain assessments were performed including tests of EF (cognitive flexibility, planning, inhibition, working memory), selective and sustained attention. Reaction time and accuracy were used to measure test performance. T-scores were employed to compare athletes to a representative normative sample of the general population. Two-way ANOVAs were performed on each test (factors: Sex, Sport category) and Bonferroni corrections were used for multiple comparisons. The significant level was set at p<0.05.

Experts performed in the average range compared to a normative sample on all six domains of cognitive functions. There was no significant interaction between factors but a significant main effect of Sport category on cognitive flexibility accuracy ($F[2, 204]=4.621$, $p=0.011$, $\eta^2=0.045$) and selective attention reaction time ($F[2, 228]=3.265$, $p=0.040$, $\eta^2=0.029$) where speed-strength sports performed better than team sports ($p=0.010$ and $p=0.035$ respectively). There was a main effect of Sex on reaction time of selective ($F[1, 228]=30.078$, $p<0.001$, $\eta^2=0.119$) and sustained attention ($F[1, 224]=12.916$, $p<0.001$, $\eta^2=0.056$) where males performed faster compared to females.

The advantage of experts on general multi-domain cognitive tests was not evident from these preliminary results in this sample of 230 elite athletes. However, sport-specific demands may place greater demands on specific cognitive functions such as EF and selective attention, especially in sports where high speed and decision making are intertwined.

VISUAL PERCEPTION AND DECISION MAKING IN DYNAMIC ENVIRONMENTS. AN EXPERIMENTAL STUDY IN BEACH VOLLEYBALL

VELENTZAS, K.1,3, VIETMEIER, N.1,2, POLLMANN, D.1

1.BIELEFELD UNIVERSITY, 2.HUMBOLDT-UNIVERSITY BERLIN, 3.CITEC BIELEFELD

High athletic performance requires an optimized interaction of perception and action. In beach volleyball, two athletes must compete on each side of an uneven 16 x 8 m court, defending and hitting balls at speeds of up to 130 km/h from a distance of 4-10 m. From this point of view the anticipatory ability, the defenders can be seeing as crucial for performance. Our study aims to gain insights into the relationship between perceptual strategies and decision making in beach volleyball and to investigate the differences in this between novices and advanced players. We hypothesized that (1) advanced players would make faster and more accurate decisions, as reflected by reduced RT and a higher number of correct decisions; (2) there would be fewer fixations and longer fixation durations for advanced players in comparison to novices and different gaze patterns between novices and advanced players (e.g., Williams & Jackson, 2019; Klostermann et al., 2020)

Using a video-based visual occlusion paradigm, 32 participants, with n = 18 novices and n = 14 advanced players in beach volleyball or volleyball, were shown 48 randomized beach volleyball attacks from a defender perspective. Participants were asked to classify the attacks as smashes or shots as quickly and accurately as possible. Reaction times and number of correct decisions were measured by keyboard entries (CMC; Heinen, 2010). Gaze behavior was scrutinized using SMI® eye tracking glasses (120Hz).

Advanced players showed a lower response time and higher response accuracy compared to novice players. However, these differences were not significant (response time: $t(27.978) = -1.068$, $p = .147$; number of correct decisions: $t(28.319) = -1.209$, $p = .118$). Both groups showed similar gaze behavior. Besides advanced players making significantly more fixations in total than novices ($t(21.831)$, $p = .018$), there was no significant difference in the total duration of fixations [$t(28.035) = 0.521$, $p = .303$], suggesting shorter fixations for advanced players than for novices.

The results of the present study are only partially consistent with previous studies and cannot support our hypotheses. Advanced players showed more, shorter fixations than novices, but similar gaze patterns, response time, and accuracy. Further studies with mixed-method designs are needed to better understand cognitive and attentional processes during visual search strategies (e.g., peripheral perception when looking into empty space). Beyond its limitations, particularly the sample size and the lack of expert-level participants, the study provides an initial foundation in the study of decision making and gaze strategies in beach volleyball.

EFFECTS OF EXERGAME TRAINING ON COGNITIVE AND CARDIAC AUTONOMIC FUNCTIONS IN HEALTHY MIDDLE-AGED AND OLDER ADULTS

CHU, I.H., YU, T.C.

KAOHSIUNG MEDICAL UNIVERSITY

Introduction

Previous studies have shown that regular exercise is effective in improving cognitive function, and in preventing or delaying the onset of dementia [1]. Some studies also suggest that open-skill exercise appears to be more effective than closed-skill exercise in improving executive function [2]. Recently, exergame has become widely popular and is considered a mode of open-skill exercise. However, few studies have investigated the effect of exergaming on cognitive function. Additionally, researchers have proposed that cardiac autonomic control, assessed via heart rate variability (HRV), is associated with cognitive function. Yet, the effect of this proposed mechanism remains largely unknown. The purpose of this study was to investigate the effects of 10-week exergame training on cognitive function and HRV in middle-aged and older adults. The relationships between HRV and cognitive function were also examined.

Methods

This study was a randomized controlled trial. Ninety participants who met the study criteria were recruited and randomly assigned to exergame training group or control group. The training program was 50 minutes per session, twice per week for 10 weeks. The control group was instructed to maintain their usual lifestyle. All participants filled out questionnaires and received assessments of executive functions (digit span test, Tower of London test) and electrocardiography at baseline and post intervention.

Results

After 10 weeks, all three digit span test parameters improved in the exergame group and these changes were significantly better than the control group (all $p<0.05$). The total initiation time (TIT) of the Tower of London test also improved significantly in the exergame group and this change was significantly better than the control group ($p=0.035$). No significant change was observed in HRV and there was no significant correlation between the cognitive function tests and HRV.

Conclusion

A 10-week exergame training program was effective in improving cognitive functions of attention, alertness, auditory memory, working memory, and the ability of planning in healthy middle-aged and older adults.

THE EFFECT OF ATTENTIONAL BIAS CAUSED BY INCREASED ANXIETY ON AVOID AND APPROACH BEHAVIORS

SAKEMOTO, N., TANAKA, H.

TOKYO UNIVERSITY OF AGRICULTURE AND TECHNOLOGY

INTRODUCTION: The negative effects of anxiety on motor performance may, in part, be due to attentional bias toward threatening stimuli that elicit performance anxiety, such as when a penalty kicker faces a goalkeeper in football (Wilson et al., 2009). The relationship between attentional bias and motor performance has been severely neglected in the sport science research field. Against this background, the present study examined the effects of attentional bias on both avoid and approach motor executions in anxiety-producing situations.

METHODS: Thirty-two participants performed either an avoid or an approach task. Attentional bias was manipulated using the visual-probe paradigm (Mogg & Bradley, 1999), in which a threat or nonthreat emotional cue accompanied by a neutral cue (an angry or happy face with a neutral face, intended to represent fan emotions) was briefly displayed before presenting a probe-target (a shadow figure representing a teammate or opponent). In the avoid task, the participants were asked to push a target button on the opposite side of the probe target as quickly as possible. In the approach task, the target button was on the same side as the probe target. The participants' anxiety levels were manipulated using an electric shock method. Previous studies determined that if a participant has a bias to direct their attention toward the threatening cue, their response times to the probe target will change. We hypothesized that the execution of the avoid task would be more affected by the threatening cue with increased anxiety than that of the approach task.

RESULTS: For both types of task, the perceived level of anxiety, as measured by a visual analog scale questionnaire, significantly increased under threat conditions (random electric shocks) as compared to safe conditions (no electric shocks). The cue stimuli (angry vs. happy) were found to have a significant effect for the approach task, whereas they had no effect in either the safe or threat condition and no interaction effect. Reaction times significantly decreased when the threat cue stimuli were presented on the same side of the probe target than when presented on the opposite side. In contrast, the avoid task had significant effects from the cue stimuli and a significant interaction effect. Reaction times significantly increased when the threat cue stimuli were presented on the same side of the probe target than when presented on the opposite side under the threat condition, but this was not the case under the safe condition.

Discussion & Conclusions:

The results from the approach task were consistent with previous findings, suggesting that threat cues can evoke attentional bias toward threatening stimuli. Results from the avoid task suggest difficulty releasing attention from the threat stimuli when anxiety levels increase. Our findings are likely useful for the development of a method to improve performance under high psychological pressure.

THE EFFECT OF A SUPERVISED 9-WEEK EXERCISE PROGRAM ON EXECUTIVE FUNCTION IN COLLEGE STUDENTS

SCHAERZ, S., ONTKEAN, N., PURKIS, N., ROBDRUP, D., AGUILAR RAMIREZ, D., QUESADA, R., GALLAGHER, D., VOGEL, C.

LETHBRIDGE COLLEGE

INTRODUCTION: Executive function (EF) encompasses a set of cognitive skills that help students plan, prioritize, and manage their academic tasks [1]. Research suggests that exercise can lead to improvements in EF [2]. Our aim was to determine whether a 9-week exercise program improved EF in college students.

METHODS: The study-design consisted of an experimental group (EG: n=15, ♀=8) that participated in a 9-week exercise program (3x50min/week), and a control group (CG: n=16, ♀=5). We collected this data as part of a larger study that also incorporated mental health outcomes. We applied a ANCOVA model (using pre-intervention scores, age, and sex as covariates) to determine between-group post-intervention differences in EF (assessed via Digit Span [3], Stroop Colour-Word [4], and Part B of the Trail Making Test [5]) and VO2max (assessed via Yo-Yo Endurance test [6]) and Pearsons product-moment correlation coefficient to investigate the relationship between VO2max and EF.

RESULTS: After adjusting for sex, age, and pre-intervention scores, post intervention scores for the Digit Span (EG: 26.4±4.7, CG: 27.8±3.3, $p = 0.509$), Stroop Colour-Word (EG: 52.7±15.6, CG: 50.6±14.9, $p=0.240$), Part B of the Trail Making test (EG: 48.1±23.7, CG: 37.0±15.1, $p=0.292$), and VO2max (EG: 35.4±8.6, CG: 39.9±12.5, $p=0.905$) did not significantly differ be-

tween EG and CG. We observed a significant positive association between VO2max and Stroop Colour-Word (r=0.422, p<0.05) and Digit Span scores (r=0.411, p<0.05).

CONCLUSIONS:

The 9-week exercise program did not significantly impact EF or VO2max in our sample of college students. The observed association between VO2max and EF measures (i.e., Stroop Colour-Word, Digit Span) suggests that exercise-induced improvements in EF are likely dependent on concomitant improvements in VO2max.

THE RELATIONSHIP BETWEEN BELIEFS ABOUT ERRORS AND THE IMPACT ON POST-ERROR PERFORMANCE DURING MATCHES

SUDO, R., SEKIYA, H.

HIROSHIMA UNIVERSITY

Introduction

Errors cause various impacts on subsequent plays (Sudo & Sekiya, 2022), such as performance decrements (Harris et al., 2021). However, no study has examined the factors that influence the impact of errors. Therefore, this study investigated the relationship between beliefs about errors and the impact of errors on post-error performance.

Methods

Participants responded to 50 items asking about the impact of errors made according to Sudo & Sekiya (2022) using a 5-point scale (1: never happened to 5: always happened), and 42 items asking about their beliefs about errors made according to Shibahara et al. (2019) using a 5-point scale (1: strongly disagree to 5: strongly agree).

Results

An exploratory factor analysis on the beliefs about errors revealed three factors: negative image, inevitable image, and positive image. The positive image refers to the belief that errors increase motivation. An exploratory factor analysis on the impact of errors revealed five negative-impact factors: performance decrements, confusion, movement deterioration, desire to avoid, and safety-oriented strategy, and one positive-impact factor: beneficial impacts. Cluster analysis on the factor scores for the beliefs about errors revealed five clusters; Cluster 1: high negative, high inevitable, and high positive beliefs about errors (n=65), Cluster 2: low negative, moderate inevitable, and moderate positive beliefs (n=39), Cluster 3: high negative, moderate inevitable, and moderate positive beliefs (n=73), Cluster 4: low negative, high inevitable, and high positive beliefs (n=75), and Cluster 5: low negative, low inevitable, and low positive beliefs (n=15). Cluster 1 experienced moderate negative and positive impacts. Clusters 2 and 4 often experienced positive impacts and rarely negative impacts. Clusters 3 and 5 often experienced negative impacts and rarely positive impacts.

Discussion

Individuals whose beliefs about errors were negative or not inevitable often experienced negative impacts and rarely positive impacts. Individuals whose beliefs about errors were inevitable and positive rarely experienced negative impacts, and often experienced positive impacts. However, individuals whose beliefs about errors were high negative, high inevitable, and high positive experienced moderate negative and positive impacts. In other words, inevitable and positive beliefs about errors may counteract the effect of negative beliefs.

TO JUMP OR NOT TO JUMP – DECISION MAKING IN HIGH-STRESS SITUATIONS

FRÜHAUF, A., WILHELM, M., WACHHOLZ, F., NIEDERMEIER, M., KOPP, M.

UNIVERSITY OF INNSBRUCK

Background:

Decision-making under stress, which is influenced by multiple variables such as affective and behavioral factors, is mostly investigated in controlled laboratory settings with reduced transferability to real-life situations. Therefore, the present project aimed to compare affective, behavioral and decision-making variables between a real-life high-stress situation (bungee jump) and a control condition in physically fit adults.

METHODS: Using a within-subject crossover design, 19 university students (47% female, mean age: 23.0 SD:2.1 years) without prior experience in bungee jumping, completed both a 192m bungee jump and a 1m control jump in a randomized starting order. Decision-making tests (BART, Go/No-Go), affective states and behavioral variables were assessed before and after the jumps. Condition-by-time fully repeated measures analyses of variances were used for the statistical analyses.

RESULTS: Average number of pumps (BART) showed significantly higher values pre and post bungee jump compared to the control jump, p=.044; part.eta-squared:0.21, without showing a significant condition by time interaction p=.511; part.eta-squared:0.02. Accuracy and average reaction time according to the Go/No-Go task, were similar across conditions and time points, p>.116. Pre-action self-efficacy (transfer to the next relevant study task) was significantly higher after the bungee jump compared to the control jump, p=.031; part.eta-squared:0.23. Affective valence showed a significant condition by time interaction, p<.001; part.eta-squared:0.33 with the lowest values immediately before the bungee jump followed by an increase after the bungee jump whereas no changes were seen in the control condition. Arousal did not show a significant condition by time interaction, p=.416; however, it was significantly higher in the bungee jump condition compared to the control jump, p<.001; part.eta-squared:0.60.

Discussion:

Exposure to a real-life high-stress situation as induced by a 192m bungee jump was shown to potentially impact risk-taking but not inhibition and impulsiveness in decision-making. The present study showed heightened arousal and increased affective valence in the bungee jump condition which was not induced by a similar study design by Castellà et al. (2020), who further found divergent results in decision making. Thus, the role of affective states in high-stress situations requires further research. Students were more confident to reach their next study task after performing the bungee jump compared to the control condition. We conclude that high-stress situations could have potential implications for increasing pre-action self-efficacy, although a potential riskier decision-making should be taken into account.

EFFECT OF COACHS POINTING GESTURES AND PLAYERS EXPERTISE ON VISUAL ATTENTION AND MEMORIZATION OF TACTICAL SCENES IN BASKETBALL

BEN CHIKHA, H.1, ZOUDJI, B.1, KHACHAREM, A.1,2

1 LARSH - LABORATOIRE DE RECHERCHE SOCIÉTÉS & HUMANITÉS, UNIVERSITÉ POLYTECHNIQUE HAUTS-DE-FRANCE, VALENCIENNES, FRANCE. 2 UFR SESS-STAPS, PARIS-EAST CRÉTEIL

Introduction

Learning tactics from a static diagram has been shown to increase learning among basketball players, as it is the preferred tool for coaches to convey tactical information (Khacharem et al., 2013). In addition to the verbal presentation, coaches make pointing gestures to direct players' attention to the key elements of paly and to optimize teaching of tactical combination. The aim of this study was to examined the effect coaches' of pointing gestures on the memorization of tactical scenes and whether this effect can be modulated by player experience.

Method

Ninety-six participants (48 expert basketball players and 48 novices) took part in the experiment based on predetermined criteria. They were instructed to watch one of two experimental conditions, in which the coach either described the development of an offensive play system (no-gesture, No-G), or described the same play system while making pointing gestures (with-gesture, W-G). After visualisation, participants were instructed to rate their mental effort and reconstruct the game elements on a sheet of paper. Total fixation duration on the diagrams of play was measured using eye tracking.

Results

The results showed that novice players in the W-G condition achieved higher recall scores, lower investment of mental effort and more fixation time on the diagrams of play than novices in the N-G condition. However, expert players achieved the same recall scores, same investment of mental effort and the same fixation time on the diagrams of play in both experimental condition.

Discussion

The findings revealed that for novice players, incorporating pointing gestures into speech when presenting game information is an effective technique to direct their attention to the game elements mentioned in the speech and improve their performance. Based on the cognitive load theory, learners cognitive resources are limited and attention can only be paid to a part of the incoming information a particular moment. Another explanation is that pointing gestures add a visual modality to the auditory modality (speech), which has a positive effect on learning, as explained by the modality effect. However, experts showed the same results under the two experimental conditions. These players do not need external guidance to learn the tactical knowledge because their prior knowledge provides complete guidance. The results can be explained by the expertise reversal effect, which suggests that an instructional design that is effective for novices can reverse and be ineffective for experts. The results suggest that the inclusion of pointing gestures in the learning material depends on players' level of expertise.

PS-PL03 Tendinopathy – Why does it happen, and can it be prevented?

CAN TENDINOPATHY BE PREVENTED? WHERE ARE WE & WHERE DO WE NEED TO GO?

BAHR, R.

NORWEGIAN SCHOOL OF SPORT SCIENCES, NORWAY

It has been over 25 years since the 4-step injury prevention research model was introduced by van Mechelen et al., to combat the adverse effects of injuries resulting from sports participation. This fundamental model proposes four steps: 1. Identify the extent of the injury problem (incidence/severity), 2. Identify their risk factors and mechanisms, 3. Introduce preventative measures, and 4. Testing their effectiveness. Since then, substantial progress has been made for acute, traumatic injuries, while research on overuse problems like tendinopathy has been lagging.

The two main reasons for this are: 1. That injury surveillance methods mainly have been based a narrow injury definition, requiring time loss from sport, and 2. That only crude measures (e.g. hours of training) have been available to examine the effects of training and competition load.

Development of new methodology based on the Oslo Sports Trauma Research Center Questionnaire on Health Problems (OSTRC-H) has facilitated the capture of all complaints, including overuse complaints that result in frequent exacerbations and are managed with adjustments to training intensity, the typical cause for tendinopathies. Also, new technology like GPS-based systems and purpose-built accelerometers allow for granular capture of load data, e.g. the number and intensity of jumps, runs, accelerations and changes of direction.

Recent prospective studies using this methodology have documented that in several sports, previously thought to represent a low risk of injury, as many as 30-50% of all athletes report an injury problem at any given time. Importantly, depending on the sport, the burden of overuse problems like tendinopathy frequently far exceeds that of acute, traumatic injuries or that of illness. In this talk, prof Bahr will share data from prospective studies on diverse athlete populations, from youth athletes to the absolute elite, including unpublished data based on >35 000 weekly reports from Norwegian Olympic and Paralympic athletes.

There is ample clinical experience to document that specific loading patterns lead to an increased risk for specific injuries, as evidenced by the diagnostic labels established for some of these, such as jumper's knee, golf elbow, tennis elbow and runner's knee. What is not clear is why some runners develop runner's knee and some volleyball players jumper's knee - while others do not.

To better understand what causes tendinopathy (and inform prevention programs), there is a need for large, prospective studies capturing both relevant load and complete injury data, as well as athlete characteristics. As an example, Prof Bahr will present results from one such study. The aim of his lecture is to inspire future research to untangle the question: Who gets tendinopathy - and how and why? This is needed to advance to stages 3 and 4 in the van Mechelen model.

TENDON PHYSIOLOGY AND PATHOPHYSIOLOGY IN EXERCISE AND PHYSICAL TRAINING

KJAER, M.

BISPEBJERG HOSPITAL

Human tendon consists predominantly of collagen that has a general dynamic turnover rate during growth, but after adolescence (~17 yrs) only a minor fraction of this is turned over regularly (around 5%) and most fibril and fascicular structures (around 95%) remain stable. Collagen synthesis can be stimulated by physical exercise as well as by growth hormone or insulin-like growth factor I, and conversely collagen synthesis is inhibited by physical inactivity (e.g. 14 days). The drop in collagen synthesis with inactivity cannot be counteracted by blocking inflammation.

The dynamic part of the tendon matrix seems to be under circadian control, and with mechanical overloading, an accumulation of water - predominantly between fascicles - is observed and this contributes to tendon swelling in tendinopathy. Along with this, heavy mechanical loading and overloading of tendon results in increased tendon blood flow, as well as in increased pain and nociceptive signaling over the first months with subjective symptoms. In the later and more chronic phase of tendinopathy, stimulation of collagen synthesis and new matrix formation is observed leading to structural changes of the matrix in tendon.

The regulation of tendon matrix quality control is poorly understood, but evidence that autophagy regulates tendon homeostasis by controlling procollagen is documented. Further it has been demonstrated that cell-cell communication in tendon tissue is facilitated by extracellular vesicles - including exosomes - that are released by tendon fibroblasts, and that this control of communication is under circadian control. Further, exosomes derived from tendon fibroblasts differ

markedly in protein content from those derived from either myoblasts or muscle fibroblasts. This suggests a role for tendon fibroblast exosomes in tendon fibrosis.

Resistance training of a heavy or moderate nature is documented to be the preferable treatment towards tendinopathy, but exactly what molecular and cellular mechanisms are behind this is not described, but it is observed that individuals with chronic tendinopathy have had an increased matrix turnover for several years prior to the current tendinopathy, and this remains to be explained.

Biomechanics

CHARACTERISTICS OF THE MECHANICAL ENERGY CHANGES DURING THE SINGLE LEG JUMP MOVEMENT IN SPEED SKATERS

YUDA, J.1, YOKOZAWA, T.2

1 JAPAN WOMENS COLLEGE OF PHYSICAL EDUCATION, 2 JAPAN INSTITUTE OF SPORT SCIENCES

INTRODUCTION: There are some imitating motions used in dry land training to develop the push-off movement required in speed skating (1). Particularly, the single leg jump movement is not only a dry land training motion but also a useful test for evaluating the power exertion needed in the lower limb. This study identified the characteristics of the mechanical energy changes during the single leg jump movement in speed skaters.

METHODS: This study enrolled 10 junior (17.2 ± 1.0 y) and 9 senior (21.8 ± 1.4 y) elite male Japanese skaters providing informed consent, and who had participated in the 500-m race of a domestic speed skating competition in Japan or a time trial. The skaters performed single leg skate jump test on a floor that required maximal effort to reach the maximal height. Two synchronized high-speed video cameras (250 fps) were used to record their performance using a direct linear transformation technique. Ground reaction forces (GRF) of the right support leg were determined using the force platform (500 Hz). The GRF and three-dimensional coordinates of the segment endpoints were determined to calculate the kinetic variables of the right support leg by using an inverse dynamics approach. Parameters related to mechanical energy of the right support leg were calculated to identify the energetic characteristics, and they were normalized from onset of push to take-off time.

RESULTS: Although goal time of the 500-m race for the senior group (36s 45 ± 0s 73) was significantly faster than that of the junior group (37s 96 ± 0s 65, $p < 0.001$), no significant difference in the maximal height of center of mass during the single leg junp movement was observed between the two groups. While mechanical energies of the thigh and shank slightly increased during the mid-phase of the single leg junp movement in both groups, the mechanical energies of the junior group were greater than those of the senior group. Significant differences were observed in the values of normalized time at 60, 70, and 80-% ($p < 0.05$-0.01). During the final phase of the single leg junp movement, mechanical energies of the thigh and shank greatly increased in both groups, and the mechanical energy of the junior group during take-off was greater than that of the senior group.

CONCLUSION: Results in this study indicate that speed skaters with high performance avoid increasing the mechanical energies of the thigh and shank of their support leg during the mid-phase of the single leg jump movement. Single leg skate jump movement could be a useful test to identify an effective technique in the support leg extension of speed skaters.

THE IMPROVEMENT OF FREESTYLE STROKE IN PRESCHOOLERS BY THE STRUCTURED PROGRAM

SATO, K.

INTERNATIONAL CHRISTIAN UNIVERSITY

INTRODUCTION: There have been few studies of the effective swimming programs for infants. In preschool, the students are mostly free to play and walk in the pool. Also, those children can perform the motion of jumping and rock-paper-scissors in underwater. However, practice of breathing in water that leads to swim is hardly held (Fujita 2017). Therefore, in this research, we investigated the effects of the skill practice for freestyle in preschoolers, through our programs.

METHODS: The participants in this study were 14 children (8 boys & 6 girls, Age: 4.1±0.8 yrs old, Height: 107.3±7.6cm, Body mass:18.1±3.0kg, Swimming history 1.3±0.9 yrs). We designed originally the structured swimming program for improving skill level of preschoolers. We instructed the motions during 30-minute practice sessions at twice in two days. As for the measurement method, the motions were measured by two video cameras from poolside and underwater. The analyzing parameters were as follows: the swimming speeds, and the numbers of stroking & kicking times in freestyle. In the analysis, one way ANOVA was used to examine the effects of the structured program for improving swimming skill.

RESULTS: The significant effects were obtained in the freestyle swimming speed ($F(2.39) = 43.3$, $P=0.001$), the number of times freestyle stroke ($F(3.39) = 9.1$, $P=0.001$) by our practice program. On the other hands, the freestyle kicking times did not change through program.

CONCLUSION: It could be concluded that the motions of the freestyle could be improved effectively by our structured swimming program in preschoolers.

ANALYSES OF THE BILATERAL LOWER EXTREMITIES OF FEMALE BASKETBALL PLAYERS: A PILOT STUDY

TSENG, P.C., HSIAO, H.W., LEE, H.J.

NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: Female basketball players have the highest probability of lower limb injury, and the risk of injury is more significant than male basketball players [1]. Since basketball is a sport with unilateral dominance, it may cause asymmetry in strength and balance on landing between the dominant side and the non-dominant side of the lower limb. Therefore, the purpose of this study was to discuss the bilateral differences in lower limb strength and dynamic posture stability of female basketball players during single-leg drop jump landing by reactive strength index (RSI) and time to stabilization (TTS).

METHODS: There were 7 Division I female basketball athletes recruited in this study. Subjects had no severe head and lower extremity injuries or surgery within half a year. Within three months before the start of the experiment, subjects are without acute lower extremity injuries. During the experiment, kinetics data were collected by a Kistler force plate at 1000Hz and were used for data analysis during the single leg drop jump, including Jump height, RSI, Impact force, and TTS.

RESULTS: The results of this study show that the dominant side RSI is significantly greater than the non-dominant side ($p<.05$) during the single leg drop jump, but there were no significant differences in jumping height and landing impact force. The dominant side of ML-TTS was significantly shorter than the non-dominant side ($p<.05$), but there was no significant difference between AP-TTS and V-TTS.

CONCLUSION: Jumping injuries are common in basketball, especially when landing on a single leg. However, there was no significant difference in jumping height between the dominant and non-dominant sides. The difference in RSI showed that the dominant side could reach the same jump height with a shorter movement time, which may be related to specific movements of basketball patterns, such as unilateral jumping.

The symmetry of the lower limbs helps reduce the risk of injury [2]. Landing in the ML direction is a complex movement for humans, and poor dynamic postural stability is a known risk factor for ACL injury in athletes. Therefore, the difference in the RSI and TTS-ML between the dominant and non-dominant sides of the womens basketball players in Division I may be one of the potential injury risks. There are currently only seven subjects in this study, and the experiment will continue in the future. After enough subjects, the results will be more convincing.

BIOMECHANICAL CHARACTERISTICS AND ANECDOTAL REPORTS OF LOW BACK PAIN DURING ACTIVITIES OF DAILY LIVING IN INDIVIDUALS WITH CENTRAL OBESITY: A PILOT FEASIBILITY STUDY PROTOCOL

NAHORNA, A., BAUR, H.

BERN UNIVERSITY OF APPLIED SCIENCES

INTRODUCTION: Based on limited existing knowledge on the description and evaluation of the movement patterns of people with low back pain and central obesity, a study is proposed that aims at evaluating the feasibility to quantify whole-body motion during activities of daily living in individuals with central obesity.

METHODS: 20 individuals with central obesity will be invited for a single visit to the Bern Movement Lab at Bern University of Applied Sciences. Participants will be equipped with 39 retro-reflective skin markers according to the Plug-in Gait full body configuration. They will be asked to perform five repetitions of level walking, chair rising and object lifting and to stand and sit upright for a duration of 10 seconds. Kinematics will be recorded using a 16-camera motion capture system (Vicon, Oxford, UK; sample rate 200 Hz). Ground reaction forces and trunk/thigh muscle activity (PICO®, CometaSystems, Milano, IT) will be measured using two embedded force plates (AMTI, Watertown, MA, USA). Motion and force data will be processed using the Nexus software (Vicon, Oxford, UK). This includes marker reconstruction, filtering of marker trajectories, setting of relevant temporal events, as well as joint angle and moment calculation based on the Plug-in Gait full body model. Body composition will be assessed and processed using the body composition analyzer Tanita (Tanita Europe GmbH, MC 780 MA P, Japan). Low back pain status within the preceding 6 months will be assessed using a short self-developed questionnaire. Comparative data from individuals without central obesity will be taken from a previous study (KEK Bern Project ID: 2017-00820). Inclusion criteria are aged between 18-60 years, central obesity (waist–hip ratio: ≥ 0.85 in females, ≥ 0.90 in males; waist-to-height ratio: ≥ 0.50) (1,2), ability to perform the required tasks. Exclusion criteria are pathologies, diseases, injuries, surgeries or pain limiting activities of daily living like normal movements of the spine and lower extremities, known current pregnancy or breastfeeding mothers, psychological impairments to follow instructions, any comorbidities or circumstances limiting lifting capabilities.

RESULTS: -

CONCLUSION: Obtained results will be generated a pilot dataset that can serve as a basis in the planning of a larger study.

COMPARISON OF RATE OF TORQUE DEVELOPMENT DURING SINGLE-LEG AND DOUBLE-LEG WEIGHTLIFTING DERIVATIVES

HAYASHI, R.1, YOSHIDA, T.2

1: GIFU UNIVERSITY, 2: JAPAN INSTITUTE OF SPORTS SCIENCE

INTRODUCTION: Weightlifting derivatives such as hang power clean (HPC) are resistance training used to improve explosive strength and power development in the lower extremities (1). System-level rate force of development (RFD) during the single-leg hang power clean (SHPC) has been found to be greater than double-leg hang power clean (DHPC) when using 60% and 90% of the estimated one repetition maximum (1RM) (1). System-level and joint-level kinetic characteristics may not necessarily correspond (3). The purpose of this study was to compare the rate of torque development (RTD) of the three lower extremity joints during SHPC and DHPC.

METHODS: Ten male track and field athletes performed the SHPC and DHPC using external loads of 30%, 60%, and 90% of 1RM. The 1RMs in SHPC and DHPC were measured separately, and the external loads at 30%, 60%, and 90% of the 1RM used were determined based on the different 1RMs in SHPC and DHPC. We calculated the joint moment of three lower extremity joints of the SHPC and DHPC, using a motion capture system (250 Hz) and force platforms (1,000 Hz). The RTD was calculated as delta joint moment/delta time (0.004 s). Maximum RTD during the concentric phase was calculated and compared between SHPC and DHPC for each joint. Two-way ANOVAs (2 exercises, 3 loads) were used for comparison.

RESULTS: The analysis showed no significant interactions for all joints. There was a significant main effect of the load factor on the hip joint (extension-flexion) ($p < 0.05$), but the results of the post-test showed no significant difference. A significant main effect was found for the exercise factor at the hip joint (abduction-adduction) ($p < 0.05$); the RTD during the SHPC was shown to be significantly greater than the DHPC for all external loads ($p < 0.05$). In addition, a significant main effect was shown in the load factor at the ankle joint (planter flexion-dorsiflexion) ($p < 0.05$); the RTD of 90% 1RM was shown to be significantly greater than the 30% 1RM for both HPCs ($p < 0.05$).

CONCLUSION: The novelty of the study findings is that the RTD of the lower extremity does not differ between SHPC and DHPC in the flexion-extension axis at all loads, whereas the RTD of SHPC is greater than that of DHPC in the abduction-adduction axis at the hip, regardless of the load. In addition, the RTD of the ankle joint may be load-dependent for both SHPC and DHPC. These results suggest that when using heavy external loads, the RTD around the flexion-extension axis of the three lower extremity joints is similar for SHPC and DHPC, but the RTD around the hip abduction axis is greater for SHPC than for DHPC.

STROKE IMBALANCE OF CHINA ELITE SHORT-DISTANCE FREESTYLE ATHLETES

SHANG, M.

BEIJING SPORT UNIVERSITY

INTRODUCTION: In freestyle, the bilateral imbalance of stroke arm restricts the improvement of swimming skills, which not only destroys the streamline of the body and makes athletes lose their best mechanical advantage, but also brings injuries. Therefore, exploring the causes of bilateral imbalance in freestyle and how to evaluate and correct training are the contents that cannot be ignored in swimming training.

METHODS: In this study, the problem of bilateral imbalance in short-distance freestyle of five elite women in China was explored by inertial measurement unit. After the standard warm-up procedure of daily training, the 15× 200m freestyle test was carried out, and the athletes speed was required to be kept at 80-90% of the maximum heart rate (monitored by polar), and the contribution rate (ICV) of bilateral movement speed was evaluated by inertial measurement unit (Tritonwear, Canada). Using Excel software to explore the swimming data output by the swimming inertial measurement unit, evaluate and record the left and right ICV, so as to obtain the speed contribution value of the right upper limb and the left upper limb in each cycle. The data is corrected by calculating the average speed, and the speed contribution of each swimmers two upper limbs is estimated. At the same time, the swimming speed and the athletes heart rate (Polar) are captured.

Using Excel software to explore the swimming data output by the swimming inertial measurement unit, evaluate and record the left and right ICV, so as to obtain the speed contribution value of the right upper limb and the left upper limb in each cycle.

RESULTS: The data is corrected by calculating the average speed, and the speed contribution of each swimmers two upper limbs is estimated. At the same time, the swimming speed and the athletes heart rate (Polar) are captured.Evaluating two upper limbs is called index (SI)(Robinson, Herzog, &Nigg, 1987):

SI(%)=(X_d-X_nd)/(1/2(X_d+X_nd))×100

Where Xd and Xnd are the average values of peak forces recorded by dominant upper limbs and non-dominant upper limbs, respectively. As recommended by the author, 10% < SI< 10% means symmetry, while Si < 10% and SI>10% means asymmetry.Where Xd and Xnd are the average values of peak forces recorded by dominant upper limbs and non-dominant upper limbs, respectively. As recommended by the author, 10% < SI < 10% means symmetry, while SI < 10% and SI>10% means asymmetry. Left and right ICV Mean±SD and (SI=Mean±SD): 0.05±0.17m/s（SI=2%±9%）、0.16±0.14 m/s（SI=5%±5%）、0.04±0.17 m/s（SI=2%±6%）、0.02±0.37 m/s（SI=3%±4%）、0.02±0.37 m/s(SI=6%±21%).

CONCLUSION: The research and analysis show that: 1. The imbalance of swimmers strength, posture, stroke efficiency, joint mobility and stroke path constitutes the main cause of the bilateral imbalance of freestyle; 2. The female short-distance freestyle athletes did not appear unbalanced expansion in the process of gradual fatigue; 3. There are two female short-distance freestyle athletes in the research object, and their asymmetry is above 10%.; 4. Freestyle breathing does not seem to affect the size of athletes bilateral imbalance; 5. The application of swimming special inertial measurement unit and wearable equipment is an effective means to evaluate the bilateral imbalance of freestyle at present.

EFFECT OF FOUR-WEEK PLYOMETRIC TRAINING ON DELAYING MUSCLE FATIGUE IN ROWERS

CHANG, C.H.1, CHEN, C.Y.2, YEH, H.C.1, WU, C.Y.1, HO, C.A.1, HO, C.S.

1 NATIONAL TAIWAN SPORT UNIVERSITY; 2 NATIONAL TAIPEI UNIVERSITY OF BUSINESS

INTRODUCTION: Rowing is an Olympic sport based on distance, which is characterized by repetitive muscular cycles and high demands on several components of physical fitness, such as cardiorespiratory endurance, muscular fitness, and maximal strength (1,2). In many exercises training, plyometric training (PT) is an effective way to improve muscle strength and power, even in a short period of time (<10 weeks). It is a type of physical training that can be used to improve the stretch-shortening cycle (3,4). However, only a few studies in the past have demonstrated that PT can increase rowing power and related strength parameters in rowers. There is no clear evidence to support whether PT can delay the timing of muscle fatigue in rowers during time trials. The purpose of this study was to investigate the effects of PT on delaying muscle fatigue in rowers after 4-weeks of training.

METHODS: Twelve male rowers were randomly assigned to the PT group (n=6) and the general strength training group (GST, n=6) and trained for 4-weeks at the same time. A 2000m rowing time trial was conducted before and after the training session. The EMG signals of the vastus medialis of the dominant limb were collected by surface electromyography during rowing time trials. The EMG signals were used to calculate the slope of the median frequency (MDF) to quantify the fatigue rate (5). We calculated the slope using the MDF of each 500th-meter (e.g., 0km, 0.5km, 1km, 1.5km, and 2km) EMG signal (6). Two-way ANOVAs were used to compare the difference in fatigue rate between the two training methods.

RESULTS: The results revealed that in the pre-test 2000m time trial (before four weeks of training), the MDF of vastus medialis in GST decreased from 103.49±8.77 Hz to 87.69±4.06Hz, and its fatigue rate was -7.51±2.98%. The MDF of vastus medialis in PT decreased from 113.81±19.14Hz to 95.72±14.68Hz, and its fatigue rate was -7.56±2.71%. In the post-test 2000m time trial (after four weeks of training), the MDF of vastus medialis in GST decreased from 98.51±5.32Hz decreased to 85.81±5.02Hz, and its fatigue rate was -6.14±4.12%; the MDF of vastus medialis of PT decreased from 104.72±16.38 Hz to 95.88±14.90 Hz, and its fatigue rate was -3.13±0.95%. ANOVA results showed that different training methods significantly interacted with fatigue rates (P=0.046). In PT, the fatigue rate was significantly reduced between pre- and post-test (P=0.006); however, in GST, the fatigue rate did not reach a significant reduction between pre- and post-test (P=0.211).

CONCLUSION: Rowing is a repetitive muscular cycling movement and a highly physiologically demanding competitive sport. The quadriceps muscle group experienced more than 220 repetitions of the rowing cycle during the 2000m time trial (1). How to effectively delay the generation of fatigue is critical. According to the results, four weeks of plyometric training can significantly reduce the fatigue rate of the rowing time trial compared with the general strength training.

THE EFFECTS OF FUNCTIONAL MOVEMENT TRAINING ON BAT-HEAD SPEED, BATTING KINEMATICS, AND FUNCTIONAL MOVEMENT SCREEN IN ADOLESCENT BASEBALL PLAYERS

KUO, Y.L., CHENG, H.S.

NATIONAL CHENG KUNG UNIVERSITY

INTRODUCTION: Functional movement screening (FMS) and training have been used to assess and improve the ability of core control and fundamental movement patterns. Poor fundamental movement patterns may influence sports performance and increase injury risk in athletes. The effects of functional movement training in adolescents is not fully understood, and no study included kinematic measurement of the lumbopelvic-hip complex during sports activity. The aim of this study was to investigate the effects of 8-week functional movement training on bat-head speed, batting kinematics, and FMS score in adolescent baseball players.

METHODS: Twenty-six junior high school baseball players with the FMS score less than or equal to 14 were randomly assigned to either the experimental group or the control group. The experimental group performed functional movement training twice a week for 8 weeks while the control group performed routine training as usual. Outcomes were measured before and after the intervention period, including the bat-head speed, the rotation angles and velocities of the pivot hip, pelvis and lumbar spine, the inter-joint coordination, and the FMS score. Repeated-measures analysis of variance and chi-square tests were conducted to determine the effects of functional movement training on outcome measures.

RESULTS: The experimental group significantly improved the bat-head speed (95% confidence interval [CI] of mean difference 2.82 to 10.08, p=0.002) and FMS score (95% CI of mean difference 1.37 to 3.24, $p < 0.001$) than the control group after training; however, no significant changes were found in most kinematic data at the events of foot contact and ball contact during baseball batting ($p<0.05$). More participants in the control group than those in the experimental group changed their pivot hip and lumbar spine coordination pattern during the 3rd (51%-76%) and 4th (76%-100%) sub-phases of normalized baseball batting time after training; however, no consistent change pattern could be identified.

CONCLUSION: Eight-week functional movement training improves bat-head speed and FMS score but has limited effects on kinematics and inter-joint coordination in the lumbopelvic-hip complex of adolescent baseball players.

DIFFERENT EFFECTS OF KNEE BRACE AND KINESIO TAPING ON THE BIOMECHANICS OF LOWER EXTREMITIES ON PATELLOFEMORAL PAIN SYNDROME SUBJECTS DURING CYCLING

LIN, H.T., YANG, J.F.

KAOHSIUNG MEDICAL UNIVERSITY

INTRODUCTION: Cycling has relatively less load on the lower limbs, and it is also the first choice for many patients with knee injuries for rehabilitation after injury (1). However, long-term wrong riding posture may lead to other injuries (2). Knee brace or taping are often used as adjuvant therapy to relieve pain for Patellofemoral Pain Syndrome (PFPS) subjects. The purpose of this study was to investigate whether the intervention of knee brace and Kinesiology® Tape can relieve the pain of PFPS patients when riding, and EMG responses after the intervention.

METHODS: In this study, 19 females with 20-50 ages with riding experience were recruited including 10 healthy subjects and 9 subjects with PFPS. The riding resistance is 80W and 100W, the speed was fixed at 80 rpm, and the riding was for 4 minutes. The motion analysis system (Qualisys□, Sweden) was used to investigate the kinematics of the lower extremity joints and the electromyography system (Delsys□, USA) was used to detect the muscle contraction of the gluteus medius (GM), vastus medial oblique (VM), vastus lateral (VL), and rectus femoris (RF) during cycling.

RESULTS: The results found that the subjects feel pain were decreased, the abduction-adduction range of motion of the knee joint was decreased, the flexion-extension range of motion was increased, and the internal-external rotation was decreased after both of the interventions. Moreover, after the interventions, the maximum activation of muscles was all increased, the time point of maximum activation and the onset time was earlier, the total activation time was increased, and the iEMG was larger.

CONCLUSION: Wearing a knee brace or taping when riding can reduce the abduction or rotation angle of the lower limb joints, and can also activate the quadriceps and gluteus medius. By stabilizing the joints and increasing muscle activation, the symptoms of knee pain can be reduced during cycling.

NURSES' PHYSICAL BURDEN DURING REPOSITIONING OF BEDRIDDEN PATIENTS

GRÄF, J., ARGUBI-WOLLESEN, A., OTTO, A.K., WOLLESEN, B., MATTES, K.

UNIVERSITY OF HAMBURG

INTRODUCTION: Everyday nursing work is characterized to a large extent of heavy lifting, carrying, and standing activities, such as repositioning, transporting or mobilizing bedridden patients. The resulting forced postures pose a risk for the development of musculoskeletal complaints (Feyer et al., 2000; Nöllenheidt and Brenscheidt, 2013). The study focuses on the physical strain of the nurses during the transfer of bedridden persons to analyze phases of increased physical load. This study aims to answer the question which upper body posture is adopted during the repositioning process and in which sequences ergonomically poor upper body postures are being adopted.

METHODS: In a crossover study design, two trained nurses performed the 30° positioning with a total of N = 15 participants. The body angles of the nurses were measured via direct kinemetry for extension/flexion, rotation, and lateral flexion of the trunk (Xsens MVN 2018) for the phase of preparation with positioning to the edge of the bed until lateral positioning of the participant (sequence one), as well as the positioning of the assistive device in the back of the participant until final positioning (sequence two). In addition, an SPM (Statistical Parametric Mapping) analysis was performed to determine the change in upper body posture over time.

RESULTS: Both nurses showed a strongly pronounced upper body flexion during the whole positioning process. Furthermore, the second nurse showed strongly pronounced upper body lateral flexion during the start and the end of the positioning process, as well as strongly pronounced upper body rotation during the second sequence. SPM analysis showed significant differences between the two nurses in flexion in sequence one (51-100%; $p < 0.001$), sequence two (0-31%; $p < 0.001$), lateral flexion in sequence one (1-30%; $p = 0.001$), and rotation in sequence one (55-87%; $p = 0.003$).

CONCLUSION: In view of the increasing workload in the nursing profession due to the shortage of skilled workers and the rising number of people in need of care, physical relief must be established for prevention. Particularly in the second sequence of the positioning process, long-lasting extreme upper body postures defined according to the German guidelines of ergonomic posture (DIN EN 1005-4) were found in both nurses, which require special support to prevent nurses' physical overload.

EFFECT OF DIFFERENT BICYCLE WHEELSET DESIGNS ON AERODYNAMIC DRAG

CHEN, C.H.1, LEE, C.Y.1, WANG, H.H.2, LIN, Z.J.2, TSAI, W.C.3, TSAI, P.C.1

1 NATIONAL PINGTUNG UNIVERSITY OF SCIENCE AND TECHNOLOGY, 2 NATIONAL TAIWAN SPORT UNIVERSITY, 3 KAOHSIUNG ARMED FORCES GENERAL HOSPITAL ZUOYING BRANCH.

INTRODUCTION: During a bicycle competition, wheelsets account for 10-15% of total aerodynamic drag. Therefore, it is still possible to decrease the aerodynamic drag produced by the wheelset by improving its design. The aim of this study was to investigate the aerodynamic drag resulting from different wheelset designs.

METHODS: A computational fluid dynamics (CFD) simulation package, FLUENT 2019 R2 version, as well as the k-ε model with wall function and k-ω SST model have been implemented for simulation. Herein, a low-profile wheelset (diameter: 667mm, rim height: 388mm) and a high-profile wheelset (diameter: 667mm, rim height: 588mm) were used for simulation under multiple wind directions which includes parallel to the wheelset, 20 degrees relative to the wheelsets' direction. In addition, wind velocities simulated in this study ranges from 9.72 m/s (35 km/hr) to 15.27 m/s (55 km/hr).

RESULTS: Based on the results, wheel rim, hubs, and spokes accounted for 60%, 20%, and 20% of the total aerodynamic drag produced by the wheelset, respectively. Furthermore, larger wind direction relative to the wheelset increased the percentage of aerodynamic drag produced by the rim (up to 80%). Finally, high-profile wheelset has a 40% higher aerodynamic drag compared to the low-profile wheelset.

CONCLUSION: Among the three components, the wheel rim produced the highest aerodynamic drag. However, by improving the streamlined shape of the hub and spoke, it is able to reduce aerodynamic drag in a smaller wind direction relative to the wheelset. Cyclists are recommended to choose a wheelset based on wind direction to minimize the resistance from the wind.

THE INFLUENCE OF CARRY ON CLUB LENGTH AND LOFT ANGLE IN COLLEGE GOLFERS

KASHIWAGI, Y.1, HIRANO, T.2, WADA, T.2, SHIMATANI, S.3, FUNATO, K.2

1: SENSHU UNIVERSITY INSTITUTE OF SPORT, KANAGAWA JAPAN 2: KOKUSHIKAN UNIVERSITY, TOKYO, JAPAN; 3: KANAGAWA UNIVERSITY, KANAGAWA, JAPAN.

INTRODUCTION: Golfers hit distance differently depending on the loft angle and club length of iron club sets. Previous research have reported that carry is affected by loft angle by 80% and by club length by 20% （Tutelman D.2016）, but the influence of loft angle and club length on the actual human swing action is unknown. The purpose of this study was to clarify the effects of loft angle and club length on carry using single-length clubs and single-loft angle clubs in college student golfers.

METHODS: The subjects were eighteen right-handed college male golfers (age: 20.7 ± 1.4 years; height: 174.3 ± 4.0 cm; body mass: 69.6 ± 9.4 kg; Best score: 70.1 ± 3.9). The special club settings were a 37-inch single-length club with a loft angle of 26°to 46°and a single-loft club with a loft angle of 26° and a 35-inch to 37.5-inch loft angle. Subjects obtained five swings data using their own iron golf clubs and specially configured single-length and single-lofted clubs. Swing data was measured using the distance trajectory tracking system Trackman system. Ground reaction force and kinematic data during the swing were simultaneously acquired by motion capture system (VICON) to compare the three club conditions.

RESULTS: The carry of the single-length and normal clubs increased with decreasing loft angle, with an overall difference of 6.5 ± 5.9 yrds(%Diff.4.2%). The carry Gap was 12.1 ± 2.4 yrd for the normal clubs and 10.1 ± 3.8 yrd for the single-length clubs, with no statistically significant difference. On the other hand, the single-lofted clubs shows a difference of about 15 yards in the 2.5 inch range of club length variation. Compared to the normal clubs, the carry difference decreased with increasing club length, and the carry Gap was greater for the shorter clubs and decreased with increasing club length. The peak ground reaction force during the swing did not change significantly. Thus, it was shown that golfers might be adjusting their distances according to club length and loft angle.

CONCLUSION: The loft angle had a greater influence on iron club distance than club length, suggesting that a single-length club is an effective option for golfers to accurately distinguish distance.

LOADED COUNTERMOVEMENT JUMP EXERCISE USING ELASTIC BANDS POTENTIATES SUBSEQUENT JUMP PERFORMANCE FOLLOWING A COMPREHENSIVE TASK-SPECIFIC WARM-UP

MINA, M.A.1, BLAZEVICH, A.J.2, TSATALAS, T.3, GIAKAS, G.3, VAN ENIS, A.J.1, KOKKOTIS, C.4, SIDERIS, V.5, KAY, A.D.6

1: UOD , 2: ECU , 3: UOT , 4: D.U.TH , 5: ASPETAR , 6: UON

INTRODUCTION: Performing voluntary muscle actions using elastic bands (EB) to precondition the muscle in combination with free-weight (FW) resistance can alter the loading characteristics of these actions to impose a greater mechanical stimulus and increase subsequent performance [1]. Whilst these actions can precondition the neuromuscular system, the limited warm-up commonly utilised in these studies [2] could invalidate the findings of potentiation often reported. Thus, the impact of loaded countermovement jumps using elastic bands on subsequent jump performance requires further investigation. The aim of the present study was to examine the influence of EB resistance following a comprehensive warm-up on subsequent countermovement jump (CMJ) performance.

METHODS: Fifteen active men (age = 21.7±1.1 y, height = 1.8±0.1 m, mass = 77.6±2.6 kg) volunteered for the study. On two separate occasions, following a comprehensive warm-up consisting of 5 min cycling, 10 continuous unloaded squats, 5

continuous CMJs at ~70% of maximum, then maximal jumps every 30 s until 3 jumps were within 3% of maximum jump height, participants performed 5 repetitions of either EB- or FW-loaded CMJs at 50% 1-RM (35% of load generated from elastic resistance during EB). CMJs were then performed 30 s, 4 min, 8 min, and 12 min later, with jump height and electromyograms (EMG) of the vastus lateralis (VL), vastus medialis (VM), gluteus maximus (Glut) and gastrocnemius medialis (GM) recorded.

RESULTS: Compared to baseline, no significant ($P \geq 0.05$) changes in CMJ height (0.3-2.7%) or EMG activity (VL = 0.6-7.1%; VM = 0.8-1.6%; Glut = 3.1-8.7%; GM = 0.6-6.4%) were observed in the FW condition. Significant increases in CMJ height (4.6-8.0%) and peak concentric VL EMG activity (10.3-18.8%) were found at 30 s and 4 min in the EB condition; no changes in jump height (0.3-0.9%) or EMG activity (VL = 6.0-7.9%; VM = 2.1-4.4%; Glut = 3.2-5.3%; GM = 1.8-7.1%) were found at 8 min or 12 min.

CONCLUSION: The lack of change in CMJ performance in the FW condition is consistent with previous research [1] and indicative that the comprehensive warm-up induced significant potentiation that subsequent FW contractions provided no further improvements. However, the further improvements in CMJ height in the EB condition at 30 s and 4 min, associated with increases in peak vastus lateralis (VL) concentric EMG activity, is indicative of further potentiation through alteration of the motor control strategy to improve jump performance. These data suggest the use of elastic resistance may provide a superior warm-up protocol for athletes to provide short-term improvements in strength and power performance under some conditions.

MUSCLE FIBER CONDUCTION VELOCITY AND SELECTED BIOMOTOR ABILITIES IN SOCCER PLAYERS

KURZ, E., PRÖGER, S., GIZZI, L., SCHWESIG, R., DELANK, K.S., BARTELS, T.

MARTIN-LUTHER-UNIVERSITY HALLE-WITTENBERG

INTRODUCTION: Higher muscle fiber conduction velocities (CV) were related to the training status. Within trained participants, sprinters showed higher CV than endurance runners. Based on the muscle fiber CV, the cross-section of the muscle fibers can be estimated. Muscle fibers with a larger cross-sectional area would suggest a higher distribution of type II (fast-twitch) fibers. The aim of this study was to examine the selective influences of muscle fiber CV on strength, speed, and endurance test results in soccer players.

METHODS: Sixteen professional male soccer players (age: 17-29 years, BMI: 20-25 kg/m²) participated in this cross-sectional study. Muscle fiber CV of the vastus lateralis muscle was recorded in monopolar mode (EMG-USB2+, OT Bioelettronica, sampling rate: 2048/s) using a linear electrode array (ELSCH004, Spes Medica) concurrently with the isometric force (SM-2000N, Forza, gain: 200). Linear sprinting time was measured indoors with photoelectric timing gates at 10 meters (best of two trials). Endurance performance was determined via an incremental test on a treadmill (Saturn, h/p/cosmos) using a gas analyzer (Metalyzer 3B, Cortex). All tests were performed at the beginning of the pre-season period. The maximum voluntary torque (MVT) of the knee extensors and the maximum oxygen uptake (VO2max) were normalized to athletes' body mass. Athletes were divided into "slower" and "faster" groups according to their vastus lateralis muscle fiber CV outcome using the median split method. Differences between groups were estimated using Student's unpaired t tests and effect sizes (d), respectively.

RESULTS: The lower CV group revealed on average similar MVT (4.0 Nm/kg) as compared to the higher CV group (4.1 Nm/kg, $t(14) = -0.29$, $d = -0.15$). Likewise, the groups did not differ in their sprinting times (either: 1.8 s, $t(14) = -0.08$, $d = -0.04$). There was a moderate effect of the muscle fiber CV ($t(14) = -1.16$, $d = -0.58$), with the higher CV group demonstrating higher VO2max (55.6 ml/min/kg) compared to the lower CV group (53.1 ml/min/kg).

CONCLUSION: Soccer players with lower muscle fiber CV at the vastus lateralis muscle are equally able to generate maximum knee extensor torque and linear sprint over 10 m as their counterparts with higher muscle fiber CV. However, they appear to show a higher endurance capacity. In turn, these findings confirm that in soccer players with higher muscle fiber CV and thus a larger fast-twitch fiber proportion the endurance capacity is not adversely affected.

RELATIONSHIP BETWEEN LOWER LIMB AND TRUNK ANGLES DURING THE ROWING MOTION AND MUSCLE STRENGTH IN HIGH-SCHOOL CANOE SPRINT ATHLETES

NAKAGAWA, K., HAMADA, K., OKAZAKI, S.

TAKASAKI UNIVERSITY OF HEALTH AND WELFARE / GUNMA UNIVERSITY HOSPITAL / FUJIOKA GENERAL HOSPITAL

INTRODUCTION: In this study, we investigated the relationship between motion analysis results and trunk and lower limb muscle strength measurements in Japanese high-school students. We hope that this will serve as a starting point for future feedback to athletes based on motion analysis results and physical function results.

METHODS: The subjects were eight high-school canoe sprint athletes who primarily compete in kayaking and had both motion analysis and physical function test results (mean age: 15.8 ± 0.6 years, five males and three females).

During motion analysis, an inertial measurement unit, myoMOTION (Noraxson), was used to measure the acceleration and angles of each body part. The motions were measured on a kayak ergometer (Dansprint DNK), with rowing motions at a pitch of 80 bpm and at the individuals maximum speed for 60 s. From the data obtained, data for five strokes were extracted 10 s after the start, and the average value was used as the representative value. The extracted angles were total rotation angles of the thoracic spine, lumbar spine, pelvis, and hip joint, as well as flexion angles of the knee joint. For the hip and knee joints, the ratio of the percentage of flexion angles between the right and left sides was calculated (LR ratio).

Muscle flexion and extension strengths of the trunk and lower limbs were measured at two angular velocities, 60° and 180°, using the isokinetic muscle function evaluation device, BIODEX System4 (Biodex Medical Systems, Inc.). For knee flexion muscle strength, the LR ratio was calculated.

Spearmans correlation coefficient was calculated as the correlation between the LR ratios of each lower limb angle and muscle strength, as well as the thoracic spine, lumbar spine, and pelvis angles and each trunk muscle strength.

RESULTS: The lumbar spine, pelvis, hip, and knee joint values at 80 bpm and maximum speed velocity all had strong correlations, but the thoracic spine had none (lumbar spine, r = 0.86; pelvis, r = 0.97; hip, r = 0.74; knee, r = 0.88; thoracic spine, r = 0.082). The LR ratio of knee extensor strength at 60° angular velocity and the LR ratio of hip rotation at 80 bpm had a moderate positive correlation (r = 0.62), whereas the LR ratio of knee extensor strength at 180° angular velocity and the hip rotation at maximum speed had a strong positive correlation (r = −0.79). Moreover, the trunk flexor strength at 60° angular velocity and pelvic rotation angle at 80 bpm had a moderate negative correlation (r = −0.55), while the trunk flexor strength at 180° angular velocity and pelvic rotation angle at maximum speed had a moderate negative correlation (r = −0.56).

CONCLUSION: In inexperienced high-school kayakers, upper body movements may not be used as a smooth kinetic chain from the lower trunk to the pelvis to the lower extremities. Regarding the left-right difference, it is possible that the pelvis and hip rotation are influenced by knee extension and trunk flexion muscles.

AN ANALYSIS OF KEY PERFORMANCE INDICATORS DURING 50 AND 100 METER SWIM LENGTHS ACROSS FOUR SWIM STROKES

BOZYIGIT, G., OZUAK, A., PATTERSON, J., LOCKWOOD, K.

BROCK UNIVERSITY

INTRODUCTION: Key performance indicators (KPI's) are skill-based metrics used by coaches and athletes to adjust technique, track training, develop race strategies and predict performance times. The purpose of the study was to investigate the effect of swim-specific KPI's [stroke count (SC;#), stroke length (SL;cm), stroke rate (SR;#/s), and kick frequency (KF;#/s)] on total swim time (s) during 50m and 100m swim lengths across four swim strokes [butterfly, backstroke, breaststroke, and freestyle].

METHODS: Varsity-caliber competitive swimmers (n=12 males; 20yrs) were recruited. Anthropometric measures including height (182.1cm), seated height (146cm), leg length (98.3cm), wingspan (191.1cm), hand length (20cm) and weight (80.2kg) were recorded. Shoulder and ankle range of motion (ROM) measurements were obtained, and a Y-balance test was conducted to profile the athlete's upper and lower limb mobility. Athletes completed four swim sessions consisting of a standardized warm up, 50m kick, 50m pull, 50m swim and 100m swim distances per stroke. KPI data was collected using a portable device (TritonWear, ON, Canada) secured inside the athletes' swim cap. TritonWear measures SC(#), SL(cm), SR(#/s) and total swim time (s). A GoPro Hero 6 (GoPro, California, USA) collected underwater video to facilitate calculating KF(#/s).

RESULTS: Descriptives were calculated for all anthropometric, ROM and KPI variables across the two swim lengths and four swim strokes. Pearson product-moment correlations revealed significant relations between anthropometric measures and select KPI's; and between ROM measures and select KPI's ($p<0.05$) suggesting that both anthropometrics and ROM have the potential to influence swim technique and race strategies. A series of repeated-measures ANOVA's with Greenhouse-Geisser corrections revealed significant differences in select KPI's (SC, SL and KF) during the execution of 50m and 100m swim lengths across all of the four strokes ($p<0.05$), suggesting the technique employed by specific strokes had the potential to influence the KPI's per stroke. A series of repeated-measures ANOVA's with Greenhouse-Geisser corrections also revealed significant differences in select KPI's (SR, SL, KF) during the execution of 50m versus 100m swim lengths using butterfly, backstroke, breaststroke, and freestyle strokes ($p<0.05$), suggesting that swim length utilizes different KPI related strategies for strokes.

CONCLUSION: Data-driven metrics obtained from portable instrumentation during swim performances facilitated understanding the relationship between anthropometrics, ROM and KPI's and how to adjust select KPI's relative to an athlete's anthropometrics, technique and race strategy across four different swim strokes and two swim lengths. These sport specific skill-based metrics can empower coaches and athletes to use KPI's to optimize athlete potential and target performance goals.

TRADE-OFF RELATIONSHIP BETWEEN SPEED AND ACCURACY AT A SPECIFIC TIME EXAMINED USING A VERTICAL JUMP TASK

MURAKAMI, H., YAMADA, N.

CHUKYO UNIVERSITY

INTRODUCTION: Human movement is governed by a tradeoff between speed and accuracy, demonstrated by experiments on hand movements (1,2). However, studies that have examined that during full-body movements (e.g., sports) have not reported uniform findings on how that is established. Schmidt explains that one of the two exceptions to that is "cases in which extremely rapid and forceful actions are involved" (3); however, in actual sports movements, there are cases that require high control while exerting max speed. Therefore, to analyze sports movements that require both speed and accuracy, this study confirmed this phenomenon and examined the mechanism of that by adding landing position control to a vertical jump task that normally does not require accuracy.

METHODS: 18 adults participated in this study. They performed 10 trials for each vertical jump on a single force plate under the following conditions: 1) normal condition (nc) trials, in which they jumped with max effort, and 2) adjusted condition (ac) trials, in which they jumped with max effort and landed in the takeoff position. Signal outputs from the force plate were digitized at 1000 Hz and captured on a computer. From the acquired force data, the mass (m) and 3D acceleration vector of them were calculated, and the 3D velocity and position vectors were calculated by the numerical integration of the accelerations. From these variables, the position vectors for takeoff (to) and landing (lan) and the jump height were calculated. Furthermore, the 3D velocity vectors were plotted, and the entropy of each condition was calculated using methods in a previous study (4).

RESULTS: A comparison of the jump height of their between conditions showed that it was significantly lower in the ac (0.46±0.02 m) than in the nc (0.50±0.02 m, $p<0.01$). The xz coordinates of their at lan and to were plotted for each condition, from which 95% probability ellipses were calculated to evaluate variability. In the nc, the values were almost the same for to (0.072 m2) and lan (0.074 m2), whereas in the ac, the values were lower for lan (0.068 m2) than for to (0.078 m2). It is possible that the speed was adjusted to accurately control the landing position because the jump height is determined by the takeoff velocity. The entropy was lower in the ac (2.50±0.62) than in the nc (2.61±0.09, $p<0.01$) for approximately 0.2–0.3 seconds after the start of sinking before to. Therefore, during this time, the smaller variation in the velocity vector for ac suggesting that the velocity was controlled to increase accuracy for lan.

CONCLUSION: Even in the vertical jump task, which is normally performed with max effort, increased accuracy and decreased velocity were observed when the landing position was the target of control. Furthermore, a tradeoff relationship between speed and accuracy may be established within a specific time.

RELATIONSHIP BETWEEN BODY CENTRE OF GRAVITY VELOCITY AND LOWER LIMB JOINT ANGLES IN LUNGE MOVEMENT OF FENCING ATHLETES

CHIDA, K.1, INAMI, T.2, YAMAGUCHI, S.1,2, YOSHIDA, Y.2, KOHTAKE, N.1

KEIO UNIVERSITY: KEIO GIJUKU DAIGAKU

INTRODUCTION: The lunge in fencing is the most fundamental attack movement. Although previous studies investigated the relationship between lower limb joint (hip, knee, and ankle joints) angles and sword velocity during lunging [1], knowledge of body (centre of gravity) velocity, which determines lunge movement quality, is lacking. Therefore, this study aimed to clarify the relationship between the body centre of gravity (peak velocity) and lower limb joint angles in the lunge movement of fencing athletes.

METHODS: Fourteen right-handed male university student fencing athletes (mean competition history, 9.7±3.1 years) were included. Lunge distance was defined as the horizontal distance from the rear leg toe to the target during the engirdle, with the length set at 1.5× the height of each subject [2]. The subjects performed three lunge trials towards the target, and the trial with the highest peak body centre of gravity velocity was considered representative. A three-dimensional motion analysis system (Miqus M3) was used for the data collection. Eight high-resolution cameras were used to capture images. Three-dimensional coordinate values were measured by the analysis software, and the centre of body gravity and the centres of the hip, knee, and ankle joints were calculated based on the three-dimensional coordinates. The start of the lunge movement was defined as the toe-off of the front leg, after which the front leg swung forward in coordination with the rear leg, and heel contact with the front leg was defined as the end of the movement [3]. To determine the lower limb joint angles influencing the peak lunge velocity, multiple regression analysis was performed with the peak velocity of body centre of gravity in the lunge as the dependent variable and the lower limb joint angles (peak flexion angle, peak extension angle, and total joint range of motion) as predictor variables.

RESULTS: The peak velocity of the body's centre of gravity in the lunge was 1.88±0.16 m/s. Multiple regression analysis showed that the rear hip total range of motion ($\beta=0.592$) was significantly related to the peak velocity of body centre of gravity, with a coefficient of determination adj. $R2=0.297$.

CONCLUSION: The results of this study were similar to those of a previous study [1]; however, the knee joint findings differed. One possible reason for this is that the target distance in the present study was shorter than those in previous studies. The findings suggest that, when the target distance is longer, the knee joint is involved in addition to the hip joint; thus, the joint angle during lunge movement may be significantly influenced by both distance and velocity.

ESTIMATIONS OF BODY SEGMENT PARAMETERS AND WHOLE-BODY COMPOSITION IN JAPANESE ADULT FEMALES USING MRI METHODS

FURUTA, N., HIRANO, T., FUNATO, K.

KOKUSHIKAN UNIVERSITY

INTRODUCTION: Body segment parameters (BSPs) are one of the critical parameters in order to estimate the segment forces of movement in both sports and exercise. Whole-body composition (WBC) i.e., fat mass (FM) and skeletal muscle mass (SM) might be influenced for the predictions of BSPs. Recently, magnetic resonance imaging (MRI) methods has been reported to predict BSPs, WBC and Limb composition (LC) accurately. However, relations between BSPs and WBC as well as the reliability WBC assessments by MRI methods remained unclear. This study aimed to be estimations of BSPs and WBC in Japanese adult females using MRI methods.

METHODS: Whole-body MRI scans of 14 Japanese adult females were obtained using 1.5-T device. Thirteen tissue areas such as bone, muscle, fat and so on, were identified using Fiji/ImageJ software. WBC and LC were calculated to be multiplied by each area,10-mm slice thickness and respective tissue densities. Fourteen body segments such as head and neck, trunk, upper arm, forearm, hand, thigh, shank and foot were identified according to the anatomical landmarks. Air displacement plethysmography (ADP) method was used to measure whole- body FM and lean body mass. Data from ADP and MRI methods were compared by paired t-test as well as Pearson's correlation ($p<0.05$). Segment mass obtained from MRI (%M) was compared with previous studies.

RESULTS: Whole-body mass, volume and density obtained from MRI and ADP were almost identical in both absolute and relative values (%difference <1%). FMs obtained from MRI and ADP were highly correlated ($r = 0.981$, $p < 0.001$). On the other hands, significant absolute differences in the FM were found between the two methods (ADP; 12.0±4.5 kg vs MRI; 13.8±4.5 kg, $p < 0.001$). It was suggested that estimated FM equation of ADP method (Brozek et al., 1963) affected difference of results, because whole-body density was identical value. This study trended to be smaller upper arm (2.4±0.3 %M) and forearm (1.3±0.1 %M) than typical values (Dempster,1955 and Clauser et al.,1969). Females was bigger thigh and shank than males of same segmentation protocols, as sex difference affected %M (Zatsiorsky, 2002).

CONCLUSION: Estimation of whole-body mass by MRI method was equivalently evaluated with ADP method. In Japanese adult females, estimation of BSPs (%M) by MRI method showed to be smaller upper body and bigger lower body than previous studies.

INFLUENCE OF MEDIAL LONGITUDINAL ARCH HEIGHT AND REDUCED ANKLE DORSIFLEXION ON KNEE DYNAMIC ALIGNMENT DURING SINGLE LEG SQUAT

KAGAYA, Y.

SHOWA UNIVERSITY

INTRODUCTION: Single leg squat (SLS) test is recognized to identify core strength, and simpler to perform in sport or clinical site than drop jump test. Also, we reported hip abductor and hindfoot dysfunction during SLS were risk factors causing dynamic knee valgus (Kagaya et al., 2015). However, influence of medial longitudinal arch height or reduced ankle dorsiflexion (DF) on dynamic alignment in SLS remains unclear. This study aimed to determine how navicular height and DF angle contribute to SLS test.

METHODS: Eighteen female basketball players (36 legs) agreed to participate in this study. Their age was 21.0±1.9 years, height and weight were 166.5±5.9cm and 62.6±5.8 kg, respectively. Subjects clasped hands behind their back and performed SLS by bending the knee of the supporting leg to about 60°. This procedure was recorded simultaneously using a 2D video camera in the front on the subjects. Knee-in distance (KID) was measured as the distance from hallux to the point where the line connecting the center of the patella and the anterior superior iliac spine (ASIS) intersects the floor. Hip-out distance (HOD) was measured as the distance from hallux to the projection of ASIS on the floor. Additionally, we measured DF angle, and navicular drop (ND) as the subtraction of navicular height on sitting and standing position. The collected data from subjects were divided into either limited or flexible group by excluding the subjects among average ±1/2 SD of the DF and the ND, respectively. The limited DF or ND group was compared between flexible DF or ND group using Mann-Whitney tests, respectively.

RESULTS: Limited DF group (n=12, 32.0±3.1°) demonstrated greater KID (9.3±3.1cm vs 6.5±3.9cm) than flexible DF group (n=10, 49.7±4.2°) ($p<0.05$). However, the HOD (15.7±1.6cm vs 14.7±1.4cm) did not significantly differ between the limited and flexible DF group. Also, the KID (7.8±4.9cm vs 9.0±5.9cm) and HOD (14.1±1.4cm vs 15.4±1.4cm) did not significantly differ between the limited ND group (n=12, 2.8±0.9mm) and flexible ND group (n=10, 8.9±2.1mm).

CONCLUSION: Limited DF range has been reported as a possible contributor to excessive knee valgus and has been linked to harmful landing mechanics (Lima et al., 2018). Our study also revealed that female basketball player having limited DF augmented dynamic knee valgus during SLS. It was suggested that subjects having reduced DF try to compensate for this lack of range in the sagittal plane with movement in the frontal plane as they perform SLS. However, it was not considered that navicular height led to dynamic knee valgus. KID values for single leg squat had been greater for athletes with flexible hindfoot than for athletes with normal hindfoot function, whereas HOD values did not significantly differ between that groups (Kagaya et al., 2015). The hindfoot and medial longitudinal arch might not completely be linked throughout the kinetic chain and need to be evaluated individually.

TEMPORAL CHARACTERISTICS OF HOPPING MOVEMENT IN PRESCHOOL CHILDREN

SASAKI, R., ISHIZAWA, J.

KEIO UNIVERSITY

INTRODUCTION: Hopping, one of the fundamental locomotor skills, is a rhythmically cyclic movement that requires significant muscle strength, multi-limb coordination, and dynamic balance. Typically developing children begin hopping around the age of three and improve on it during early and middle childhood. Previously, we reported the developmental changes in motor coordination patterns of arms and legs during hopping in preschool children. In this study, we have expanded on the previous study by focusing on the temporal aspects of hopping movement patterns in preschool children.

METHODS: Participants were 157 typically developing children aged between 4 and 6 years. They were asked individually to perform the hopping movement on their preferred foot. Hopping movement has been demonstrated before the test, and a video recording of each individual was captured. The recording (30 fps) was analyzed in terms of temporal parameters: hopping cycle time, flight phase and stance phase duration. Based on these parameters and criteria from a previous study by Halverson and Williams, 1985, children were classified into 4 developmental levels of leg action.

RESULTS: The number of children categorized in each developmental level of leg action, from step 1 to 4, was: 0 (0.0%), 104 (66.2%), 42 (26.8%),and 11 (7.0%), respectively. The average age in each developmental level group (step 2, 3, 4) was 67.7, 71.0, and 71.7 months, respectively. As for the temporal parameters of hopping, the cycle and the flight phase duration both increased with advancing level of development. On the other hand, the stance phase duration decreased with the level of development.

CONCLUSION: Overall, the hopping performance improved with aging in 4 to 6 year-old children. However, the level of development was not uniformly distributed, with the majority of subjects being at levels 2 and 3. This means they were still improving in the movement (Halverson and Williams, 1985, Masci et al, 2012). The flight phase duration was longer in the advanced movement levels than in the lower ones. The duration of the stance phase has decreased with the advancing levels of development. These findings suggest qualitative changes in the neuromuscular function in these children during hopping.

LONG-DISTANCE RUNNER'S VASTUS LATERALIS ARCHITECTURE PARAMETERS ARE LARGER THAN THE CONTROL GROUP, BUT KNEE EXTENSOR TORQUE IS NOT.

MATTA, T., BACCHIN, E., ALBARELLO, J., HALMENSCHLAGER, G., OLIVEIRA, L.

UNIVERSIDADE FEDERAL DO RIO DE JANEIRO

INTRODUCTION: The scientific literature is sparse regarding adaptations in muscle architecture concerning long-distance runners. Chronically, no differences in vastus lateralis (VL) architecture were observed after 12 weeks of training for a marathon (1), and professional distance runners had a reduced VL fascicle length (FL) than the control group (2). However, both studies acquired ultrasound images at one site only; 50% of the VL. The muscle architecture from runners, using the ultrasound extended-field-of-view technique (EFOV) has not yet been evaluated, as well as the voluntary torque production capacity of the knee extensors of this sample. This study aimed to compare the muscle architecture of the VL and the knee extensor torque between long-distance runners and control participants.

METHODS: The runners group consisted of 21 amateur long-distance runners and the control group of 12 healthy young participants, with similar anthropometric characteristics between groups. All participants in the running group had at least two years of training and performed at least one long-distance race (≥ 10km) in the last year. An experienced evaluator acquired panoramic mode ultrasound scans of the VL at 50% of muscle length for anatomical cross-sectional area (CSA) normalized by the body mass (BM) (3) and at two VL lengths to assess distal and proximal muscle length (4) normalized for the muscle length (ML). To assess torque production capacity, the isometric peak torque, concentric and eccentric peak torque at 60°/s, and the concentric and eccentric angle of the peak torque were measured. The T-test for independent samples was used to compare the means for the FL/ML, CSA/BM, and torque parameters ($p \leq 0.05$).

RESULTS: No statistical differences were found between groups for the knee extensor torque parameters ($p > 0.05$). The EFOV ultrasound scans of the group of runners showed statistically higher values for the normalized fascicle length of the proximal (0.23 ± 0.02) and distal length (0.22 ± 0.02) compared to the group control (0.21 ± 0.02 and 0.20 ± 0.02 - proxi-

mal and distal, respectively) (p=0.034 and p=0.027, respectively). In the same way, the runners had larger normalized CSAs (0.38 ± 0.06) compared to the control group (0.34 ± 0.05) (p=0.028).

CONCLUSION: It appears that long-distance amateur runners have longer FL/ML (proximal and distal) of the VL, as well as CSA/BM. Although speculative, these results may be due to VL adaptation in response to the demand imposed by specific training performed. In addition, the results suggest that the EFOV method for acquiring ultrasound images is more suitable for such functionality compared to the one-site ultrasound images. The isometric and dynamic torque production capacity, as well as the dynamic torque peak angle, are not statistically different between groups.

DUAL-TASK INTERFERENCE ON TRUNK-PELVIS COORDINATION DURING GAIT IN INDIVIDUALS WITH PARKINSONS DISEASE

SAM, M., WELMAN, K.
STELLENBOSCH UNIVERSITY

INTRODUCTION: Parkinson's disease (PD) is a heterogeneous neurodegenerative disorder. Atypical posture and mobility of individuals with PD (IwPD) increase the risk of falls and limits the capabilities of daily activities. Reduced range of motion in IwPD is attributed to rigidity and may be hindering trunk coordination, and consequently contribute to gait dysfunction (i.e., decreased step and stride length), turning difficulties, and poor posture. In a neurotypical gait pattern, there is a progressive transition mainly from in-phase to anti-phase coordination, in the axial plane, as gait speed increases. An in-phase pattern is more evident in IwPD; resulting in the trunk and pelvis to display synchronous axial rotations in the same direction. Furthermore, IwPD have increased difficulty performing more than one task simultaneously, possibly due to restricted central processing. It's hypothesized that trunk-pelvis coordination (TPC) will be aggravated during dual-task (DT) activities, and greater DT inference (DTI) will occur during motor-motor DT (MMDT) than cognitive-motor DT (CMDT). The primary aim of this study was to establish if DT activities, in contrast to single-task (ST) conditions, affect TPC during walking in individuals with mild to moderate PD compared to apparently healthy age- and sex-matched individuals (Control group). The secondary aims were to compare two DT paradigms, and to determine which condition resulted in the most interference for TPC, gait variables and other coordination indices, during walking in IwPD compared to the control group.

METHODS: This was a cross-sectional within-group and between-group quasi-experimental study design. Participants were asked to randomly perform a ST (i.e., 2 Minute Walk) and DT activities (i.e., CMDT by serial three subtraction, and MMDT by carrying a tray with two glass

RESULTS: Twenty-two IwPD (age 72.50 ± 4.35 years; 1.82 ± 0.66 Hoehn & Yahr scale) and 22 healthy age- and sex-matched Control group (age 72.77 ± 4.30 years) were tested under ST, MMDT and CMDT conditions. Significant interaction effects were found for gait speed, gait variability, gait speed variability and TPC variation ($p < 0.01$), with post-hoc results indicating that CMDT cause a great deterioration in gait in both groups. Results of the DTI show significant interaction effects for gait speed ($p < 0.01$), stride time ($p = 0.02$),gait variability ($p = 0.02$), and gait speed variability ($p < 0.01$). Great DTI was observed in MMDT than CMDT for TPC in the PD group and Control group.

CONCLUSION: The findings suggest that DT gait performance is influenced by MMDT and CMDT in IwPD. Dual-task interference on gait parameters were significant in both DT conditions in the PD and Control group. The findings may contribute to the way healthcare professionals treat IwPD, by modifying expectations and monitoring the cognitive and/or motor demands placed on IwPD both in everyday life and during rehabilitation may improve quality of life and independence.

THE FMS PROFILE WITH TRAINING INTENSITY FOR TENNIS PLAYERS OF COLLEGE TEAM AND HIGH SCHOOL TEAM

TANG, W., TUNG, L., CHANG, J.B.

NATIONAL TAIWAN SPORT UNIVERSITY

INTRODUCTION: Athletic tennis is a sport that requires a lot of training and practice to fit for high-intensity, low-intensity intermittent competitions. Not only does it require developing technical skills, but it also requires developing specialized fitness abilities.

Kekelekis (2020) shows that most tennis injuries are related to overuse and a chronic time process. For professional athletes and coaches, it is important to avoid overtraining or cumulative injuries that can lead to injuries during training. In Taiwan, training of tennis players with tennis major from in high school and college team have heavy intensive training. Therefore, this study aims to investigate the training time between high school and college and both related FMS profile and the relationship between training time and FMS and sub-FMS scores to provide a reference for coaches or players in their training plans to prevent injury.

METHODS: The study recruited 46 male tennis players with tennis major. Twenty-two were college athletes, and 24 were high school athletes. All participants were informed of potential risks of the study and provided written informed consent. The FMS scores were calculated according to the guidelines described in the Functional Movement Screen manual. The data collected included the weekly training time and frequency. The FMS scores were calculated according to the Functional Movement Screen manual. Participants also filled out a personal information form that included information about their physical fitness and training time. The FMS score is calculated by giving a score of 0-3 for each item, with a maximum score of 21. Independent sample T-test and Chi-square test of SPSS 25.0 were used to test a significant difference in training time and FMS scores. Spearmans correlation analysis was used to examine the relationship between the FMS and training time.

RESULTS: The results shows that high school players investing more both technique (HG 24.1±8.0, CG17.1±13.9 hrs) and physical training time (HG 24.1±8.0, CG17.1±13.9 hrs, $P<.05$) There is no significant difference on total FMS scores, but on sub-FMS score: HG > CG on shoulder mobility and active straight leg raise while CG> HG on In-line lunge and Trunk stability push-up. Besides, only HG showed mild negative relationship between physical training time on deep squat ($r=-.444$, $p<.05$) and Rotary stability scores ($r=-.507$, $p<.05$).

CONCLUSION: our study showed HG is better in shoulder and pelvis mobility, but CG better is related to pelvis and trunk stability and strength. It may be due to young age and long training time but less strength training. Also, young athlete demonstrates the negative effect on long time training which is about 30 hours weekly. It suggested that increasing training pelvis and trunk strength and stability are important to young athletes.

SCAPULAR MUSCLES ACTIVATION DURING TWO ADAPTATIONS OF THE SHRUG EXERCISE

TORRADO PINEDA, P., MARINA EVRARD, M.

INEFC

INTRODUCTION: Shrugging exertion with barbell or dumbbell is commonly used to strengthen the upper fibers of the trapezius (UT) because this exercise has been traditionally recommended as the function of elevating the scapula. However, it has been suggested that the transverse orientation of the upper and middle fibers of the trapezius does not allow for the elevation of the scapula (1). This observation was evidenced by a higher UT activation when adopting an arm abduction of 90º and 150º during the shrug (2). On the other hand, when doing the dumbbell shrug with an arm abduction of 30º the UT and lower trapezius (LT) were more solicited (3). Nevertheless, other conditions with a lower deltoid solicitation have not been studied yet for conditioning purposes. We aimed to examine whether activity of scapular muscles varies when performing shoulder shrugs under three different conditions.

METHODS: Eight volunteers performed shoulder shrugs under three conditions: the traditional barbell shrug at a 0º (BS0) and at a 30º (BS30) of abduction with a barbell and using a pulley (PS30) aligning the resistance with the arm. EMG activity was collected from levator scapulae (LS), UT and LT, and serratus anterior (SA) during 5 repetitions at a load of 25% relative to the 1RM of each one of the three conditions. Root mean square was used to measure levels of muscle activity for the whole repetition and normalized (nRMS) with the isometric maximal voluntary contraction. The duration of each repetition was standardized with a metronome.

RESULTS: Significant exercise and muscle main effects were found ($p<0.006$). In addition, the interaction of exercise and muscle was significant ($p=0.041$). Post-hoc analysis revealed a higher activity in the UT and SA muscles during the BS30 than the BS0 ($p<0.026$). Additionally, BS30 solicited more the LS and SA muscles than the PS30 ($p<0.037$). On the other hand, LT muscle was activated in a similar way in the three conditions. When comparing muscles activity, no significant differences were observed between the UT and LS in the three conditions, while the UT was more solicited than the LT in the three conditions ($p<0.05$), and the SA with the BS0 and PS30 exercises ($p<0.037$). Finally, LS showed greater activity than the SA in all three conditions ($p<0.05$), and the LT during BS0 and BS30 situations ($p<0.013$).

CONCLUSION: Contrary to preconceived ideas, the UT is not the greater elevator of the scapula, like it is the case for the LS. Therefore, performing traditional shrugs (BS0) does not seem the best option to stimulate the UT. For practical purposes, we suggest adopting the BS30 to better activate the UT, thanks to the facilitation of the scapular upward rotation.

FUNCTIONAL ANKLE INSTABILITY SCORES ARE NOT RELATED TO DYNAMIC POSTURAL STABILITY INDICES IN NETBALL PLAYERS.

GREEN, A., KWONG, D.

UNIVERSITY OF JOHANNESBURG

INTRODUCTION: It is well known that the ankle joint is the most frequently injured body part court-based sports. Research further indicates that postural stability deficits during landings following vertical and horizontal jumps are a precursor for future ankle injuries (1). A common practice to highlight deficits in postural stability associated with the incidence of ankle injury, has been the use of the forward facing vertical drop-landing task. Studies reveal that increasing the single leg lateral landing orientations of a drop jump showed significant alterations in postural stability values (2). The Functional Ankle Instability (FAI) questionnaire has been widely used to determine ankle instability (3). Additionally, assessments of postural control during landing tasks, like the Dynamic Postural Stability Index (DPSI) have provide quantitative metrics to evaluate landing stability (4, 5). The aim of this study was to investigate the relationships between FAI scores and metrics of landing stability and dynamic postural control.

METHODS: 25 female netball players (age: 20.7±2.01 years; stature: 174.4±4.72cm; mass: 67.2±9.52 kg) performed anterior and lateral drop landings from 40cm onto a force plate. FAI was evaluated using the idFAI questionnaire with a cut-off of >11 indicating instability. DPSI was calculated over three seconds from initial plate contact. Correlations were run between FAI scores and landing stability metrics for anterior and lateral landings.

RESULTS: 12 athletes presented with FAI and 13 did not surpass the threshold (FAI scores: 11±9). Landing indices for anterior landings were: ML: 0.07±0.01; AP: 0.05±0.03; Vertical: 1.21±0.22; DPSI: 1.21±0.22, peak BW force: 3.93±0.87. Lateral indices were: ML: 0.479±0.01; AP: 0.08±0.02; Vertical: 1.24±0.16; DPSI: 1.24±0.16, peak BW force: 4.06±0.87. No significant correlations were noted between FAI scores and landing metric for anterior and lateral landings ($p>0.05$) .

CONCLUSION: The lack of relationships between FAI scores and indices of landing postural stability would indicate that dynamic tasks, such as landing, are more complex than pure kinetics. Additionally, it is apparent that postural control during landing is mediated by the lower kinetic chain and ankle joint weaknesses can be mitigated by the knee and hip. Kinematically, postural control is highly variable, and the pure kinetic assessment may not be a prudent evaluation of DPSI or ankle stability.

DONIMANT VERSUS NON-DOMINANT FOOT INITIATION OF THE SIT TO WALK MOVEMENT: DIFFERENCES OF THE VERTICAL GROUND REACTION FORCE TEMPORAL PROFILE

BOUDOLOS, K., NIOTI, P., EMMANOUIL, A., ROUSANOGLOU, E.

NATIONAL AND KAPODISTRIAN UNIVERSITY OF ATHENS, GREECE, SCHOOL OF PHYSICAL EDUCATION AND SPORT SCIENCE

INTRODUCTION: The Sit to Walk (STW) movement is performed about 60 times per day [1] and is a fundamental activity for daily living independence. The STW is often initiated from a staggered feet placement, that is one foot is slightly in front of the other. The foot dominance does not appear to affect the magnitude of the Ground Reaction Forces (GRFs) during a staggered STW initiation [2]; however little is known about the timing of the vertical (Fz) GRF profile. This study aimed to examine the foot dominance effect on the Fz temporal profile when the STW is initiated from a staggered foot placement.

METHODS: Fifteen healthy men and women (22.1+2.2 years) performed STW trials from two staggered foot placements, (a) the dominant foot (DF) slightly in front of the other, and (b) the non-dominant foot (NDF) slightly in front of the other (4 trials per condition, preferred distance between feet). A force plate was used to collect the GRF data (sampling at 1000 Hz, Kistler Type 9286AA). A low pass filter (cut-off frequency at 10Hz) was applied to all data. The extracted variables concerned the total STW and the feet unloading duration (feet backward preparatory action), as well as the duration of the intervals defined by the subsequent Fz dips and peaks (Interval A: Fz 1st dip to Fz first peak, Interval B: Fz 1st peak to Fz 2nd dip, Interval C: Fz 2nd dip to Fz 2nd peak, and Interval D: Fz 2nd peak to STW termination). The timing of the Fz variables was expressed as a percentage of the total STW duration, and the 4 trials' average was used in statistical analysis (SPSS 28.0, $p=0.05$).

RESULTS: The magnitude of all Fz peaks and dips did not differ significantly between the DF and the NDF condition ($p>0.05$). However, in the NDF, the STW duration and the feet-unloading phase were significantly prolonged (+35%, $p=0.035$, +10.5% $p=0.012$, respectively). Except for the significantly longer time to reach the 2nd Fz dip (+19.2%, $p=0.000$), the absolute timing of the Fz peaks and dips was not altered in the NDF condition. However, the temporal profile of the Fz Intervals was significantly altered (shorter Interval A and Interval B, -9.4% $p=0.038$ and -6.3%, $p=0.030$, respectively, and longer Interval C +42.1% $p=0.000$) with no significant alteration for Interval D (+2.3%, $p=0.363$).

CONCLUSION: The foot dominance does not appear to affect the magnitude of the Fz peaks and dips when STW is initiated from a staggered foot placement. However, the significant temporal alterations in the NDF placement most possibly indicate the necessity for more time to address the feet backward preparatory action (feet unloading phase) as well as for a longer propulsion time (Interval C) of the supporting foot at walk initiation [3].

INERTIALLY SENSED BREATHING 3D LINEAR ACCELERATIONS OF THE ABDOMINAL WALL IN THE HEADSTAND AND THE UPRIGHT STANCE

ROUSANOGLOU, E., FOSKOLOU, A., EMMANOUIL, A., BOUDOLOS, K.

NATIONAL AND KAPODISTRIAN UNIVERSITY OF ATHENS, SCHOOL OF PHYSICAL EDUCATION AND SPORT SCIENCE

INTRODUCTION: In popular fitness modalities, the participants are often required to maintain inverted body stances such as the HeadStand [1]. Inverted body stances challenge breathing mechanics as the respiratory muscles are necessitated to reverse their normal activation pattern, and expiration is resisted rather than assisted by the gravitational force. This study aimed to compare the breathing-related 3D linear acceleration of the abdominal wall between the HeadStand (HS) and the Upright Stance (US).

METHODS: Twenty-five men and women (27.6 ± 7.3 years, all experienced in maintaining the HS for at least 40s) performed normal breathing trials while in the HS and the US (3 trials per body stance). A triaxial inertial sensor (LORD MicroStrain®, 3DM-GX3®-45, sampling at 100 Hz) was used to record the 3D linear acceleration of the abdominal wall [2]. With the participant in the US, the inertial sensor was securely positioned on the left side of the abdominal wall (at 2 cm from the umbilicus and at 2 cm above the umbilicus height). Acceleration signals presented clear peaks and dips that served to visualize the breathing cycles' initiation and termination, as well as to define the first time point of the 30s breathing duration that was extracted for further analysis. All signals were pre-processed (high pass filtering followed by low pass filtering, at 0.5Hz and 6Hz cut-off frequency, respectively, MatLab R2021b). In continuance, across the three trials, the mean and the RMS, as well as each participant's individual coefficient of variation (Acc-IndCV) were estimated for the anterioposterior (AP-Acc), the mediolateral (ML-Acc) and the vertical (V-Acc) linear acceleration of the abdominal wall. Paired t-test was applied for the differences between the HS and the US (SPSS 28.0, $p<0.05$).

RESULTS: In the HS, the ML-Acc, the AP-Acc, and the V-Acc were all significantly increased compared to the US (+15, +15, and +20%, respectively, p=0.00 for all). In both body stances, the values were greater for the V-Acc, with ML-Acc and AP-Acc rising to 75 and 54% of V-Acc and to 56 and 39% of V-Acc, in the HS and the US, respectively. The Acc-IndCV was 12.8, 10.1, and 9.7% in the US, with a significant increase in HS for the AP-Acc (+18%, p=0.013) but not for the ML-Acc (+12.6%, p=0.929) and the V-Acc (+13.4%, p=0.187).

CONCLUSION: Inertial sensing effectively recorded the breathing-related 3D linear acceleration of the abdominal wall, in both the US and the HS. Taken into account that HS may necessitate a greater activation of the abdominal muscles to ensure trunk stabilization, the significant HS differences appear to highlight the greater postural disturbances imposed due to the reversal of normal breathing mechanics [3], as the expiration muscles are counteracted rather than assisted by the gravitational force.

EFFECT OF AN EXERCISE BOUT ON WALKING SYMMETRY AND REGULARITY FOR PEOPLE WITH TRANS-TIBIAL AMPUTATION

STRIKE, S.

UNIVERSITY OF ROEHAMPTON

INTRODUCTION: To be able to walk, people with trans-tibial amputation (PTTA) use a prosthetic limb which does not fully replicate the anatomical limb. The limitations of the prosthetic limb result in compensatory movements which may lead to gait asymmetry, and differences in the repeatability of the stride-to-stride walking pattern. Gait symmetry indicates healthy gait and is often stated as an aim of rehabilitation (1). Increased asymmetry has been associated with increased falls occurrence in PTTA and is considered a key contributor to lower back pain (2), osteoarthritis (3) and osteoporosis (4).

This study aimed to determine if step symmetry and stride regularity were changed after brisk walking (completing a six minute walk test).

METHODS: Data for fourteen active PTTA were analysed. An accelerometer (MSRelectronics, MSR145) was attached to the lower back using double sided tape and recording started prior to initiating the walking test. First, participants were asked to complete a ten-meter walk test at their self-selected walking speed. Second, they completed a six minute walk test (6MWT). Finally, they returned to the start line and performed another the ten-meter walk test.

Data were extracted from the accelerometer and assessed in Matlab 21.0 (R2020b, The Mathworks Inc). Autocorrelation was used to determine the step to step symmetry and the stride to stride repeatability. Vertical, anterior-posterior and mediolateral directions were assessed. Paired t-test was used to determine difference before and after exertion ($p \leq 0.05$).

RESULTS: No significant differences were found for symmetry or regularity in any dimension.

Symmetry pre-post: autocorrelation r=1 indicates perfect regularity and symmetry:

ML r=0.68 - 0.65; AP r= 0.81 - 0.88; Vert 0.73 - 0.70.

Regularity pre-post: autocorrelation mean (SD):

ML r=0.82 - 0.81; AP r= 0.92 - 0.90; Vert r= 0.92 - 0.91.

CONCLUSION: PTTA are encouraged and want to use walking as a health-related activity, as one of the most accessible forms of physical activity. There is little research to investigate if this is a safe activity which is resilient to fatigue. By assessing the risk factors for falling and asymmetrical loading, albeit for a short walking bout, we have found no evidence that walking increases risk for falls or bone health.

POSTURAL CONTROL IN CHILDHOOD AND ADOLESCENCE

SAHINIS, C.

ARISTOTLE UNIVERSITY OF THESSALONIKI

INTRODUCTION: The development of systems influencing postural control occurs at different ages with the somatosensory system maturing first, followed by the visual and vestibular systems (Hirabayashi & Iwasaki 1995). As visual input predominates over somesthetic information in children, the afferent contributions of the somesthetic system are seriously limited when visual information is available (Foudriat et al. 1993). Our study explored the age-dependent modifications of postural control in healthy children and adolescents.

METHODS: Four sensory conditions were used: eyes open or closed (stresses proprioception) while standing on stable or unstable surface (foam mat; disrupts proprioceptive acuity). Moreover, to evaluate the contribution of proprioceptive inputs, bilateral Achilles tendon vibration (60 Hz) was applied with the eyes closed. Three 60-s trials were conducted in each condition. The following variables were calculated: the Center of Pressure position (CoP), the mean velocity and the standard deviation (SD) of the CoP excursion in antero-posterior and medio-lateral direction.

RESULTS: The CoP velocity was greater in children compared to adolescents in all sensory conditions ($p < 0.05$), while no differences were observed in CoP SD. However, the adolescents presented greater postural displacement due to vibration compared to children ($p < 0.05$).

CONCLUSION: The balance control and the processing of sensory integration are still developing in children, however, it seems that they did not rely primarily on leg muscle proprioception compared to adolescents during postural control.

HOW TO AFFECT THE DIFFERENT SHOE-LACING ON IMPACT ACCELERATION AND PERCEIVED CONFORT RUNNING?

SÁNCHEZ-RIBES, E., CATALÁ-VILAPLANA, I., SANCHIS-SANCHIS, R., MARZANO-FELISATTI, J., SENDRA PÉREZ, C., PÉREZ-SORIANO, P., ENCARNACIÓN-MARTÍNEZ, A.

UNIVERSITY OF VALENCIA

INTRODUCTION: The regular practice of running has increased in popularity due to the benefits it brings (1). However, an increase in injuries is observed (2). Several studies present shoe-lacing pattern as a risk factor that it has effects on performance and comfort (3).

METHODS: The study sample consisted of 24 runners (12 men and 12 women). The participants performed a prolonged running test on treadmill (h/p/cosmos pulsar® 3p, h/p/cosmos, Nußdorf, Germany), formed by a warm-up of 5 min at 2,22 m/s and 20 min of running at 2,77 m/s with an incline of 1%. Two shoe-lacing patterns were tested: conventional crossover lacing and heel look lacing. The biomechanical accelerometry variables were collected using Xsens DOT sensors (Xsens Technologies B.V., Enschede, The Netherlands), heart rate by a pulsometer (Polar V800, Polar Electro, UK and perception of effort by a Borg' scale (6-20)(4); throughout the prolonged running test at minute 1, 5, 15 and 20. Finally,

comfort test was recorded after running using a visual analogue scale. The statistical analysis was carried out using the statistical package for social sciences software SPSS V26 (IBM Corp., Armonk, NY). The differences were tested using a repeated measures ANOVA, establishing the shoe-lacing pattern and instant as within-subject factors and the sex of the participants as an between-subject factor, the effect size was calculated using the partial eta squared and a significance level of $p<0.05$ was established.

RESULTS: In relation to the type of shoe-lazing pattern, they didn't influence the heart rate and effort perception variables.

On the other hand, we found that maximum impact peak was higher at right tibia ($p= 0.043$, ES=0.219) and head with the conventional crossover lacing ($p=0.003$, ES= 1.175). The impact magnitude on the head with both legs: right leg ($p= 0.22$, ES= 1.166) and left leg ($p= 0.01$, ES= 0.917) were higher in conventional crossover lacing also. The values to attenuation were higher with left leg ($p=0.038$, ES=1.014) at the heel lock lacing.

Finally, comfort results show a decrease comfort perception at plantar sensation in crossover lacing ($p=0.017$, ES=0.231) and the loop comfort perception was the best comfort at heel lock lacing.

In relation to the instant, the values of heart rate and perception effort increased during time running test, in this sense-head magnitude impact with both legs-right ($p= 0.22$, ES= 1.166) and left ($p= 0.01$, ES= 0.917) were higher at instant 5, and the attenuation values were higher with the impact of the left leg ($p=0.038$, ES=1.014) at all instants.

CONCLUSION: The conventional crossover lacing shows higher peaks impact head. The impact attenuation increases with the heel lock at the beginning and it is maintained during the rest of running test. Finally, these results show that the use of different lacing could modify running impact variables and perceived comfort.

MEASURING CADENCE IN ROAD CYCLING BASED ON MACHINE LEARNING AND SEAT POST MOTION

HOLLAUS, B., VOLMER, J.C., FLEISCHMANN, T.

MCI INNSBRUCK

INTRODUCTION: Cadence is a parameter of major interest in cycling. The most common mode of measurement is based on a permanent magnet and a hall effect sensor. Alternative methods utilize the motion of the pedals [1] or measure the angle of the crank arm directly [2]. These given systems have drawbacks regarding costs, exposure or are providing limited information. Therefore, this work conducts a study to examine the possibility of cadence measurement based on the motion of the seat post [3].

METHODS: In a first step, an embedded system was developed to be able to record the motion data as well as the analog cadence signal from a hall effect sensor in a synchronized fashion. Secondly, an experiment was planned out and ethically approved. After all participants had signed a form of consent, the experiment conducted to gather corresponding data. Four road cyclists (males and females, aged from 23 to 57) carried out 13 rides in total and provided 642 minutes of data, comprised of three-dimensional accelerations, spin rates and magnetic flux densities combined with the analog cadence signal from the hall effect sensor. The recorded data was resampled to 50 Hz. The analog cadence signal was preprocessed to get wider impulses in the cadence signal, so the optimizer needs to focus more on the impulses during training. The preprocessed data was subsequently split into training, validation and test sets. The neural network, which was based on a convolutional neural network architecture, using dense and pooling layers in combination with a long short term memory, was trained using a mean squared error loss function and the Adam optimizer [4]. The final network requires merely the last 50 samples of the acceleration data as input and predicts the current analog cadence signal. Based on the predicted and measured cadence signal, the cadence is calculated by counting the number of peaks in both signals within a minute.

RESULTS: The accuracy of the network for the prediction of the cadence signal was 92.9%. The comparison of the predicted cadence to the ground truth above 50 rpm showed an overprediction of cadence by approximately 0.9 rpm on average with a standard deviation of approximately 2.05 rpm.

CONCLUSION: The original goal was to find out whether it is possible to measure cadence based on the motion of the seat post. The results show strong evidence that it is possible, but with limitations regarding the accuracy. Nevertheless, this supports the hypothesis that cadence measurement may be conducted by motion sensors in smart devices, without the need of external measurement systems.

INERTIALLY SENSED INTER- AND INTRA-TRIAL RELIABILITY OF MOVEMENT PATTERN DURING REPETITIVE SQUATTING

EMMANOUIL, A., ROUSANOGLOU, E., BOUDOLOS, K.

NATIONAL AND KAPODISTRIAN UNIVERSITY OF ATHENS, SCHOOL OF PHYSICAL EDUCATION AND SPORT SCIENCE

INTRODUCTION: Repetitive squatting is one of the most widely used exercises in strength, power, and mobility training worldwide, thus triggering the research interest concerning its spatiotemporal pattern [1]. Inertial sensing allows a valid detection of spatiotemporal patterns and may be applied in field settings [2]. This study aimed to estimate the inertially sensed intra-trial reliability of spatiotemporal variables during repetitive squatting to determine the number of trials and repetitions per trial that allows a reliable evaluation of the squat pattern.

METHODS: Thirty active men and women (26±6 yrs) performed 3 trials of 20 squats per trial (preferred tempo). An inertial sensor (Xsens MTw Awinda, sampling at 100Hz, attached to the trunk at L5 level) was used to record the angular displacement trajectories (sagittal plane). Angular displacement demonstrated clear periodic peaks (anterior direction) and dips (posterior direction) and served to define the squat cycle initiation and termination. For each squat cycle (1st and 20th were excluded to eliminate the effect of trial initiation and termination) and after signal pre-processing (2rd-order Butterworth lowpass filter; cut-off frequency at 2 Hz, Matlab R2021b) the following variables were defined: squat cycle duration (tcycle), squat tempo (cycles per minute), absolute (s) and relative (%tcycle) ascent and descent phase duration, and the trunk tilt (degrees). For all variables, the inter- and intra-trial reliability were estimated using the relative (ICC: intraclass correlation coefficient, ICC 2-way random effects absolute agreement method) and the absolute (SEM%: percentage standard error of measurement) reliability index. Both reliability indices were applied for repetition accumulation (2nd to 3rd, 2nd to 4th, ..., 2nd to 19th) for the average of 2 and 3 trials, respectively (SPSS 28.0, $p<0.05$). The ICC values were interpreted as poor (<0.40), fair to good (0.40-0.75), and excellent (>0.75) [3].

RESULTS: Overall, a total of just 2 trials with 3 repetitions per trial proved sufficient for excellent relative reliability (ICCs □ 0.93 across all variables). However, the SEM% indicated a total of 3 trials (3 repetitions per trial) for absolute reliability ranging well below 5% across all variables.

CONCLUSION: The reliability analysis applied for repetition accumulation revealed that 3 trials with 3 repetitions per trial (that is a data collection with 5 repetitions per trial to exclude the 1st and the last one) are sufficient to ensure an excellent - both relative and absolute-inter- and intra-trial reliability across all examined spatiotemporal variables of the squat pattern during repetitive squatting.

RELATIONSHIP BETWEEN ANTHROPOMETRIC CHARACTERISTICS AND BALL VELOCITY IN ELITE ADOLESCENT HANDBALL PLAYERS

NOUTSOS, K., MELETAKOS, P.

NATIONAL & KAPODISTRIAN UNIVERSITY OF ATHENS

INTRODUCTION: The performance evolution of handball players needs to be studied in many areas such as anthropometric characteristics and ball velocity. The purpose of this study was to investigate the effects of anthropometric characteristics on ball velocity in handball.

METHODS: In this study, 60 handball players age= 17.61±1.53 years, body height =183.77±5.9 cm, body mass = 82.68±9.03 kg, with an average training experience of 6.86 ± 2.03 years and weekly training volume 8.21 ± 2.71 (hrs) participated and were evaluated. The measurements included body height(cm), body mass, body mass index (Kg/m2), arm span(cm), hand length(cm), hand width (cm), five skin folds thicknesses (mm) (biceps, triceps, subscapular, suprailiac and calf), three circumferences(cm) [calf and biceps girth (relaxed and tensed)] and two widths(cm) (femur, humerus). Fat Mass percentage (%), fat free mass (kg), Fat mass (Kg), and Sum of 5SKFS (mm) were all calculated. The precise anatomical sites of measurement by the respective somatometric instruments and the measurement procedures were all carried out according to Norton et al., 2000. Ball velocity was measured using a Radar Gun (Sports Radar 3300, Sports Electronics Inc) with ±0.1 Km/h accuracy within a field of 10o from the gun. The Pearson's correlation coefficients were calculated between all parameters. A stepwise multiple regression analysis with the anthropometric indices as the dependent variables and ball velocity as potential predictors was carried out.

RESULTS: A statistically significant simple positive correlation was found between age (r = 0. 423, p = 0.001), humerus breadth (r = 0. 280, p = 0.030), upper arm flexed and tensed girth (r = 0. 274, p = 0.034), upper arm relaxed girth (r = 0. 307, p = 0.017), fat free mass (r = 0. 483, p = 0.000), fat mass (r = 0. 275, p = 0.033), BMI (r = 0. 356, p = 0.005), hand width (r = 0. 347, p = 0.007), hand length (r = 0. 378, p = 0.003), and ball velocity at standing position, and a negative correlation between weekly training volume and ball velocity at standing position. The multiple linear regression identified that anthropometric characteristics provided good explanatory power for ball velocity at standing position 35% (p =

0.024). The anthropometric characteristic with the highest explanatory power in the regression model for ball velocity at standing position was fat free mass (p = 0.024) followed by age and hand length.

CONCLUSION: Variables related to fat free mass, age, hand length may contribute to handball throwing performance.

STRUCTURAL RELATIONSHIP BETWEEN SUBJECTIVE CONFIDENCE AND OBJECTIVE KNOWLEDGE IN DECISION-MAKING

NAGAMINE, K.1, AOYAGI, O.1, KOMURE, I.1, YAITA, A., TAGATA, S.2, ANNOURA, T.3, OHYAMA, Y.4

1FUKUOKA UNIVERSITY, JAPAN, 2HITACHI HIGH-TECH COUGARS, JAPAN, 3JAPAN UNIVERSITY OF ECONOMICS, JAPAN 4NATIONAL INSTITUTE OF TECHNOLOGY, SASEBO COLLEGE, JAPAN

INTRODUCTION: During a basketball game, it is necessary to execute instantaneous decision-making to perform effective plays. However, since various situations change instantaneously in basketball games, it is not easy to examine the instantaneous decision-making process. However, subjective confidence and knowledge of decision-making, which are the basis for instantaneous decision-making, can be examined because they are not time-bound and can be taken up as research subjects. Furthermore, it is easy to analogize that the subjective confidence and objective knowledge of decision-making for basketball games differ among basketball players and others. Therefore, the purpose of this study is to clarify the knowledge that is structurally related to the confidence that is important in effective play selection, based on the relationship between both that confidence and knowledge. By doing so, it is possible to identify the objective knowledge that is necessary for PE classes in which students acquire a sense of self-efficacy in improving their own ability for decision-making.

METHODS: The subjects consisted of 346 university students taking PE basketball classes. The content of the 18 subjective confidence questionnaire items was based on a Japanese version of the questionnaire items created by Elferink-Gemser, et al. (2004), and they were revised in order to be specific to basketball skills, which were surveyed with a 5-point scale. The objective knowledge test consisted of 16 multiple-choice tests with 4 items on Offense, 4 items on Defense, 4 items on Transition, and 4 items on Rebounding. From the two sets of data, correlation ratios were computed and a cross table, consisting of 1s for the combinations of items that showed significant values and 0s for the combinations of items that did not, was created. The two-dimensional configuration was displayed, and groupings were made using Quantification Theory Type Three. In grouping, clusters were created using hierarchical cluster analysis to investigate structural associations between subjective confidence and objective knowledge groups.

RESULTS: As a result of cluster analysis, the following four clusters were extracted: "Cluster 1 (C1): General decision-making," "C2: Individual situational judgment," "C3: Instantaneous decision-making" and "C4 Decision-making in interpersonal play." The results suggest that improving subjective confidence, which was classified into four clusters, improves knowledge of each of the decision-making cases necessary for basketball games. In addition, with "C3 Instantaneous decision-making," many of the objective knowledge test items were related, suggesting that the students need to watch the opponents movements during the game and choose the best play to make.

CONCLUSION: Gaining knowledge of decision-making before a game, such as how to defend against opponents and understand transitions, is thought to lead to increased confidence and improved skills.

THE CLASSIFICATION AND PREDICTION OF FACTORS REGARDING AWARENESS OF COMPREHENSIVE COMMUNITY SPORT CLUBS USING A TREE STRUCTURE

ANNOURA, T.1, AOYAGI, O.2, NAGAMINE, K.2, KOMURE, I.2, TAGATA, S.3, OHYAMA, Y.4, YAITA, A.

1JAPAN UNIVERSITY OF ECONOMICS, JAPAN, 2FUKUOKA UNIVERSITY, JAPAN, 3HITACHI HIGH-TECH COUGARS, JAPAN, 4NATIONAL INSTITUTE OF TECHNOLOGY, SASEBO COLLEGE, JAPAN

INTRODUCTION: The features of comprehensive community sport clubs (CCSCs) in Japan are that young and old people with an athletic level from poor to excellent can get familiar with sports in their community. CCSCs have been advocated as one measure to promote sports by the Ministry of Education, Culture, Sports, Science and Technology since 1995. They are independently managed by people who live in their communities. However, the degree of awareness of them is not necessarily sufficient and acknowledgement and recognition of them by people are needed prior to promoting them. It is important to discriminate to understand whether CCSCs are using these features. Thus, this study investigated the factors that make people come to recognize the existence of CCSCs using a decision tree. Although multivariate analysis that uses composite scores summing up all weighted variables is usually used, it was thought to be impractical in this case. Therefore, this study used a decision tree method using a few variables to assess it in a practical way.

METHODS: A questionnaire containing the following 10 items in addition to "whether or not CCSCs are known" was conducted: individual features such as "Gender," "Age," "Confidence in physical fitness/sports," "Like or dislike of PE classes in elementary school," "Lessons other than exercise/sports," "Family members who play sports," "Acquisition of information on sport clubs through the media" and "Desire to play sports alone, with two to four others, or with more than five others." The questionnaire was conducted on 1,361 people. Of these, the responses of the 560 people who answered that they do not exercise nor play sports were used for the analysis. While using as few items as possible, a tree structure classifying two groups of people who know about CCSCs and those who do not was derived. A rpart() function in R was used for the analysis and the cp (complexity parameter) was set to 0.001.

RESULTS: As a result, a tree-based model with four layers and four nodes that branch to the right and left in two ways depending on the options to the question was obtained. The correct discriminant rate was 87.3%. Although the specificity to correctly find out the group that did not know about CCSCs was 98.6%, indicating fairly high, the sensitivity to correctly

find out the group that did know of CCSCs was very low at 3.0%, indicating that this tree structure is effective in predicting those who do not know about CCSCs. Since the items included in this tree structure were "Acquisition of information on sport clubs through the media" and "Desire to play sports alone, with two to four others, or with more than five others," people who know about CCSCs often see advertisements for sport clubs, and want to exercise or play sports alone or with fewer people.

CONCLUSION: Contact with information about sport clubs and the desire to exercise or play sports alone or with a small number of people are involved in the awareness of CCSCs.

TRAINING DISTRIBUTION IN ROWERS: A CASE STUDY OF AN OLYMPIC GOLD MEDALIST

WANG, Y.

BEIJING SPORT UNIVERSITY

INTRODUCTION: Against the backdrop of the postponement of the Tokyo Olympic Games, the Chinese National Rowing Federation made training measures and load adjustments for the competition year of the Tokyo Olympic cycle. As a result of the load design, Chinese elite rowers won a gold medal and two bronze medals at these Olympic Games. The purpose of this paper is to analyze the overall load differences between the two years of preparation for the Olympic Games using the two-year training cycle of the bronze medal-winning Chinese women rowers as an example

METHODS: METHODS: Subject

Table 1 : Elite rowers personal information

Number Year High body

weight（kg）

X1 24 179 74

X2 30 187 78.4

X3 27 188 80.6

X4 29 181 85

X5 28 181 85

X6 29 181 76

X7 27 180 81

X8 29 185 78.5

Eight female former and current China elite rowers (Table 1). All athletes had won a least one individual Olympic or World Championship senior gold medal during their career.

Design

The training schedule was adjusted to September 2019-August 2020 for the Olympic qualifiers and September 2020-August 2021 for the Olympic competition. During this cycle, the researchers have systematically and accurately recorded the rowers training routines. The training consisted of training time on the water, dynamometer （Concept2） training, strength training, cross training and other training.

RESULTS: For the womens eight-man single scull, the total load for the two competition years was 1243.26 hours and 988.37 hours, respectively. Water training was reduced by 20.18 hours, Concept2 training time was decreased by 98.32 hours, strength training was accelerated by 141.40 hours, cross training was reduced by 3.08 hours, another training was increased by 42.82 hours, stretch regeneration was decreased by 34 hours, and overall training time was reduced by 254.89 hours, according to a comparison of the two competition years.

CONCLUSION: This case study is the first study in Chinese rowing to adjust the load for the summer Olympic Games competition year, and the total load for the two competition years supports the previous conclusion that elite endurance athletes train up to 1000 hours per year and are not significantly altered by changes in Olympic competition time limits.

PERFORMANCE INDICATORS THAT PREDICT SUCCESS DURING COUNTER-ATTACKS IN WORLD CUP MATCHES

APOSTOLIDIS, N., ARMATAS, V.

UNIVERSITY OF ATHENS

INTRODUCTION: It has been reported that although counter-attacks occur less frequently during soccer matches than organized attacks, they are the most effective style of play for scoring goals, especially against an imbalanced defense. Moreover, as football is a low scoring sport, general measures of offensive effectiveness such as scoring opportunities, shots on goal, and final third pitch entries have been proposed as good indicators. The present study aimed to investigate the factors associated with final third entries during counterattacks during men's, women's and u20 men's World Cup (WC) matches.

METHODS: The sample consisted of 48 knockout World Cup matches (16 Men's WC 2018, 16 Women's WC 2019 and 16 u20 Men's WC 2019). The study design included the analysis of the following indicators: (a) situational indicators, (b) defensive performance indicators, (c) offensive performance indicators, (d) the possession result, "final third entry" or "no final

third entry", was used as a dependent variable. Intra- and inter-reliability of the observational instrument was tested, as described previously, with mean kappa statistics of k=0.95 and k=0.89 classified as "perfect" agreement respectively. Binary logistic regression models were constructed for each tournament included the above performance indicators as predictors and the dichotomous result as the predicted variable. The backward Wald method was used and all assumptions of binary logistic regression were met.

RESULTS: The following indicators increase the likelihood of entering into the final third during counter-attack for each World Cup tournament: (1) Men WC 2018 : low defenders' position, inside penetration zone, low pass number, high penetrative pass number, long duration and offensive half pitch recovery, (2) Women WC 2019 : low defenders' position, inside penetration zone, low pass number, high penetrative pass number, long duration and offensive half pitch recovery, (3) Men u20 2019 : low defenders' position, 4-5 defenders, 1-3 attackers, long duration and offensive half pitch recovery.

CONCLUSION: The regression models identified common indicators in order to increase the likelihood of entering the final third during counter-attack between the three tournaments. No previous study has used final third entry as predicted variable for success during women's and youth's tournaments. Consistent with previous studies, our results revealed agreement for recovering inside opponent's penetration zone and inside offensive half pitch, with high proportion of penetrative passes, participating 1-3 attackers. The present results provide practical implications for training counter-attacks both from offensive and defensive point of view, as well as for coach's decision making prior and during match-play.

A KINEMATIC ANALYSIS OF THE EFFECT OF THE DIFFERENT BALL MASS ON THE KICKING MOTION IN THE SOCCER PLAYER OF ELEMENTARY SCHOOL

TAGO, T., KANEKO, K., TSUCHIOKA, D.

TOKUSHIMA BUNRI UNIVERSITY

INTRODUCTION: This study was to establish guidelines for proper selection of soccer balls for elementary school students by conducting a kinematic analysis of the form displayed by students of a youth soccer team when kicking two types of balls with differences in mass—a size 4 ball and size 3 ball .

METHODS: Ten youth soccer team players aged 8-11 years, who all kicked using their right foot, were included in this study. On a youth soccer pitch, the participants were asked to perform an instep kick with full strength to hit a stationary soccer ball toward a target 8 m away. Two types of balls were used in the experiment—a size 4 ball weighing 360 g (hereafter, normal) and a size 3 ball weighing 300 g (hereafter, light). The kinematic parameters calculated were the angular velocities of the hip joints of the kicking and supporting legs.

RESULTS: The mean rebound ratio (the ball speed divided by the speed of the toes immediately before impact) was 1.126 ± 0.076 for normal and 1.214 ± 0.049 for light balls. The ratio of these rebound ratios (light/normal) was 1.077. The participants were divided into groups in reference to this ratio: SG group, rebound ratio < 1.077 and WG group, rebound ratio > 1.077. Three participants were selected: one in the SG group whose mean light/normal ratio was close to the mean light/normal ratio of the entire SG group (HS), another in the WG group with the lowest light/normal ratio (SO), and another in the WG group with the highest light/normal ratio (KS). These selected participants were compared as typical examples. With respect to the adduction/abduction angular velocity of the hip joint of the kicking leg on impact, there was no significant difference in the peak value between the normal and light balls for HS from the SG group, while it was apparently higher with the light ball than with the normal ball for SO and KS from the WG group. With respect to the extension/flexion angular velocity of the hip joint of the kicking leg on impact, after an initial large extension angular velocity, HS from the SG group exhibited a gradual decrease in velocity, whereas SO and KS from the WG group demonstrated a sudden decrease. All three selected participants exhibited a high extension/flexion angular velocity of the hip joint of the supporting leg on impact, with no significant difference.

CONCLUSION: For SO and KS from the WG group, the adduction angular velocity of the hip joint of the kicking leg was high on impact with the light ball. For HS from the SG group, the adduction angular velocity of the hip joint of the kicking leg was high with the normal ball. This suggest that the adduction angular velocity of the hip joint of the kicking leg might have been insufficient for the normal ball in the WG group. In particular, SO tended to exhibit a lower adduction angular velocity of the hip joint of the kicking leg with the normal ball, suggesting the effect of the difference in the ball mass.

CHARACTERISTICS AND DIFFERENCES IN THE VERBAL RESPONSES OF EXPERT AND NOVICE BASKETBALL COACHES ELICITED BY COGNITION OF FIXED VTR IMAGES AND VR IMAGES

YASUYUKI, N.

NIIGATA UNIVERSITY OF HEALTH AND WELFARE

INTRODUCTION: In this study, in order to examine how coaches perceive phenomena during a basketball game, we reproduced fixed VTR images that captured the entire space where the phenomena occurred and VR images recorded with a 360-degree omnidirectional camera, and explored the differences in the coaches' verbal responses during viewing of each type of image.

METHODS: The persons to be analyzed are 2 novice coaches and 2 proficient coaches in the college basketball club. As for the image collection method, the practice games of the college basketball were recorded by installing a fixed video camera and a 360-degree omnidirectional camera on the side of the benches where the coaches sit. 4 subjects uttered

while watching the images recorded by a fixed video camera (hereinafter referred to as "fixed VTR images") and the images recorded by a 360-degree omnidirectional camera (hereinafter referred to as "VR images"). The subjects freely utter what they think while watching the recorded game images.

RESULTS: As a result of classifying utterances, there were 9 categories. The categories are situation description, expectations and proposals, prediction, retrospection, praise (general), praise (concrete), instruction, and criticism. The fixed VTR images were able to elicit a certain amount of verbal responses from the novice coaches in categories that objectively captured the phenomena taking place, such as situation description, prediction, and general praise or criticism. Among the proficient coaches, the same verbal responses were elicited during fixed VTR image viewing as during VR image viewing, regardless of category. While viewing the VR images, the novice coaches tended to make fewer verbal responses in all categories, whereas the proficient coaches made similar verbal responses in all categories as they did while viewing the fixed VTR images. In addition, more verbal responses of the expectations and suggestions, praise, and instructions categories were made by the proficient coaches during VR image viewing than during fixed VTR image viewing.

CONCLUSION: 1) From fixed VTR images, both novice and proficient coaches tended to observe phenomena objectively, in terms of being able to describe the situation and offer guidance and criticism.

2) From VR images, proficient coaches tended to offer praise or instructions on the basis of specific individual characteristics of player or team movements.

A STUDY ON PERFORMANCE COMPOSITION OF UNEVEN BARS

MURAYAMA, D.

KYOTO UNIVERSITY OF ADVANCED SCIENCE

INTRODUCTION: In recent years, there have been big changes in the composition of the uneven bars in womens gymnastics. In particular, the pattern of move between high and low bars (bar change) is clearly different from that of 10 years ago. It is important for gymnasts and coaches to select a training subject suitable for the times at the training field. For that purpose, it is necessary to grasp the trend of performance composition that changes day by day from the results of actual competitions.

This study examined all the performances of top Olympic games over the last 30 years. And we revealed what changes in performance composition have occurred throughout history. In addition to that, by showing the performance trends as of 2023, we aimed to give effective knowledge to the training field.

METHODS: In this study, the following methods were used.

1) Video clips were checked of the performance composition of all gymnasts who participated in the finals of each Olympic event from 1988 to 2021. The performance number was 72.

2) In the performance, we categorized the type of swing elements, support elements, bar change element and dismounts.

3) We clarified the changing trends in acting over the past 30 years and showed the acting trends as of 2023.

RESULTS: As a result of the analysis, it was found that the frequency of performing swing elements has been decreasing, and as of 2021, the percentage during performance was 50%. Among the bar change elements, there was an increasing tendency to "Inner front support on low bar, back circle through handstand with flight to hang on high bar". As of 2021, all finalists have performed the element more than once.

CONCLUSION: The guidelines for future training have been clarified from the trends in the composition of the uneven bars. In other words, rather than emphasizing the practice of swing elements on the high bar, it is better to incorporate many of the element of the "Inner front support - back circle", into the training target.

Through this research, we were able to obtain useful knowledge for training on uneven bars.

A STUDY ON IMPROVEMENT OF TEACHING SKILL OF BALL MOVEMENT IN UNIVERSITY STUDENT AIMED BECOME SPORTS INSTRUCTOR

YAMADA, M.

DOHO UNIVERSITY

INTRODUCTION: The skill coaching ability greatly influences depth of sports experience of the sports instructor himself/herself. In the field of sports practice, immediate response is required for various movements that exhibit complex structures. If coaches and teachers do not have the depth of variations in movement and the diversity of teaching techniques, athletes/students will not improve their movement. Movement using a ball is the basis for developing various sports, so the instruction must be done carefully. It is especially important for young children and those new to movement. There are few studies that show the relationship between sports experience and skill coach ability of sports instructors and improve coaching ability. This study focused on specialized classes related to ball movement instruction in the training course of sports instructors (physical education teachers), and verified the effects based on specific instructional practices.

METHODS: The subjects were 20 university students aiming to become sports coaches or physical education teachers. We extracted the subjective sensory consciousness generated in the ball-throwing movement in teaching practice and analyzed it from a phenomenological standpoint. The observational analysis of movement was conducted by the first author.

Observers focused on the formation and execution of movement images and the results of movement. In addition, we recorded students behavior on repetition after instruction of the movement.

RESULTS: As a result of the analysis, it was found that the skill of ball movement and the build of the movement image were performed. In addition, the subjects showed an increase in variations in movement patterns and repetitive phenomena. From these results, it was found that it is possible to improve movement skill coach for college students who have little sports experience.

CONCLUSION: Through this study, we were able to deepen the sports experience of the sports instructors, and obtained new knowledge to improve their coaching ability of ball movement.

STUDY ON ATHLETIC ABILITY THAT DETERMINE INFANT'S ABILITY OF LONG THROW : EXAMINATION OF CONTRIBUTION BY MULTIPLE REGRESSION ANALYSIS

MURAKAMI, K., HISAYUKI, T.

ODAWARA JUNIOR COLLEGE

INTRODUCTION: The purpose of this study was to examine the motor ability that contributes to infants long throwing ability based on multiple regression analysis.

METHODS: A total of 173 boys and girls aged 3 to 5 years were the participants. To measure long-distance throwing ability, participants were asked to throw a softball ball (hereafter referred to as ball throwing) twice. Out of the two times, good records were adopted. The motor ability test consists of items that can be performed by infants and are commonly used to measure motor ability, such as sprint (25m), standing long jump, long sitting forward flexion, standing on one leg on a pole, maintaining body support, jumping over both legs continuously, and grip strength. Then, multiple regression analysis was performed with the results of ball throwing as the objective variable and the results of each motor ability test as the dependent variable for each age and gender, and partial regression coefficients were obtained. Then, we calculated the standardized regression coefficient (β) and examined the contribution of motor ability to determine throwing ability.

RESULTS: As a result, the ball-throwing record improved with age for both boys and girls. This result is like previous studies such as Fujii (2006). This was particularly noticeable in boys, and the standard deviation tended to increase with age (3; 3.03±1.07m, 4; 5.40±2.18m, 5; 7.64±4.19m). A previous study reported that "because the throwing movement is an ontogenetic movement, its ability contributes to acquired factors". Based on this report, it is suggested that boys experience value for acquiring throwing ability is polarized between boys with high throwing ability and boys with low throwing ability. This was more pronounced with increasing age. The results of multiple regression analysis showed that men and women tended to have different motor abilities that determine throwing ability. Examination of the degree of contribution based on the standardized regression coefficient (β) revealed that grip strength had the highest value in boys ($\beta = 0.499$). Girls showed high values in standing long jump and long sitting forward bending (Standing long jump; $\beta = 0.631$, Long sitting forward bending; $\beta = 0.441$).

CONCLUSION: Grip strength is an index of whole-body muscle strength, and it is possible that boys throwing ability is determined by muscle output rather than kinematic dexterity and coordination. On the other, the standing long jump and long sitting forward bending require dexterity and coordination, suggesting that girls throwing ability is determined by the coordination of body manipulation. From these results, it is conceivable that there is a possibility that there is a gender difference in the performance of throwing ability from infants when there is no difference in physique and muscle mass. This is a finding that will be helpful in teaching for exercise for infants.

FEATURES OF VISUAL SEARCH BEHAVIOR DURING BALL TRACKING IN UNIVERSITY TABLE TENNIS PLAYERS

SUGAJIMA, Y.1, KATO, T.1, SAKAMOTO, S.1, NISHIMURA, M.1, NOMURA, Y.1, YOSHIDA, M.1, YOSHII, I.2

1> ASAHI UNIVERSITY; 2> OSAKA METROPOLITAN UNIVERSITY

INTRODUCTION: Table tennis is a game in which players must quickly and accurately return balls with a racket to scores points; in this context, accurate returns require instantaneous reading of the movement of the opponent, racket, and ball. As such, investigation of the visual search behavior of players to the batted ball is important to consider the ideal prediction method. Hence, the purpose of this study was to clarify the characteristics of the visual search behavior of university table tennis players using a wearable eye-tracking device.

METHODS: In total, 37 players, including 24 university table tennis players (16 men and 8 women) and 13 non-table tennis players (all men), hit 10 balls each under four conditions: forehand stroke (F), backhand stroke (B), F+B, and interpersonal rally (R). A wearable eye tracker (Tobii Pro Glasses3, Tobii Co.) was used to capture the front background image and visual search behavior at 50 frames/s to analyze the ball return duration, ball tracking duration, and tracking rate during play. In addition, the distance between the opponents was divided into five areas (opponent, Area I; opponent's end side, Area II; opponent's net side, Area III; own net side, Area IV; own end side, Area V), and the fixation duration and fixation-duration ratio of the gaze during play were analyzed for each area.

RESULTS: The eye tracking duration for the batted balls and tracking rate for return duration were shorter in elite players than in non-table tennis players (56–65% vs. 72–77%). In addition, regarding the fixation duration of the gaze, non-table tennis players concentrated on the Area I during ball play (F, B, and F+B) and on the Area II during R. However, the table tennis players concentrated on the Area II to the Area III, regardless of the trial.

CONCLUSION: University table tennis players have a shorter eye tracking duration and lower tracking rate than non-table tennis players, meaning that they can identify and predict the ball to return balls more quickly. In addition, non-table tennis players were tracking the ball while keeping their eyes on the opponent and elite table tennis players keeping their eyes near the opponents net. These results suggested that elite college table tennis players mainly focused on the area around the net, and acquired visual information of the opponent and the ball while playing by covering the whole area with peripheral vision.

DECISION-MAKING OF PLAYERS WITH SOCCER AND FUTSAL BACKGROUND

SMIRNIOTOU, A., GIOLDASIS, A., THEODOROU, A., BEKRIS, E., APOSTOLIDIS, N.
KAPODISTRIAN UNIVERSITY OF ATHENS

INTRODUCTION: Acquisition of perceptual-motor skills in sports domains is a multidimensional process. In team sports such as soccer, the development of skills can be enhanced through practice under multi-interacting constraints during task performance (e.g. playing soccer with different formats, dimensions, number of players, and rules such as those of Small Sided Games or futsal). Based on the concept of affordances, futsal enriches the learning process and benefits skill acquisition which may be transferred to the "parent" sport [1]. Transferable elements are mainly motor, perceptual, and conceptual while tasks with similar elements are expected to allow greater transfer between domains. Futsal is an indoor 5-a-side variant of soccer many of its tactical, technical, and perceptual skills replicate the 11-a-side game. Playing with reduced personal space has the potential to improve skills because players are forced to make quicker technical and tactical decisions. Taking into account that decision-making skills part of which consist of recognition and recall skills transfer between sports, it is essential to assess their transferability. The aim of the study was to examine whether the decision-making of players is specific to futsal and/or soccer or whether it may be transferred between them.

METHODS: 26 male players (17.19±0.91yrs) with 7.81±2.32 years of experience, 11 of which had also played futsal (3.09±0.83yrs) participated in this study. The participants viewed 60 life-size (1.5mX1.5m with 0.50cm distance from floor) video sequences of soccer and futsal footage that a panel of UEFA-qualified coaches selected and rated. The videos are based on temporal occlusion decision-making procedures. Each footage started with a 3sec frozen frame with a circled player of which the participant played his role, followed by a 7sec video evolution and ended when a 3sec frozen frame appeared with 3 passing options. During the final 3sec frozen frame, the participants were required to select the option they would execute. ANOVA was used to analyze differences in decision-making tasks according to sports background ($p< 0.05$).

RESULTS: Significant differences were found between groups on decision-making in both futsal ($F= 5.03$, $p< 0.05$) and soccer ($F= 4.67$, $p< 0.05$) footage. Players with a futsal background showed higher decision-making performance in both futsal (115.50±5.24 vs 106.35±5.99) and soccer (234.50±5.93 vs 227.29±9.45) tasks.

CONCLUSION: It seems that although decision-making skills are transferable across sports, the transferability of players with a soccer background was lower. This is probably explained by the fact that futsal constraints are more relevant to soccer and players with a futsal background have developed recognition and pattern recall skills more than players with a soccer background. Additionally, it is possible that acquired visual search behaviors of futsal players may be transferred between sports [2].

EYE TRACKING ANALYSIS DURING VOLLEYBALL SPIKE USING WEARABLE DEVICE -COMPARISON OF BEGINNER, INTERMEDIATE AND ADVANCED PLAYERS-

KATO, T.1, HONDA, K.1, UMENO, S.1, YOSHII, I.2, TAKAMI, K.3, SUGAJIMA, Y.1
1> ASAHI UNIVERSITY, 2> OSAKA METROPOLITAN UNIVERSITY, 3> HOSEI UNIVERSITY

INTRODUCTION: In volleyball, visual information is crucial to ensure that the ball is not dropped in your own court and in order to ensure that the ball is dropped in the oppositions court. When receiving instructions on how to perform a spike in volleyball, how many of us remember receiving information on where to look? Therefore, the aim of the study was to determine the gaze characteristics of novice, intermediate and expert volleyball players using a wearable eye tracking device. It was thought that teaching based on new visual information and the analysis of this information may be able to find the key to improving volleyball spike techniques and performance.

METHODS: The experiment was conducted with 21 university students belonging to the Department of Health and Sports Science, divided into 3 groups: beginners (3 adult female kendo players and 4 table tennis players), intermediate (5 adult male baseball players, 1 male tennis player and 1 male handball player) and advanced players (7 male members of volleyball team). Participants were fitted with smart glasses (Tobii Pro Glass 3, Tobii Technology), to analyse their eye gaze dynamics from the first touch to the spike hit. The dwell time that the eye gaze was stationary in certain areas of interest at less than 100 deg/sec was measured. This wearable device in the form of glasses, which uses a stereo imaging method to detect the scotopic pupil using the corneal reflections of two pairs of cameras on the top and bottom of the glasses lenses, which detect eye movement. The participants performed the trials twice, with Phase 1 from the receiver's first touch to the setters touch and Phase 2 from the setters touch to the spike hit, and the eye dwell time and eye dwell locations for each phase were analysed. The spiker's eye dwell locations were: 1) the ball, 2) near the ball, 3) the setter, 4) near the setter, 5) the receiver, 6) others. The definitions of near ball and near setter were defined as two balls around the ball and

the setter, not including when the eyes were on the ball or setter. The eye dwell time was expressed as a % of total time, and a one-way analysis of variance was used to test for significant differences among the beginner, intermediate and advanced groups, with multiple comparisons using the tukeys HSD.

RESULTS: Statistical analysis revealed that in Phase 1, beginners and intermediate players had significantly shorter % eye dwell times of 1) the ball (10.8, 4.2 vs 20.4%) and 4) near the setter (21.5, 10.5 vs 42.7%) than advanced players. In Phase 2, there were no significant differences.

CONCLUSION: This result suggested that the key to a successful spiking action exists in the early spike preparation phase (Phase 1). In addition, while the eye dwell locations of 5) receiver and 6) others for advanced players were 0% and 4.9% respectively, for the beginner and intermediate players they were 15%-20%. It is therefore evident that advanced players limit the number of gaze locations to the relevant information.

CHANGES IN PLAYERS' PERCEIVED RECOVERY AND MUSCLE SORENESS DURING AND AFTER A CONGESTED WEEK IN A U-19 SOCCER TEAM FROM THE CZECH REPUBLIC

PALUDO, A.C.1, VENCL, O.2, ZAJIC, L., CACEK, J.1, HRUBY, M.1

1 MASARYK UNIVERSITY; 2 FOOTBALL CLUB, PARDUBICE

INTRODUCTION: An increase in training load with reduced recovery periods characterizes congested weeks, and it could result in residual fatigue, increasing the risk of match-play injury [1] and non-contact injury [2]. Monitoring the perceived recovery and muscle soreness during this period is essential to understand how players tolerate the stress imposed. Therefore, the study aimed to determine changes in perceived recovery and muscle soreness during and after a congested week.

METHODS: Sixteen Czech male soccer players (age 18.3± 4.1 yr; height 183 ± 5.5 cm; weight 73.5 ± 8.1 kg) from a professional U-19 team were monitored during a 5-days training camp, pre-season. The training included technical/tactical (n=7) and strength and conditioning (n=2) sessions, as well as friendly matches (n=2). A Self-reported Likert Scale from 0 to 10 was used to assess players' perceived recovery (0= poor recovery to 10= maximum recovery) and muscle soreness (0= absence of soreness to 10= very intense soreness). Total distance (m) and sprint (m) derived from a global positioning system (GPS) was used as load indicator from technical/tactical sessions and matches. Repeated measures ANOVA was used to compare the days, with Bonferroni post-hoc to detect significant differences. Significance was set at $p<0.05$.

RESULTS: During the 5-day, load indicators were progressively reduced (total distance, day 1= 5.444 ± 680 m and day 5 = 3.470 ± 876 m; sprint, day 1= 420 ± 154m and day 5= 72 ± 138m). Recovery was significantly impaired ($F=21.2$; $p<0.001$) after day 1 (7.73 ± 1.91) and continued during the days (day 2= 4± 0.9; day 3= 4.2± 0.9; day 4= 4.4 ± 1.3; day 5= 3.7 ±1.0 u.a) returning to normal values after one-day resting (7.7 ± 1.0). Similarly, the soreness increased significantly ($F=22.2$; $p<0.001$) after day 1 (2.2 ± 1.7) and continued during the days (day 2= 6.5 ± 1.4; day 3= 6.4± 1.3; day 4= 6.3 ± 1.0; day 5= 7.0 ±0.9 u.a) returning to normal values after one-day resting (2.4 ± 0.8).

CONCLUSION: A congested week demonstrated impairment in players' perceived recovery and muscle soreness after day 1 and remained across 5 days. Even though the load decreased progressively, it can suggest that players presented cumulative fatigue according to the perceptual measures. However, besides the significant reduction in players' recovery and increased muscle soreness, a subsequent return to initial conditions occurred by taking one day of rest after the congested week.

Disabilities

KNOWLEDGE ABOUT SLEEP HYGIENE AND SLEEP BEHAVIORS OF PARALYMPIC ATHLETES: TOKYO 2020 PARALYMPIC GAMES

MELLO, M.T., GRADE, I., MACULANO, A.E., LIRA, F., PADILHA, C.S., STIELER, E., BRANDT, V., SILVA, S., LOURENÇO, T., SILVA, A.

UNIVERSIDADE FEDERAL DE MINAS GERAIS; COMITÊ PARALÍMPICO BRASILEIRO

INTRODUCTION: Paralympic athletes have a high rate of sleep complaints, poor sleep quality, excessive daytime sleepiness, and acute or chronic sleep restriction (1). Sleep disorders in this population have been associated with the occurrence and severity of health problems (2). Sleep hygiene strategies (SHS), such as counseling on behaviors, lifestyle, and environmental factors that can positively influence sleep (3), and improving sleep quality is associated with better sports performance. Therefore, our objective was to evaluate the knowledge about sleep hygiene and the sleep behaviors practiced by medalist and non-medalist para-athletes at the Tokyo 2020 Paralympic Games.

METHODS: This is a cross-sectional study with 98 Paralympic athletes, who represent 52% of the paralympic athletes summoned by the Brazilian Paralympic Committee. Among them, 30 won a medal at the Paralympic Games. All had physical-motor disabilities, and competed in athletics (n = 34), sitting volleyball (n = 26), swimming (n = 14), wheelchair tennis (n = 6), table tennis (n = 8), and bocce (n = 8). =7), fencing (n = 2), and parataekwondo (n = 1). Through an online form, they answered the Sleep Beliefs Scale, the Athletes Sleep Behavior Questionnaire, and a structured questionnaire to investigate the frequency of SHS one month before the trip to the Tokyo 2020 Paralympic Games.

RESULTS: Paralympic athletes had low global knowledge about SHS (57% correct answers), as well as low knowledge about behaviors incompatible with sleep (68%), sleep-wake cycle behaviors (54%), thoughts and attitudes related to sleep

(50%), and high frequency of maladaptive sleep behaviors (48.7 ± 5.9). 26% of Paralympic athletes consider SHS necessary, and the frequency of the technical committee encouraging SHS was significantly higher among medalist Paralympic athletes compared to non-medalists (29% vs. 13%, p = 0.04).

CONCLUSION: Paralympic athletes had low knowledge about SH, a high frequency of behaviors negatively influencing sleep, and few considered SH important. In addition, medalist para-athletes had more significant SHS incentives when compared to non-medalists. This way, technical committee members can combat behaviors negatively influencing sleep through SHS.

EFFECTS ON BODY TEMPERATURE OF PROTECTING THE SKIN OF PERSONS WITH SPINAL CORD INJURY TO PROMOTE PHYSICAL ACTIVITY IN A HOT ENVIRONMENT

HAYASHI, S., ISHIMOTO, Y.

FUKUYAMA CITY UNIVERSITY, KAWASAKI UNIVERSITY OF MEDICAL WELFARE

INTRODUCTION: Spinal cord injured persons have a marked increase in deep body temperature due to reduced sweating and dysfunctional vasomotor activity in the paralyzed area, which is greatly influenced by exercise and ambient temperature. To eliminate the limitation of physical activity in a hot environment, it is necessary to develop a strategy for body cooling in persons with spinal cord injury. This study examined the effect of skin protection to reduce the increase in core temperature in persons with high spinal cord injury in a hot environment.

METHODS: The subjects were three persons with cervical cord injury. Subjects spent 30 minutes in an environment with an outside temperature of 35.0±0.2 °C in a control condition with no measures, a condition with long sleeves and long pants covering the skin, and a condition with clothing covering the skin and wearing an ice vest. Measurements included core temperature, tympanic temperature, mean skin temperature, heart rate, and 9-point thermal sensation. Mean skin temperatures were calculated from the skin temperatures of the chest, upper arms, thighs, and calves.

RESULTS: Compared to the 27.0°Cindoor baseline (32.06 ± 0.40°C), skin temperatures in the control condition were significantly higher (38.03 ± 1.48°C). In particular, skin temperatures on the chest and thighs were above 40°C. The skin temperature in the clothing-covered condition increased to 36.28±0.15°C, but was 2°C lower than in the control condition. When an ice vest was used in combination with the clothing, skin temperatures remained at levels similar to those of abled-bodied persons. On the other hand, inspiratory temperature increased significantly (38.02±0.44°C) from baseline (36.10±0.34°C) in all conditions, influenced by radiant heat, although there was some sweating from the head.

CONCLUSION: In a hot environment, SCI with impaired thermoregulatory function has a significant increase in skin temperature, due to the large influence of radiant heat. Core temperature also increases significantly as skin temperature. However, the skin temperature increase was suppressed by simply covering the skin with clothing, and remained at the same level as that of able-bodied subjects. The same effect can be obtained with a breathable towel instead of clothing. Measures to control the increase in tympanic temperature by shielding the head from insolation exposure may also be necessary. Furthermore, the combination of an ice vest suppressed the increase in core temperature. These results not only contribute to outdoor activities in SCI, but also to the improvement of quality of life.

SPRINT-INTERVAL TRAINING AFFECTS CARDIORESPIRATORY COORDINATION IN OLDER ADULTS WITH INTELLECTUAL DISABILITIES

TAMULEVICIUS, N.1, OVIEDO, G.R.2,3, GUERRA-BALIC, M.2, FONT-FARRÉ, M.2, SIMÓN-SILES, S.2, CHILDS, C.4, GARCÍA-RETORTILLO, S.4

1:THE UNIVERSITY OF TAMPA, USA; 2: UNIVERSITY RAMON LLULL, SPAIN; 3: INTERNATIONAL UNIVERSITY OF CATALONIA, SPAIN; 4: WAKE FOREST UNIVERSITY, USA

INTRODUCTION: Older adults with intellectual disabilities (ID) have lower fitness levels and a greater likelihood of suffering from cardiovascular disease than older adults without disabilities (1). Implementing continuous aerobic training (CAT) or sprint interval training (SIT) could benefit the cardiac and respiratory systems. Currently, there is no research studying the effects of exercise on the coordination between the cardiac and respiratory systems in older adults with ID. Cardiorespiratory coordination (CRC), evaluated through principal components analysis (PCA), measures the co-variation of cardiorespiratory variables during exercise.

Objective: to investigate and compare the effects of two different exercise programs on CRC in older adults with ID during a maximal cardiorespiratory exercise test.

METHODS: This is a tree-arm randomized controlled trial. Seventy-one older adults with ID were randomly divided into three groups (CAT=24, 47.88±6.36 y.o.; SIT=23, 51.87±7.36 y.o.; Control=24, 49.92±6.58 y.o.). Participants completed a progressive maximal cycling test before and after the training period (72 sessions; 3 times/week; 90 min). The SIT performed bouts of 5 to 10-min of exercise consisting of 5 to 20-s all-out sprints followed by 15 to 60-s of low cadence recovery. The CAT performed aerobic bouts of 5 to 10-min at intensities of 55-85% of the HR reserve. PCA was performed on the time series of selected cardiorespiratory variables: ventilation per minute, the expired fraction of O2, the expired fraction of CO2, and heart rate. The number of PCs and the first PC Eigenvalues (PC1) were computed for each group before and after the training intervention.

RESULTS: The SIT (18.6 vs 23.8 ml/kg/min, $p<0.001$) and the CAT (18.5 vs 21.3 ml/kg/min, $p<0.001$) improved their cardiorespiratory fitness. SIT reduced the number of PCs from two to one, and increased PC1 Eigenvalues (2.64 ± 0.31 Vs 2.84 ± 0.25; Z=146, p=0.009; d=0.7). Notably, CAT and Control did not decrease the number of PCs or improved PC1 Eigenvalues after the training period.

CONCLUSION: These results show that 72 sessions of SIT or CAT are able to improve the cardiorespiratory fitness of older adults with ID. Nevertheless, the SIT was the only group improving the CRC during the cycle ergometer tests. As reported previously (2), the coordination and network interactions between subsystems are important indicators of physiological state and function. Since alterations in cardiorespiratory coordination may differ based on the type of training intervention, analyzing cardiorespiratory coordination along with other performance metrics can provide a more accurate assessment of physiological adaptations following CAT or SIT interventions.

Health and Fitness

EFFECT OF A SIX-WEEK CROSSFIT TRAINING ON THE BLOOD LIPID PROFILE AND ATHEROGENIC INDEX OF PLASMA (AIP) IN PHYSICALLY ACTIVE MEN

SADOWSKA-KREPA, E., DOMASZEWSKI, P., OZNER, D., ROZPARA, M.

THE JERZY KUKUCZKA ACADEMY OF PHYSICAL EDUCATION

INTRODUCTION: Research shows that regular low or moderate-intensity exercises improve blood lipid profiles while regular high-intensity intermittent exercises reduce atherogenic indexes [1]. A popular multimodal form of high intensity training is CrossFit, which consists of various physical exercises performed in a circuit format with or without short rest periods [2]. Our study sought to determine the effect of a 6-week CrossFit workout programme on the blood lipid profile and atherogenic index of plasma (AIP) in healthy young men.

METHODS: Ten young men (aged 24.1 ± 1.7 years, body height 183 0 ± 7.8 cm, BMI 24.7 ± 2.0 kg/m2) participated in a workout programme based on the CrossFit training guide that recommends a five-day-on and two-day-off pattern. Training units of about 50 minutes started with a warm-up and ended with intense full-body stretching. Each training unit involved one, two, or three of the following, distinct modalities: monostructural metabolic conditioning, gymnastics, and weightlifting. Venous blood samples were collected from the participants at baseline and week 6 and were analysed for the concentrations of total cholesterol (TC), high-density lipoprotein cholesterol (HDL-C), low-density lipoprotein cholesterol (LDL), and triglycerides (TG). To determine participants' risk of developing vascular disease, the lipid ratios (TC/HDL-C), LDL-C/HDL-C, TG/-HDL-C), and the atherogenic index of plasma [AIP=log10(TG/HDL) with TG and HDL-C expressed in molar concentrations] were calculated.

RESULTS: The baseline levels of the lipid profile components were within reference ranges (TC ≥ 190 mg/dl, TG ≥ 150 mg/dl, LDL-C ≥ 100 mg/dl) in all participants. The concentrations of TC, TG, and LDL-C, all lipid ratios (TC/HDL-C), LDL-C/HDL-C, TG/HDL-C), and AIPs obtained post-intervention were lower than at baseline, but the changes were not signficant. A 4.1% increase in the concentration of HDL-C was observed.

CONCLUSION: A combination of aerobic and strength exercises during CrossFit workouts is reported to improve aerobic and anaerobic endurance, the activity of mitochondrial enzymes, and insulin sensitivity in overweight men [3]. Therefore, it can also be expected to improve lipid ratios that, together with the AIP, are the best risk predictors of coronary artery disease (CVD). An improvement in blood lipid profiles and reduction in participants' AIPs by an average of 57% showed that CrossFit training can moderate decrease the risk of developing CVD.

THE INFLUENCE OF A SERIES OF TEN SAUNA BATHS ON HEMATOLOGICAL BIOMARKERS AND CHANGES OF PLASMA VOLUME FOLLOWING A SUBMAXIMAL EXERCISE TEST IN ELITE ATHLETES

POKORA, I., WOLOWSKI, L., KEMPA, K.

ACADEMY OF PHYSICAL EDUCATION IN KATOWICE

INTRODUCTION: It is known that numerous conditions, including environment, exercise and training, can affect changes in plasma volume. These modulations pose a particular problem when trying to determine the consequences of incorporating regular sauna bathing into the training process of elite athletes. Elite athletes often have developed certain thermal adaptations as a result of their long-term training history, which may limit the effectiveness of thermal interventions (HA), such as plasma volume increases, or greatly hinder the ability to identify the beneficial effects of HA on the body. The purpose of this study was to examine the effects of a series of ten sauna baths on selected hematological biomarkers and changes of plasma volume following a submaximal exercise test in elite athletes.

METHODS: The study included 14 male professional cross-country skiers (VO2max 64.5 ± 6.33 ml/kg/min). Selected hematological (Hb, RBC, HCT, MCV, RBCSD) and biochemical (TPP, ALB) biomarkers were studied twice: before [C] and after completed ten Finnish sauna baths [MT] with two days of rest between 5-6 heat exposures. In each phase participants performed a running exercise in thermoneutral conditions at the predetermined intensity, below HR-AT for ~60 min. The average heat stress (HS) session lasted ~35 min (internal temperature >38.5 oC). Sauna baths took place in the afternoon after part of the days training session in the transition (TP) and preparatory (PP) phase of the training program. Blood samples were taken: at rest (t0), post-exercise (t1), 1 hr (t2) and 24 hr (t3) of recovery, in each series of experiments, respectively. Relative changes in plasma volume (del PV%) were calculated according to the formula of Dill and Costil (1974).

RESULTS: The results of this study indicated that there were significant differences in resting hematological biomarkers between the TP and PP phases for RBC [$p<0.05$], MCV [$p<0.05$] and RCBSD [$p<0.05$]. The PV had increased after MT by 2.38%, <+1.5 +3.72> in both TP and PP phases. The regular MT had impact on resting Hb [$p=0.06$] and TPP [$p= 0.04$] in the TP phase. No significant difference was found between the TP and PP phase in del PV% either in control or after MT, immediately after exercise (t0-t1), and after 1 h recovery (t0-t2). The plasma volume increased after 24h recovery [+0.69% vs +3.92%; $p<0.05$] mainly in TP.

CONCLUSION: The results of the present study indicate that ten sauna baths included in the annual training program induced in a small expansion of PV in elite cross-country skiers. However, MT had an effect on post-exercise plasma volume recovery after a submaximal exercise test. This effect was noted mainly during the transition phase of the training program.

EFFECTS ON EXERCISE ON AD7C-NTP LEVELS AND COGNITIVE FUNCTION AMONG ACTIVE ELDERLY KOREAN ADULTS

KIM, D.H., JAMRASI, P., LI, X., SUNG, Y., AHN, S.H., KANG, Y.S., SONG, W.

SEOUL NATIONAL UNIVERSITY

INTRODUCTION: Alzheimer-associated neuronal thread protein (AD7c-NTP) has been demonstrated to have high diagnostic accuracy in patients with Alzheimer's disease (AD). This protein has been found to be elevated in the urine from AD and Mild Cognitive Impairment (MCI) patients. Furthermore, this protein has been demonstrated to increase with age in a healthy population. However, it is unclear whether exercise has an effect on the level of AD7c-NTP among active elderly adults. Objective of study was to assess the effect of exercise on cognitive function and AD7c-NTP levels in urine among active elderly Korean adults, and to examine the correlation between Korean Mini-Mental State Exam (K-MMSE) scores and AD7c-NTP levels in urine in active elderly Korean adults.

METHODS: In total, 40 elderly adults whose activity levels were above ≥ 600 MET-minutes/week were selected and divided into three groups: Control group (CG, n=10), Resistance + Aerobic exercise group (RAG, n=12), aerobic exercise group (AG, n=18). CG performed dynamic stretching 2 times/week. RAG visited the center and performed Thera-band resistance exercise 2 times/week, as well as walking exercise according to the walking guidelines. AG performed walking exercise according to walking guidelines. A total of 12 weeks of exercise intervention were implemented. At week 0 and 12, body composition (weight, muscle mass, body fat percentage), Korean Mini-Mental State Exam (K-MMSE) and Stroop test were measured and a morning urine sample was obtained from each subject. The level of AD7c-NTP was measured using competitive ELISA. SPSS version 29 was used as a statistical tool. Two-way repeated measures ANOVA was used to see the group interaction by time. One-way ANOVA was used to see the group interaction before and after exercise. Bonferroni post-hoc test was used to see the group difference.

RESULTS: After 12 weeks of exercise intervention, there was a significant difference on the level of AD7c-NTP between RAG (1.04 ± 0.73 ng/ml) and CG (2.16 ± 1.23 ng/ml) ($p=.026$), AG (1.16 ± 0.90 ng/ml) and CG (2.16 ± 1.23 ng/ml) ($p=.032$) respectively. The AD7c-NTP levels in urine showed negative correlation with K-MMSE scores ($r=-.390$, $p=.013$) in all participants after exercise intervention. Furthermore, the activity levels showed positive correlation with muscle mass ($r=.316$, $p=.047$) and negative correlation with body fat percentage ($r=-.362$, $p=.022$) in all participants after exercise intervention. However, there was no significant difference of body composition and cognitive function tests (K-MMSE, Stroop test) between groups after exercise interventon

CONCLUSION: This is the first study looking at exercise effect on AD7c-NTP levels in urine among active elderly adults. This study demonstrates that exercise has an effect on the level of AD7c-NTP between groups and there is a negative correlation between AD7c-NTP levels and K-MMSE scores. However, further research is required with larger number of sample size and long-term intervention.

THE COVID-19 EFFECT ON HEALTH- AND RISK BEHAVIOUR AND LIFE SITUATION OF UNIVERSITY STUDENTS IN HUNGARY

UVACSEK, M., SZEMES, Á., DAVIES, W., JOHNSON, A.W.

HUNGARIAN UNIVERSITY OF SPORTS SCIENCE AND BRIGHAM YOUNG UNIVERSITY

INTRODUCTION: Covid-19 increased the Hungarian mortality rate in 2021 and induced significant changes in our lifestyle during and following the prescribed countrywide shutdown (HCSO 2022). In collaboration with international researchers, we wanted to know how university students' health and risk behaviours and their life situations changed due to the pandemic.

METHODS: The Brigham Young University researchers created the questionnaire; the Hungarian version was approved by the Hungarian University of Sports Science ethical committee (TE-KEB/04/2022). Full time university students completed the online questionnaire in April 2022 (n = 245; 54% women; mean age 21,90±3,13 yr). We analyzed the data with SPSS v25 using descriptive statistics and independent t tests.

RESULTS: According to our results, 75% of males and 84% of females belonged to the normal nutritional status category. Of the students, 8.2% smoked and 60% consumed alcohol regularly. We found that access and opportunity to study and work were not affected by Covid-19, however, according to 51% of respondents, the number of their in-person meetings decreased. About 65% indicated their free time activity did not change, they spent the same time outside and inside as before Covid-19. Responses from 58% of the students indicated their physical activity did not change and 62% said their recreational time remained the same. The prevalence of smoking increased by 1.6% and the prevalence of alcohol consumption increased by 11.6% during and following the pandemic.

CONCLUSION: Based on this study, we conclude there were no significant changes in health and risk behaviours and in life situations among this population.

HCSO 2022: Hungarian Central Statistical Office https://www.ksh.hu/stadat_files/nep/en/nep0009.html

COMPARISON OF MOTIVATION AND GENDER DIFFERENCES AMONG UNIVERSITY STUDENTS ATTENDING PHYSICAL ACTIVITIES COMPULSORILY AND VOLUNTARILY

NG, S.K.

THE CHINESE UNIVERSITY OF HONG KONG

INTRODUCTION: This study aimed to examine the effects of gender on university students motives for participating in organised mandatory and voluntary physical activities (PAs).

METHODS: A total of 434 respondents were participating in compulsory PAs (73 men, mean age: 21.6±2.2 years old; BMI=18.3±1.0 kg/m2; 150 women; mean age: 19.0±1.8 years old; BMI=20.2±2.8 kg/m2) and voluntary PAs (38 men, mean age: 19.4±1.6 years old; BMI=21.7±2.3 kg/m2; 42 women; mean age: 19.2±1.6 years old; BMI=20.3±1.7 kg/m2). They completed the Exercise Motivation Inventory-2 (EMI-2; Markland & Ingledew, 1997) and some demographic data during the first meeting. The type of PAs consisted of various racket games and physical fitness.

RESULTS: The results of the MANOVAs test showed a significant main gender effect on the combined dependent variables, Wilks Lambda = .88, $F(15, 416) = 3.74$, $p = .000$, $\eta 2 = .012$; a significant main effect for two types of activities, Wilks Lambda = .91, $F(15, 416) = 2.70$, $p = .001$, $\eta 2 = .089$; and non-significant interaction of gender and two-type of activities, Wilks Lambda = .96, $F(15, 217) = 1.11$, $p = .343$, $\eta 2 = .039$. These results indicated that exercise motivations varied by both gender and two-type of activities.

Univariate tests showed significant activity effects for 4 of the 14 motives. Respondents reported greater motivation to join voluntary PAs than mandatory PAs for revitalization, enjoyment, strength and endurance, with the most significant effect size difference for health pressure. In contrast, respondents rated health pressure higher as motivation to participate in mandatory PAs.

Analyses revealed significant gender effects for four motivational subscales. Male respondents rated higher levels of motivation than female respondents for the subscale of challenge, competition, social recognition and affiliation, with the most significant effect size difference for competition subscale.

In addition to these main effects, we found a significant two-type of activities by gender interaction for seven variables. Follow-up comparison scores indicated that female respondents participating in compulsory PAs rated the lowest motivation levels than other respondents for enjoyment, challenge, social recognition, affiliation and competition subscales. In contrast, male respondents attending mandatory PAs indicated higher motivation levels than other respondents for health pressure and nimbleness. Among all the respondents, the highest and lowest motives were positive health and health pressure, respectively.

CONCLUSION: All respondents were motivated to participate in the PAs compulsorily or voluntarily by an intrinsic factor such as health benefits. Still, they reported low levels of perceived pressure to be healthy.

THE EFFECTS OF A GUIDED EXERCISE PROGRAM ON FITNESS LEVEL AND ON SELF-ESTEEM IN MENOPAUSE: A LONGITUDINAL STUDY

KNEFFEL, ZS., SZALAI, H.

HUNGARIAN UNIVERSITY OF SPORTS SCIENCE

INTRODUCTION: A mix of physical, emotional and psychological changes take place during menopause. The reduction in oestrogen results these changes and may have effect on overall quality of life. Hormone replacement therapy, could be effective against the negative symptoms, however, the earlier publised side effects has resulted alternative treatment methods, such as regular exercise. The purpose of this study was to see whether is any changes in fitness level and physical self-esteem after a 1.5 year long exercise program.

METHODS: During the intervention, participants attended 2x1 hours of resistance training and 1x1.5 hours endurance training (i.e. cycling, walking) per week. Resistance training was executed with various strength-training tools, as well as, with participants' own bodyweight. Fitness test contained a sit and reach test (flexibility), a 2-minute step test (endurance), and handgrip measurement (strength). Body composition was measured with a TANITA BC-545N bio-impedance scale. Physical Self –Description (PSD) was measured with the short version of PSDQ by Marsh et al. (2010). Data were collected in June 2021 (N=20), in June 2022 (N=13) and in December 2022 (N=11). Descriptive statistics (means ± SEM) calculated for each variable and Wilcoxon test was used to analyze the data of fitness level and to see differences in PSDQ data through the intervention period.

RESULTS: Significant improvement was detected in all fitness tests: in flexibility, in strength and in endurance (cm: 12.4±2.5 vs. 21.1±4.8; N: 28.8±4.5 vs. 30.7±10.6; times: 82.9±3.6 vs. 124.26.5, respectively). Although the mean body weight decreased, it did not reach the significant level (kg:70.8±2.9; 67.9± 3.2; 67.6± 4.3). Significant difference were seen in muscle mass (kg:7.8±2.9 vs. 47.0±5.5) and in body fat percentage (33.63± 3.8 vs. 36.0± 6.5). BMI (29.6± 3.8; 29.6± 5.5; 30.8± 7.0), and bone mass (kg:2.4; 2.4; 2.2) slightly changed but none of them reached the significant level. Self-description of the women changed significantly over the intervention period and in 14 cases showed significantly better values at the end of the first year and additional 4 cases at the end of the 1.5 year period. These cases clustered in „Action, Global Esteem and Physical Esteem" which fit to the objectively measured data, however, participants underestimated their development in flexibility.

CONCLUSION: The high drop-out rate indicates that women in menopause with less experience in sport and a lower fitness level might need more attention to support their progression in lifestyle changing. Furthermore we concluded that both fitness level and self-esteem of postmenopausal women could be improved with a regular and guided exercise program.

EFFECT OF TIME-EFFICIENT OCCUPATIONAL EXERCISE ON CARDIORESPIRATORY FITNESS IN FIREFIGHTERS

HAINES, M.

UNIVERSITY OF HUDDERSFIELD

INTRODUCTION: Firefighters require a good level of cardiorespiratory fitness (VO2peak) for safe occupational performance and to pass annual fitness examinations. High intensity interval training (HIIT) is a time-efficient and potent exercise stimulus to increase fitness in healthy adults. The aim of this study was to investigate the effects of a novel workplace based HIIT intervention on cardiorespiratory fitness with a population of operational firefighters during their tour of duty. We also aimed to determine affective (pleasure and displeasure) responses to HIIT because a high degree of discomfort might lead to poor exercise adherence.

METHODS: Fifteen active firefighters were randomly allocated to either HIIT or moderate intensity continuous training (MICT) performed eight times over 4-weeks. HIIT involved 10 × 20 s intervals at maximal intensity interspersed with 40 s of recovery at low intensity, whereas MICT involved continuous exercise at 65% maximal heart rate. This training frequency was chosen to accommodate the on-duty shift pattern for the firefighters involved in the study. Exercise was completed on shift with two sessions performed on each tour of duty (i.e., one day and one night shift each week, leaving one day of rest in between). VO2peak and time trial performance were the primary outcome measures. Affective (pleasure/displeasure) responses to exercise were a secondary outcome.

RESULTS: A two-way mixed (condition x time) ANOVA showed a moderate increase in VO2peak for HIIT (6%) and MICT (8%) although this did not reach statistical significance ($P = 0.06$, $\eta 2 = 0.26$). A significant main effect for time trial performance ($P < 0.01$, $\eta 2 = 0.51$) was observed for HIIT and MICT (2% for both groups). Affective responses were more favourable for HIIT, but both exercise conditions avoided excessive sensations of displeasure. Differences between groups were not significant.

CONCLUSION: Despite a significantly reduced time commitment, 4-weeks of workplace based HIIT improved VO2peak and time-trial performance to a similar magnitude as MICT. This study highlights a novel exercise strategy that is time-efficient whilst avoiding overly negative affective responses with potential to improve occupational health of firefighters. Furthermore, implementation of this exercise strategy was feasible within the working firefighter environment with high adherence and no adverse effects reported.

COULD A SINGLE SESSION OF BALANCE AND COORDINATION EXERCISES IMPROVE ATTENTION IN OLDER ADULTS?

DUNSKY, A., UNGER, L., FOX, O.

THE LEVINSKY-WINGATE ACADEMIC COLLEGE

INTRODUCTION: The cognitive decline that is characteristic of older adults has led researchers to seek methods for improving cognitive functions in this population in the short and long term. One broadly studied aspect relates to physical activity interventions and their impact on cognitive functions in older adults. This study examines the effect of a single session of balance and coordination exercises on cognitive functions in older adults, compared to that of a single session of aerobic exercises or a single control session of reading.

METHODS: The study included 30 physically active participants (23 females), with an average age of 73 (±5) years. The participants completed computerized cognitive tests to assess attention and executive functions in five separate sessions: two without interventions and three with interventions (aerobic exercise; balance and coordination; and reading while sitting). The interval between each session was at least two weeks. The order of interventions between participants was random.

RESULTS: While no differences were seen between the three types of intervention in executive function scores, our findings indicate that a single session of aerobic exercises and a single session of balance and coordination exercises led to higher scores on the attention test than in the control condition.

CONCLUSION: The present findings support and enhance the literature on improved attention in healthy older adults following a single aerobic exercise session, indicating the positive effect of a single balance and coordination exercise on attention among healthy older adults. As such, in addition to the importance of balance and coordination training in older adults, these findings could be used to encourage the developing of balance and coordination exercise programs for adults in general. Future research should be designed to assess the effect of chronic balance and coordination on cognitive function among older adults.

OBESITY AND NUTRITIONAL STATUS OF HUNGARIAN TEACHERS

BALOGHNÉ BAKK, A., BIRÓNÉ ILICS, K.

ELTE SEK PPK

INTRODUCTION: The epidemic of obesity is one of the most serious health problems worldwide and the World Health Organization predicts that it will continue to increase in the coming decades. Hungary has the highest proportion of obese people among the adult population in Europe.

Several causes contribute to the development of overweight, such as genetic, hormonal, psychological, sociocultural economic or environmental factors, which cannot be influenced by the individual. Today, almost 40 percent of young adults in Hungary and more than 70 percent of those over the age of 65 struggle with excess weight.

The aim of our research is to present the nutritional status of Hungarian teachers. The research was primarily conducted following the health promotion guidelines outlined in the Ottawa Charter, with a special focus on the workplace, one of the most important aspects that affect quality of life in many ways.

METHODS: Our research was conducted in 2020-2021 among Hungarian teachers. Participants were selected by random sampling. The sample included teachers from both lower and upper primary school, and secondary school as well. Participants body composition was determined using the Inbody 720 Body Composition Analyzer. After measuring the body height, the subject was put on the body composition measuring machine, where the measurement was started after entering the personal data. In the study we recorded participants height (BH/cm), fat-free weight (FFM/kg), fat mass (BFM/kg), body weight (BW/kg), muscle mass (SMM/kg), body mass index (BMI), body fat percentage (PBF%), waist-to-hip ratio (WHR), visceral fat (VFA/cm2), and obesity degree (%). Based on the data, we obtained a complex picture of the nutritional status of the individuals, through which, among other things, the degree of early obesity can be diagnosed.

RESULTS: The sample's average age was 43.9 years (female: 43.07 years; male: 44.8 years). The average weight was 56.6 kg (female: 46.4 kg; male: 66.6 kg) and had an average height of 172.5 cm (female: 167.3 cm; male: 177.8 cm). The average body fat percentage (PBF%) was 25.65% (female: 30.6%; male: 20.7%).

Based on the results it can be stated that there is a significant relationship between body fat mass and age in the examined sample ($p<0.0027$), and between waist-to-hip ratio (WHR) and visceral fat (VFA/cm2) ($p <0.001$) as well as body fat mass (BFM/kg) ($p<0.003$). With regards to gender, it can be stated that there is a significant correlation between womens lean fat mass and age ($p<0.002$). For men, we found no relationship between the two data.

CONCLUSION: Based on our results it can be stated that age is a key risk factor in the development of overweight and obesity. The data shows that the accumulated fat mass concentrates in the abdominal area, which poses an increased risk factor regarding the development of metabolic diseases. To stop or reverse this trend, targeted interventions are needed among the Hungarian population of working age

BROWN ADIPOSE TISSUE ACTIVATION DETECTED BY THERMAL IMAGING IN TACTICAL ATHLETES

DA ROSA, S.1, NEVES, E.2, MACHADO, F.3, SOUZA, L.3, DOS REIS, V.1

(A) UNIVERSIDADE DE TRAS-OS-MONTES E ALTO DOURO (UTAD), (B) TECHNOLOGICAL UNIVERSITY OF PARANÁ (UFTP), (C)BRAZILIAN ARMY PHYSICAL FITNESS RESEARCH INSTITUTE (IPCFEX)

INTRODUCTION: Military personnel are recognized as tactical athletes because they have high physical and performance demands daily, like sprint run, bypass obstacles and movements under load. Though, this group had a high prevalence of obesity. Brown adipose tissue (BAT) is the new target in the quest to increase caloric expenditure and reduce body fat. It is inversely correlated with body mass index, but it is still not clear what correlation with Fat Mass Index (FMI). Infrared thermography (IRT) can detect BAT activation using cold stimulation. The purpose of this study was to compare BAT activation by cold stimulation evaluated by IRT in military men.

METHODS: Seventy-two military men from Brazilian Army were classified by FMI rages, Normal (35.9 ± 5.9 years, FMI: 4.84 ± 0.8 kg/m2), Fat Excess (35.8 ± 7.6 years, FMI: 7.68 ± 0.7 kg/m2) and Obesity (36.2 ± 10.1 years, FMI: 11.8 ± 2.8 kg/m2). Mean skin temperature in the supraclavicular right region (SCVTR), left region (SCVTL) and Sternum (STRT), determined as the control region, was measured by infrared camera E75 FLIR®, immediately after volunteers remained 30min in a thermoneutral environment (22.6 ± 0.2ºC) for acclimation. Then, after five minutes both hands submerged in a container with ice water at 13.0 ± 0.4ºC the temperatures were revaluated. The blood biomarkers were assessed and body composition using double X-ray absorptiometry was evaluated. Shapiro-Wilk normality test was applied and confirmed parametric approach. Two-way repeated measures ANOVA with Tukey post-hoc comparisons were conducted. The level of significance was $p< 0.05$.

RESULTS: The obesity group had lower mean skin temperatures and worse metabolic indicators than compared to the other two groups. There was a significant interaction between group factor (FMI) vs group moment (BAT activation) in the region SCVTR ($F(2,69) = 4.21$, $p < 0.001$, $\eta2 =0.010$) and SCVTL ($F(2,69) = 4.81$, $p=0.011$, $\eta2=0.013$). No interaction was found between groups STRT ($F(2,69) = 0.01$, $p= 0.986$, $\eta2 =0.00$). Only Normal and Excess of Fat groups presented a significant increase in SCVTR and SCVTL regions. Obesity group did not show a significant increase in SCVT (right side: $p = 0.368$; left side: $p = 0.096$). No significant increase in STRT was observed in all groups.

CONCLUSION: Tactical athletes classified with obesity by FMI did not activate BAT after exposure to cold. All others classifications of FMI showed significant BAT activation.

HYBRID-TYPE, MULTICOMPONENT INTERVAL TRAINING IMPROVES CARDIAC MORPHOLOGY IN MIDDLE-AGED OVERWEIGHT AND OBESE ADULTS: A 1-YEAR DOSE-RESPONSE PRAGMATIC RANDOMISED CONTROLLED TRIAL

BATRAKOULIS, A., JAMURTAS, A., POULIOS, A., PAPANIKOLAOU, K., TSIMEAS, P., SYROU, N., DRAGANIDIS, D., GEORGAKOULI, K., DELI, C., FATOUROS, I.

UNIVERSITY OF THESSALY

INTRODUCTION: The increasing prevalence of overweight/obesity is a serious public health challenge negatively affecting more than one in two adults globally. Physical exercise is an essential component of an all-inclusive strategy for preventing, managing and treating obesity. In particular, a hybrid-type, multicomponent interval training programme (DoIT) has been reported as an effective exercise solution for lowering various cardiovascular risk factors. This study examined the dose-response effects of a 1-year DoIT on cardiac morphology parameters in previously inactive overweight and obese adults in a real-world gym setting

METHODS: Ninety-seven middle-aged (44.8 ± 5.2 years) overweight and obese individuals (31.2 ± 5.7 kg/m2) (66% female) were randomly assigned to the following groups: (i) no-intervention control (CON, n=29), (ii) DoIT performed once weekly (DoIT-1, n=24), (iii) DoIT performed twice weekly (DoIT-2, n=23) and (iv) DoIT performed thrice weekly (DoIT-3, n=21). DoIT was a time-efficient, intermittent-based, multicomponent exercise protocol using progressive loaded fundamental movement patterns with prescribed work-to-rest intervals (1:3 to 2:1) in a circuit format (2–3 rounds). Left ventricular mass (LVM), left ventricular internal diameter end systole (LVIDs), left ventricular posterior wall end diastole (LVPWd), interventricular septum end diastole (IVSd), right ventricular end diastole (RVD), body surface area (BSA), left ventricular mass index (LVMI), and relative wall thickness (RWT) were assessed by an electrocardiogram at baseline and 12 months following intervention.

RESULTS: No baseline differences were detected among groups in all outcome variables, including habitual physical activity levels and caloric intake. The overall training-related injury rate was 3.3% (3/90; 1 participant in each DoIT group). Attendance rates for DoIT-1, DoIT-2 and DoIT-3 were 87.8%, 86.3% and 85.0%, respectively with an overall dropout rate of 19%. CON exhibited no changes in any measures, besides LVM (-1.3%, $p<0.001$) and LVMI (-1.7%, $p<0.001$). All DoIT groups showed beneficial changes in LVM (+1.9%–8.7%, $p<0.001$), LVPWd (+1%–4.9%, $p<0.001$), LVIDs (+1.2%–4.9%, $p<0.001$), RVD (+1.1%–3%), and LVMI (+2.2%–9.1%, $p<0.001$) in time. In LVPWd and IVSd, DoIT-2 and DoIT-3 demonstrated greater in-

creases compared to baseline (+3%–4.8%, p<0.001), while DoIT-3 induced more beneficial changes than DoIT-1 (+6.9%, p<0.001). No significant differences were found in BSA and RWT within and between groups.

CONCLUSION: These results indicate that a multicomponent exercise approach incorporating bodyweight drills and resistance-based alternative modes performed under real-world conditions may improve cardiac morphology markers, but not widely in a dose-dependent manner in previously inactive, middle-aged overweight and obese adults. The present findings will enable physicians and exercise professionals to follow more efficient exercise prescription guidelines for this popular and effective exercise modality.

FITNESS CONDITION OF HUNGARIAN SECONDARY SCHOOL STUDENTS BEFORE AND AFTER THE COVID-19 PANDEMIC

TOTH, O., KOLTAI, M., TAMÁSI, L., EKLER, J.

EÖTVÖS LORÁND UNIVERSITY FACULTY OF EDUCATION AND PSYCHOLOGY

Introduction

The topic of our research is the effect of the COVID-19 pandemic situation on the fitness condition of secondary school students. The NETFIT is the National Unified Student Fitness Test, which has been a unified, criterion-oriented test system since 2014 to assess the fitness status of students from upper elementary school to the end of secondary school. The main mission of NETFIT is to develop the demand for lifelong physical activity in children and to promote health-conscious lifestyles among students, their families and public education stakeholders (Kaj, 2020). The tests assessed in NETFIT are divided into four main groups: body composition and nutrition profile, aerobic fitness profile, skeletal muscle fitness profile, and flexibility profile.

Materials and methods

The investigated class was the 12th D class of the Jurisich Miklós High School in Kőszeg, Hungary, English-Hungarian bilingual section, N=30. We compared the students by gender based on the NETFIT results of the 2018/19 school year and the 2021/22 school year, and the differences between the pre- and post-epidemic fitness indicators were compared to the national averages at the same years. The students were given tasks to complete at home during the online education. The physical education teachers gave the students exercises known from functional training, different self-bodyweight exercises and circuit training tasks.

Results

Like the national results, the aerobic capacity of the pupils studied decreased significantly after the epidemic (p=0.031* boys, p=0.006** girls), but was still strongly significantly (p<0.001) better than the national average in 2021/22. Boys performed significantly better in the handgrip strength (p=0.008**) and flexibility (p=0.003**) tests, while girls performed significantly better in the paced curl-up (p=0.042*) and paced push-up (p<0.001***) tests after the pandemic.

Conclusion

According to the aerobic fitness index of the studied class, the aerobic capacity of the students deteriorated less compared to the national average. Significant performance improvements were observed in several tests of skeletal muscle fitness profile. Students showed statistically significant improvements in many areas, however seeing the data, we should also emphasize the importance of daily physical education and attendance education as well, to encourage pupils for lifelong physical activity, so they become physically, mentally healthy young people.

EXAMINING THE EFFECTS OF POSTURE IMPROVING EXERCISES DURING PE CLASSES

NAGYVARADI, K., SZIGETHY, M., BIRÓNÉ ILICS, K., GORDOS, K.

EÖTVÖS LORAND UNIVERSITY

INTRODUCTION: Inactivity due to much sitting also causes damage to the motor organs of an increasing number of children. The 2018 Health Behaviour in School-aged Children (HBSC) study is one of the studies on the physical activity of young people and the frequency of physical activity. It turns out that only one-sixth of children aged 11 to 17 years are likely to exercise enough daily. This rate is lower compared to the results recorded four years earlier, at that time one-fifth of children were characterized by a sufficient amount of daily movement. (Kun, Nemeth, Demetrovics, 2019).

The aim of our research is to perform a physiological examination of the spine of students and their spine's functional condition and assess the interventional effect of exercises applied over 12 weeks.

METHODS: The sample included 10th grade students (n=40) of the Jurisich Miklós Secondary Grammar School in Kőszeg, Hungary. Participants were divided into intervention (n=22) and control (n=18) groups. The intervention group performed 12 different posture-improving exercises in all PE classes over a period of 12 weeks.

The Spinal Mouse device was used to examine the spinal column. The device can examine the morphological characteristics and mobility of all vertebrae between C7 - S1 of the spine. Body weight and body height data were taken from the NETFIT test system. As an additional measuring tool, the Maligen test was applied, as well as an examination of the ef-

fects of some of the exercises aimed at posture correction,for example, the forward bending of the lumbar spine and the twisting of the lower back and lumbar spine.

In addition to the basic statistical calculations, an independent two-sample T-test approach was also used. Comparing the results revealed the relationship and differences between the two samples. Statistical tests were conducted with the CogStat 2.2 and the IBM SPSS v.25 tools.

RESULTS: The average height of the group is 171.6 cm, that of boys is 178.18 cm, while that of girls is 166.74 cm. Average body weight is 61.83 kg, boys weighing an average 66.29 kg and girls 58.52 kg. The second measurement among girls showed a significant relationship between the intervention and control groups regarding the position of the sacrum and the pelvic bone relative to each other. The result of Welchs D-test: t(23)=2.167; p=0.045.

The most evident deviations appeared only in the boy group after the Matthias test. There was a significant relationship between the data on the lumbar section and the position of the hips. It was on the second measurement of the lumbar section that the correlation was revealed. The standard deviation of the groups is the same (the Leven test was not significant (p=0.87)).

CONCLUSION: Our innovative training protocol included several combined exercises to preserve and develop torso and spine mobility. The research has proven that if students regularly perform general posture-improving gymnastic exercises, the physiological state of the spine can be improved (Gordos, 2022).

CHANGES IN LIFESTYLE BEHAVIORS AND PHYSICAL FITNESS OF JAPANESE CHILDREN DURING THE COVID-19 PANDEMIC: RESULTS FROM A 7-YEAR REPEATED CROSS-SECTIONAL STUDY

HYUNSHIK, K.

SENDAI UNIVERSITY

INTRODUCTION: The COVID-19 pandemic appears to have had a great adverse impact on the healthy behaviors of preschoolers, in particular outdoor play. However, details are still unclear. Thus, this study aimed to investigate changes in lifestyle behavior and physical fitness of Japanese children during the pandemic.

METHODS: This study collected longitudinal data before and during the pandemic and objectively assessed changes in the physical fitness and lifestyle (outdoor playtime, screen time, and sleep) of Japanese preschoolers. Participants were 4,882 preschoolers in Hiroshima Prefecture who evaluation objective health and fitness assessments (25-m sprint, standing long jump, tennis ball throw); their parents answered questions on their demographics, physical activity, screen time, and sleep duration. Chi-squared test, ANOVA, and t-test were applied.

RESULTS: Among lifestyle behaviors, outdoor playtime decreased significantly in both boys and girls ($p<0.01$ and $p<0.05$, respectively), while sleep duration decreased significantly in boys alone ($p<0.05$). Among physical fitness items, significant differences were observed for the 25-m sprint ($p<0.001$ and $p<0.01$, respectively) and long jump in both boys and girls ($p<0.001$ and $p<0.01$, respectively).

CONCLUSION: The results showed negative effects of the pandemic on children's health and lifestyle behaviors, and fitness, thus endorsing various interventions to promote physical activity under pandemic conditions. preschools must increase organizational physical activity time, and local communities must seek effective policies for outdoor play of preschool children.

ANALYSIS OF FALL RISK AND GAIT PATTERNS DURING WALKING ACCORDING TO FALL EXPERIENCE IN OLDER KOREAN WOMEN

KANG, H.J.1, LEE, B.K.2, KIM, Y.S.3

SOONCHYNHYANG UNIVERSITY1, SANGMYUNG UNIVERSITY2, SEOUL NATIONAL UNIVERSITY3

INTRODUCTION: The purpose of this study was to compare the gait patterns and the relative risk of falling between Older Korean women that fall and do not fall based on the walking speed during flat walking and in the presence of obstacles.

METHODS: The study included 148 women, aged 65 years or older (22 fallers, aged 75.05±5.38 years; 126 non-fallers, aged 71.80±5.14 years). The gait variables were measured in a space of 9 m×1 m, and obstacle walking was measured while crossing obstacles measuring, 5 cm and 30 cm. A t-test, correlation analysis, and logistic regression analysis were performed to compare the gait patterns to determine if there was a fall and to analyze the relationship and the risk ratio of a fall at a walking speed.

RESULTS: Out of 148 participants, 22 participants (14.9%), fell while walking. During flat ground walking, right step length ($p<.01$) left step length ($p<.05$), and stride lengths ($p<.01$) were smaller in the faller group, while the stance phase ($p<.01$) and double-support time ratio ($p<.05$) were smaller in the non-faller group. In obstacle walking, slower walking speeds were observed for the 5-cm obstacles ($p<.01$) and 30-cm obstacles ($p<.05$) in the faller group. For the low-speed and medium-high speed groups, the odds ratio of the fall experience was 2.844 (1.125-7.191) ($p<.05$) for flat gait, 3.585 (1.354-9.491) ($p<.05$) for the 5 cm obstacle, and 4.877 (1.731-13.742) ($p<.01$) for the 30 cm obstacle. As the height of the obstacle increased, the fall odds ratio increased.

CONCLUSION: In the faller group, the step and stride lengths were smaller during flat walking, and the walking speed of the obstacles was low. The low-speed group had a high falling experience odds ratio, and as the height of the obstacle increased, the falling experience odds ratio increased.

DOES PINCH STRENGTH HAVE A RELATIONSHIP WITH SHOE TYING SPEED IN COLLEGE WOMEN ATHLETES?

STUCK, P., DAVIS, A., HEIN, S., MILKS, H., SHIM, A., FIAUD, V.

COLLEGE OF SAINT MARY

INTRODUCTION: Activities of daily living (ADLs) are essential for independent living in all ages and allow individuals to physically care for themselves, along with carrying out daily routine tasks. ADLs are an indication of functionality and may also show when preventative measures need to be implemented1. Research has shown low ADL functionality in tasks such as these, bathing, shoe-tying, and eating, has been linked to an increase in the risk of mortality and hospitalization in the elderly. Goetzinger et al., (2022) recently demonstrated there was a moderate negative correlation between pinch strength and buttoning speed, however, no studies have affirmed or denied a relationship between shoe-tying speed with pinch strength.

METHODS: 20 college female athletes (20.5 ±1.5 years) from a Midwest institution were recruited for this study. All participants were healthy and had no injuries to the wrist within the last 6 months. All subjects were shown a short instructional video, demonstrating how to tie the shoe for the study before the data collection took place. All subjects began by holding the laces at the center of the string, away from the shoe, where they were then instructed to begin tying the shoe as fast as possible upon command. When they were done tying the shoe, they held their hands up in signaling they were done, and the timer was stopped. The best time of two attempts was taken. The participants then used a Baseline LITE hydraulic pinch dynamometer to measure pinch strength in kgs., using their thumb superior to their index finger at a maximal effort one time. Pinch strength was assessed on dominant and non-dominant hands.

RESULTS: A Pearson correlation between the dominant hand pinch strength and shoe-tying speed was low to moderate ($r = -0.35$; $p = 0.126$). The correlation between the non-dominant hand pinch strength and shoe-tying speed was similar ($r = -0.32$; p-value = 0.163). Both pinch strength and shoe tying speed were not significant ($p < 0.05$).

CONCLUSION: This study was the first study to determine if there was a significant relationship between shoe-tying speed versus pinch strength in female college athletes. Although there was a moderate negative correlation between buttoning speed and pinch strength, the relationship between shoe-tying speed and pinch strength was weak compared to alternative ADL activities. The variety of shoe-tying methods used by the participants from experience could have played a role with the overall outcome of this study.

INTERVAL AEROBIC/RESISTANCE EXERCISE TRAINING DEPRESSES ADRENERGIC-INDUCED APOPTOSIS OF CD4+ LYMPHOCYTE IN SEDENTARY MALES

WANG, J.S.

CHANG GUNG UNIVERSITY

INTRODUCTION: Exercise paradoxically influences adaptive immune function, depending on the type, intensity, and amount of exercise. Sympathetic stimulation affects lymphocyte autophagy and apoptosis by modulating β1-adrenergic receptor (β1-AR) and G protein-coupled receptor kinase 2 (GRK-2) downstream signaling. This study investigated how combined aerobic and resistance exercise training on the interval or continuous pattern influences β1-AR/GRK-2 signaling and corresponding apoptosis/autophagy of CD4+ lymphocytes in sedentary males.

METHODS: Thirty-four sedentary males were randomized and divided into interval training (IT, n=17) and continuous training (CT, and=17) groups. These subjects performed IT (bicycle exercise at alternating 40% and 80%VO2max and isokinetic exercise at alternating 60°/s and 180°/s) or CT (bicycle exercise at continuously 60%VO2max and isokinetic exercise at continuously 120°/s) for 30 min/day, 5 days/week for 6 weeks. CD4+ lymphocyte autophagy/apoptosis and β1-AR/GRK-2 signaling were analyzed using flow cytometry.

RESULTS: Both IT and CT groups increased isokinetic strengths at various angular velocities, whereas only IT significantly enhanced muscle endurance, indicated by lowering fatigue index. Moreover, the IT group revealed a higher improvement in VO2 max than the CT group. The graded exercise to VO2max (GXT) augmented (i) GRK2 and protein kinase A expressions, (ii) LAMP2 upregulation and acridine orange staining, (iii) mitochondrial transmembrane potential decreasing, caspase 3 activation and PS exposure caused by the epinephrine in CD4+ lymphocytes. However, the epinephrine-induced CD4+ lymphocyte apoptosis potentiated by GXT was suppressed by 6 weeks of IT.

CONCLUSION: The IT is superior for the CT to effectively enhance aerobic/muscular fitness and simultaneously ameliorate apoptosis of CD4+ lymphocytes evoked by intense exercise or adrenergic stimulation. These experimental findings can help to determine an effective combined aerobic and resistance exercise regimen to increase aerobic/muscular fitness and minimize the risk of infections and immune disorders at performing intense exercise.

AEROBIC EXERCISE IMPROVES PHYSICAL FITNESS IN OLDER ADULTS BY MEDIATING MIR-21 AND BODY COMPOSITION: A RANDOMIZED CONTROLLED TRIAL

HSU, C.C., FU, T.C., WANG, J.S.

KEELUNG CHANG GUNG MEMORIAL HOSPITAL

INTRODUCTION: Emerging evidence suggests that aerobic excise is associated with changes of body composition and circulating microRNA (c-miRNA) expressions in older adults. This study highlighted mediating roles of body composition and c-miRNA for the physical fitness progress after aerobic exercise trainings in older adults.

METHODS: We included 58 community inhabitants with age>= 60 years and instructed them to walk >= 8000 steps per day during a 24-week follow-up (F/U) period. Among them, 28 were randomly allocated to the supervised exercise training (SET) and 30 were assigned to the home exercise training (HET) groups. Only SET participants underwent an additional 24 sessions of 8-week SET at 70% of maximal predicted heart rate for 30 min per session. Estimated maximal oxygen consumption (eVO2max), calf circumference (calf_circ), handgrip strength (HGS), 5-time sit-to-stand duration (StoS), normalized body fat mass (nBFM), normalized skeletal muscle mass (nSKM), circulating miR-21 (c-miR-21), c-miR-126, c-miR-146a, and c-miR-222, were measured at baseline, and week 8 and 24 after recruitment.

RESULTS: A greater percentage of SET participants (81.6%) adhered to the instruction than HET participants (46.4%) during F/U. The HET participants developed a trend towards decreased calf_circ and HGS during F/U. In the SET participants, eVO2max, nSKM, and all tested c-miRNA levels significantly increased, but nBFM significantly decreased during F/U. The HGS, StoS, nSKM, all c-miRNA levels in SET participants were significantly greater than the HET participants at week 8 and/or week 24. The c-miR-21 was involved in the mediation of SET-associated improvement of StoS and eVO2max. SET affected muscle performance by mediating body composition.

CONCLUSION: A short-term in-hospital supervised exercise training program is beneficial for increasing exercise adherence, which help aging population maintain muscular fitness and improve cardiorespiratory fitness. A significant decline of muscular fitness has been observed in older adults without SET. The current study has also disclosed that the aerobic exercise can affect tissue component and induce post-transcriptional modification to improve physical fitness. The c-miRNA levels, especially c-miR-21, as well as body composition could be used as a clinical indicator for monitoring aerobic exercise effects on both muscular and cardiorespiratory fitness in older adults.

EFFECT OF TWO WEEKS AROMATHERAPY ON PAIN, FUNCTION OF LIFE, AND NECK FLEXION ENDURANCE AMONG PATIENTS WITH CERVICOGENIC HEADACHE

SHU CHENG, L., YUE YUAN, C., HO CHENG, C., DAI EN, Z., JING YU, L.

TAINAN UNIVERSITY OF TECHNOLOGY

INTRODUCTION: Headache is one of the common symptoms nowadays. In the past, studies have shown that the activation of the trapezius muscle of the cervical muscle group increased by the observation of electromyography (EMG) in the present of cervical migraine (Jensen, Bendtsen & Olesen, 1998), showing that patients with cervical headache may have a certain correlation between the trapezius muscle and the posterior neck muscle during headache (Lo Martire et al., 2017). In the treatment of migraine, aromatherapy (Aromatherapy) is one of the common alternative treatments. It has been often used in clinical care over the years. However, there are many comorbid symptoms caused by pain, which may cause anxiety and sleep disturbance. Therefore, the purpose of this study was to investigate the effect of 14-day of aromatherapy massage on pain improvement, daily life and quality of patients with cervicogenic headache.

METHODS: Study with single-blind, matching method. Twenty-four cervicogenic migraine patients were recruited in this study, who had to be diagnosed by a doctor first, and in accordance with the criteria of HIS: migraine lasted for more than one year with more than 2 attacks per month and no psychiatric disorder. Before intervening in, research objects need to fill in the brief pain inventory-short from (BPI-SF) and perform the neck flexion endurance test (NFE test) and then be divided into aromatherapy group (T group) and placebo group (P group) according to the pain scores. Conduct a 14-day experiment (once a day, 20 minutes of aromatherapy each time), the aromatherapy contains 15 minutes of inhalation and 5 minutes of essential oil roller application for the splenius cervicis muscle and upper trapezius muscle (Organic compound essential oils for T group; Carrier oil for P group). After intervening in, Acute and post-14 day group filled in BPI-SF and performed NFE test. The experimental data were analysed with two-way mixed design ANOVA.

RESULTS: 1. The percentage of pain improvement showed that the post-14 day of A group was significantly better than acute ($p < 0.5$), but not in P group ($p > 0.5$). 2. In terms of daily life impact score, acute and post-14 day of two groups were significantly lower than pre ($p < 0.5$), and the 14-day of A group was significantly lower than that of acute ($p < 0.5$), but not in P group ($p > 0.5$). 3. There was no difference in the NFE test, but it was significantly positively correlated with the pain score and the daily life impact score ($p < 0.5$).

CONCLUSION: Aromatherapy can reduce nociception and the impact on quality of life in patients with cervicogenic migraine. Cervical muscle endurance might be associated with nociception and the influence on daily life.

CIRCUIT AEROBIC TRAINING IMPROVES BIOENERGETICS AND DEPRESSES SENESCENCE OF LYMPHOCYTES IN SEDENTARY MALES

LIN, Y.T., CHU, M.E., WANG, J.S.

CHANG GUNG UNIVERSITY

INTRODUCTION: Appropriate aerobic exercise can improve the regulation of acquired immunity. The immune function of lymphocytes is related to their mitochondrial bioenergetics that depends on the operating efficiency of their electron transport chain. Circuit Aerobic Training (CAT) is a novel exercise strategy that utilizes multi-sports equipment for improving systemic aerobic fitness. However, the CAT effect on lymphocyte immunity has not yet been established. The study was to investigate the effects of CAT and traditional aerobic training (TAT) on phenotype characteristics and mitochondrial bioenergetics of lymphocytes in sedentary males.

METHODS: Thirty healthy sedentary males were randomized and divided into CAT (n=10), TAT (n=10), and control (n=10) groups. These subjects progressively performed CAT on multi-sports equipment or TAT on a bicycle ergometer from 60%

to 80% maximal workload for 30 min/day, 5 days/week for 6 weeks. A graded exercise testing (GXT) and an isokinetic strength test were conducted to evaluate cardiopulmonary fitness and muscle strength, respectively. The phenotype characteristics and mitochondrial respiratory capacity in lymphocytes were analyzed using flow cytometry and high-resolution respirometry, respectively.

RESULTS: After the intervention for 6 weeks, either CAT or TAT significantly increased the VO2 values at the anaerobic threshold and maximal performance as well as the isokinetic strength of the quadriceps. The two exercise regimens also heightened degree of behavioral changes related to physical activity.

Both CAT and TAT reduced blood senescent T lymphocyte count at rest and diminished the mobilization of senescent helper T lymphocytes into the peripheral blood following the GXT. However, CAT rather than TAT lowered the proportion of senescent cytotoxic T lymphocytes in the blood. Either CAT or ICT effectively depressed lymphocyte mitochondrial oxidant burden caused by the GXT. Furthermore, the two exercise regimens improved mitochondrial bioenergetic efficiency in lymphocytes by stabilizing the mitochondrial membrane potential and improving the capacity of the electron transport chain following the GXT.

CONCLUSION: Both CAT and TAT enhance cardiorespiratory/muscular fitness as well as improve lymphocytic bioenergetic efficiency. However, CAT is superior to TAT for slowing the senescence of cytotoxic T lymphocytes in blood.

MOVE WELL, BE STRONG: GRASSROOT COACHES' AND PHYSICAL EDUCATION TEACHERS' KNOWLEDGE, ATTITUDE AND CONFIDENCE TOWARDS DEVELOPING THE MOVEMENT COMPETENCY OF CHILDREN IN SAUDI ARABIA

DE STE CROIX, M., AYALA, F., HUGHES, J., ROBERTS, W., WING, K.

UNIVERSITY OF GLOUCESTERSHIRE

INTRODUCTION: There are significant knowledge gaps amongst grass-root coaches and PE teachers regarding movement competency and injury prevention programmes [1]. As children are a high-risk group for non-contact sporting injuries, they are an important target group fpr improving movement competency. It is unclear if coaches and PE teachers have the knowledge, attitude towards and confidence to deliver such and if differences exist between sexes.

METHODS: 95 grass-root coaches and PE teachers (25 females, 70 males) from across the Kingdom of Saudi Arabia completed a validated questionnaire exploring use, knowledge, attitude towards and confidence to deliver youth movement competency training. A Bayesian factor was used to quantify the evidence for and against the hypothesis of independence (H0) in each of the survey questions and with regards to sex differences using an assumed Poisson sampling scheme (as there was no a priori restriction on any cell count, nor on the grand total) (BF10 Poisson). Bayes factors were categorised into discrete categories ranging from extreme evidence to anecdotical evidence.

RESULTS: 93% of participants thought injury risk management in children was possible, with 61% considering children to be at high risk of injury. Participants ranked helping children to develop movement skills as their most important role (47%) with developing technical skills as their least important role (15%). No sex differences were observed in terms of the importance of developing movement skills (BF10 Poisson = 0.16). Only 35% of participants had heard of any injury prevention programmes and 47% included movement competency training in their coaching/PE. In both cases significantly more males had knowledge of and were using injury prevention in their coaching and PE lessons than females (BF10 Poisson = 2.67 and 1.4 respectively). Nearly all participants (93%) felt that incorporating an injury prevention programme would be good for children. Most coaches indicated they needed more knowledge around injury prevention programmes (90%), understanding of growth and maturation and injury (87%) and specific exercise to improve movement competency (87%). Two thirds of participants had a positive attitude towards (68%) and were confident to deliver (67%) movement competency training.

CONCLUSION: Despite two thirds of coaches/PE teachers rating their knowledge, attitude towards and confidence to deliver movement competency training as good, less than half of participants were using such training. Training and upskilling is required to provide coaches/PE teachers with the skills and confidence to deliver movement competency training. Appropriate resources need to be developed that are culturally suitable and delivered in an accessible way to PE teachers and grassroot coaches. Sex differences in the knowledge around movement competency training indicates that females should be provided with training to increase knowledge and confidence.

SYSTEMATIC REVIEW ON THE EFFECTS OF EXERCISE WITH AND WITHOUT BREAKFAST CONSUMPTION ON COGNITIVE PERFORMANCE

HSIEH, S.S., CHENG, C.Y., CHEN, Y.C.

KINGSTON UNIVERSITY LONDON

INTRODUCTION: Both acute bouts of exercise and breakfast consumption have been shown to improve cognition. Further, research has also shed light on the potential interactive effects of exercise and breakfast consumption (consumed before exercise) on cognition. Hence, the aim of this systematic review was to review the current evidence on the effects of acute exercise with and without preceding breakfast consumption on cognitive performance.

METHODS: This systematic review followed the Preferred Reporting Items for Systematic Reviews and Meta-Analysis guidelines and is registered in the International Prospective Register of Systematic Reviews (CRD42023396125). Studies were included if they investigated the acute effects of exercise without and without preceding breakfast intake on performance of cognition measured during and following exercise in adults without any cardiovascular disease, history of brain injury, or psychiatric or neurological disorder. Eligible studies from 4 electronic databases, PubMed, Scopus, MEDLINE, and

Web of Science, were searched and screened from 6 November 2022 to 29 January 2023. Study quality was assessed using the Physiotherapy Evidence Database (PEDro) scale.

RESULTS: A total of 609 studies were screened. Five studies, involving 70 participants (42 women, aged between 18 and 50 years) in total (sample size per study: 10-24), were eligible for inclusion in this review. The included studies had a mean PEDro score of 4.0 (scored between 3 and 5), suggesting 'fair' methodological quality. The synthesized results showed that 2 of the 5 studies found a positive effect of acute exercise, either delivered as moderate-intensity continuous aerobic exercise or high-intensity intermittent exercise, on processing speed measured during exercise in young healthy men [1] and inhibitory control and cognitive flexibility measured post-exercise in overweight perimenopausal women [2]. However, such exercise induced changes in cognition were not differed by breakfast consumption before exercise, regardless of the composition of macronutrients provided during breakfast [1,2].

CONCLUSION: Preliminary evidence did not support that exercise induced changes in cognition would be differed by prior breakfast consumption. However, the actual interactive effects of breakfast consumption and exercise on cognition warrant further verification given a) the small sample size of studies included, b) the heterogeneity across studies in exercise protocols, participants' characteristics, and selection of cognitive tasks, and c) the lack of good methodological quality in studies included.

COMPARISON BETWEEN AUGMENTED REALITY AND TRADITIONAL LOWER EXTREMITY STRENTHENING TRAINING ON RANGE OF MOTION, BALANCE AND PROPRIOCEPTION IN HEALTHY ADULT

YU, J.

SUNMOON UNIVERSITY

INTRODUCTION: Augmented Reality(AR) is a computer technology providing users with additional information about the observed situations. AR is considered the future of rehabilitation because it allows patients to easily access and participate in rehabilitation training regardless of time and place. The purpose of this study was to compare the effect between augmented reality and traditional lower extremity muscle strength exercise on range of motion(ROM), balance, proprioception.

METHODS: 52 healthy male and female university students were participated in this study. The subjects were divided into randomized augmented reality training group (ARG) and traditional exercise group (TG). All the subjects have conducted AR or traditional lower extremity strengthening training according to groups in three times a week for a total of four weeks. ROM, balance and proprioception variables were measured before and after 4 weeks intervention. For data analysis, we used matching sample t-test for comparison between groups and the independent-sample t-test for comparison of changes in groups.

RESULTS: In the comparison within group, ARG showed statistically significant differences in balance and proprioception($p<0.05$). TG showed statistically significant differences in ROM of knee flexion during walking and balance($p<0.05$). In the comparison between group, there was no significant differences between the groups in knee ROM while walking, balance and proprioception($p>0.05$).

CONCLUSION: As a result of this study, compared to TG, it was found that AR can show the same effect as there is no difference in each variable after 4 weeks of strength training. Also the group with ARG showed changes in balance and proprioception after lower body strengthening. Therefore, AR training can be a good training method for the elderly who are at high risk of falling due to deficits in balance and position sense, regardless of time and place.

APPLYING A FIREFIGHTER FITNESS PROGRAM USING A KINECT-BASED MIXED REALITY DEVICE

PARK, J.J.

PUSAN NATIONAL UNIVERSITY

INTRODUCTION: Recently, a Korean firefighter fitness program (KFFP) combined with a Kinect-based mixed reality device was developed. Since the Kinect sensor can identify movements and provide visual feedback to correct incorrect movements, it helps to increase the Korean firefighters' exercise participation rate, which is low due to the lack of exercise instructors. A previous study validated the KFFP moderate-intensity program for male participants in general. However, in the previous study, the participants' VO2max was lower than that of Korean firefighters, and the high-intensity program has not yet been verified. Therefore, the aim of this study was to investigate the effects of medium- and high-intensity KFFP combined with a Kinect-based mixed reality device on the aerobic abilities and muscular functions of Korean firefighters.

METHODS: Korean male firefighters were divided into a Kinect-based mixed reality device exercise group (EG, n = 10) and a control group (CG, n = 10). The EG group participated in an intervention consisting of medium- to high-intensity KFFP for 3 days/week, while the CG group was asked to maintain their lifestyle without any extra exercise for 8 weeks. Aerobic ca-

pacity was assessed by a graded exercise test with a respiratory gas analyzer, and muscular function was measured by an isokinetic dynamometer.

RESULTS: There was no significant interaction between group type and time in VO2peak and HRpeak. However, The VO2peak of the EG group was significantly increased by about 1 MET (from 42.2 ± 6.2 mL/kg/min to 45.9 ± 4.3 mL/kg/min, p = .04) and HRpeak was decreased by about 3 beats/min (191.3 ± 6.8 beats/min to 188.8 ± 8.3 beats/min, p = .04) after the intervention. There was no significant change in VO2peak and HRpeak in the CG group. There were significant interactions between the groups and increases in peak torque of the knee extensors (p = .04), knee flexors (p = .002), shoulder extensors (p = .03), shoulder flexors (p = .04), and trunk extensors (p = .02). There were also significant interactions between the groups and increases in total work of knee extensors (p = .02), shoulder extensors (p = .02), and shoulder flexors (p = .047).

CONCLUSION: These results suggest that KFFP combined with a Kinect-based mixed reality device can help firefighters perform firefighting tasks by improving the cardiorespiratory capacity, muscular strength, and muscular endurance of Korean firefighters.

EFFECT OF P. GINGIVALIS INDUCED BACTEREMIA ON SKELETAL MUSCLE INJURY HEALING IN VIVO

SHIMIZU, S.

TOKYO MEDICAL AND DENTAL UNIVERSITY, FACULTY OF DENTISTRY

INTRODUCTION: P.gingivalis, one of the most causative bacteria of periodontitis, has been reported that it aggravates various diseases by invading the body from oral cavity. There is a possibility that P.gingivalis has adverse effect to skeletal muscle healing, however, there is lack of research investigating the direct relationship between P. gingivalis-induced bacteremia and skeletal muscle healing. Therefore, in this study, we investigate the effect of P. gingivalis to skeletal muscle healing in vivo. It has been reported that young people, who have bad oral hygiene, even though they didn't be diagnosed as periodontitis, P. gingivalis was also found in their oral cavity. Thus, to clarify the relationship among P.gingivalis-induced bacteremia and skeletal muscle wound healing is important for not only elderly people but also athletes.

METHODS: In this study, a total of fifty-six 8-week-old male Wistar rats were utilized. The animals were randomly divided into two groups. One group intraperitoneal administered with sonicated P. gingivalis (ATCC33277) once per week for three weeks(PG group), and another group administered with an equal amount of saline (CO group). Skeletal muscle injury was induced in gastrocnemius by injection with cardiotoxin to both groups in three weeks after from the first intraperitoneal administration. During days 1, 3, 5, 7, 11, and 14 after injury, animals were euthanized, and gastrocnemius was extracted. The cross-sectional area of regenerating skeletal muscle cell was evaluated by HE-staining, and the degree of muscle fibrosis was evaluated by Massons-Trichrome staining. The expression of Pax7 and MyoD were analyzed to identify the stage of muscle cell regeneration by immunohistochemical staining. In addition, a lower minimum calcaneus height between walking was measured by motion analysis using treadmill walking for evaluating functional ability at days 1, 3, 5, 7, 11, and 14 after injury.

RESULTS: The cross-sectional area of regenerating muscle cells were significantly smaller in the PG group at day 7 after injury, but no significant difference observed in the cross-sectional area at day 14 after injury. Area of fibrosis is significantly larger in the PG group. Pax7+/MyoD- ratio was significantly lower in the PG group compared to the CO group at day 1 after injury. Motion analysis of treadmill walking showed that the PG group had a lower minimum calcaneus height than the CO group at days 3, 5, 7, and 11 days after injury.

CONCLUSION: The results of this study suggest that rats administered with sonicated P. gingivalis may delay the healing process of muscle injury, particularly apparent in the early stages, compared to control group. Delayed healing resulted in increasing muscle fibrosis, and it may increase the risk of recurrent injury. From the results of this study which shows that to maintain clean oral hygiene may help athletes to recover quickly from skeletal muscle injury.

CONCURRENT INFLUENCE OF FAMILIAR BACKROUND' DIFFERENT FACTORS ON CHILDREN ACTIVITY LEVEL AND NUTRITIONAL STATUS

SZMODIS, M.

HUNGARIAN UNIVERSITY OF SPORTS SCIENCE

INTRODUCTION: The lifestyle of the young generations is determined by the socio-economic background of the family, and parental role modeling is also important. Our aim was to define the "familiar" variables that most influence the level of habitual physical activity (PA) and nutritional status.

METHODS: A total of 2 825 children and adolescents between the ages of 7 and 19 years (n=1 413 males, n=1 412 females) were enrolled in this analyses from the cross-sectional cohort study. They provided anthropometric and physical activity data. Data about their parents and socio-economic background were measured with the use of self-reported questionnaires. Gender differences were tested with Student's t-test, and chi-squared test, differences in the respective subgroup's means were tested by one-way ANOVA. We conducted binary logistic regression models to examine the associations of settlement' type, parents BMI and education level with children' physical activity (sporting or not sporting) and BMI (normal or overweight and obese).

RESULTS: The BMI and the percentage of body fat were the lowest among boys and girls in the capital, The muscle percentage was the highest in children of towns in both genders, and BMI was the significantly highest among boys in

towns. The children in the capital had the most sport activity hours per week (boys: 4.81±4.44, girls: 3.65±4.10 hrs/week, average: 3.91±3.74 and 3.07±3.39 hrs/week).

BMI, fat percentages and sport activities differed by parents education categories. Education level of mother may effect on BMI and hours per week of sport activities in both girls and boys. There were significant differences in BMI and sport activities in children by father's education. Boys and girls sport activity differed by parents sport: 3.3±3.6/2.43±3.11 (parents no sport) vs 4.9±3.7/3.8±3.4 hrs/week (both parents play sport).

More than three hours PA was associated with the residence in the capital (OR=1.25 95% CI 1.06-1.47), normal maternal BMI (OR=1.41 95% CI 1.15-1.71), and higher maternal education (OR=3.16; 95% CI 2.38-4.2).

Normal children' BMI was associated with the normal maternal BMI (OR=2.63 95% CI 2.08-3.32), and higher maternal education (OR=1.67; 95% CI 1.22-2.29).

CONCLUSION: The main findings were that children with less „risk familiar factors" had better BMI and physical activity level.

MODERATE INTENSITY AEROBIC EXERCISE AFTER PARTIAL SLEEP DEPRIVATION DOES NOT AFFECT AORTIC PULSE WAVE VELOCITY AND AUGMENTATION INDEX RESPONSES IN HEALTHY YOUNG ADULTS

KIM, D., PARK, S., LEE, E., SON, J., HWANG, M.

INCHEON NATIONAL UNIVERSITY

INTRODUCTION: Chronic sleep deprivation increases morbidity and mortality of cardiovascular disease (CVD). Arterial stiffening is an independent risk factor for CVD. Aortic pulse wave velocity (PWV) and augmentation index (AIx) are representative clinical indicators to assess arterial stiffness. Aerobic exercise is known to be beneficial for dampening arterial stiffness. To date, it is difficult to find studies investigating the combined effects of sleep deprivation and aerobic exercise on aortic PWV and AIx. Thus, the purpose of this study was to evaluate the effect of moderate intensity aerobic exercise after partial sleep deprivation on aortic PWV and AIx, compared to recommended sleep condition, in healthy young adults.

METHODS: Six healthy young adults (22.2±0.3 yrs) participated in this study. Participants performed moderate intensity aerobic exercise at 70% of peak heart rate for 30 minutes each under the partial sleep deprivation (SD; 2.5-3 hrs) and the recommended sleep (RS; 7-9 hrs) conditions by a randomized crossover design. The wash-out period between two sleep conditions was set to one week. Carotid-femoral PWV as aortic PWV and AIx as pulse wave reflection were measured using SphygmoCor Xcel system.

RESULTS: There was no significant difference in carotid-femoral PWV, AIx, and AIx adjusted at 75 beats/min of heart rate (AIx@75) responses to moderate intensity aerobic exercise between SD and RS condition (P □ 0.16).

CONCLUSION: In conclusion, one-time partial sleep deprivation does not influence aortic pulse wave velocity and pulse wave reflection responses to moderate intensity aerobic exercise in healthy young adults.

RESPONSE OF PERIOSTIN ON THE INTAKE OF N-3 POLYUNSATURATED FATTY ACIDS

IMAI, T., WATANABE, K.

AICHI INSTITUTE OF TECHNOLOGY, UNIVERSITY OF TSUKUBA

INTRODUCTION: Athletes are exposed to air pollution, allergens,cold and dry air during high-intensity training with an increase in the ventilation volume (1). These environmental and exercise stress stimulations cause airway epithelial injury repeatedly and may result in chronic airway inflammation. Therefore, athletes are at a high risk of exercise-induced asthma.

Recently, periostin, a matricellular protein, has been reported to play an essential role in the mechanisms of type 2 allergy. IL-4 and IL-13 induce periostin, showing a high level with multiple allergic diseases, such as allergic rhinitis and bronchial asthma. Therefore, periostin is focused on the type 2 biomarker (2). Although fractional nitric oxide (FeNO) has also been a known type 2 biomarker, periostin may be a chronic type 2 biomarker.

n-3 polyunsaturated fatty acids (PUFAs) are observed to inhibit the arachidonic acid cascade and have anti-allergy effects. However, it has not been known whether PUFAs are effective on periostin. Therefore, we investigated whether the intake of n-3 PUFA supplements affected periostin production. Purpose: To investigate the effect of intake of n-3 PUFAs supplements on periostin in athletes.

METHODS: University athletes who participated in this study were divided into two groups: PUFAs group (FeNO≥25 ppb, n=6) and control group (FeNO<25 ppb, n=7). The PUFAs group took supplements containing 260 mg of docosapentaenoic acid and 600 mg of eicosapentaenoic acid (EPA) daily for 3 weeks. Baseline measurements of FeNO, respiratory function, dietary intake (food frequency questionnaires), and blood tests were taken. FeNO levels were measured weekly, and the rest were measured after three weeks. The plasma periostin value was determined by ELISA.

RESULTS: Serum periostin values were not significantly different between the PUFA and control groups at baseline and 3 weeks (baseline: PUFAs; 78.0±7.2 ng/mL vs. control; 75.4 ± 9.8 ng/mL; 3 weeks: PUFAs; 71.7±10.2 ng/mL vs. control; 73.7±14.9 ng/mL). However, the FeNO levels of the PUFA group significantly decreased after 3 weeks compared with baseline (baseline: PUFAs; 59.3±32.3 ppb vs. 3 weeks:45.8±27.6 ppb). The FeNO level of the control group was not

change between baseline and at 3 weeks (PUFAs group; baseline, 15.1±2.7 ppb vs. 3 weeks; 15.4±4.7 ppb). The pulmonary function was not significantly different between the PUFAs and control groups at baseline and at 3 weeks.

CONCLUSION: Periostin production was not changed by the intake of n-3 PUFA supplements in the short term.

DAILY PHYSICAL ACTIVITY ENHANCES EFFICACY OF TREATMENT WITH SGLT2 INHIBITORS IN PATIENTS WITH TYPE 2 DIABETES

YAMAMOTO, K., KAI, R., MIZUNO, M.

TEIKYO HEISEI UNIVERSITY

INTRODUCTION: Sodium-glucose cotransporter 2 (SGLT2) inhibitors are newer hypoglycemic agents for patients with diabetes mellitus. Although daily physical activity is promoted as an essential component in the management of type 2 diabetes, combined health benefits of daily physical activity and SGLT2 inhibitor treatment are poorly understood. Thus, we investigated the combined effects of daily physical activity and SGLT2 inhibitor treatment on glycemic control in patients with type 2 diabetes using a large health insurance claims data and health check-up data in Japan.

METHODS: A retrospective cohort study was conducted using JMDC, Inc. (JMDC) database (2013-2019). JMDC has created a database, using data collected from health insurance societies in Japan, consisting of ledgers of insureds, claims (for hospitalization, outpatient treatment, drug preparation), and health checkup results. Our primary analysis included glycemic uncontrolled 1,403 patients (HbA1c >= 7.0%; mean age 51.4 years, SD 7.3 years) who were administrated SGLT2 inhibitors for more than 3 months and had neither regular exercise nor daily physical activity before SGLT2 inhibitor treatment. Controlled blood glucose level was defined as HbA1c lower than 7%. Daily physical activity was defined as walking or physical activity equivalent to walking in a daily life for at least one hour per day. The patients were assigned to one of two categories based on their daily physical activity status during treatment: no physical activity or physical activity. We used logistic regression models to estimate odds ratios and 95% confidence intervals (CI) for glycemic control after SGLT2 inhibitor treatment. The analysis was adjusted for age, sex, regular exercise, hypertension, dyslipidemia, number of co-administration antidiabetic drugs, body mass index, and baseline HbA1c in a multivariable model.

RESULTS: The blood glucose levels were controlled by 36.7% (515/1403) in total patients after SGLT2 inhibitor treatment (median: 7 months; interquartile range: 5-10 months). The glycemic control rate was significantly greater in daily active individuals (45.5%, 90/198) as compared to individuals with no daily activity (35.3%, 425/1205; P=0.006). Compared with reference group (i.e., no daily physical activity), the adjusted odds ratio in daily active individuals was 1.61 (95% CI 1.17-2.22; P=0.004).

CONCLUSION: The combination of daily physical activity and SGLT2 inhibitor treatment resulted in a higher glycemic control rate than SGLT2 inhibitor treatment without daily physical activity. This result reinforces the importance of daily physical activity to better control of blood glucose in patients with type 2 diabetes.

SKIN ADVANCED GLYCATION END-PRODUCT LEVELS AND LIFESTYLE-RELATED HABITS OF WOMEN COLLEGE ATHLETES DURING AND AFTER SELF-RESTRAINT PERIOD

NAKAJIMA, S.

KYORITSU WOMENS JUNIOR COLLEGE

INTRODUCTION: Advanced glycation end-products (AGEs) are harmful compounds formed through an excess of protein and sugar in the human body. Excessive accumulation of AGEs has been reported to accelerate the aging process and contribute to diseases such as arteriosclerosis and diabetes. The first the self-restraint period due to the coronavirus disease 2019 pandemic was announced in Japan for about a month in April 2020. For university athletes who exercised regularly before the self-restraint period, there was a concern that their amount of physical activity will significantly reduce. This study investigated lifestyle-related habits, including eating habits, during and after the self-restraint period and determined whether these habits affected skin advanced glycation end-product (AGE) levels.

METHODS: The subjects were female university students belonging to a physical education university in Tokyo. A questionnaire was administered, and answers on (1) lifestyle-related items, (2) exercise habits, (3) eating habits, and (4) luxury grocery items (e.g., alcohol and tobacco) were obtained. A regarding the measurement time, it was set on a schedule 3 months or more, after the end of the self-restraint period since the skin AGE value is not a short-term index but an index showing the condition 2–3 months ago. First, the AGE value was measured in September 2020. Furthermore, these surveys were conducted in October 2021 for comparison with 2020 AGEs values.

RESULTS: The average skin AGEs value for female students in 2020 was 143.7±24.0 AU.

After the self-restraint period, we could not possible to measure the same subjects. So we measured the skin AGEs values of student athletes from the same university in 2021 for comparison with the 2020 results. The average skin AGEs value for female students in 2021 was 173.9 ± 26.2 AU.

CONCLUSION: In this survey, there were concerns that student athletes lacked knowledge about nutrition, or even if they had knowledge, they could not make full use of it. This study determined the issues faced by students, such as the lack of knowledge about nutritional requirements of college athletes and practical methods to implement that knowledge.

EFFECTS OF 24-WEEKS OF RESISTANCE EXERCISE WITH INSTABILITY ON FUNCTIONAL MOBILITY, BALANCE, AND MUSCLE STRENGTH OF OLDER PEOPLE WITH PROBABLE MILD COGNITIVE IMPAIRMENT: A RANDOMIZED CLINICAL TRIAL

CAMPOS, I.R.A., DA SILVA, D.T., SILVA, M.S., TOMAZ, M.L.L., XAVIER, M.C.C., BEZERRA, N.V.R., CAVALCANTE, B.R., SOUZA, M.F.

UNIVERSIDADE FEDERAL DO VALE DO SÃO FRANCISCO

INTRODUCTION: Mild Cognitive Impairment (MCI) individuals have higher risk of functional deterioration compared to their peers without MCI, which may substantially increase falls risk, hospitalizations, and disability. Resistance exercise (RE) is a well-established strategy to mitigate functional decline trajectories. Resistance exercise with instability (REI) –RE performed under metastability states of equilibrium (e.g., balance pad)– is a promising modality to improve physical functioning. Despite previous findings showed the efficacy of 12-weeks of REI to improve physical components of healthy older adults, their long-term effects in people with signs of cognitive deterioration is not well established. Here, we analyzed the effects of 24-weeks of a REI on functional mobility, balance, and lower limb strength of older individuals with probable MCI.

METHODS: This was a randomized controlled trial (RBR-9bv3dc9) delivered in a single-center in Petrolina-PE, Brazil. Ninety-one participants (mean age=71 years) with probable MCI (MoCA=20±4.5 points) were eligible to the study. Out of 91, 45 were randomly assigned to REI (free-weights-based exercises combined with unstable surfaces/devices including balance discs, foam pads, Bosu®, and Swiss ball) and 46 to a SHAM, attention-matched, control group (unstructured light activities without load progression). Both groups received 24-week intervention (2-times/week) and assessments took place at 0, 12 and 24 weeks. Outcomes included the Short Physical Performance Battery (SPPB), 6-minute walk test (6MWT), Timed Up and Go (TUG), MiniBESTest and isokinetic test. Treatment effects were examined using ANCOVA adjusting by age and baseline of each outcome.

RESULTS: We did not observe significant changes in physical function over 12-weeks in both groups. During 24-week period, REI group improved performance on the SPPB (Δ=0.6 points; 95%CI=0.2;1.0); Usual gait speed (Δ=0.09m/s; 95%CI=-0.03;0.15); 6MWT (Δ=26.7 meters; 95%CI=7.5;45.8) and MiniBESTest (Δ=1.5 points; CI95%=-0.5; 2.6). Similar chances occur in SHAM group for SPPB (Δ= 0.5 points; CI95%=0.1; 0.85) and MiniBESTest (Δ= 1.3 points; CI95%=0.3; 2.3). At completion of 12- and 24-weeks, no difference between-group differences were found (p>0.05). Exploratory per-protocol analysis revealed similar results, with exception for the 6MWT, where REI significantly improved functional capacity (Δ=22.1 meters; 95%CI=1.7; 42.6) at completion of 12-week.

CONCLUSION: Opposing to our initial hypothesis, compared to a SHAM control, 24-weeks of REI did not promote physical function of older people with probable MCI. Despite findings, participants of REI experienced a maintenance of functional mobility, dynamic balance and lower limb strength over study period.

MECHANICAL PROPERTIES OF QUADRICEPS AFTER FATIGUE AND VIBRATIONAL RECOVERY IN LONG DISTANCE RUNNERS

CHEN, Y.C., CHANG, W.L., LIN, Y.C., CHENG, K.C., TSAI, Y.J.

CHENG KUNG UNIVERSITY

INTRODUCTION: Long-distance running has become a popular sport in the world due to its great health benefits. However, regular training or intense competition of the long-distance running usually puts strong demand on both cardiopulmonary and musculoskeletal systems, and thus results in sport injuries especially in the lower extremity. Recovery or relaxation for the major lower extremity muscles after fatigue are important for long-distance runners to prevent injuries. A number of previous studies had demonstrated the effects of using a foam roller on muscle strength, flexibility, range of motions and athletic performance. However, studies investigating the effects of using vibrational gun as relaxation intervention are rare despite the vibrational gun has been commonly used. The purpose of this study was to investigate the effects of fatigue and using the vibrational gun for recovery on muscle mechanical properties and athletic performance in long-distance runners.

METHODS: A total of 12 long-distance runners who has been trained at least 30 km/week for at least 6 months were recruited in this preliminary study. They all received standardized procedures for the aerobic and muscular fatigue, followed by standardized recovery intervention using the Hypervolt vibrational gun on the right rectus femoris. The mechanical properties of right rectus femoris was assessed using a myotonomer. The athletic performance including maximal knee extensor strength, knee flexion range of motion, flexibility of rectus femoris, maximal jumping height, and triple hopping distance were also assessed. All measurements were performed before and after fatigue, and after recovery intervention of vibrational gun.

RESULTS: The results demonstrated that only the maximal strength of quadriceps was changed after fatigue and intervention. The maximal strength of quadriceps significantly decreased after fatigue (P=0.001). The strength improved after vibra-

tional recovery (P=0.020); however, it was still lower than the strength at the baseline (P=0.008). No other changes were observed after fatigue and recovery.

CONCLUSION: The current findings of the pilot study did not support our hypothesis. Several explanations were provided including small sample size, not enough exhaustion and recovery too soon. Further research is still required.

STEPS PER DAY ARE ASSOCIATED WITH BETTER PHYSICAL FUNCTIONING BUT NOT GLOBAL COGNITION IN OLDER PEOPLE WITH PROBABLE MILD COGNITIVE IMPAIRMENT

TOMAZ, M.L.L., CAVALCANTE, B.R., CAMPOS, I.R.A., SILVA, D.T., SILVA, M.S., RODRIGUES, C.F.F., SOUZA, M.F.

UNIVERSIDADE FEDERAL DO VALE DO SÃO FRANCISCO

INTRODUCTION: The aging process is directly associated with a decline in physical and cognitive capabilities. Physical Activity (PA) play a significant role in terms of boost physical and cognitive functioning, which may alleviate the risk of disability, loss of autonomy, hospitalizations and premature death. Previous studies showed the PA volume (e.g., steps/day), instead intensity, could be a target priority to promote healthy benefits, particularly in older adults–a subgroup of population that have experience higher barriers to engage and maintain healthy behaviors. With this in mind, we explored the association between steps/day with physical and cognitive variables in older adults with probable mild cognitive impairment (MCI)–a population at risk of faster decline in such outcomes.

METHODS: We performed a cross-sectional analysis using baseline data from a clinical trial (RBR-9bv3dc9) that looked at the effects of Resistance Training with Instability on falls incidence in older people with probable MCI [Montreal Cognitive Assessment (MoCA)=20.0; SD=4.7]. The final sample of this sub-study involved 81 community-dwelling older adults (mean age=71 years; SD=0.24; 76% women). The independent variable was the number of steps/day, which was obtained using accelerometry (ActiGraph GT3x) for 7 consecutive days. Physical function was assessed using the Timed Up and Go (TUG), TUG with cognitive demand (animal naming), 6-minute walk test (6MWT) and Short Physical Performance Battery (SPPB) tests. The assessment of global cognitive function was determined through MoCA. The association between PA volume with each physical and cognitive outcomes was tested using multiple linear regression analysis adjusted for age, sex, education level and time spent in moderate-vigorous physical activity. The significance level was set at $p<0.05$.

RESULTS: The adjusted analysis showed a significant and negative association between the number of steps/day and TUG performance (β= -0.44; b= -0.0003; 95% CI: [-0.0005, -0 .0000]; $p<0.01$). No significant associations were observed between the PA volume with TUG (animal naming), 6MWT, SPPB as well as MoCA ($p>0.05$ for all).

CONCLUSION: Our findings revealed that a higher number of steps/day is related to better functional mobility in cognitively impaired older adults. The clinical relevance of these findings are that, for each increment of 2,000 steps/day may potentially to promote a reduction of roughly 0.6 seconds in TUG performance. Therefore, behavioral interventions that encourage an increase in the daily volume of PA (e.g., establishing reasonable steps/day targets) may be promising to improve functionality in this population.

ARE FUNCTIONAL MOBILITY AND BALANCE VARIABLES ASSOCIATED WITH EXECUTIVE FUNCTIONING IN OLDER ADULTS WITH PROBABLE MILD COGNITIVE IMPAIRMENT? A CROSS-SECTIONAL ANALYSIS

SILVA, M.S., CAMPOS, I.R.A., DA SILVA, D.T., TOMAZ, M.L.L., BEZERRA, N.V.R., XAVIER, M.C.C., CAVALCANTE, B.R., SOUZA, M.F.

UNIVERSIDADE FEDERAL DO VALE DO SÃO FRANCISCO

INTRODUCTION: Individuals with Mild Cognitive Impairment (MCI), a risk factor for Alzheimer's Disease, have higher probability to progress for states of functional and executive function declines, which may lead to further adverse outcomes including physical and cognitive frailty, falls, hospitalization, and death. Despite physical and cognitive functioning declines often co-exist in normal aging trajectories, it is not well established whether some domains of functionality and cognition are correlated in impaired cognitive states. Herein, we analyzed the association between functional mobility and balance components with executive functioning in older adults with probable MCI.

METHODS: We performed a secondary analysis using baseline data from a clinical trial who looked at the effects of metastability resistance training on fall prevention. Eighty-two participants (mean age=71 years; SD=0.24; 76% female) met the criteria of probable MCI (MoCA=20.0; SD=4.7) and were included in the study. Variables related to functional mobility and balance involved single- (TUG) and dual-task- Timed Up and Go (TUGcog), Short Physical Performance Battery (SPPB), Six-minute walking test (6MWT) and MiniBESTest. Executive functions were assessed using the Stroop Color-Word Test, Trail Making Test Part A (TMT-A), Digit Symbol Substitution Test (DSST), Digit Span Forward and Backward, Semantic and Phonological Verbal Fluency (VF). The associations between physical domains and executive functioning were determined from crude and multiple linear regression analyzes controlling for factors such as age, sex, body mass index, global cognition (Montreal Cognitive Assessment – MoCA) and total physical activity (GT3X accelerometer).

RESULTS: In the adjusted analysis, we identified that the SPPB was positively associated with DSST (b= 1.99; SE= 0.70; 95%CI= 0.60; 3.39) and phonological VF (b= 1.93; SE= 0.86; 95%CI= 0.22; 3.64), and negatively associated with Stroop part II (b= -2.03; SE= 0.97; 95%CI= -3.95; -0.10), Stroop part III (b= -8.82; SE= 3.52; 95%CI= -15.83; -1.81). We also observed a significant association between MiniBEST with TMT-A (b= -3.87; SE= 1.69; 95%CI= -7.24; -0.49). Nonsignificant associations were found between other domains of physical and cognitive functioning ($p>0,05$).

CONCLUSION: In summary, we demonstrated that, in older people with probable MCI, better functional mobility and dynamic balance performance were independently associated with better executive functioning. The clinical relevance of

these results is that tailored interventions aiming to promote functional benefits can potentially boosting cognitive functioning such as inhibitory control and working memory in people at risk of cognitive decline.

Alves JFN, Cavalcante BR, Valença AA, Campos IR, Tomaz MLL, Araújo RC, et al. Association between physical functioning with cognition among community-dwelling older adults: a cross-sectional study. Geriatr Gerontol Aging. 2021;15:e0210025.

AGE-RELATED DETERIORATION OF MUSCLE QUALITY OCCURS EVEN IN YOUNG ADULTS DURING A 2-YEAR FOLLOW-UP PERIOD

IKEZOE, T.1,2, OTA, M.2, TATEUCHI, H.2, ICHIHASHI, N.2

1 KANSAI MEDICAL UNIVERSITY; 2 KYOTO UNIVERSITY

INTRODUCTION: Muscle strength has been influenced not only by muscle mass but also by muscle quality, that is, the proportion of non-contractile tissue such as intramuscular fibrous and adipose tissue. Therefore, it is important to understand the age-related changes in muscle characteristics such as muscle mass and quality to develop an evidence-based approach for improving muscle performance. Several cross-sectional studies have shown that age-related changes in muscle quality may occur at an earlier age than the loss of muscle mass. Furthermore, our longitudinal study demonstrated that the degree of age-related decrease in lower-limb muscle mass depends on the muscle. However, no longitudinal study has focused on age-related changes in individual muscle quality, including various lower-limb muscles. Moreover, no longitudinal studies have examined the characteristics of age-related changes in each age group.

This longitudinal study aimed to investigate the age-related changes in muscle mass and quality using the proportion of non-contractile tissue of lower-limb muscles.

METHODS: The participants comprised 37 healthy women aged 20-69 years (mean age, 43.1 ± 13.6 years). The thicknesses of the rectus femoris, vastus lateralis, vastus intermedius, biceps femoris, gastrocnemius, soleus, and tibialis anterior muscles were measured as an index of muscle mass using a B-mode ultrasound device. We also evaluated echo intensity on ultrasonography images as a muscle quality index. Enhanced echo intensity indicates changes in muscle quality due to increased intramuscular fibrous and adipose tissue. Muscle thicknesses and echo intensities were assessed before and after the 2-year follow-up period.

To examine differences in the characteristics of age-related changes by age, participants were classified into two subgroups (aged ≤ 39 years vs. ≥ 40 years), and paired t-tests were conducted to determine changes in muscle thickness and echo intensity between baseline and 2 years later.

RESULTS: Regarding changes in muscle thickness during the 2-year follow-up period, a significant decrease was observed in the tibialis anterior muscle in the middle-aged and older group aged ≥ 40 years, whereas no significant difference was observed in the young group aged ≤ 39 years. With regard to the changes in echo intensity during the 2-year follow-up, significant increases were observed in all muscles in the young group aged ≤ 39 years and the middle-aged and older group aged ≥ 40 years.

CONCLUSION: This longitudinal study showed that age-related muscle atrophy was the greatest in the tibialis anterior muscle among the lower-limb muscles. Additionally, our findings suggest that muscle quality, which is determined by the proportion of non-contractile tissues, such as intramuscular fat, may be more susceptible to aging than to muscle atrophy and that age-related deterioration of muscle quality occurs even in young adults aged ≤ 39 years.

EFFECTS OF SPORTS AND RECREATIONAL ACTIVITIES ON FUNCTIONAL FITNESS AND PSYCHOLOGICAL FUNCTIONING IN THE ELDERLY

SUGIURA, H.1, SUGIURA, A.2, SUGIURA, H.3

<1> AICHI GAKUIN UNIVERSITY, <2> WASEDA UNIVERSITY, <3> GIFU UNIVERSITY OF MEDICAL SCIENCE

INTRODUCTION: Having the capacity to live independently as people age is important. Being able to socialize and actively participate in social interactions is therefore the goal of health in old age. In order to achieve this goal, health promotion should begin at an early age.

In this study, we investigated the effects of sports and recreational activities on functional fitness and psychological functioning in elderly people.

METHODS: Thirty-seven subjects aged 65 to 89 years old were enrolled in the present survey. Twenty-five subjects performed sports and recreational activities (Ex group). The control group consists of 12 individuals not engaged in either sport activities or recreational activities (Co-group). The subjects in the Ex-group were asked to participate in 90-minute sports and recreational activities. The intervention was set every two weeks for one year (total participation = 24 times). In addition, we implemented a non-supervised exercise regimen. For this reason, we advised the participants to do stretching and resistance training at least three days a week at home. Before and after the one-year-long intervention, each group was assessed by functional fitness tests, including grip strength, standing on one leg with open eyes (SLE), the time up and go test (TG), the 5-meter normal walking test (5-mNW), and the 5-meter maximum fast walking test (5-mMFW). In psychological functioning, subjective well-being, smile scores, and the positive and negative affect schedule (PANAS) scores were investigated.

RESULTS: The results demonstrated that the SLE score, TG score, 5mNW score and 5mMFW score in the post-intervention of the Ex-group was higher than those in their pre-intervention (P <0.05- P < 0.0001), but not in the Co group. The SLE score, TG score, 5mNW score, and 5mMFW score of post-interventions in the Ex-group were significantly higher (P <0.05–P <0.01) than those in the Co-group. The psychological functions in the Ex-group were significantly higher than that in the Co group (P <0.05).

CONCLUSION: These finding suggest that the intervention regimen adopted in this investigation, which included unmonitored exercise therapy, is a successful strategy for enhancing functional fitness and some of the psychological functions in elderly people. Furthermore, we propose that an intervention program that incorporates sports and leisure activities may be able to partially prevent the decrease of functional fitness in the elderly.

THE IMPACT OF HIGH-INTENSITY INTERVAL TRAINING ON REPRODUCTIVE HEALTH

PESTERAC-KUJUNDZIC, A.1,2, NEDOVIC, N.1, VUJICIC, D.1, JOVANOVIC, S.1

1. ACADEMY OF APPLIED STUDIES BELGRADE, THE COLLEGE OF HEALTH SCIENCES, SERBIA 2. UNIVERSITY OF BELGRADE, FACULTY OF MEDICINE, MODULE APPLIED RESEARCH IN SPORTS MEDICINE AND MOTOR SKILLS

INTRODUCTION: Exercise is well established to improve human health, but also as a therapy for preventing and managing many diseases.

The aim of this study is to investigate the impact of high-intensity interval training (HIIT) on reproductive health.

METHODS: We reviewed the studies available in full text in the past 15 years, English language articles that focused on the effects of high-intensity interval training on reproductive health, using a MEDLINE/PubMed database

RESULTS: Analysis of the literature has shown that HIIT has the greatest impact on insulin resistance, positive changes in reproduction-related hormones, improve testosterone levels, improved menstrual cycles, increase mitochondrial respiration, increased level of adiponectin, decreased fat percentage, improve semen parameters, sperm DNA integrity, and pregnancy rate, improve body composition and cardiorespiratory fitness

CONCLUSION: HIIT is time-efficient training that affects metabolic, hormonal, and anthropometric parameters, and also increased cardiorespiratory fitness.

EFFECTS OF A MULTIMODAL CARE INTERVENTION ON SUBMAXIMAL EXERCISE PERFORMANCE AFTER KIDNEY TRANSPLANTATION – RESULTS OF THE KTX360° STUDY.

HAUFE, S., BOECK, H.T., BOYEN, J., SCHIEFFER, E., PAPE, L., SCHIFFER, M., DE ZWAAN, M., TEGTBUR, U.

CLINIC FOR REHABILITATION AND SPORTS MEDICINE

INTRODUCTION: Kidney transplantation (KTx) is the therapy of choice for patients with end stage renal disease. However, mental and physical impairments are common in patients undergoing KTx. Patients typically report low energy levels and fatigue, low physical activity, poor exercise capacity, and a sedentary lifestyle, factors all of which have been associated with increased risk of cardiovascular events and mortality.

METHODS: As part of KTx 360°, an interdisciplinary, multimodal aftercare program, we included adult KTx recipients after signing informed consent and a general medical examination by a physician. To estimate exercise capacity (peak workload in watt [W]) for subsequent physical activity prescriptions, patients performed an incremental bicycle exercise test until volitional exhaustion. At baseline (BSL), month 6 and 12 a submaximal constant workload test (CWT) of 25 min at 50% of peak exercise capacity was performed. Heart rate, arterialized blood lactate concentration and arterial blood pressure (BP) was recorded at min 0, 15, 20 and 25 of the CWT. Patients received personal training recommendations based on their current activity and physical performance level. The guided training included increasing of daily steps, targeted endurance units and suitable strength exercises. Between the personal appointments at the study center every six months, the training was controlled via telemonitoring (video/telephone). For motivation and training control, patients were equipped with a training diary illustrating suitable exercises and a wearable activity tracker with heart rate measurements.

RESULTS: Out of 814 patients, 715 performed the incremental exercise test at BSL (35% women, age: 57±14 ys, BMI: 26.1±4.7 kg/m2, time from Tx: 4.7±5.7 ys). Patients achieved a peak power output of 112±41 W (women: 89±26 W, men: 127±43 W, p <0.01). This corresponds to 70±20 % of the calculated target power from a healthy norm population. After the 12-month guided program, 206 patients completed the CWT at BSL, month 6 and month 12. The mean heart rate during the constant workload phase of the CWT (from minute 15 to minute 25) was 108.4±18.0 bpm at BSL, 106.2±17.6 at month 6 and 105.6±17.3 bpm at month 12 (p<0.01 for overall time effect). Lactate concentrations did not change significantly when comparing the CWTs at the three visits. The mean systolic BP during the constant workload phase was 150±21 mmHg at BSL, 143±20 mmHG at month 6, and 142±19 mmHG at month 12 (p<0.01 for overall time effect).

CONCLUSION: As previously described in smaller cohorts, performance of kidney transplant patients is significantly reduced as compared to normative values. A 12-month telemonitoring-supported multimodal treatment including psychological, social and physical activity-promoting content shows significant but small effects on submaximal exercise performance in KTx patients.

COMMON RISK FACTORS FOR SPORTS INJURIES IN AMATEUR RUNNERS

ZHAI, J., XIAO, Q., SU, X., LI, X.

BEIJING SPORT UNIVERSITY

INTRODUCTION: The risk ratio was used to identify runners injuries and protective factors to provide runners with suggestions and guidance for preventing sports injuries. To collect and extract the relevant risk factors of sports injury, a questionnaire was designed for runners to investigate sports injury risk factors.

METHODS: The target population was set as adults who exercise regularly, regardless of gender. The questionnaire was put through Netease positioning and questionnaire star platform in the form of electronic files, utilizing trap questions and manual screening to review the quality. The reliability of the questionnaire was tested by three rounds of the Delphi method and repeated distribution of the questionnaire, which resulted in the final version of the questionnaire. Factor analysis and Binary logistic regression models were developed to identify risk factors for injury. All statistical analyses were conducted utilizing IBM SPSS Statistics Editor for MAC Version 26. A p-value of 0.05 or less was considered significant.

RESULTS: A total of 18316 valid questionnaires were collected and included in the statistical analysis. Among them, 6365 people chose running as their main exercise mode (male: 3305, age = 36.82±7.11years; height = 174.50±4.93 cm; and body mass = 69.99±7.75 kg; female: 3060, age = 32.2±7.38years; height = 163.53±4.95 cm; and body mass = 56.01±6.97kg). The results of the questionnaires showed that the risk ratio of injury for runners was 71.9% (4579/6365) [38.4% (2444/6365) for men and 33.5% (2135/6365) for women]. The results of Bartletts spherical test showed that the KMO values for male and female data were 0.665 and 0.695 ($p < 0.001$). Four common factors were extracted by the principal component method of factor analysis for both male and female runners and named strength quality, exercise habit, fatigue recovery, and physical factors according to risk factor characteristics. The total variance contribution rates of the common factor rotation were 71.021% for males and 69.467% for females, which could generally explain the risk factors of sports injuries for runners.

CONCLUSION: In this study, the injury risk questionnaire has been proven to have good reliability and can effectively collect information on the risk factors of sports injury for runners. To evaluate the sports injury risk for runners, four aspects (strength quality, exercise habits, fatigue recovery and physical factors) could be considered. In addition, fatigue recovery has the greatest impact on the risks of running injuries, while strength training has the least impact on them. Therefore, in the prevention of sports injuries, runners should focus on fatigue problems.

LONG-TERM EFFECTS OF METASTABILITY RESISTANCE TRAINING FOR PREVENT FALLS IN COMMUNITY-DWELLING OLDER ADULTS WITH PROBABLE MILD COGNITIVE IMPAIRMENT: STUDY PROTOCOL WITH PRELIMINARY FINDINGS

SOUZA, M.F., SILVA, D.T., CAMPOS, I.R.A., SILVA, M.S., TOMAZ, M.L.L., BEZERRA, N.V.R., XAVIER, M.C.C., DE ARAÚJO, R.C., RODRIGUES, C.F., CAVALCANTE, B.R.

UNIVERSIDADE FEDERAL DO VALE DO SÃO FRANCISCO

INTRODUCTION: Falls is the most common accident among older adults and is associated with poor functional independence, hospitalizations, and greater economic burden. Older adults with Mild Cognitive Impairment (MCI) have higher rates of falls annually (~70%). Falls prevention guidelines suggests a targeted approach to multicomponent programs that focus on strength and balance, appear to be particularly effective. Previous studies showed that Metastability Resistance Training (MRT)–a strategy of high motor complexity that promotes proprioceptive stimulation through resistance exercises performed under metastable states of equilibrium– is effective to improve functional mobility, balance, muscle strength, and cognition health of older people. However, evidence about its efficacy on falls prevention is unknown. Herein, we will present a study protocol designed to verify the effects MRT as a strategy to prevent falls in older adults with probable MCI.

METHODS: This is an ongoing single-site, randomized controlled trial (RBR-9bv3dc9) which is recruiting (target sample size=286) non-disabled, sedentary, community-dwelling older adults with probable MCI (Montreal Cognitive Assessment=20.0 points, SD=4.5), aged 65 years and older. They will be randomly allocated into two experimental groups: MRT group or SHAM match-attention control group, twice-weekly for 6-months. The MRT protocol will consist of seven weight-bearing and dumbbell exercises (3 sets, 10-15 repetition maximum target zone), simultaneously (and progressively) performed under metastable states of equilibrium (e.g., BOSU, balance disc, Swiss ball, foam pads and suspension traps) throughout the intervention. The SHAM group will perform group-based classes of low-intensity (no progression load) strength/balance, stretching and relaxation exercises. Our primary outcome will be falls rate over 6-months. Secondary outcomes will include concerns about falling, functional mobility/balance, gait biomechanics and cognitive function. These assessments will take place after baseline, 3-, and 6-months. At completion of 6-months, the incidence of falls and the concerns about falling will continue to be monitored for 6-months (follow-up).

RESULTS: Between February and April 2022 (first wave), a total of 196 older adults were screened. Ninety-one participants were eligible, and they were randomly allocated into MTI(n=45) or SHAM(n=46). Most of participants were female (78%) and had a mean age of 71 years (SD=4.8). The dropout rate during 6-months intervention was 15% and 11% for MRT and SHAM, respectively. Participants are currently being monitored for falls incidence and concerns about falling. In February 2023, we started a second wave of recruitment with almost 300 older adults are being screened for eligibility criteria.

CONCLUSION: This innovative trial may to provide insights on the efficacy of a novel exercise modality that could lead a significant reduction of falls rate and improve falls related variables among older adults with MCI.

DO COLLEGE MALE CYCLISTS HAVE LOW BONE MASS? —COMPARING OSTEOGENIC RESPONSES WITH THOSE OF VOLLEYBALLERS

HONDA, A.1, WATANABE, M.2, BAN, T.2, UMEMURA, Y.3

1,2 ASAHI UNIVERSITY, 3 CHUKYO UNIVERSITY

INTRODUCTION: The immobilization and reduction of physical activities lead to decreases in muscle and bone mass, i.e., sarcopenia or osteoporosis in old age. Therefore, physical activities, especially during young, are very important as a countermeasure for these disorders. Cycling and swimming are popular sports and have positive effects on muscle mass and health. Conversely, many studies reported that the bone mass of cyclists and swimmer were lower compared with aged-matched counterparts or weight-bearing sports players, such as runners or volleyballers. However, cyclists also currently carry out various weight-bearing trainings; thus, whether their bone mass is low is uncertain, although the effects are site specific. Thus, this study aimed to investigate osteogenic responses in cyclists by comparing with those of volleyballers.

METHODS: The participants were male college cyclists (n=13, age = 20.7 ± 0.5 years, height =171.5 ± 6.2 cm, weight = 71.2 ± 6.5 kg) and volleyballers (n=13, age = 19.6 ± 0.8 years, height = 177.7 ± 7.2 cm, weight = 71.5 ± 10.2 kg). Serum bone markers, osteocalcin, bone-specific alkali-phosphatase, and tartrate-resistant acid phosphatase 5b, and 1,25-(OH)2 vitamin D (VD), were measured. Bone stiffness, broadband ultrasound attenuation (BUA), speed of sound (SOS), and Z-score at the calcaneus were measured by defining the dominant and nondominant hand side using quantitative ultrasound (QUS).

RESULTS: The athletic career of cyclists (6.0 ± 0.4 years) was significantly shorter than that of volleyballers (8.8 ± 3.1 years). All bone parameters of the cyclists, except BUA, were significantly lower compared with those of the volleyballers. No significant differences were noted between the dominant and nondominant sides in both groups. The range of Z-score in cyclists were −1.0 to 2.7 at the dominant side and −0.7 to 3.5 at the nondominant side, and in volleyballers, 0.3 to 4.2, and 0.2 to 4.9, respectively. Many cyclists maintained above basal level in terms of Z-score, although only a few cyclists showed a low level (less than 0). Additionally, the bone markers, except VD, had no significant change in both groups. The VD of cyclists was significantly higher than that of volleyballers, which was probably due to the difference in time spent outside.

CONCLUSION: The bone parameters of the calcaneus using QUS were reported to be strongly correlated with bone mineral density at the lumbar spine and femoral neck. Our data showed that osteogenic responses of cyclists were certainly low compared with those of volleyballers; however, college cyclists do not necessarily have less bone mass. It was suggested that various weight-bearing trainings, such as weight training, contributed to bone maintenance in cyclists.

EFFECTS OF EXERCISE BY TYPE AND DURATION ON MILD TO MODERATE IDIOPATHIC SCOLIOSIS IN ADOLESCENTS: A SYSTEMATIC REVIEW AND META-ANALYSIS.

PENG, C., TIANXIAO, G., JING, M.

BEIJING SPORT UNIVERSITY

INTRODUCTION: Adolescent idiopathic scoliosis is a common spinal disease that occurs in a specific age group and poses a serious threat to the physical and mental development of adolescents. Appropriate exercise interventions can produce good corrective effects, but the therapeutic effects of different exercise methods and the optimal exercise time are currently unclear. We conducted a meta-analysis to compare the effects of different types and duration of exercise on mild to moderate idiopathic scoliosis adolescents (AIS).

METHODS: Two researchers searched the electronic databases (PubMed、Web of science、Embase、The Cochrane library、CBM、CNKI et al.). The Cochrane bias risk assessment tool evaluated the methodological quality and publication bias. The data analysis were implemented by Revman 5.4 and Stata 17.0. A total of 18 out of 778 articles were involved into analysis. The Cobb angles was used as the outcome indicator.

RESULTS: The meta-analysis results showed that the Schroth exercise group (MD = -3.48, 95% CI -4.73 to -2.23, $p < 0.00001$), the strength exercise group (MD = -3.43, 95% CI -4.06 to -2.80, $p < 0.00001$), the combined exercise group (MD = -2.76, 95% CI -3.18 to -2.34, $p < 0.00001$), and the suspension exercise group (MD = -2.54, 95% CI -4.13 to -0.95, $p = 0.002$) effectively improved the Cobb angle.

The included studies were divided into two subgroups in regard to exercise duration, less than 60 minutes and more than 60 minutes, to examine the effects of exercise duration on the outcome. The meta-analysis included ten articles with a total sample size of 437. The results of the meta-analysis showed that the group with exercise duration of fewer than 60 minutes (MD = -3.02, 95% CI -3.53 to -2.51, $p < 0.00001$) performed better than the group with more than 60 minutes (MD = -2.49, 95% CI -3.18 to -1.80, $p < 0.00001$) in terms of the effect of Cobb angle.

CONCLUSION: This study confirms that Schroth exercises and strength exercises better affect Cobb angle among the many common exercise modalities for AIS patients. In clinical practice, the appropriate exercise method is selected according to the patients condition to achieve optimal efficacy. Second, this study confirms that the effect on the Cobb angle is better in the group with less than 60 minutes than in the group with more than 60 minutes. Patients with AIS can achieve a better effect with exercises within 60 minutes at a time, but it is essential to ensure the quality of the training.

EXAMINING THE EFFECT OF SUPERVISION ON INDIVIDUAL RESPONSES TO EXERCISE TRAINING IN TERTIARY EMPLOYEES

BELL, L., HUNTER, J., VAN NGUYEN, H., OBRIEN, B.

FEDERATION UNIVERSITY AUSTRALIA, LA TROBE UNIVERSITY

INTRODUCTION: Inter-individual variance of responses to exercise have been reported, however the effect of supervision type on individual responsiveness is less understood. Our primary aim was to examine the effect of supervision type on the incidence and distribution of individual responses to exercise training in tertiary employees. The secondary aim was to determine if adaptations at week 8 predicted changes at week 16.

METHODS: Seventy-eight tertiary employees (females n = 55, males n = 23, mean age = 42±9.9) were randomly assigned to three groups: direct supervision in gym (1:1, n = 28), indirect supervision in gym (1:25, n = 24), and non-supervised control (home-based exercise, n = 26) which each completed resistance and aerobic exercise. Cardio-respiratory fitness (VO2peak), muscle strength (sum of bench and leg press (kg), fat loss (mass), mean arterial pressure, and total cholesterol were measured at baseline, 8 and 16 weeks of the intervention. A mixed-methods approach including mixed-effects linear models, technical error of measurement, bivariate profile analysis, and random-intercept random-slope mixed models were employed to determine low, average, and high responders.

RESULTS: A wide range of inter-individual variance of responses were observed, with no consistent responses between outcomes within individuals. Direct and indirect supervision had significant effects on VO2peak (both $p < 0.001$) and muscle strength (both $p < 0.001$) compared to control at week 16. Direct supervision had a significant effect on fat loss at week 8 ($p < 0.05$) and week 16 ($p < 0.001$), but indirect supervision did not have a significant effect ($p > 0.05$) compared to control. Direct supervision appeared to attenuate the incidence of low responses in muscle strength (n = 0/28) and fat loss (n = 3/28) but there was no statistically significant difference compared to other groups ($p = 0.06$ and $p = 0.23$, respectively). Training adaptations at week 8 predicted the magnitude of adaptations at week 16 for all outcomes very highly ($p < 0.001$).

CONCLUSION: Responsiveness to exercise training vary between tertiary employees and do not aggregate consistently across outcomes, highlighting the need for a personalised approach. Direct supervision of exercise may attenuate low responses in strength and fat loss, which may have implications for workplaces and organisations aiming to improve the health of sedentary employees. In addition, training adaptations observed after 8 weeks of training commencement can be used to predict training response 8 weeks later. Early identification of individual responsiveness may alert practitioners to the need for personalised exercise prescription to attenuate the incidence of low responses in healthy, untrained people.

EXERCISE AMELIORATES MITOCHONDRIAL OXIDATIVE CAPACITY IN CARDIOVASCULAR DISEASES: A META-ANALYSIS

LIM, A.Y.

CHANG GUNG UNIVERSITY

INTRODUCTION: A strong correlation between reduced mitochondrial oxidative capacity and cardiovascular diseases (CVD) has been shown. Our previous studies demonstrated that moderate-intensity continuous and high-intensity interval exercise regimens improved mitochondrial functions of platelets in patients with heart failure [1], stroke [2], and peripheral artery disease [3]. Exercise is potentially a strategy to restore mitochondrial health and fight against CVD. This systematic review aimed to clarify the effect of exercise on mitochondrial oxidative capacity in individuals with CVD and to assemble the exercise protocols.

METHODS: We searched using the PubMed, Web of Science, and Scopus databases using terms including "mitochondria", "exercise", "oxidative capacity", and "cardiovascular disease" in varied combinations. We excluded animal studies, studies involving subjects with hereditary disease, studies with only one bout of exercise, and articles written in languages other than English or have no available full text.

RESULTS: The search yielded 643 records for abstract screening, of which 11 articles met the inclusion criteria. Eight studies examined skeletal muscle while three studies examined peripheral blood cells. The studies measured mitochondrial oxidative capacity (oxidative phosphorylation, mitochondrial ATP rate, phosphocreatine measures, and citrate synthase activity) in patients with heart failure, stroke, or peripheral artery disease after at least four weeks of aerobic or resistance training. Five of the recruited articles were eligible for a meta-analysis, which although with high heterogeneity among the studies ($I2=75\%$, $p=.003$), demonstrated a significant effect size of exercise in improving mitochondrial oxidative capacity (SMD=4.78, CI=2.99 to 6.57, $p<.01$). The findings indicated that aerobic exercise enhanced succinate-involved oxidative phosphorylation. In summary, the exercise regimens proposed low-to-high-intensity aerobic or resistance training, ranging from 10 to 60 minutes per session, low to high weekly volume, and a training period ranging from six to 24 weeks.

CONCLUSION: Exercise training improves the mitochondrial oxidative capacity in skeletal muscles and platelets in patients with CVD. However, exercise protocols employed in the studies were diverse and inconclusive. Further studies are necessary to explain how exercise modifies the pathway of mitochondrial oxidative capacity.

SLEEP AND PHYSICAL FUNCTION ON MENTAL HEALTH IN COMMUNITY-DWELLING OLDER ADULTS: A CROSS SECTIONAL STUDY

PARK, H.1, JANG, M.W.2, YANG, J.1, THAPA, N.1, PARK, H.J.1, SON, H.3, BAE, S.1, KIM, G.M.4, KIM, C.S.5, PARK, J.2
DONG-A UNIVERSITY 1 &3, PUSAN NATIONAL UNIVERSITY HOSPITAL 2, PUSAN NATIONAL UNIVERSITY 4, DONGDUK WOMENS UNIVERSITY 5

INTRODUCTION: Depression is a common problem among older adults, and it is associated with physical pain, poor medical health and cognitive impairment. Previous research has found a link between poor physical function (handgrips strength, HGS; gait speed, GS; etc), sleep quality and psychological distress. However, the underlying synergistic mechanisms of this connection have still not been well explored. The aim of this study was to examine the roles of HGS, GS, sleep quality and in the link between these risk factors and psychological depression among community-dwelling older adults.

METHODS: In this study we included a total of 117 men and women aged 70.1±4.2 years. We defined depression using Korean version of the short form Geriatric Compression Scale (SGDS-K) developed by Sheik & Yesavage (1986). HGS was measured with hand-held dynamometer with an adjustable grip (TKK-5101, Takei Scientific Instruments Co., Japan). We measured GS was participants walked around a 7 m walkway at comfortable paces. Sleep duration was measured using a modified Munich Chronotype Questionnaire. Older individuals were assessed using the International Physical Activity Questionnaire, body impendence analysis, mobility and aerobic endurance were also measured as a confounding factor.

RESULTS: Thirty-four participants were identified as having depression. In older adults, physical function and sleep quality had a substantial direct influence on depression. Linear and non-linear regression models showed that after controlling data for age and/or sex, depressive score was associated with sleep and physical function. Stronger and significant ($p < 0.05$) associations were also observed for the 70 or more years old age group than <70 years. Results from the multivariate-adjusted logistic regressions showed that individuals who have lowest HGS, GS, short sleep duration (<5 h), and those in combination group (lowest tertile of HGS and GS and short sleep duration) were 2.1 (1.01-3.42), 3.0 (1.09-5.01), 3.7 (1.13-4.89), and 5.8 (1.93-9.37) times more likely to have depression, respectively, compared to those in the highest tertile groups of HGS, GS, sleep and those in the combination group (highest tertile of HGS and GS and adequate sleep time).

CONCLUSION: Each of the physical functional measures and sleep duration was associated with the risk of depression in the older adults. Moreover, participants with poor physical performance in combination of short sleep duration had the highest risk of depression. Given the significant health benefits of exercise and daily physical activity and its favorable effects on physical function and sleep pattern, strategies including exercise focused program should be considered in the prevention of depression in older adults.

THE RELATIONSHIP OF MOTOR COORDINATION WITH HEALTH AND FUNCTIONAL OUTCOMES AMONG CHILDREN IN HONG KONG DURING PANDEMIC-RELATED SOCIAL RESTRICTIONS

EGUIA, K.F.1, CAPIO, C.M.2
<1> HONG KONG POLYTECHNIC UNIVERSITY, <2> EDUCATION UNIVERSITY OF HONG KONG

INTRODUCTION: Children with Developmental Coordination Disorder (DCD) display impaired motor proficiency that interferes with age-expected daily activities. In addition to motor proficiency issues, they also have difficulties in other domains of health and function, all of which may be exacerbated by social restrictions such as those imposed during the COVID-19 pandemic. This study aimed to estimate the prevalence of probable DCD among children in Hong Kong and examined the relationship of motor coordination with health and functional outcomes.

METHODS: The participants consist of a population-representative sample of parents of children aged 5-12 years from across Hong Kong (N=632). The parents responded to an online survey that consisted of the Developmental Coordination Disorder Questionnaire-Chinese version, DCDQ-C (1) and components of the Patient Reported Outcome Measurement Information System (PROMIS) Parent Proxy Scale - Global Health, Physical Activity, Positive Affect, and Cognitive Function (2).

RESULTS: Based on the total DCDQ-C score, 19.1% (n=121) of the participants were categorized as "suspect DCD". Children suspected of DCD had significantly lower global health ($U=14888.00$, $Z=-8.89$, $p<0.001$), positive affect ($U=18184.00$, $Z=-7.11$, $p<0.001$), and cognitive function ($U=20844.50$, $Z=-5.56$, $p<0.001$) scores than those who were "probably not DCD". There was no difference in the physical activity score between groups.

For children who are probably not DCD, their DCDQ-C score is significantly correlated with their Global Health ($r=0.45$, $p<0.001$), Positive Affect ($r=0.27$, $p<0.001$) and Cognitive Function ($r=0.31$, $p<0.001$). For children suspected of DCD, their DCDQ-C score was significantly correlated with their physical activity ($r=0.17$, $p=0.05$) and positive affect ($r=0.19$, $p=0.03$). The general coordination subscale of DCDQ-C was particularly associated with Global Health ($r=0.22$, $p=0.014$), Physical Activity ($r=0.28$, $p=0.002$) and Positive Affect ($p=0.24$, $p=0.009$) among children suspected of DCD.

CONCLUSION: The findings revealed a high prevalence of children displaying indications of probable DCD in Hong Kong during the period of pandemic-related restrictions. The relationship between motor difficulties and health and functional outcomes differed between children who were suspected of having DCD and those who were not. However, positive affect was consistently related to motor difficulties among all children. Motor coordination, in particular, was associated with health-related outcomes among those suspected of DCD. As we move towards returning to regular school and social activities, activities that promote motor coordination are crucial to mitigate the extensive negative effects of the pandemic on childrens well-being.

EFFECTS OF A 13 -WEEK PHYSICAL EDUCATION CLASS ON UNIVERSITY STUDENTS EXERCISE MOTIVATION, MOOD AND BODY IMAGE

HON, S.

THE CHINESE UNIVERSITY OF HONG KONG

INTRODUCTION: Exercise motivation has been a topic well researched in the past, however, not many researches have been conducted on the relationship among the exercise motivation, mood and body image. The present study examined whether a 13-week physical education class will improve exercise motivation, mood and body image of university students.

METHODS: The participants in this study were enrolled in undergraduate physical education classes at a university in Hong Kong. A total of two hundred female respondents were recruited in this study. Measurement on Exercise Motivation Inventory 2 (EMI-2) and Body Appreciation Scale-2 (BAS -2) and Mood Questionnaire (The Positive and Negative Affect Scale) were used in the study. Participants filled in the three instruments at the first class and the last class. Data were analyzed at the significance level of $p<.05$ for one group pre-test and post-test of the data set.

RESULTS: The Mann-Whitney showed significance at the $p<.05$ for the Body Appreciation Scale-2 and the Mood Questionnaire. One hundred and twenty students (17 ± 2.1 years; 1.55 ± 0.15 m; 50 ± 6.4 kg;) reported increased body appreciation (mean value from 3.6 to 4.0) and one hundred and forty students reported positive mood (mean value from 3.9 to 4.3) after the 13-week class. The students reported to achieve health as the most important exercise motivation. The majority students desired to continue to do exercises in the future.

CONCLUSION: This study suggests that a 13-week physical education class showed increasing positive body image and enhancing mood after participating in physical education classes. Health was a very important concern of students when choosing to exercise. Since the participants in this study were all girls and future study can examine the gender difference on the topic.

LONG-TERM FOOTBALL TRAINING AND C-MIR-1303 EXPRESSION: EFFECTS ON PROLIFERATION, MIGRATION AND INVASION OF HUMAN BREAST CANCER CELL LINES MCF-7

MANCINI, A., VITUCCI, D., ORLANDELLA, F.M., ERMIDIS, G., RANDERS, M.B., KRUSTRUP, P., ORRÙ, S., SALVATORE, G., BUONO, P.

UNIVERSITY PARTHENOPE, NAPOLI, ITALY AND CEINGE-BIOTECNOLOGIE AVANZATE "FRANCO SALVATORE", NAPOLI, ITALY

INTRODUCTION: We analyzed the effects of long-term football training on circulating miR-1303 expression and on the proliferation, migration and invasion pathways in the human breast cancer cell line (MCF-7).

METHODS: 15 veteran football players (VPG; trained at least 40y) and 15 active untrained (CG) healthy males matched for age (66–72 y) were recruited by prof. Krustrup in Denmark. Blood samples at rest (VPG and CG) and immediately after a football match for VPG were collected. MCF-7 cells were cultured to confluence in DMEM with 10% FBS1.

MCF-7 proliferation and migration were assessed by wound healing assay. In brief, cells were starved in 0.5% FBS for 18h, scratched and cultured in 5% sera pool from VPG or CG or FBS (as control) or transiently transfected with 25□M of miR-1303 or miR-1303-Inhibitor (miR-1303-I; mirVana®miRNA mimic, Thermo Fisher, Italy) for 24h and 48h, respectively. The wound closure percentage was calculated in each group and among the groups. The expression of cmiR-1303 in sera from VPG and CG pools and in transfected MCF-7 cells was determined by RTqPCR. For the invasion assay, cells were treated as described above and then layered at a confluence of 5000 cells/well over GrowDex in the 24-transwell chamber. After 24 hours, the cells were fixed and stained with crystal violet and then counted. Phospho-AKT (Ser473) and mTOR protein expression levels were determined by western blot in MCF-7 cells after 48h of treatment.

RESULTS: miR-1303 expression was downregulated in the serum pool from VPG compared to CG ($p<0.05$), and parallel the expression found in the vastus lateralis muscle biopsy from VPG compared to CG2. A 18% increase in wound closure was observed in miR-1303 MCF-7 cells treated compared to FBS or miR-1303-I ($p<0.05$), respectively at 24h. Moreover, MCF-7 cells treated with VPG pool sera shows a 15% compared to CG ($p<0.05$) and 21% compared to miR-1303 transfected cells ($p<0.01$) reduced wound closure, respectively at 24h. miR-1303 over-expression increase the MCF-7 invasion compared to miR-1303-I ($p<0.01$) treated cells; VPG pool sera treatment induces a shut-down of invasion process in MCF-7 cells compared to CG ($p<0.05$). Significant Phospho-AKT (Ser473) and mTOR protein expression increase were found in miR-1303 compared to FBS or miR-1303-I treated MCF-7 cells ($p<0.05$) after 48h.

CONCLUSION: Our preliminary results indicates that the expression of cmiR-1303 was lower in VPG compared to CG; cmiR-1303 expression affect proliferation, migration and invasion process in MCF-7 cells by targeting PI3K-AKT-mTOR pathways. Ongoing experiments are in progress in order to further elucidate the pathways.

SHORT-TERM EFFECTS OF COVID-19 ON PHYSICAL PERFORMANCE, TRAINING LOAD AND MENTAL HEALTH — A STUDY OF CHINESE YOUNG WELL-TRAINED SPRINT KAYAKERS

DENG, S.1, LI, Y.1, DENG, J.1, YIN, M.1, CHEN, Z.1, NASSIS, G,2

1SHANGHAI UNIVERSITY OF SPORT, SHANGHAI, CHINA; 2UNITED ARAB EMIRATES UNIVERSITY, AL AIN, ABU DHABI, UAE

INTRODUCTION: COVID-19 has a complex impact on multiple body systems affecting both physical performance and mental health [1]. Evidence-based information on the effects of COVID-19 on athletes' performance can help towards safe return-to-play protocols and clinical management strategies [2]. This study aims to examine the short-term effects of COVID-19 on physical performance, training load, and mental health in young well-trained sprint kayakers during the 2022-2023 season.

METHODS: 17 kayakers (8 male,9 female, age 17.5 ± 1.6 yrs, height 176.03 ± 7.02 cm, body mass 68.8 ± 10.0 kg; mean±SD) underwent two upper-body strength tests and anthropometric measurements before (2 weeks) and after a mild COVID-19 infection (up to 2 weeks after retraining). Mild COVID-19 infection was defined as being without hospitalization and without any health complications lasting longer than 14 days [3]. Peak and mean power output (PP and MP), peak and mean propulsion velocity (PV and MV), and 40-s maximal repetitions of bench pull and bench press were measured with a linear transducer (Gymaware) before and after COVID-19. CR-10 session rating of perceived exertion (sRPE) for training load and Hooper questionnaire for mental status were measured daily and averaged weekly. Nose swab PCR/antigen tests for COVID-19. Statistical analysis included the use of Wilcoxon signed rank test, Student t-test, Pearsons and Spearmans r correlation coefficients.

RESULTS: Duration of main symptoms, detraining, and retraining was 2.9 ± 1.1, 10.4 ± 1.8, and 12.1 ± 1.1 days. There was a significant improvement in body mass, fat-free mass, muscle mass, flexed biceps circumference, absolute and relative PP, and MP of bench pull before and after COVID-19 ($p < 0.05$). There was a significant reduction in training hours per week, sRPE, sRPE-TL, fatigue levels, muscle soreness levels, and Hooper index before and after COVID-19 ($p < 0.05$). However, the duration of main symptoms and detraining were negatively correlated with PP, MP, and PV of bench press after COVID-19 [range $r = -0.51$ ($p < 0.05$) to $r = -0.67$ ($p < 0.01$)]. Duration and training hours per week of retraining were positively correlated with body mass, fat-free mass, muscle mass, flexed biceps circumference, PP, MP, PV, and MV of bench pull and bench press [range $r = 0.50$ ($p < 0.05$) to $r = 0.73$ ($p < 0.001$)]. Sleep quality, stress, fatigue, muscle soreness levels, and Hooper index during the retraining period were negatively correlated with PP and MP of bench pull and bench press [range $r = -0.48$ ($p < 0.05$) to $r = -0.85$ ($p < 0.001$)].

CONCLUSION: A mild COVID-19 infection resulted in changes of anthropometric, training, mental health, and performance variables, but did not result in a reduction of physical performance in well-trained young athletes after short-term retraining. The results of this study will provide valuable information to inform clinical management and improve return-to-play protocols.

A NOVEL ANTHROPOMETRIC METHOD FOR CENTRAL OBESITY: A PILOT STUDY

ALAHMADI, M.A.1, MUKHERJEE, S.2, AL-DAGHRI, N.M.3

1TAIBAH UNIVERSITY, SAUDI ARABIA; 2NANYANG TECHNOLOGICAL UNIVERSITY SINGAPORE, SINGAPORE; 3KING SAUD UNIVERSITY, SAUDI ARABIA

INTRODUCTION: We developed a novel anthropometric method for estimating central obesity. A novel index was also produced to test its correlation with percentage body fat measured using with bioelectrical impedance analysis.

METHODS: 72 university male students participated in the study (Age, mean ±SD, 22.49 ± 1.17 year). Waist circumference (WC) and hip circumference (HC) were also measured. The waist-hip ratio (WHR) and the waist-height ratio (WHtR) were calculated. Measuring central obesity included the following: 1) the length of the vertical abdominal line was measured with an anthropometric tape from the tip of the xiphoid process to the upper margin of the symphysis pubis. An equation was produced to determine a central obesity index (COI) as a measure of central obesity. Percentage body fat was measured using bioelectrical impedance analysis.

RESULTS: Percentage body fat was significantly correlated with both vertical abdominal line and COI ($r = 0.27$, $P = 0.05$; $r = 0.72$, $P = 0.001$) respectively. There was also a significant positive correlation between COI and BMI, WC, WHtR, and WHR. However, vertical abdominal line was correlated significantly only with BMI and WC.

CONCLUSION: Our method is simple, requires minimal training and could an accurate alternative to measure central adiposity in practice especially with large populations.

EXPLORING THE PARADOX OF NORMAL LUNG FUNCTION AND IMPAIRED MUSCLE OXYGENATION DURING MAXIMAL EXERCISE IN UNCOMPLICATED TYPE 2 DIABETES

JLALI, I.1, TOUIL, I.2, HAJ AMOR, H.2, BOUZID, M.A.3, HAMMOUDA, O.4, CHTOUROU, H., BAQUET, G.1, TAGOUGUI, S.1
1UNIV. LILLE, UNITÉ DE RECHERCHE PLURIDISCIPLINAIRE SPORT SANTÉ SOCIÉTÉ, 2TAHER SFAR HOSPITAL, MAHDIA, TUNISIA, 3HIGHER INSTITUTE OF SPORT AND PHYSICAL EDUCATION OF SFAX,4 PARIS NANTERRE UNIVERSITY

INTRODUCTION: Type 2 diabetes (T2D) has been linked to micro and macro-vascular complications due to long-term hyperglycemia, which may affect pulmonary function and muscle oxygenation. The aim of this study was to evaluate all stages of the oxygen pathway in obese individuals with uncomplicated T2D and matched obese individuals without T2D.

METHODS: The study included obese adults with T2D free from clinically detectable microangiopathy (glycated hemoglobin 'HbA1c':8.3±1.2%), and 15 obese adults without T2D, matched for gender, age, and physical activity level. Lung function was assessed at rest and 15 minutes after exercise using spirometry. Participants performed a maximal incremental exercise test during which muscle oxygenation was monitored by near infrared spectroscopy "NIRS". Arterial blood gas samples were collected from the radial artery at rest and during maximal exercise.

RESULTS: Dynamic lung volumes (forced vital capacity: 102.2 ± 11.74 vs. 106.8 ± 16.15 %; forced expiratory volume in 1 second: 100.6 ±10.5 vs. 105.13 ± 16.5 %) were normal in both T2D and controls groups at baseline. There were no significant difference in spirometric lung function between pre- and post-exercise. During maximal exercise, the accumulation and increment in [THb] were significantly lower in the T2D group compared to the control group. [HHb] accumulation from rest to maximal exercise was significantly lower in type 2 diabetes relative to control. Despite similar physical activity level and heart rates at exhaustion (158.2±21.6 vs. 166.2±10.5 bpm, respectively), individuals with T2D had lower VO2max than controls. There were no significant differences in arterial blood gas analyses (PaO2 and PaCO2) between groups.

CONCLUSION: Pulmonary function is normal in individuals with uncomplicated T2D at rest. The defect in maximal oxygen consumption may be due to impaired skeletal muscle oxygenation during exercise, related to reduced limb blood flow and altered muscle deoxygenation in uncomplicated type 2 diabetes.

BRAIN HEALTH AND FITNESS CLASSES IN OLDER ADULTS: INITIAL FINDINGS OF A PILOT PROJECT

BARDUTZ, H., SINGH, J., SHAFIQ, A., VANCE, C., NEARY, J.
UNIVERSITY OF REGINA

INTRODUCTION: Research suggests that learning and being actively engaged in a community can be beneficial for neurological health. The purpose of this study was to assess the feasibility and initial findings of brain health and fitness classes on subjective hope and heart function.

METHODS: Ten participants completed brain health and fitness classes over 8-weeks. The classes educate the participants about exercise, sleep, stress, nutrition, and socialization. Each class is interactive and includes activities based on the topic of the week. The Adult Hope Scale was completed prior to beginning the courses and after 8-weeks. Participants were given a cardiac sensor that measures vibrational heart activity using seismocardiography (LLA RecordisTM) to take home and take their recordings once per week. The sensor provides cardiac cycle timing intervals, including heart rate, systolic time, diastolic time, and isovolumic contraction and relaxation times (IVCT and IVRT, respectively). Finally, participants were given a Actigraph (Phillips RespironicsTM) to wear before sleeping to record percent sleep efficiency (time asleep/total time spent in bed).

RESULTS: All 10 participants completed the full 8-week course and had no issues with data collection or concerns with the study length (100% retention and adherence to the study procedures). Six (60%) participants had an increase in the Adult Hope Scale at the follow-up in comparison to baseline. All participants collected cardiac data with no difficulties reported, and there were minimal variations in any of the cardiac intervals on a week-to-week basis. There was a non-significant decrease in heart rate from the first 4-weeks at 68 bpm to 63 bpm during the last 4-weeks. All participants reported no issues associated with the use of the Actigraph. Sleep efficiency per participant ranged from 79 to 91%, with minimal week-to-week variations.

CONCLUSION: The Brain Health and Fitness classes can be effectively completed for research purposes, with the methods being simple for the participants to understand and adherence remaining high, suggesting good feasibility. Future research will include larger sample sizes and stratification of the patient population by neurological conditions.

IMPROVING RESISTANCE TRAINING PRESCRIPTION THROUGH THE LOAD-VELOCITY RELATIONSHIP IN FEMALE BREAST CANCER SURVIVORS: THE CASE OF THE BOX SQUAT EXERCISE

DÍEZ-FERNÁNDEZ, D.M., BAENA-RAYA, A., ESTEBAN-SIMÓN, A., RODRÍGUEZ-ROSELL, D., SORIANO-MALDONADO, A., RODRÍGUEZ-PÉREZ, M.A.
UNIVERSITY OF ALMERIA

INTRODUCTION: Breast cancer is the cancer type with the highest incidence in women worldwide, with almost 2.1 million new patients diagnosed every year [1]. A negative side effect of the treatment is the loss of approximately 25% of the lower body muscle mass compared to healthy subjects [2]. Resistance training is an effective method to increase muscular strength levels in breast cancer survivors [3]. Movement velocity allows to accurately quantify relative load to prescribe an effective resistance training program [4]. Due to a close relationship has been found between movement velocity and the relative load (%1RM) during the bilateral leg-press exercise in breast cancer survivors [5], the aims of this study were to

analyze the load-velocity relationship during the box squat exercise in female breast cancer survivors and to examine what type of adjustment and velocity variable allows to predict with greater precision the velocities associated with each %1RM.

METHODS: Nineteen breast cancer survivor's women (age: 50.2 ± 10.8 years, weight: 69.6 ± 15.2 kg, height: 160.51 ± 5.25 cm, 1RM box squat exercise: 50.1 ± 10.3 kg), as part of the EFICAN project [6], performed an incremental load test until 1RM in the bench press exercise. The mean propulsive velocity (MPV) and the peak velocity (PV), measured using a linear velocity transducer (T-Force System), were analyzed by lineal (LA) and polynomic (PA) regression models.

RESULTS: A very close relationship between MPV and relative load (%1RM) was observed (R2 = 0.900; $p < 0.0001$; SEE = 0.06 m.s-1 by LA and $R^2 = 0.900$; $p < 0.0001$; SEE = 0.06 m.s-1 by PA). Whereas for PV a worse relationship between %1RM and PV was observed ($R^2 = 0.704$; $p < 0.0001$; SEE = 0.15 m.s-1 by LA and $R^2 = 0.704$; $p < 0.0001$; SEE = 0.15 m.s-1 by PA). The MPV of 1RM was 0.22 ± 0.04 m·s-1, whereas the PV at 1RM was 0.63 ± 0.18 m.s-1

CONCLUSION: LA and PA allow to predict the velocities associated with each %1RM and the estimated 1RM with a great precision during the box squat exercise in female breast cancer survivors. MPV was considered the most recommended velocity variable to prescribe the relative load during resistance training.

EFFECTS OF A SIXTEEN-WEEKS HIGH-SPEED RESISTANCE TRAINING PROGRAM ON BONE MINERAL DENSITY AND CONTENT IN INDEPENDENT OLDER ADULTS

DUARTE MARTINS, A.1,2, BATALHA, N.1, FERNANDES, O.1, BILRO, V., RAIMUNDO, A.1, PAULO BRITO, J.2,3

1COMPREHENSIVE HEALTH RESEARCH CENTRE, UNIVERSIDADE DE ÉVORA 2LIFE QUALITY RESEARCH CENTRE, SPORTS SCIENCE SCHOOL OF RIO MAIOR 3RESEARCH CENTRE IN SPORT SCIENCES, HEALTH SCIENCES & HUMAN DEVELOPMENT

INTRODUCTION: The United Nations estimates 1.5 billion people aged over 65 years in 2025, compared with 703 million in 2019 (1). Unfortunately, the aging process involves the development of many chronic diseases, namely osteoporosis. Osteoporosis is characterized by low bone mass and microarchitectural deterioration of bone tissue (2). Reduced bone mineral density (BMD) and bone mineral content (BMC) with age increase the likelihood of fall-related fractures (3). A recent meta-analysis recommended the use of resistance training programs for increasing BMD and BMC in older adults (4). This study examined the effects of a 16-weeks high-speed resistance training (HSRT) program on BMD and BMC.

METHODS: This study included 21 independent older adults (age, 69.00±4.32 years). The HSRT program lasted 16 weeks, with 3 sessions per week of 50–60min, each session of 5–6 exercises, 2–3 sets, and 6–10 reps/exercise. The intensity was gradually increased after each session in accordance with the movement velocity (>1.3–0.75 m/s) representing approximately 20% to 60% of one repetition maximum. Participants executed the exercises rapidly and explosively, making all repetitions for each shortening phase (concentric phase) performed as quickly as possible with the lengthening phase of the muscle (eccentric phase) being controlled for 2–3sec. The velocity of the concentric phase in each exercise was monitored by a BEAST™ sensor (Beast Technologies, Brescia, Italy). BMD and BMC for whole-body and dominant femoral neck were measured by dual-energy X-ray absorptiometry. The Ethics Committee of the University of Évora approved the study. The protocol was registered at the ClinicalTrials.gov (NCT05586087).

RESULTS: After the intervention period, the bone indicators demonstrated significant improvements: whole-body BMD ($p>0.001$; effect size (ES)=-0.29 [-0.43, -0.17]); whole-body BMC ($p>0.001$; ES=-0.15 [-0.24, -0.07]); and dominant femoral neck BMD ($p=0.040$; ES=-0.10 [-0.20, -0.01]). No significant difference was found for dominant femoral neck BMC.

CONCLUSION: The results suggest that the HSRT program is an effective and safe exercise approach to improve BMC and BMD in independent older adults.

THE ASSOCIATION BETWEEN PHYSICAL ACTIVITY AND BONE MINERAL LOSS IN KOREAN OLDER ADULTS WITH MAJOR DEPRESSION DISORDER: FINDINGS FROM A CROSS-SECTIONAL SURVEILLANCE STUDY

LEE, H.1, HAN, J.2, VITIELLO, D.2

1SANGMYUNG UNIVERSITY; 2UNIVERSITÉ PARIS CITÉ

INTRODUCTION: Research shows that major depression disorder (MDD) is associated with bone mineral density (BMD) loss in both male and female older adults, which may increase the risk of osteoporotic fractures [1, 2]. Unhealthy behaviors that are detrimental to bone health (e.g., physical inactivity and/or poor diet), physiological changes (e.g., elevated proinflammatory cytokines and/or disruption of sex hormones), and negative side effects of anti-depressant (e.g., TCAs, SSRIs) are thought to be potential mechanisms of BMD loss [3, 4]. Therefore, we hypothesized that doing more physical activity despite MDD condition may alleviate the BMD loss. The purpose of this study was to examine the moderating

effects of physical activity on the association between MDD and BMD loss in representative samples of Korean older adults.

METHODS: Data were retrieved from a subsample (n=2,527) of 2007-2011 Korea National Health and Nutrition Examination Survey, population-representative surveillance data. MDD was measured with a single-item questionnaire ("have you ever been diagnosed with MDD by a doctor?). Time spent in moderate- to vigorous-intensity physical activity (MVPA) and walking were measured using IPAQ. Bone mineral density was measured using DXA and dichotomized into osteopenia (BMD loss) vs. normal. Sex-specific logistic regression analyses were performed with BMD loss as dependent variable, and MDD, MVPA, and walking, as independent variables. To test the moderation effects, interaction terms between MDD and MVPA and walking (hours per week) were included. Variables that may be associated with BMD loss (i.e., age, total energy intake, smoking, drinking alcohol, vitamin D and calcium intake, BMI, marital status, and socioeconomic status) were included as covariates.

RESULTS: In the male model, MDD was associated with 95% increased risk for BMD loss (OR=1.95, p=.030). Doing 1 hour per week of additional MVPA (OR=0.96, p=044), however, not walking (OR=0.89, p=.110), significantly alleviated the risk for BMD loss associated with MDD in males. In the female model, meanwhile, MDD was not significantly associated with odds of BMD loss (OR=1.63, p=.393).

CONCLUSION: In the current study, MDD was a significant risk factor for BMD loss in older men but not women, despite BMD loss being a more prevalent health burden for menopausal women. We also found that doing more MVPA but not walking seems to protect against BMD loss in older male MDD patients. The results of this study suggest that MVPA should be proactively included as a regimen by mental health professionals.

THE IMPACT OF AEROBIC DANCE EXERCISE ON COGNITIVE FUNCTION IN YOUNG ADULTS: EXAMINING THE ROLE OF MOTOR COMPLEXITY

KIMURA, K.

TOKYO DENKI UNIVERSITY

INTRODUCTION: Recently, emerging evidence has revealed that a combined exercise program involving physical and cognitive tasks can improve and maintain various psychological functions, such as cognitive and mental health. Similarly, research has shown that physical exercise, such as dance, can play an important role in maintaining the psychological health of the elderly and children, particularly when the exercise is tailored to the individual's task complexity. However, it is still unclear whether motor complexity itself could have a positive effect on cognitive function. The present study conducted a 12-week exercise intervention involving aerobic dance, in which motor complexity was systematically controlled. The study aimed to investigate how motor complexity in dance exercises affects the executive cognitive function of young adults.

METHODS: More than 60 people aged 18–20 years participated in this study. They were randomly divided into three groups: 1) Dance exercise (DE), 2) Aerobic exercise (AE), and 3) Control (Co). The participants in the DE group participated in aerobic dance exercises, while the AE group participated in aerobic exercise using a stationary bike. The participants in both groups attended the 30-min workout three times a week for three months (12 weeks). The Co group were not provided any instructions or targets regarding their daily physical activity. Throughout the dance exercise intervention, the instructor gradually increased the level of motor complexity every three weeks. The intensity of physical exercise between the DE and AE groups was controlled in the same range of 50%–60% HRR. Computer-based cognitive reaction time tests were administered to investigate the effects of training on cognitive function (i.e., cognitive flexibility and working memory). All participants took part in the tests before and after the three-month exercise intervention.

RESULTS: Task performance (i.e., reaction time and correct response rate) of the cognitive tests was analyzed to compare the effect sizes between groups. The 2-way ANOVA (time by group) was conducted to reveal the effects of the dance exercise intervention on cognitive performance.

CONCLUSION: This study demonstrates that regular physical exercise interventions that incorporate motor complexity may have a greater effect on cognitive function compared to simple aerobic exercises.

EFFECTS OF LIFESTYLE ON THE PHYSICAL ACTIVITY OF THE ELDERLY

SAKAI, T.1, NAKANO, T.2, HAYASHI, Y.3, MURAYAMA, T.4, OYAMA, Y.5, KAMEYAMA, M.4

1 NAGOYA GAKUIN UNIVERSITY, 2 CHUKYO UNIVERSITY, 3 HOSEI UNIVERSITY, 4 NIIGATA UNIVERSITY, 5 TOIN UNIVERSITY OF YOKOHAMA

INTRODUCTION: In addition to the number of steps and the levels of moderate- and high-intensity activities, recently, sedentary activity time has also been evaluated in physical activity studies. In studies using accelerometers, a common condition for data analysis is that the device must be worn for at least 10 hours each day. However, this device-wearing time does not take into consideration the effects of each persons lifestyle. Therefore, in the present study, the effects of lifestyle on daily physical activity were investigated.

METHODS: The participants were 55 elderly individuals who understood the purpose of the study and had given informed consent to participate. From July to November 2021, each participant was requested to wear an M430 running watch (Polar, Inc.) for 24 hours each day as well as a wGT3X-BT activity monitor (ActiGraph, LLC) from the time they wake up in the morning until going to bed at night. The waking and sleeping times were evaluated using the M430 watch, whereas

the times spent at each activity intensity level and the step counts were evaluated with the wGT3X-BT monitor. Data were collected on seven consecutive days, including weekends. Days on which the participant did not wear the device for more than 10 hours and/or when waking and sleeping times could not be confirmed were excluded from the analysis. Only those participants with valid data for at least three days, including one day of the weekend, were included finally. Analysis-target days were classified as (i) early-rise days, when the individual got up before 6:00 a.m.; (ii) late-night days, when the individual went to bed after 11:00 p.m.; and (iii) standard days, on which neither (i) nor (ii) applied.

RESULTS: Of the 385 days when the accelerometer was worn, 334 days were included in the analysis. Classification of the analysis-target days by lifestyle type revealed 95 as early-rise days, 84 as late-night days, and 155 as standard day. On early-rise days, approximately 2,790 steps were taken by 7:30 a.m., and the individuals tended to go to bed early in the evening. By contrast, on late-night days, the participants showed a tendency to increase physical activity in the evening, with 2,540 steps found to have been taken after 8:00 p.m. The step counts were significantly higher on early–rise days than on late-night and standard days. The ratio of moderate- and high-intensity activity time to total device-wearing time was significantly lower on standard days than on the other two groups of days. By contrast, the ratio of low-intensity activity time to total device-wearing time was significantly higher on standard days.

CONCLUSION: It was shown that the characteristics of physical activity differed according to lifestyle, with individuals who rose early tending to take more steps before breakfast and those who stayed up late taking more steps in the evening.

ASSOCIATION BETWEEN CAROTID INTIMA MEDIA THICKNESS AND FRAILTY AND PHYSICAL ACTIVITY IN OLDER ADULTS

BAE, S.1, LEE, J.1, WANG, K.1, NOH, E.1, CHOI, J.1, KIM, C.2, PARK, H.1

DONG-A UNIVERSITY1, DONGDUK WOMENS UNIVERSITY2

INTRODUCTION: Frailty is widely prevalent geriatric condition whereby individuals experience age-related functional decline. Although frailty is a risk factor for cardiovascular diseases (CVD), the relationship between frailty and preclinical atherosclerosis remains unclear. Moreover, physical activity has been shown through scientific evidence to be an effective way to improve CVD markers. However, most of these studies were conducted in younger and middle populations. Therefore, the aim of the present study was to clarify relationship between frailty, preclinical atherosclerosis and physical function in older adults.

METHODS: A total 186 older adults (mean age: 77.0 ± 3.5 years) participated in the study. Participants were divided into non-frail, pre-frail, and frail groups using Fried's frailty index (weight loss, low physical activity, exhaustion, slow walking speed, and muscle weakness). Carotid intima-media thickness (CIMT) was measured by high-resolution ultrasound, and divided into three group according to tertiles. Moderate-to-vigorous intensity physical activity (MVPA) time was measured by triaxial accelerometer. Pearson's correlation, one-way ANCOVA and multivariate logistic regression analysis was used to examine the relationship between level of CIMT and frailty and physical activity.

RESULTS: The frailty status of the participants was 94 (50.5%) non-frail participants and 92 (49.5%) pre-frail or frail participants. Physical function such as gait speed ($p < 0.05$) and grip strength ($p < 0.05$), which are used to evaluate frailty were negatively related to CIMT, while MVPA ($p < 0.05$) was reversely related to CIMT. The CIMT in highest tertile had 2.42 times (95% confidence intervals: 1.30-4.09) higher risk of frailty compared to those with CIMT in the lowest tertile. MVPA was higher in lowest tertile of CIMT than middle and highest tertile (respectively, $p < 0.05$).

CONCLUSION: This study showed the strong association between the frailty and increased CIMT. These results suggested that CMIT was an earlier marker of frailty identification. Moreover, physical activity has been shown to be effective in the age-related decline in cardiac autonomic activity and artery structural changes. Longitudinal studies will be needed to confirm the effect of physical activity on the progression of carotid atherosclerosis and frailty among older adults.

ECHOCARDIOGRAPHIC ANALYSIS OF THE HEART OF FEMALE ADOLESCENT ATHLETES

VERTEMATTI, S., KAHAKURA, J.C., GORZA, L.L., MARIN, V.L.S., ARMÍNIO, G., ARNONI, R.T.

EDMUNDO VASCONCELOS HOSPITAL

INTRODUCTION: Athletes develop a combination of cardiac alterations known as athlete heart. There is scientific evidence that in the population of adolescent athletes this also happens. Analyzing the echocardiographic parameters based on reference values by age group it improves the diagnostic accuracy in the possible abnormalities to be identified in this population.The objective of this study is to analyze the heart measurements of the left side of the heart of female athletes, adolescents and to correlate them to age, height, weight, BMI and body surface (BSA), in addition to training time.

METHODS: Retrospective observational cross-sectional study in which the medical records of pediatric patients and female athletes were analyzed. The inclusion criteria were: female athletes who underwent a transthoracic echocardiographic evaluation. The exclusion criteria were: impossibilities in obtaining results of exams for analysis, cardiological alterations and older than 18 years of age. The descriptive analysis of correlated factors (age, height, weight, BMI, body surface and training time) was made. The echocardiographic criteria for morphological were: aortic root (AoR), dimensions of left atrium (DAE), LV end-systolic dimensions (LVESD), LV end-diastolic dimensions (LVEDD), shortening fraction (ΔD), posterior wall thickness (LVPW), interventricular septum thickness (IVS) and left ventricular mass (LVM).

RESULTS: 69 individuals, mean age M= 13,82, DP= 2,10, 41 basketball athletes (59,42%) and 28 volleyball (40,58%). ΔD was not related to any anthropometric variable, BMI was related to DSVE and DDVE (2 out of 8 echocardiographic variables). The training hours were related to AoR, LVESD, LVEDD and LVM. Multiple linear regression analysis considered the following variables: age and BSA. The BSA obtained significant results for all observations, with a percentage of explained

variance of 15,8% (AoR) to 45,8% (LVM), on the other hand, the age variable proved to be an infective predictor for echocardiographic measurements. Nomograms were constructed from the allometric equations by Cavaretta et al *, which demonstrated the non-statistical significance of the age group variable, and a directly proportional correlation of BSA with all echocardiographic measurements, except ΔD.

CONCLUSION: This study suggests an influence of sports practice in the echocardiographic parameters and demonstrated a positive correlation of cardiac measures of the left side of the heart with time of practice and BSA. Standardizing the analysis of cardiac measures related to the development seems to be the right way.

VALIDITY AND RELIABILITY EVIDENCES OF OBJECTIVE PHYSICAL ACTIVITY MEASURES AND WEARABLE MONITORS: A META-SYSTEMATIC REVIEW

SHIN, J.1, KWON, S.1, NA, C.1, CHA, B.1, LEE, H.1, KIM, J.1, KANG, M.1, OH, C.1, CHOI, J.2, LEE, M.1

1.KOOKMIN UNIV, SEOUL, REPUBLIC OF KOREA; 2.SEOUL NATIONAL UNIV, SEOUL, REPUBLIC OF KOREA

INTRODUCTION: The purpose of this study was to conduct a meta-systematic review related to the validity and reliability evidences of objective physical activity (PA) measures, focusing on accelerometers and wearable activity monitors for adults.

METHODS: The objective measures of physical activity for the review were including ActiGraph accelerometers (i.e., GT3X+, wGT3X+, wGT3X-BT and GT9X) and ActivPAL due to the most frequently employed for several decades. In addition, wearable devices and Smartphone applications (mHealth APP) were also included. All data were collected from PubMed, Medline (OVID), and Web of Science.

The topic keywords were including 'PA measurement tool name' AND 'accuracy' OR 'validity' OR 'reliability' as well as 'smartphone app' OR 'wearable device' AND 'physical activity' for the smartphones and wearable devices related topics. Four measurement and statistics experts were reviewed the final 156 papers among a total of 2,280 research articles including articles of systematic reviews and meta-analyses based on the review guidelines classified by categories of validity and reliability evidences related to the PA measures. The most current publication for 10 years between 2012 and 2022 were selected for the review.

RESULTS: 1) There were numbers of validity and validation studies of ActiGraph in different versions, and GT3X and GT9X were relatively accurate. Freedson cut-points (1998) has been still widely employed in the PA researches as well as combination equations (Lyden et al., 2011). Wearing the PA devices on the waist were the most accurate compared to other wear-positions. Enough evidences were provided to include weekends and weekdays, at least four days per week and at least 10 hours a day of PA should be measured. The Length of the epoch was frequently set to 60 seconds.

2) ActivPAL was more accurate to wear on the thigh than on the arm. Estimating walking and light activity was more precise than moderate-to-vigorous PA (MVPA).

3) Validation studies of wearable devices were compared to ActiGraph, and seldomly K4b2 (Italy). Among various wrist-worn wearable devices (i.e., Fitbit, Jawbone, Apple Watch, Garmin, Xiaomi Band), Jawbone UP was relatively accurate in light activity and SB, while Fitbit models were accurate during MVPA.

4) Smartphone employed Behavior Change Technology (BCT) including the topics of goal and plan settings, behavior feedbacks, and behavior comparisons, or the utility of the Mobile App Rating Scale (MARS). The higher ranked application provided real-time energy consumption, heart rate, and visualization services, while the lower ranked model provided the number of steps only.

CONCLUSION: The ActiGraph accelerometer has provided acceptable qualities of the validity and reliability evidences to measure PA. Smartphone and wearable devices were able to promote participating in PA in free living, but still not to measure accurately enough.

THE STIFFNESSES OF PECTORALIS MINOR AND MIDDLE TRAPEZIUS ARE CORRELATED WITH THE KYPHOSIS ANGLE OF THE THORACIC SPINE

YAMADA, C.1, OKUDA, Y.1, UMEHARA, J.2,3, YANASE, K.1,3

1: DOSHISHA UNIVERSITY, JAPAN 2: KANSAI MEDICAL UNIVERSITY, JAPAN 3: KYOTO UNIVERSITY, JAPAN

INTRODUCTION: Round shoulder posture (RSP) is a condition of increased thoracic kyphosis and may lead to pain and disabilities. RSP is thought to be caused by an imbalance in the stiffness of thoracic muscles (1,2). However, there are no studies to quantitatively examine whether this imbalanced stiffness influences the kyphosis angle of the thoracic spine. The purpose of this study was to examine association between thoracic muscle stiffnesses and the kyphosis angle of the thoracic spine. Since the change in muscle stiffness of the pectoralis minor is a possible factor in RSP, we hypothesized that the stiffness of the pectoralis minor increases in RSP and that the stiffness of the trapezius muscle consequently decreased by habitual lengthening in RSP.

METHODS: Twenty-seven healthy males (21.4 ± 2.2 years, 173.4 ± 4.9 cm, 67.7 ± 8.1 kg) participated in this study. Shear elastic moduli of the pectoralis minor, pectoralis major (upper, middle and lower), and trapezius (upper, middle and lower) were measured in supine or prone position using ultrasound shear wave elastography. The shear elastic modulus was used as an index of muscle stiffness. The thoracic kyphosis angle was measured in a sitting position using the Spinal Mouse. The Shapiro-Wilk test was used to confirm normal distribution, and then Kendalls rank correlations (r) were conducted between the shear elastic moduli and the kyphosis angles of thoracic spine.

RESULTS: The Kendalls rank correlations showed a significant positive correlation between the shear elastic modulus of the pectoralis minor and the kyphosis angle of the thoracic spine ($r = 0.192$, $p = 0.046$). On the contrary, we found a negative correlation between the shear elastic modulus of the middle trapezius and the kyphosis angle of the thoracic spine ($r = -0.216$, $p = 0.025$). No significant correlations were observed between other muscle stiffnesses and the kyphosis angle of the thoracic spine.

CONCLUSION: Our findings suggest that stiffnesses of the pectoralis minor and middle trapezius are correlated with the kyphosis angle of the thoracic spine in RSP. Stiffness of the pectoralis minor muscle may lead to RSP, resulting in softening of the middle trapezius due to prolonged muscle elongation. Future longitudinal studies are needed to examine the causal relationship between muscle stiffnesses and posture.

AN EXERCISE PROGRAM INCLUDING LECTURES ON HEALTH IMPROVES PHYSICAL AND MENTAL FITNESS IN ELDERLY WOMEN

SANOMURA, M., SAHO, Y., OGAWA, Y., YAMAMOTO, A.

TEIKYO UNIVERSITY

INTRODUCTION: Exercise programs for elderly have been conducted throughout Japan for the purpose of long-term care prevention. We in cooperation with H city, Tokyo, implemented an exercise program which has been introduced as a part of its regional comprehensive care system in order to promote health among elderly residents. The aim of this study was to examine the effects of the exercise program on physical and mental fitness, such as body balance, muscle strength, and flexibility, and health-related quality of life (QOL) in elderly living in the community.

METHODS: The exercise program was held once a week for 14 weeks for 17 female elderly residents aged 65-81 years who have applied on a voluntary basis. Each program included about a 20-minute lecture on health such as exercise, nutrition, and mental health by professionals, which was followed by a 60-minute exercise session. The exercise session consisted of about 10 different exercises which helped promote body balance and build muscle strength of lower limbs, hip, and torso using body weight, elastic bands, and dumbbells. Physical fitness was measured before and after the program through 8 different evaluation methods; open-eyed one-leg standing test, grip strength test, 5-m walk test, timed up and go test, tandem gait test, functional reach test, and sit and reach test. The health-related QOL was assessed using the Short-Form Health Survey 12 (SF-12) such as general health, bodily pain, vitality, and mental health. The amount of physical activity was measured using an accelerometer, which measured the number of daily steps during the 12 weeks. Values between before and after the programs were then compared using a t-test with the significant level set at $p < 0.05$.

RESULTS: The exercise program significantly improved the results of 5-m walk, tandem gait, and functional reach tests and the mental health score of SF-12 ($p < 0.05$, respectively). There were no significant differences in the number of daily steps between before and after the programs.

CONCLUSION: The study showed that weekly exercise program, which incorporate lectures on health as well as exercises designed to enhance body balance and muscle strength, improved mental health in addition to physical fitness in elderly women. Thus, the exercise program including lectures on health may be valuable for the long-term care prevention in elderly.

RESTRICTIVE EFFECT OF VENTILATION WITH THE USE OF DIFFERENT TYPES OF MASKS IN INTENSE PHYSICAL EXERCISE

BENITO, P.J., ROJO-TIRADO, M.A., BENÍTEZ-MUÑOZ, J.A., GUISADO-CUADRADO, I.

UNIVERSIDAD POLITÉCNICA DE MADRID

INTRODUCTION: During the COVID-19 pandemic, the use of facemasks has been fundamental to control the propagation of the virus. However, there are very few studies of the comparative use of different facemasks in intense physical exercise. It is necessary to be forewarned of new similar situations and to know more precisely the effects of the use of masks on fundamental parameters of the respiratory model in exercise. Therefore, the objective of this study was to compare the use of different masks and their effect on the modification of the fundamental variables of respiration in humans who practice intense physical exercise.

METHODS: Thirteen females (22.08±1.75 years) performed a maximum voluntary ventilation. Thereafter, they performed a grad-ed exercise test on a treadmill until exhaustion. Ventilation during the maximum voluntary ventilation and during the

graded exercise test were measured breath by breath with a gas analyzer (Jaeger-CareFusion, Hochberg, Germany). The maximum voluntary ventilation and the graded exercise test were performed using an ergospirometry mask (Er-goMask) or wearing the FFP2 (ErgoMask+FFP2) or the Emotion mask (ErgoMask+Emotion) below the ErgoMask in tree randomized consecutives days and counterbalanced order. The menstrual cycle was controlled, being all tests performed during the mid-follicular phase (days 6 to 10 of the menstrual cycle) or during the mid-luteal phase (days +5 to +9 after confirmation of ovulation).

RESULTS: Maximum voluntary ventilation showed values of 121 ±16 L/min very similar to those shown by Er-goMask+Emotion 125 ±16.5 L/min (p=0.885) and by ErgoMask alone (114±21 L/min; p=0.095) and very different from those shown in ErgoMask+FFP2 (99 ±14 L/min with F(14,2)=12.4 with p<0.001). At exhaustion in the graded exercise test, it is ob-served a similar behavior pattern. The maximum ventilation with Ergo-Mask was 94±15 L/min, very similar to Er-goMask+Emotion with 90 ±12 L/min (p=0.995) and both significantly different from ErgoMask+FFP2 (75 ±13 L/min with F(14,2)=11.6 with p=0.006).

CONCLUSION: The percentage ratio between the maximum voluntary ventilation and the maximum ventilation obtained during in-tense exercise is known as ventilatory reserve. Our results indicate that exercising with an FPP2 mask can cause a very significant reduction in maximum voluntary ventilation and maximum ventilation during exercise. Since acido-sis is compensated by an increase in ventilation, this reduction in ventilation could lead to increased acidosis in people wearing FFP2 at high intensities. We can conclude that the use of FPP2 masks cause a relevant decline in the bodys ability to ventilate the lungs.

RADIAL BONE THICKNESS, BONE DENSITY, AND BONE QUALITY IN RACKET SPORTS ATHLETES -FOCUSING ON THE RELATIONSHIP BETWEEN MECHANICAL STRESS AND BONE FORMATION-

UMEDA, T.1, NAKAZAWA, T.1, FUJISAWA, Y.1, IGUCHI, J.2, HOJO, T.1

1> DOSHISHA UNIVERSITY, 2> KYOTO UNIVERSITY OF ADVANCED SCIENCE

INTRODUCTION: Bone strength is determined by bone density and bone quality, but there is no established method for evaluating bone quality. The LD-100 Ultrasonic Bone Densitometer (Oyo Electric Co.: Japan), which uses a two-wave ultrasonic method, can evaluate cancellous bone elasticity, which is considered an indicator of bone quality, in addition to bone thickness and bone density at the distal end of the radius. Bone becomes stronger when it is subjected to mechanical stress. However, the effects of different impact intensities on bone strength (bone density and bone quality) are unknown. Therefore, I focused on racket sports in which the impact on the hand during hitting is considered to differ due to differences in the weight of the racket and the ball (shuttle).

To evaluate the effects of differences in the intensity of repeated impacts on bone formation, we measured bone thickness, bone mineral density, and bone quality at the distal end of the radius using the LD-100 in racket sports athletes with different racket and ball (shuttle) weights.

METHODS: The subjects were 59 healthy male university students aged 18-23 years belonging to Doshisha University (table tennis: n=17, badminton: n=10, soft tennis: n=15, tennis: n=17). Using the LD-100, we evaluated radius bone thickness, cortical bone thickness, transmitted wave attenuation (≒bone density), cancellous bone density, and cancellous bone elasticity (bone quality), and compared them between dominant hand and non-dominant hand, and between groups.

RESULTS: Radius thickness was significantly higher in the dominant hand compared to the non-dominant hand in all groups, and significantly higher in the tennis group compared to the table tennis group ($p<0.05$). Cortical bone thickness was significantly higher in the dominant hand compared to the non-dominant hand in the badminton, soft tennis, and tennis groups ($p<0.05$). Transmitted wave attenuation was significantly higher in the dominant hand compared to the non-dominant hand in the soft tennis and tennis groups ($p<0.05$). Cancellous bone density was significantly higher in the soft tennis group compared to the tennis group ($p<0.05$). Cancellous bone elasticity did not differ significantly between the dominant hand and non-dominant hand or between groups.

CONCLUSION: Bone thickness, cortical bone thickness, and bone mass of the dominant hand were higher than those of the non-dominant hand, and these values tended to be higher when the impact on the hand during hitting was stronger, suggesting that bone formation in the cortical bone may be enhanced when the impact on the hand during hitting is stronger. The effect of impact on bone differed between cortical bone and cancellous bone, with a greater effect on cortical bone compared to cancellous bone. On the other hand, other factors such as age and nutritional status may affect cancellous bone elasticity (bone quality) more than impact.

TEXT NETWORK ANALYSIS AND TOPIC MODELING OF CHANGES IN SHOULDER PAINS AFTER 100 DAY'S SNPE

LEE, H.1, LEE, M.1

KOOKMIN UNIVERSITY

INTRODUCTION: The purpose of this study was to synthesize and scrutinize the effects of shoulder pain release after SNPE 100 day's practices by applying the text network analysis and topic modeling.

METHODS: A total of 267 recorded cases for the 100 day's SNPE experiences were adopted from the official website of the SNPE Correct Posture Spine Movement, which was based on the critically developed inclusion and exclusion criteria. Only noun words were extracted, and the user dictionary was constructed to define the similar words, deleted words, and

designated words. Frequency analysis and centrality analysis (degree centrality, eigenvector centrality, clustering) were calculated by participating to cyram 4.0. Keywords of experience cases before and after SNPE 100-day practices were extracted and a Co-occurrence network was created. Network connection structure and centrality analysis were conducted, and major topics were confirmed through topic modeling.

RESULTS: From text network analysis, it was found that the keywords of the SNPE 100-day practices experience were "motion", "pain", and "shoulder", which were high in both frequency and centrality analysis. "Motion", "pain", and "shoulder" can be said to be words that are central to the experience case after 100 days of SNPE training and have an important influence within the text. As a result of topic modeling after 100 days of SNPE training, Topic 1 was categorized as a SNPE shoulder pain relief moves because "motion", "No. 4", "No. 2", and "No. 3" were the main keywords and topics that were effective in relieving shoulder pain. Topic 2 consisted of "improvement," "lumbar spine", "leg", "student", and "cervical spine", and consists of keywords that mean improvement of shoulder pain and uncomfortable areas through SNPE, so Topic was categorized as improving shoulder pain through SNPE. Topic 3 showed "body", "symptom", "acquaintance", "No. 3", and "thymus" as the main keywords. This topic was categorized as an effect of promoting SNPE as it consists of keywords, in which people began SNPE with the recommendation from acquaintances after their pain reduction experiences. Topic 4 was categorized as an SNPE tool effect because it consisted of topics related to the effect of relieving shoulder pain through wave pillows, with "cervical spine", "muscle", "pillow", and "wave" as the main keywords. Topic 5 was categorized as keywords to express gratitude for the participants who helped during the practicing process after 100 days of practicing, with "100 Days", "leader course", "representative", "instructor", and "shoulder".

CONCLUSION: SNPE belt exercises (No. 1, No. 2, No. 3 and No. 4) were confirmed to help release shoulder pain. Thus, more effective exercise prescription of SNPE could be possible for decreasing shoulder pain.

THE RELATIONSHIP BETWEEN OBJECTIVELY-MEASURED PHYSICAL ACTIVITY AND UNIDENTIFIED SYMPTOMS IN JAPANESE WORKING WOMEN

KUNO-MIZUMURA, M.

OCHANOMIZU UNIVERSITY

INTRODUCTION: Although the social advancement of women has been promoted recently in Japan, the effect of regular employment on working women's health as well as lifestyle has not been fully elucidated. World Health Organization recommended that adults older than 18 years old should spend Moderate-to-Vigorous Physical Activity (MVPA) at least 150 to 300 minutes a week. Previous study1) reported that MVPA for Japanese women were affected by age. In addition, it is also reported that PA in Japanese workers varied among different occupations. Other previous study has pointed out that climacteric symptoms could affect work performance in women. However, Lifestyle related to physical activity of Japanese working women remains unclear. So, the purpose of this study was to investigate the physical activity (PA) of Japanese working women employed in different occupations and their unidentified complaints including climacteric symptoms.

METHODS: Eighty-four women aged from 20 to 65 years old participated in this study. PA was assessed for 7 consecutive days with a triaxial accelerometer (Active style Pro: HJA350IT), and minutes of light physical activity (LPA) and moderate-to-vigorous physical activity (MVPA) as well as sedentary behavior (SB) classified by metabolic equivalents were evaluated. We also asked them to answer questionnaires to evaluate unidentified symptoms including climacteric symptoms (US), perceived stress scale (PSS), and the sense of coherence (SOC-13).

RESULTS: The weekly average LPA in the 20s was significantly lower than that in the 50s.SOC-13 of the 20s was significantly lower than that of those older than 50s. MVPA of working women regularly employed was significantly shorter than that of women non-regularly employed, while SB of regularly employed was significantly longer than that of non-regularly employed. There was no significant difference in PA according to the different occupations of working women during weekends, although childcare teachers showed significantly higher PA than other occupations. There was no significant difference in US, PSS, and SOC-13 among different occupations of working Japanese women. A significant correlation was obtained only between PA during weekends and US. A significant positive correlation between VPA and US and a significant negative correlation between LPA and US were observed.

CONCLUSION: From the results of this study, it is indicated that regular employment would cause an increase in SB and LPA in Japanese working women. Higher PA during weekends would improve working women's health such as fewer unidentified symptoms.

ASSOCIATIONS BETWEEN PHYSICAL ACTIVITY AND FAT-FREE MASS IN JAPANESE YOUNG ADULTS AFTER THE COVID-19 PANDEMIC: A CROSS-SECTIONAL STUDY

MUTO, R., YANAOKA, T., KUROSAKA, S.

HIROSHIMA UNIVERSITY

INTRODUCTION: World Health Organization (WHO)'s guideline insists on the importance of moderate-vigorous intensity physical activity (MVPA) and muscle-strength activity [1], because loss of muscle mass has been known to increase the risk of metabolic diseases, frailty and sarcopenia [2,3]. Loss of muscle mass begins early in life and becomes noticeable with age [3]. Thus, physical activity is important for young adults to maintain and increase muscle mass. Additionally, physical activity related to muscle mass may differ between males and females because of gender differences in muscle mass [4].

However, there are no studies on body composition and physical activity among young adults in post-pandemic Japan. This study aimed to investigate the relationship between body composition and physical activity among Japanese young adults and to investigate how gender affects the association between physical activity and body composition.

METHODS: Sixty healthy young adults (33 males: age: 23.0±1.9 years, body mass index: 22.7±3.4 kg/m2 [range 17.3-29.8 kg/m2], 27 females, age: 23.0±2.2 years, body mass index: 20.5±1.8 kg/m2 [range 16.7-23.3 kg/m2]) participated in a cross-sectional study. Body mass, body fat percentage, and lean body mass were measured using a multifrequency bioelectrical impedance analysis, and the fat-free mass index (FFMI) was calculated by the lean body mass and height. Physical activity per week and sedentary time per day were assessed using the International Physical Activity Questionnaire short version. Venous blood samples were collected for measurements in total cholesterol (TC), triglycerides (TG), low-density lipoprotein-cholesterol (LDL-C), high-density lipoprotein-cholesterol (HDL-C) and glucose (GLU).

RESULTS: In all participants, FFMI had significant correlations with vigorous-intensity physical activity (VPA, r=0.591, p<0.001), MVPA (r=0.536, p<0.001), total physical activity (TPA, r=0.491, p<0.001), sedentary time (ST, r=-0.279, p=0.031), TC (r=-0.290, p=0.024) and LDL-C (-0.493, p<0.001). In males, FFMI had significant correlations with VPA (r=0.589, p<0.001), MVPA (r=0.534, p=0.001), TPA (r=0.485, p=0.004), ST (r=-0.448, p=0.009). In females, FFMI had a significant correlation with VPA (r=0.461, p=0.015).

CONCLUSION: In males, FFMI had significant correlations with VPA, MVPA, TPA and ST, while in females, FFMI had a significant correlation only with VPA. It is known that muscle gain can vary between males and females when performing exercise at moderate-intensity due to different sex hormones concentration [4,5]. Thus, in young adult women, moderate-intensity physical activity among MVPA may have no association with fat-free mass. In conclusion, significant correlations between body composition and physical activity were found in young adults, but fat-free mass in females is a significant correlation only with VPA.

EFFECTS OF A SIX-WEEK COMBINED TRAINING PROGRAM ON BODY COMPOSITION PARAMETERS IN OBESE ADULTS

BILRO, V.1, MARTINS, A.2, BATALHA, N.1, PARRAÇA, J.1

COMPREHENSIVE HEALTH RESEARCH CENTRE , DEPARTAMENTO DE DESPORTO E SAÚDE , ESCOLA DE SAÚDE E DESENVOLVIMENTO HUMANO, UNIVERSIDADE DE ÉVORA, PORTUGAL; LIFE QUALITY RESEARCH CENTRE, RIO MAIOR

INTRODUCTION: Obesity is a major public health issue worldwide, with over 1 billion people estimated to be obese by 2030 (1). Just as excess body weight is an independent predictor of cardiometabolic disease risk, excessive body fat is directly related to the metabolic syndrome. Appropriate dietary changes and exercise are crucial components in the treatment of obesity and several associated diseases (2), however, the comparative effectiveness of different exercise programs remains unclear, mainly due to the lack of systematic reviews and meta-analysis of RCT in this field (3). The aim of this study was to examine the changes in body composition parameters in obese adults after 6 weeks of combined training (High-Intensity Interval Training (HIIT) and Moderate-Intensity Continuous Aerobic Training (MICT)).

METHODS: Thirty-five obese adults were divided into 2 groups: intervention group (IG) (n=20,age,42.73±6.95) or control group (CG) (n=15, age,37.75±9.11). The combined training lasted 6 weeks, with 3 sessions per week of 45min, each session of 6 calisthenics exercises with 2–3 sets, performed for 20 sec, with 10 sec of rest between exercises and 1 min between each sets, the remaining time was applied the MICT in walking form. The intensity was controlled by the %HRmax of each participant, being that during HIIT the intensity was always >75%HRmax and for MICT at 50-65%HRmax. The intensity was monitored using the Polar M430. Anthropometric assessments included the waist circumference (WC) and hip circumference (HC) measured by a specialist and the body composition parameters [weight; fat mass; muscle mass; body mass index (BMI)] were measured by Tanita MC-780 MA.

RESULTS: The IG showed significant reductions on weight (p>0.001; effect size (ES)=0.31 [-0.31, 0.94]); fat mass (p>0.001; ES=0.47 [-0.16, 1.10]); BMI (p>0.001; ES=0.43 [-0.19, 1.06]); WC (p>0.001; ES=0.59 [-0.03, 1.24]); and on HC (p>0.001; ES=0.72 [0.09, 1.38]). No significant difference was found on muscle mass for IG. Lastly, no significant differences were observed in CG for all parameters under study.

CONCLUSION: The combined training is an effective and safe exercise approach to reducing body composition parameters in obese adults.

REGULAR EXERCISE PREVENTS AGING-RELATED ENDOTHELIAL DYSFUNCTION: LONG-TERM EFFECTS ON PLASMA ANTIOXIDANT ACTIVITY IN THE CUTANEOUS MICROCIRCULATION OF MASTER ATHLETES

SCARFÒ, G., FUSI, J., FRANZONI, F.

UNIVERSITY OF PISA

INTRODUCTION: Endothelial dysfunction is an early marker of vascular aging and cardiovascular disease. Advancing age is responsible for increased inflammatory states and oxidative stress with a consequent endothelium damage: in fact, free radicals alter membrane lipids, nucleic acids and proteins leading to the endothelial dysfunction [1]. However, regular exercise positively acts on the oxidative stress improving endogenous antioxidant defenses [2]. The aim of this prospective cohort study was to evaluate long-term effects of physical activity on plasma antioxidant capability and microcirculatory functions in a population of elderly athletes compared to sedentary controls.

METHODS: Between 2002 and 2003 (T0), 36 long-distance runners, (range: 22-74 years, VO2 max 55.1 ± 5.8 ml/kg/min) and 36 healthy sedentary volunteers (range: 20-75 years, VO2 max 34.5 ±3.1 ml/kg/min) were enrolled. Hand and foot baseline and stimulated skin blood flow (SBF) was measured by laser-Doppler flowmetry. Total Oxyradical Scavenging Capacity (TOSC) assay was used to determine plasma antioxidant capacity against peroxyl (ROO•) and hydroxyl radicals (OH•). 50 of the 72 subjects returned for a 20-year follow-up (T1): 28 athletes (range: 42-93 years) and 22 healthy sedentary subjects (range: 41-90 years) evaluated with the same methods.

RESULTS: Similarly to what happened at T0, at T1 athletes exhibited higher hand and foot stimulated SBF when compared to their respective sedentary controls ($P < 0.001$ in both cases). Interestingly, athletes at T1 had significantly higher hand and foot stimulated SBF after ischemia and after warm-up when compared to sedentary controls at T0 ($P < 0.01$ in both cases). Both at T0 and T1, plasma TOSC values against ROO• and OH• were significantly higher in athletes than in sedentary controls (P<0,001). Moreover, there was a positive correlation between plasma antioxidant activity against ROO• (P<0.001) and OH• (P<0.001) and stimulated hand and foot SBF. The same correlation was found in athletes at T1. In sedentary individuals, TOSC values were negatively correlated with age at both T0 and T1 (P<0.001).

CONCLUSION: After a 20-year follow up, regular exercise has been shown to prevent aging-related endothelial dysfunction by improving and preserving plasma antioxidant defenses in the cutaneous microcirculation.

THE EFFECT OF 10-WEEK RESISTANCE ENDURANCE TRAINING ON THE MUSCLE STRENGTH AND BALANCE IN ELDERLY WOMEN

VARJAN, M.1, BÖHMEROVÁ, L.1, HAMAR, D.1

FACULTY OF PHYSICAL EDUCATION AND SPORTS, COMENIUS UNIVERSITY

INTRODUCTION: Several epidemiological studies show that falls are a common part of elderly population. More than a third of the over-65 population falls at least once a year, and the risk increases with age. The risk of falls also significantly depends on balance skills. Although their level is influenced by muscle strength, maintaining balance is highly dependent on sensory abilities, especially visual control. This study aims to determine the effectiveness of strength endurance training in muscle strength and balance in unstable conditions with or without visual control.

METHODS: A total of 13 active, healthy elderly women participated in this study. Subjects were randomly assigned to a resistance endurance training group (REG: n = 6, sex: 6F, age: 72.8 ± 3.0 y, body weight: 69.9 ± 15.5. kg, BMI: 25.7 ± 7.6) and a control group (CG: n = 7, sex: 7F, age: 69.4 ± 3.4 y, body weight: 68.71 ± 5.7, BMI: 25.2 ± 2.6). REG followed a 10-week training program twice a week. CG was with no intervention. Before and after the intervention, 30 s stance test on an unstable platform with eyes open, 30 s stance test on an unstable platform with eyes closed, 30 s chair stand test and maximal voluntary contraction (MVC) in knee extension (right / left) were performed.

RESULTS: The mean velocity of the centre of pressure (COP) in the 30 s stance test on an unstable platform with eyes open was not significantly improved after intervention (from 14.75 ± 6.79 mm/s to 14.84 ± to 7.84 mm/s). There was a significant difference in the mean velocity of COP in 30 s stance on an unstable platform with eyes closed (from 35.63 ± 17.13 mm/s to 27.26 ± 13.36 mm/s, Z = -1.992, p = .046). Significant changes were also found in the 30 s chair stand test (from 17.83 ± 4.23 reps to 21.5 ± 6.22 reps, Z = -2.207, p = .027), MVC (right) (from 121.15 t± 44.79 N/m to 128.48 ± 44.87 N/m, Z = -1.992, p = .046) and MVC (left) (from 122.85 t ± 36.78 N/m to 128.23 ± 39.61 N/m, Z = -1.992, p = .046).

CONCLUSION: Preliminary data indicate that, in addition to improving lower extremity strength parameters, strength endurance training has a positive effect on balance in unstable conditions without visual control in elderly women, which may be helpful in reducing the risk of falls.

FOOT GROWTH CHARACTERISTICS OF CHILDREN AGED 5-17 YEARS

UEDA, K.

KIO UNIVERSITY

INTRODUCTION: The foot status of children is influenced many factors such as heredity and environment. It is assumed that the Nepal geographical condition such as hill or mountain environment affects the growth status. This study was aimed to investigate foot growth characteristics of JAN children at Nepal hill and lowlands area.

METHODS: The samples were 766 healthy children of JAN at hill area and JAN at Terai (lowlands) area (347 boys and 419 girls) aged 5-17 years, higher secondary school in/around Kathmandu Valley and Terai area, Nepal. Foot sole parameters, foot length, width, width/length ratio, arch type, were measured using a 2D foot scanner during 2015-2023. Their height and weight were also measured. Descriptive statistics of foot sole parameters, height and weight were calculated by age, sex and ethnic groups (Hill JAN and Terai JAN). The difference of these statistics was compared between ethnic groups by age and sex.

RESULTS: Mean height of Terai JAN children aged 5 -17 years ranged from 104.5-161.3 cm for boys and 103.1-149.7 cm for girls. It was smaller to Hill JAN children, which was 99.0-159.2 cm for boys and 98.7-148.0 cm for girls. Mean weight of Terai JAN children ranged from 14.5-50.6 kg for boys and 15.4-46.6 kg for girls. It was smaller than Hill JAN children, which was 17.5-50.9 kg for boys and 16.4-51.8 kg for girls. Mean foot length of Hill JAN children aged 5 -17 years ranged from 16.0-22.1 cm for girls. They are very similar to Terai JAN children, which was 16.3-22.4 cm for girls. However, the Terai JAN boys foot length ranged 18.6-24.7 cm was greater than Hill JAN boys ranged 16.6-23.9 cm. Mean foot width among the Hill JAN children aged 5 -17 years ranged from 6.8-9.7 cm for boys. It was very similar to Terai JAN boy children, which was 6.8-9.8 cm for boys. However, the Terai JAN boys foot width ranged 6.8-9.4 cm was greater than Hill JAN boys ranged 6.1-8.9 cm. Mean height of Terai JAN children aged 5 -17 years ranged from 104.5-161.3 cm for boys and 103.1-149.7 cm for girls. It was smaller to Hill JAN children, which was 99.0-159.2 cm for boys and 98.7-148.0 cm for girls. For the foot characteristics, the mean width/length ratio of both Hill JAN boys and girls was very similar to Terai JAN children. Regarding Arch type, both Terai JAN boys and girls was higher rate of high arch compared with Hill JAN boys and girls. The shape of the foot is classified into three categories; Egyptian type was 98.0%, Greek type was 2.0% and Square type was 0%. Nepal children have a high incidence of high arch and very high arch instead of the low prevalence of flat arch and hallux valgus. The width/length ratio was similar to Japanese.

CONCLUSION: Mean foot length and foot width show a steady increases from 5-14 years in boys and also a gradual increase among girls of the same age group. There is no difference of foot arch construction rate between Hill JAN and Terai JAN ; however, their normal rate is higher than Japanese children.

SOCIAL ENRICHMENT INCREASES THE ENJOYMENT OF EXERCISE BUT NOT AFFECTS SERUM 2-ARACHIDONOYLGLYCEROL LEVELS.

ARAKI, S.1, TANAKA, K.1,2, YAMASHITA, T.1,3, OKUMURA, H.1,2, MATSUKAWA, A.1,2, EGUCHI, A.1,2, TAGUCHI, N.1,2, TOBINA, T.1,2

1: UNIVERSITY OF NAGASAKI

INTRODUCTION: Endurance exercise increases serum endogenous cannabinoids (eCBs) levels and induces mental status alternations such as antianxiety, euphoria, and difficulties estimating the passage of time. As a result, these phenomena are widely known as runner's high. The 2-Arachidonoylglycerol (2-AG) is one of the significant eCBs, and we reported that a single bout of moderate-intensity exercise increases serum 2-AG levels and euphoria. Therefore, it could be the mediator of the runner's high. On the other hand, a previous study identified that it is harder to feel pain when a romantic partner is in the same space. According to those studies, we hypothesized that moderate-intensity exercise with close friends and conversation could increase serum 2-AG levels more than exercise alone or prohibit dialog. In addition, this situation could better alter the mental status during exercise.

METHODS: Ten subjects (21±1 years) were recruited in this study. Moderate intensity was defined as the lactate threshold. They carried out cycle ergometer exercise for 30 minutes at LT intensity under four situations as follows; Conversation with close friends (CONV), Prohibit Conversation (PROH), Conversation with someone who had never met (SOME), and alone (ALON). Blood samples were obtained before and after the exercise. In addition, rate of perceived exertion (RPE), mental status (Enjoyment, Discomfort, Exhilaration, Elation), and subjective passage of exercise time (e.g., How did you feel the exercise time?) were also evaluated using a 10cm visual analogue scale (0 to 100) simultaneously. Because 2-AG is rapidly isomerized to 1-arachidonoylglycerol (1-AG), the concentrations of 2-AG and 1-AG were measured using LC-MS/MS. The sum of these values (2-AG + 1-AG) was used as the index of blood 2-AG level.

RESULTS: All moderate-intensity exercise increased serum 2-AG levels, RPE, exhilaration, and elation; however, the change in their data showed no significant differences among the situations. The CONV (22 (9-38) vs. 70 (64-76); Median (Quartile), Pre vs. Post, respectively), SOME (11 (7-33) vs. 61 (49-75)), and ALON (30 (22-49) vs. 59 (47-64)) increased enjoyment but not in PROH (28 (11-51) vs. 51 (23-62)) after the exercise. In addition, the change of enjoyment was lower in PROH than in other conversation situations. Although the PROH (2 (0-21) vs. 19 (16-54)), SOME (11 (6-21) vs. 28 (10-56)), and ALON (10 (2-42) vs. 35 (22-59)) increased discomfort, the CONV (6 (0-13) vs. 7 (0-26)) did not significantly changed. Furthermore, CONV and SOME were significantly shorter in the subjective passage of exercise time than that PROH and ALON.

CONCLUSION: This study confirmed that moderate-intensity exercise increases serum 2-AG concentration; however, it did not find the synergistic effect of training and social enrichment. Exercise with close friends and conversation may independent factor for runner's high.

ASSOCIATION BETWEEN PHYSICAL ACTIVITY AND MITOCHONDRIAL DNA COPY NUMBER IN MIDDLE-AGED ADULTS IN SOUTH KOREA

HAN, S., JUN, S., KIM, N.

KEIMYUNG UNIVERSITY COLLEGE OF NURSING

INTRODUCTION: Mitochondria play a critical role in cellular metabolism, and mitochondrial dysfunction is related to metabolic disturbances. Mitochondrial DNA copy number (mtDNAcn) is considered a useful indicator of mitochondrial function. Physical Activity (PA) has been suggested as a substantial intervention to prevent and improve metabolic conditions. However, few studies have been conducted on the relationship between PA and mitochondrial function. Therefore, we aimed to investigate the cross-sectional association between PA and mtDNAcn in middle-aged adults in South Korea.

METHODS: We examined a total of 256 community-dwelling middle-aged adults using a set of questionnaires, accelerometers, and blood samples. Subjective PA was assessed by the Korean version of the International Physical Activity Questionnaire (IPAQ) short form, and objective PA was measured using the ActiGraph GT3X+ accelerometer for 3 consecutive days. MtDNAcn was measured in whole blood using a qPCR-based assay.

RESULTS: The IPAQ continuous score was calculated as metabolic equivalent of task (MET)-min/week. A total PA MET-min/week was 2422.78 ± 2915.55, walking was 1299.18 ± 1936.65 MET-min/week, moderate activity was 444.53 ± 851.45 MET-min/week, and vigorous activity was 679.06 ± 1849.92 MET-min/week. Among these indicators, total MET and walking MET were positively associated with mtDNAcn (r=.19, p=.002; r=.19, p=.002, respectively). Objective PA was based on triaxial counts, and the mean of total activity counts (TAC) was 559481.43 ± 182232.41 TAC/day (n=204). Sedentary time spent was 740.82 ± 121.96 min/day, light-intensity PA was 299.43 ± 93.35 min/day, moderate-intensity PA was 37.48 ± 25.54 min/day, and vigorous-intensity PA was 1.08 ± 3.82 min/day. Among these variables, only light-intensity PA was positively associated with mtDNAcn (r=.21, p=.003).

CONCLUSION: Our data indicate that total MET, walking MET, and light-intensity PA are positively associated with mtDNAcn. The findings suggest that PA may have positive effects on mitochondrial function, and that specifically low-intensity levels of PA appear to be beneficial. These results could be used to explain the underlying mechanism by which PA improves metabolic disturbances at the mitochondrial level.

A MULTICOMPONENT EXERCISE INTERVENTION IMPROVES GAIT IN NURSING HOME RESIDENTS

VOGEL, O., WOLLESEN, B.

HAMBURG UNIVERSITY

INTRODUCTION: Nursing home residents are known to reduce their physical activity and mobility along with aging. Additionally, falls at older age are a major risk for prolonged immobility and resulting health burdens. Therefore, the objective of this study is to investigate the efficacy of a multicomponent exercise intervention on gait performance in nursing home residents.

METHODS: Nursing home residents from 6 institutions were allocated to either a multicomponent exercise programme or to a waiting list control group. The intervention participants exercised twice a week for 16 weeks, each time 45 to 60 minutes. Individually tailored strength, endurance, balance, and flexibility exercises were combined with cognitive tasks. Pre- and post-intervention the step length and width as well as gait speed and double support phase were assessed at preferred and maximum gait speed. We conducted repeated measures analyses of variance including the age of the participants as covariate.

RESULTS: At preferred speed, only the changes of gait speed differed significantly between groups ($F = 10.144$; $p = .003$). Whereas the intervention group showed steady values, the gait speed of the control group decreased. At maximum speed, the changes in step length ($F = 6.815$; $p = .013$) and double support phase ($F = 4.364$; $p = .044$) differed significantly. The intervention group was able to improve their average step length (increase) and double support phase (reduction), whereas the average values of the control group deteriorated. The step width showed no significant group*time effects in neither of the captured gait velocities ($p > .05$).

CONCLUSION: A multicomponent training programme in nursing home residents seems to have the potential to improve specific gait parameters. Unfortunately, changes varied between different gait velocities and parameters. Interventions to promote gait performance in general and independent of varying velocities need to be further investigated. Overall, multicomponent exercise interventions to improve the gait performance can be recommended in nursing practice.

ASSESSMENT OF MECHANICAL PROPERTIES OF MUSCLE TISSUE IN HEMODIALYSIS PATIENTS

ROGOWSKI, L.1, PAWLACZYK, W.2, FEDOROW, W.3, GOLEBIOWSKI, T.4, KUSZTAL, M.4, DZIUBEK, W.3

1. THE WITELON COLLEGIUM STATE UNIVERSITY, LEGNICA, 2. LOWER SILESIAN ONCOLOGY CENTER,WROCLAW; 3. WROCLAW UNIVERSITY OF HEALTH AND SPORT SCIENCES, WROCLAW; 4. WROCLAW MEDICAL UNIVERSITY, WROCLAW

INTRODUCTION: Decreased exercise capacity due to muscle weakness and exercise intolerance reduces the ability to perform activities of daily living in patients with end-stage kidney disease. The chronic inflammatory state and uremic sarcopenia impact muscle tissue, causing morphological changes and muscle loss. After hemodialysis patients often report fatigue, muscle weakness, and stiffness. Changes in muscle properties during dialysis may provide a valuable assessment tool for detecting those at risk of painful cramps and pain. Data on the influence of the hemodialysis process itself on muscle tissue are scarce. There is still an open debate about the usefulness of hand-held myometric devices. AIM: The aim of the study was to evaluate the influence of dialysis sessions on the mechanical

properties of muscle tissue in HD patients.

METHODS: The research was carried out in stable (> 6 months) 20 chronic hemodialysis patients (dialysis time 3 – 192 months; mean age ±59,8; 11 males and 9 females) at the dialysis station. The stiffness of the quadriceps muscles was assessed with MyotonPro device, before and right after the hemodialysis session.

RESULTS: It was found that the muscle stiffness depended on the age of the patient and

was not related to the duration of dialysis. After the hemodialysis session, quadriceps stiffness increased in 16 patients (80%) in the right limb, and in 15 patients (75%) in the case of the left limb. In the case of the right limb, the average increase in stiffness was statistically significant, while in the case of the left limb, it was smaller and statistically irrelevant.

CONCLUSION: During the 4-hour hemodialysis session, the stiffness of the quadriceps muscle increased in the majority of patients. Although more studies on larger patient groups are needed, it can be assumed that myometry can be a helpful toll in the assessment of changes in mechanical muscle properties.

EXERCISE ENVIRONMENT, SEDENTARY LIFESTYLE AND AGING: IMPACTS ON BONE MASS

CASTRO, E.A.1,2, MASSINI, D.A.1, MARTINS, N.D.S.1,3, OLIVEIRA, T.P.1, MACEDO, A.G.1, ALMEIDA, T.A.F.1, SANTOS, F.J.4,5, ESPADA, M.C.4,5, PESSÔA-FILHO, D.M.1

1.SAO PAULO STATE UNIVERSITY, BRAZIL/2.LFE RESEARCH GROUP, SPAIN/3.UNIVERSITY CENTRE OF SAO PAULO STATE, BRAZIL/4.POLYTECHNIC INSTITUTE OF SETUBAL, PORTUGAL/5.LIFE QUALITY RESEARCH CENTRE, PORTUGAL

INTRODUCTION: In a terrestrial environment, low levels of physical activity have been negatively associated with bone mass [1]. On the other hand, some findings suggest that swimming practice in a low-gravitational environment (i.e., aquatic) has no effect on bone mass and, therefore, no osteogenic effect when compared to the effects observed for weight-bearing sports [2]. In addition, lack of physical activity and advancing age are factors that accelerate the osteoblastic process [3]. Therefore, this study aimed to compare athletes practicing exercise in different environments with non-active young and elderly men and women regarding bone mineral density (BMD), hypothesizing that BMD values differ between athletes according to the environment of exercise practice, but those training in a low-gravitational environment have no different stimuli to BMD increasing if compared with healthy peers experiencing reduced exercise involvement, whatever the age group and sex.

METHODS: One-hundred and four participants of both sexes were selected according to the environment of exercise practice [swimmers (N = 26) and judo fighters (N = 26)], and exercise level of involvement [non-active young (N = 26) and older adults (N = 26)]. Dual-energy X-ray absorptiometry provided BMD, lean mass, and fat mass (FM) for the whole body (WB), upper (UL), and lower limbs (LL).

RESULTS: For the BMD in WB, UL and LL no effects of group and sex were observed ($p > 0.05$). Post-hoc analyses detected higher values of BMD in UL for female swimmers compared to non-active older adults ($p < 0.05$), while judo fighters showed higher BMD in WB, UL, and LL than other participants whatever the sex ($p < 0.01$). Lower FM was observed for WB, UL, and LL when swimmers and judo fighters were compared to non-active young and older female peers ($p < 0.01$).

CONCLUSION: The findings emphasized that BMD stimuli with swimming are reduced when compared to judo, and despite the stimuli in swimming is not distinguishable from that affecting BMD in WB, UL and LL of non-active young, it is effective in differing BMD in UL among non-active older for women.

OBJECTIVELY MEASURED PHYSICAL ACTIVITY AND MENTAL HEALTH IN ASYLUM SEEKERS IN A GREEK REFUGEE CAMP.

FILIPPOU, K., TZORMPATZAKIS, E., KATSINOULA, F., MORRES, I.D., KNAPPE, F., THEODORAKIS, Y., HATZIGEORGIADIS, A., GERBER, M.

UNIVERSITY OF THESSALY

INTRODUCTION: In recent years a significant increase in forced displacement has been observed as a result of wars, natural disasters, and violations of human rights with forcibly displaced people reaching the dramatic number of 100 million. People who have been forcibly displaced frequently face physical and mental strain, which can lead to traumatic experiences and poor mental health. Though data for refugees are scarce, physical activity has been associated with better mental health. Nonetheless, most of the studies have been based on self-reported physical activity, which has been questioned as patients with mental health disorders in general and refugees in particular tend to overreport physical activity levels. Thus, research assessing physical activity through objective measures is warranted. Accordingly, the purpose of the present ongoing study was to explore the relationships of objectively measured physical activity with anxiety and depression in asylum seekers residing in a refugee camp in Greece.

METHODS: Participants were 64 asylum seekers (24 women) from Afghanistan, the Middle East, and sub-Saharan countries, with a mean age of 30.27 years. Participants were asked to wear a triaxial accelerometer device on the right hip during waking hours for seven consecutive days. Upon completion of the seventh day the device was collected from participants, who were subsequently asked to complete questionnaires assessing anxiety (General Anxiety Disorder-7) and depression (Patient Health Questionnaire-9) in their native language.

RESULTS: The analysis revealed that participants wore the accelerometer device for an average of 6.30 days. Regarding the levels of physical activity, the accelerometers showed on average 8 hours and 51 minutes of sedentary time, 2 hours and 24 minutes of light physical activity, 34 minutes of moderate and 6 minutes of vigorous physical activity per day. Regression analysis showed that light and moderate-vigorous physical activity could predict 10 % of the depression variance (p=.04) and 10 % of the anxiety variance (p=.04), with moderate-vigorous physical activity being the sole significant predictor (beta= .34 and beta= .35, respectively, p= .12).

CONCLUSION: The findings provide useful insights for the beneficial impact of physical activity on mental health indices and stress the need for the promotion and facilitation of physical activity in asylum seekers living in refugee camp.

PHYSICAL ACTIVITY CHARACTERISTICS IN INLAND OLDER ADULTS

SERRA, N., BOVOLINI, A., RÚA-ALONSO, M., BRITO, A., MARQUES, E., VILA-CHÃ, C.

INSTITUTO POLITÉCNICO DA GUARDA

INTRODUCTION: The benefits of physical activity (PA) for the quality of life and functional capacity of the elderly are widely disseminated. However, Portugal is still one of the countries with the lowest prevalence of PA among the elderly population, and in the regions with lower population density, solid information on this is lacking. The objective of this cross-sectional study was to characterise the elder population of an inland region regarding PA levels, associated barriers, functional capacities, and perception of quality of life.

METHODS: The study sample consisted of 234 individuals (130 women and 104 men) living in the municipality of Guarda. The age of the participants ranged from 60 to 96 years (75.2 ± 8.3 yrs). They were evaluated regarding PA levels (YPAS-PT), clinical and sociodemographic parameters, body composition (Inbody 270), functional capacity [Short Physical Performance Battery (SPPB) and handgrip test] and quality of life (SF-36v2 questionnaire).

RESULTS: It was observed that 66.3% of the sample presented excessive fat accumulation (44.2% in overweight and 21.1% in obesity). 46.6% of the participants reported to practice PA, on a regular basis, for more than six months and only 9% intended to start doing it (13.7% of them were in the "contemplation" and 22.6% in the "pre-contemplation" state). AF levels (YPAS-PT Scores) do not differ between genders, except for the time spent in movement, which was higher in women. Significant differences were observed between different age groups regarding PA dimensions, except for the time spent standing. The group aged 85 years or older is the one that accumulates the longest sitting time. In the walking 4-meters test, women in the older group spent, on average, 3.62 seconds more than those in the lower age group. Also, among men, a significant decline in walking speed was observed as they aged. In the five times sit-to-stand tests, the time increased, especially after age 75, for both men and women. In the handgrip strength, a negative effect of age was observed for both genders. The most reported barriers were unfavourable climate (56.3%), having an injury or disability (46.9%), fear of being injured (41.4%) or already sufficiently active (42.2%).

CONCLUSION: It is important to know the variables that characterise the older adults in inland regions will allow for better planning of public policies that promote PA and functional capacity in this population.

EFFECTS OF NONCONTACT ELECTRICAL STIMULATION BY A CONTACTLESS CURRENT STIMULATOR UNDER DIFFERENT ENERGIZING CONDITIONS UNDER REDUCED LOADING

MINAMIZONO, W., YASHIMA, N., OHSAKO, M.

東洋大学大学院ライフデザイン学研究科

INTRODUCTION: It has already been observed that electrical stimulation with a non-contact electrical stimulation device (VP electrical stimulation) suppresses bone loss in the femur under reduced weight bearing. It has been reported that low-power ultrasound pulses (LIPUS) in bone defects have different osteogenic results depending on the energizing conditions.

Therefore, we believe that effective energizing conditions exist in the energizing stimulators used in research. We believe that the electrical energization time can be reduced by studying efficient energization conditions. The purpose of this study was to investigate effective VP electrical stimulation.

METHODS: 32 male Wistar rats were used and classified into hindlimb suspension (HS, n=8) and non-contact stimulation during load reduction (VP) and control (CO, n=8) groups. VP was classified by intervention time as 15 minutes (VP15, n=8) and 30 minutes (VP30, n=8), and VP electrical stimulation conditions were 200 kHz frequency and 2.5 A current, 5 days a week for 3 weeks.

RESULTS: HS and VP15 bone Trabecula were thinner than CO, but were observed to be comparable to CO in VP30. Furthermore, cathepsin K-positive cells were more common in primary trabecular bone in HS and VP15, but the number of positive cells in CO and VP30 was lower than in those groups.

CONCLUSION: In general, bone loss is associated with osteoclast activation. Cathepsin K is also synthesized in active osteoclasts. In this study, fewer cells were positive for cathepsin K in VP30 than in VP15. Based on the above, the effect of bone mass maintenance using VP appears to emerge from 30 minutes or longer.

EFFECT OF STATIC STRETCHING AND PNF STRETCHING ON SHORT-TERM RECOVERY OF TIRED MUSCLES

LI, X.

LUXUN ACADEMY OF FINE ARTS

INTRODUCTION: To observe the difference of short-term recovery effect between static stretching and PNF stretching on tired muscles, and to provide theoretical basis for rapid recovery of muscles after fatigue and prevention of sports injury

METHODS: Recruited 15 male college students of grade 2 or above in sports training major of physical Education College and randomly divided into PNF stretching group, static stretching group and control group. Methods: Using isokinetic muscle force tester, the fatigue model of dominant quadriceps femoris muscle was modeled at 60°/s angular velocity in centrifugal-centrional motion mode. After the exercise program, the experimental group was respectively restored by static stretching and PNF stretching for 10min, while the control group remained in situ and rested. Before exercise, immediately after exercise and 10min after recovery, the maximum isometric muscle strength and muscle burst were tested, and the data were analyzed and processed by SPSS.

RESULTS: The MVIC and MP values of static stretching group and PNF stretching group were significantly decreased ($P < 0.05$), and quadriceps femoris muscle fatigue was obvious. After recovery, MVIC and MP values in PNF stretching group were significantly increased ($P < 0.05$), while the recovery effect in static stretching group was not statistically significant ($P > 0.05$). The recovery effect of MVIC and MP in PNF stretching group was significantly different from that in static stretching group ($P > 0.05$).

CONCLUSION: Compared with static stretching, PNF stretching can restore the maximum strength and explosive power of tired muscles in a short time, and can be used as an effective method to quickly recover muscle fatigue during training or competition intervals.

THE EFFECT OF SCHOOL-YEAR AND SUMMER BREAK IN HEALTH-RELATED CARDIORESPIRATORY FITNESS: A 2-YEAR LONGITUDINAL ANALYSIS

MARQUES, A., GOUVEIA, E.R., FERRARI, G., MARTINS, J., CATUNDA, R., PERALTA, M.

FACULDADE DE MOTRICIDADE HUMANA, UNIVERSIDADE DE LISBOA

INTRODUCTION: Some studies have suggested that summer break has a negative impact on children and adolescent's cardiorespiratory fitness (CRF), however evidence is still scarce. Therefore, this study aimed to assess the trends of health-related CRF during two school-years with a 3-month summer break in children and adolescents.

METHODS: A 2-year longitudinal study, including 440 6th to 8th graders (218 boys), mean age 12.3 years, was conducted. The Progressive Aerobic Cardiovascular Endurance Run (PACER) was used to assess CRF at the beginning and end of each school-year. Physical activity was measured using accelerometers. Repeated measures general linear models were used to analyses differences and trends in VO2peak and health-related CRF.

RESULTS: Overall differences between time-point VO2peak were significant for both boys ($p<0.001$) and girls ($p=0.003$). Pairwise comparisons showed that VO2peak improved from the beginning of each school-year to the end of the same school-year for boys (49.1 to 50.6 ml/kg/min, $p<0.001$; 51.0 to 52.8 ml/kg/min, $p<0.001$) and girls (41.7 to 42.5 ml/kg/min, $p<0.001$; 42.2 to 43.3 ml/kg/min, $p<0.001$). However, differences in CRF between the end of school-year 1 and the beginning of school-year 2, i.e. during summer break, were not significant (boys: $p=0.543$; girls: $p=0.343$).

CONCLUSION: Improvements in CRF were only observed during each school-year and remained unchanged during summer break. These findings provide relevant information for the health education community, suggesting the need for additional efforts to counteract the summer break effects on CRF.

History

SPORTS AND MUSIC: A HISTORICAL GLANCE

YAFI, M.
UNIVERSITY OF TEXAS JOHN P AND KATHERINE G MCGOVERN MEDICAL SCHOOL

The relationship between sports activities and music is well-known throughout history. Many sports such as ice -skating, water aerobics, and rhymical gymnastic include playing recorded music. Ballet, which requires physical training, is accompanied by live music.

While music seems to be essential in many sports, the relationship between composers, their lifestyles, and sports activities is an interesting field to explore.

The body habitus of some classical composers could potentially reveal their lifestyles. Historical paintings of J.S. Bach and G. F. Handel portrayed them as having heavy body sets. Sedentary lifestyles while composing, unhealthy diets, and lack of exercise could explain that. The photos of the Finnish composer J. Sibelius in his late life show that he was obese. He has suffered from chronic depression and was known for smoking and drinking heavily. On the other hand, photos of S. Rachmaninoff always showed his slender tall figure from a young age. Igor Stravinsky described Rachmaninoff as six feet of Russian gloom. Rachmaninoff was known for his love of canoeing, a physical activity he had enjoyed during his stay in his house on lake Lucerne. He was also an avid luxury car enthusiast; he enjoyed driving cars in nature. Stravinsky was slim as well, he was known for his love of daily gymnastics including eye-rolling exercises.

Felix Mendelssohn was a vigorous gymnast, a swimmer, and a good horseman.

Benjamin Britten is a well-known English composer, conductor, and pianist. He was also a champion in tennis and cricket.

Tennis has attracted many composers: Debussy was a keen tennis player; he often played it with his friend the composer Maurice Ravel. Debussy even tried to describe a tennis game in his last orchestral composition: Jeux (Game). The score was originally composed to accompany a ballet about two girls and a man playing tennis. Similarly, Gershwin used to play a weekly tennis match with Schoenberg. Despite the risk of getting an injury that could affect his performances, Prokofiev enjoyed tennis games in between composing his masterpieces. He was also known to be a champion in chess.

Exploring sports history from a humanistic and artistic point of view is a good reminder of the importance of sports and exercise in our lives.

TRANSLATION AND EVOLUTION OF THE CONCEPT OF “PHYSICAL EDUCATION” IN CHINA

CHANGQING, X., TENGKU KAMALDEN, T.F., NORMALA, I.
UNIVERSITI PUTRA MALAYSIA

Introduction

Greek philosophers, thinkers and educators studied the concept of “sport” or “physical education” and described a large number of athletic sports in Homer’s epic poems around the 9th and 10th centuries B.C. . By combing the development history of the concept of physical education and its translation, introduction and evolution in China, combined with the theoretical basis of many scholars’ research on the concept of “physical education”, this study finds that the concept of sports is related to specific social strata and closely linked with politics. It can be said that physical education to a certain extent represents the will of the country, and also reflects the guidance and planning of the national sports cause.

Background

In modern China, there are two main concepts of “sports”: “gymnastics” and “physical education”, both of which were translated and introduced from Japan. At the beginning of the 20th century, during the late Qing Dynasty school period, the modern education system began to be established in China, and “gymnastics” was made a compulsory subject in all levels of schools. After the May 4th Movement in China, especially the “New School System” (Renxu school system) issued by the Beiyang Government in 1922, it was obvious that the influence of American pragmatism pedagogy could be seen. At that time, China’s “gymnastics” was changed to “physical education”, free hand exercise, acrobatic sports and games, which introduced the Western physical education content into China.

Discussion

As people look at sports from multiple perspectives and dimensions, they also have a variety of understandings of sports. Indeed, there is no single attribute of sports, such as fitness, education, culture, competition, skill, recreation, and sociality are all important characteristics of sports. How to find out the decisive attribute that determines the development direction of sports or distinguishes physical education from other cultural activities from the numerous attributes of sports, that is, the essence of physical education.

Conclusion

The Chinese “physical education” vocabulary is the result of translation and borrowing from Western “sports” concepts. In chronological order, the main nouns and terms of the Western concept of “sports” from ancient times are athletics, gymnastics and sports, while “physical training” and “physical education” are terms that were formed successively after the Renaissance, and are the product of the development of disciplines and schooling in the formation of modern Western civilization, indicating that modern physical exercise, supported by physiology, psychology and other disciplines, has developed into a normative activity with the characteristics of modern experimental science. Compared with the historical

process of the generation of the notion of "physical education" in the East and the West, the concept of "physical education" in modern China experienced a reverse growth process.

MR. HYOZO OMORI WAS NOT THE FIRST TO INTRODUCE BASKETBALL TO JAPAN

KAKIYAMA, T.
FUKUOKA UNIVERSITY

Introduction

In Japan, the first person who introduced the basketball to Tokyo YMCA in 1908 is generally believed to be Mr. Hyozo Omori, who graduated from the International YMCA Training School in 1907.

However, I found a new sentence: "The second day after landing, the field sports of the girls school were held at Aoyama. The pupils exercised with dumb-bells, played basket-ball, and most of the day was spent in exercise out of doors. These gymnastic games are an innovation in the education of the Japanese girls, and they promise a healthier and broader womanhood in the future." in "The Quarterly" of Womans Missionary Friend (February 1903). If this statement is true, it could be strong evidence that basketball was introduced into Japanese girls schools before the establishment of the theory.

The purpose of this study was to verify whether or not basketball was introduced in the Aoyama Girls School in Japan before 1908.

Methods

At the Aoyama Gakuin Archives, where the archives of Aoyama Girls' School are housed, 10 historical documents with the keyword "basketball" prior to 1908 were identified. In addition, using the History of Aoyama Girls' School (Aoyama Sayuri Kai, 1973), I investigated the descriptions of basketball in the School during the same period.

Results

The earliest historical document on basketball held by the Aoyama Gakuin Archives is the first issue of the Aoyama Girls School Alumni Bulletin published in August 1903, in which a basketball game was identified in the field day order held on November 6, 1902, at the Aoyama Girls School new playground. The collection also contains a November 28, 1903 issue of TIDINGS FROM JAPAN (Vol. 6, No. 3, 1903), which states in a section titled "FIELD DAY SPORTS AT THE AOYAMA GIRLS' SCHOOL" that "Tennis and basketball proved that the Japanese girl does not intend to remain far behind her sisters across the water, and that she is going to enjoy that phase of life which means so much to the American and English girl." In addition, the collection contained a copy of the Aoyama Girls' School Field Day held on November 4, 1905, in which a basketball game was identified. Additionally, a photograph of a basketball game taken at the 6th Aoyama Girls' School Field Day held on November 2, 1907 was in the collection. On the other hand, the history of Aoyama Girls' School did not mention that basketball was played in physical education classes or extracurricular activities at that time.

Conclusion

The Aoyama Girls' School played basketball at its Field Day held on November 6, 1902, six years earlier than Omoris introduction. Therefore, it is clear that Mr. Omori was not the first person to introduce basketball to Japan.

Acknowledgments

The author would like to thank the staff of the Aoyama Gakuin Archives. This research was supported by JSPS Grant-in-Aid for Scientific Research 21K11566 and the Japanese Society for the History of Physical Education in 2022.

Mentoring/Coaching

COACHING BEHAVIOUR IN ELITE SPORT IN JAPAN: A COACHING PERSPECTIVE

YOKO, T.
NIHON UNIVERSITY

Abstract

The purpose of this study to analyse the behavioural characteristics of elite Japanese coaches and clarify the coaches' educational factors. Participants were four elite sports coaches (three men and one woman). To be included in the study, coaches were required to have worked with, or to be currently working with Olympic-level athletes. The interview guide comprised of three sections: coaching behaviour in training; coaching behaviour in competition; and athlete's skills related to coaching behaviour and summary questions. Findings revealed 11 higher-order themes, which we categorised into the following four general dimensions: analysis of situation and information (getting the latest information, social context); interpersonal relationships (teaching ability of a coach depending on the athletes' skill levels, communication, team atmosphere); intrapersonal knowledge (external self-awareness, internal self-awareness); professional knowledge (athlete safety, competitive performance, competition preparation, training performance).

Keywords: coaching behaviour, elite sport coach, high-performance coaching, interviews

DOES SUPERVISOR SUPPORT IMPROVES BETTER WORK PERFORMANCE OF SPORT COACH? IT DEPENDS ON PERSONALITY

LU, W.C.1, CHEN, Y.C.1, WU, M.H.1, HU, L.H.1, CHEN, Y.L.1, LIN, S.H.2
1.NATIONAL TAIWAN UNIVERSITY 2.NATIONAL PINGTUNG UNIVERSITY

Introduction

Grounded in the job demands-resources model, this study examines the moderating role of supervisor support and the mediating role of sports coaches' work engagement in the relationship between proactive personality and perceived work competence.

Methods

261 participants were sports coaches at all education levels in public schools in Taiwan. Convenience sampling was used to recruit participants for this study. All participants volunteered and provided informed consent. The focal variables were measured with a 7-point Likert scale, ranging from 1 (strongly disagree) to 7 (strongly agree). Proactive personality was assessed by the Chinese version (Lu & Kuo, 2016) of the Proactive Personality Scale (Bateman & Crant, 1993). Work engagement was measured by 12-item Work Engagement Scale (Schaufeli et al., 2006). Perceived Supervisor Support was measured with an 4-item scale (Chien et al., 2012). Perceived work competence was assessed by an 6-item scale (Warr, 1990).

Results

The results indicated that work engagement positively mediates the relationship between sports coaches' proactive personality and perceived work competence. Separately, supervisor support weakens the link between proactive personality and work engagement but strengthens the relationship between work engagement and perceived work competence;however, taken together, supervisor support weakens the indirect effects of proactive personality on perceived work competence through job engagement.

Discussion

Under the boundary condition of perceived supervisor support, the sports coaches' proactive personality is a critical antecedent of perceived work competence through work engagement. We suggest that proactive sports coaches are assets for schools because they possess the drive and energy for self-improvement, promoting organizational progress automatically.Moreover,the other important theoretical implication of the current study is that perceived superior support plays an important role in interpreting the boundary conditions of the JD-R model and further contributes to the interaction effect in predicting perceived work competence. Future research should incorporate other personal and situational factors to examine the dynamic process of predicting in-role and extra-role work performance

Keywords: proactive personality; work engagement; supervisor support; perceived work competence; job demands-resources model

ELITE SWIMMING ATHLETE'S CAREER DEVELOPMENT: THE PERSPECTIVE OF THE COACH-ATHLETE WORKING ALLIANCE

NATIONAL TAIWAN NORMAL UNIVERSITY

Elite swimming athlete's career development: the perspective of the coach-athlete working alliance

Teng, P-C 1, Chen, F-C 2, Teng, P-Y 1, Chen, M-Y 2, Chang, C-C2

1 Asia Eastern University of Science and Technology, Taiwan

2 National Taiwan Normal University, Taiwan

Abstract

INTRODUCTION: With the development of sport performance, the quality of the relationship between coach and athlete is becoming more and more important. Coaches and athletes must set on goals, agreement the tasks, and accomplished the tasks to achieve the goals. This study is based on coach-athlete working alliance, discuss the interaction between coaches and athletes how to influence athletes career adaptation and career transition.

METHODS: From the perspective qualitative research, this study applied in-depth interview with domestic excellent swimming coaches and the athletes they have coached. By understanding the relationship between coaches and athletes, as well as planning of athletes career adaptation and career transition, and analyzing the content of the interviews, explores the influence of the coach-athlete working alliance on career adaptation and career transition.

RESULTS: The results of the study are as follows : (1) The coach will divide the goals into competitive goal and goal college entrance goal, and assign tasks to different athletes according to their abilities, coach and the athletes can feel a sense of achievement in pursuing the common goal. (2) The coach will pay attention with the athletes to focus on the career they want to work in in the future at first, and let the athletes make their decision for college, If athletes want to engage in non-sports field, they will fully show their curiosity about the careers they interested and vice versa; Compared with coaches who believe in athletes, athletes lack confidence in their careers. (3) In athletic level, the coach will enrich himself, cooperate with talents in various fields, and provide the athletes with a high-quality training environment; In psychological level, coaches not only care about active athletes, but also contact graduates through in communication software; In psychosocial level, the relationship between the athletes and the coach like a teacher as well as a friend, the athletes can maintain

a good interaction even they are graduate; In academic vocational level, It is not only the coach who can help, but the graduates can also provide a lot of assistance to solve the doubts of their junior brother.

DISCUSSION:

Based on the conclusions of this study practical suggestions, Coaches can take the initiative to care about the athletes situation, build self-confidence, and cooperate with graduates to assist the career development of student athletes; The suggestion for Future Research can compare with different theoretical models, and expand research sample to make future research more completely.

THE STUDY OF KORAN COACH'S LEADERSHIP STYLE IN CHINESE TAIPEI ARCHERY TEAM

LEI, C.Y., LIN, D.L., CHI, L.K., CHEN, S.Y., CHEN, J.Y.

NATIONAL TAIWAN NORMAL UNIVERSITY; TZU CHI UNIVERSITY OF SCIENCE AND TECHNOLOGY

Purpose: Chinese Taipei archery team has achieved international elite performance in recent years. Besides athletes' hard-work training and the intervention of sport science, the coach leadership played as an important factor. Chinese Taipei Archery Association hired Korean coach Koo Ja-Chung during 2013-2017. Chinese Taipei archery team started to reach out top-ranked performance among international tournaments stably, allocated 32 golds, 22 silvers and 33 blonde medals in the international competition within 4 years. Therefore, this study aimed to explore the coach Koo's leadership style by interviewing athletes and coaches. Methods: This study used quantitative research method via semi-structured interview approach (Patton, 1990). The participants were Coach Koo, two assistant coaches, and athletes who coached by coach Koo in national team more than 6 months. The study used triangulation analysis to verify the interview data. Results: The results indicated Coach Koo showed a rather democracy leadership style, so that athletes receive greater autonomy-support behaviors. Meanwhile, Coach Koo gave out feedback for athletes accroding to thier individual needs. Therefore, the athletes formed higher self-recognition and the team created optimum competing climate. The athletes also agreed that Coach Koo established a sense of trust within the team by guiding leadership. Specifically, the support from coach Koo brought great confidence and peace of mind during competitions. Conclusion: the coach Koo's leadership style was identified in this study as a decisive role led to the optimal archery performance worldwide for Chinese Taipei archery team. The leadership style of Coach Koo can be used as a reference for Taiwanese coaches.

Key word: autonomy-support, self-recognition, semi-structured interview, quantitative research

ECOLOGICAL DYNAMICS PERSPECTIVE FOR SPORTS TALENT DEVELOPMENT IN ADOLESCENCE: A SCOPING REVIEW

SUM, K.W.R., STRANGE, D., LI, M.H., CHOW, J.Y., HUANG, M., RUDD, J., YANG, Y., HO, C.Y., CHOI, S.M.

THE CHINESE UNIVERSITY OF HONG KONG

Introduction

The evolution of sports talent development programs, especially during the pivotal maturation period in adolescence, dances between mechanistic perspectives and integrated approaches. Positively, there are unified agreements in general talent traits. However, the skills acquisition of higher-order attributes such as adaptability, reactivity, and creativity (dexterity) may be influenced by the design, implementation, and management of the sports ecosystem. Reviewing the value of nonlinear pedagogical strategies is critical to opening up boundaries for exploration and facilitating enriched skill acquisition, further highlighting a sports talent identification index, and bioecological influences. This study was therefore to summarize the current literature and examine the main implications within the theoretical framework of ecological dynamics, for sports talent development, in adolescence.

Methods

In this prospective study, rooted within the theoretical framework of ecological dynamics, three important areas that may enhance adolescent skill acquisition for sports talent development were reviewed. (1) Sports talent identification index: including fundamental movement skills, psychosocial skills, and dexterity; (2) Nonlinear pedagogy: including representative learning design, affordance landscapes, constraints manipulation; (3) Bioecological environment: including coaching, and relative age effects.

ERIC, MEDLINE, SPORTDiscus, Scopus, and Web of Science were searched from 2012-2022. A manual search of the literature was also performed, and reference lists of the retrieved articles were examined. We considered those studies in which ecological dynamics or sports talent development were adequately described and assessed in adolescent populations. Findings were organized to form both a descriptive and thematic summary.

Results

A total of 53 articles were included. They encompassed 45 original research, as well as eight conceptual theory papers in ecological dynamics on representative design, affordances, and constraints across a variety of sports. The findings indicate that the theoretical framework of ecological dynamics supports sports talent development in adolescence and there was near consensus that reductionist and mechanistic perspectives are outdated. An integrated approach that fosters skill adaptation and creativity is recommended, featuring the importance of motor learning, multi/donor sports, and exploration.

Discussion

The implications of this review encourage coaches to consider nonlinear approaches to support the emergence of elite sport talent skills during the critical maturation period between childhood play and senior-level competition. Further research is needed to clarify talent development across transdisciplinary platforms, which may support athlete training programs, sport academy cultures, and physical education curriculums.

ON THIN ICE: REDUCING CHOKING IN ELITE ICE HOCKEY

HUARD PELLETIER, V.
UNIVERSITÉ DU QUÉBEC À TROIS-RIVIÈRES

In their quest to be successful in major sport competitions, sport federations' stakeholders must master the aspects that lead to efficient selection procedures. However, the players who perform best in physical tests or intra-team games are not necessarily the ones who will perform best in big games when the pressure is on. In fact, the predisposition to perform at the right time becomes an important variable. Frequently used in popular culture, the concept of player's choking susceptibility is an emerging construct in the domain of applied sport psychology. Choking is defined in the scientific literature as a significant decrease in performance in a competitive pressure situation, which is attributed to an increase in anxiety and when the athlete recognizes that the standards they have set for themselves would otherwise be met (Mesagno, 2013). To date, a few interventions have been conducted to attempt to reduce choking, but few studies have focused on team sports at the elite level.

The purpose of this study is to measure the impact of sports psychology intervention aimed at preparing to perform optimally (by reducing choking susceptibility) among athletes representing their province at the 2023 Canada Games, in the discipline of ice hockey. The initial measurement for choking susceptibility of male (N=22 M age =15) and female (N=22, M age=17) athletes was done 6-months before the competition according to the calculation established by Mesagno (2008), then the anxiety state was measured during a minor competition 2 months later, and 1-week previously to competition. One month prior to the Games, 3 sessions, which consists of sports psychology conferences as well as individual consultations were offered to the athletes of both teams. Results reveal that athletes identified as susceptible to choking vary greatly in their level of on-ice performance, and that the interventions appear to have had a modest effect on player performance at major sporting events such as the Canada Games.

In consideration of the results, alternatives will be proposed for future interventions in team sports with adolescents who evolve in highly competitive ice hockey settings. In addition, comments will be made on the measurement of the pressure choking concept and on the experience of the practitioners who participated in the study.

Molecular Biology and Biochemistry

TO EVALUATE THE EFFECT AND MECHANISM OF WHOLE BODY VIBRATION (WBV) TRAINING ON BRAIN MICROVASCULAR ENDOTHELIAL CELL-DEPENDENT BRAIN INFLAMMATION

CHEN, W.C., HSIEH, H.L., CHIU, P.K.
CHANG GUNG UNIVERSITY OF SCIENCE AND TECHNOLOGY; NATIONAL TAIWAN SPORTS UNIVERSITY

INTRODUCTION: It is known that endothelial cells of Blood-Brain-Barrier (BBB) in patients with neurodegenerative diseases usually have an inflammatory state, but the mechanisms are still unclear. However we find the whole body vibration training can enhance our immune function, anti-oxidant and anti-inflammation ability. Therefore, whole body vibration training (WBV) could be used for the prevention or treatment of chronic inflammation-related diseases. We want to do the WBV to evaluate the effect on the endothelial cells inflammatory responses .

METHODS: The RBA and bEnd.3 cells were pretreated with various level of vibration (level 2, 4, 5, 6, and 7) for 30 min and then stimulated with or without TNF- α (15 ng/ml) for 24 h. After treatment, the conditioned media were collected and analyzed by gelatin zymography. The cell lysates were analyzed by Western blot using an antiserum reactive with GAPDH as a control. The bEnd.3 were treated with various level of vibration (level 2, 4, 5, 6, and 7) for 30 min and then incubated for 24 h. After treatment, the cell lysates were analyzed by Western blot using an antiserum reactive with COX-2 or cPLA2 antibody and membranes were stripped and re-probed with total GAPDH as a control. Data are expressed as mean or mean ± SEM of three independent experiments (n=3). *P<0.05; **P<0.01, as compared with the respective values of untreated cells. The image represents one of three similar experiments.

RESULTS: The data showed that pretreatment of vibration attenuated TNF- α -induced MMP-9 expression in RBA cells, suggesting that vibration may be have a anti-inflammatory effect by inhibiting the TNF- α -induced MMP-9 expression in RBA cells, attenuated TNF- α induced COX-2 expression in RBA cells, suggesting that vibration may be have a anti-inflammatory effect by inhibiting the TNF- α -induced COX-2 expression in RBA cells, attenuated TNF- α -induced MMP-9 expression in bEnd.3 cells, suggesting that vibration may be have a anti-inflammatory effect by inhibiting the TNF- α -induced MMP-9 expression in bEnd.3 cells. attenuated TNF- α -induced MMP-9 expression in bEnd.3 cells, suggesting that vibration may be have a anti-inflammatory effect by inhibiting the TNF- α -induced MMP-9 expression in bEnd.3 cells.

CONCLUSION: A thirsty minutes WBV training have an anti-inflammatory effect by inhibiting the TNF- α -induced MMP-9 expression and the TNF- α -induced COX-2 expression in RBA cells. It is suggesting that vibration may be have a brain protective effect by reducing the basal level of inflammatory proteins' expression in bEnd.3 cells.

ALCALASE POTATO PROTEIN HYDROLYSATE AND SHORT PEPTIDE ENHANCES MYOGENIC DIFFERENTIATION AND ENHANCES SKELETAL MUSCLE PROTEIN SYNTHESIS UNDER HIGH GLUCOSE CONDITION IN C2C12 CELLS

LIN, W.T., CHANG, C.F., LO, Y.H.

TUNGHAI UNIVERSITY

INTRODUCTION: Aging is inevitably associated with progressive decline in bodily function and composition with decline in muscle strength and mass, a phenomenon known as sarcopenia. The consequence of this effect includes reduction in the aerobic capacity causing reduced mobility and quality of life in elderly subjects. The annual cost, in the United States, on the health effects of sarcopenia accounts to 18.5 billion dollars and the scenario is likely to be global as the aging population grows in most developed countries. In spite of huge allocation of resources there has been no drug therapy identified for this condition. Present treatment strategy recommends Protein nutritional uptake and physical exercise to maintain muscle function. APPH is an alcalase hydrolysate of potato protein fraction possessing lipolysis-stimulating with efficient anti-obesity potential. Nevertheless, the effect of APPH and short peptide on skeletal muscle protection is not determined yet. In this study, the effect of APPH and short peptide supplementation on the skeletal muscle atrophy and high glucose induced myogenic aversions is investigated.

METHODS: APPH treatment in C2C12 cells showed dose dependent activation of Akt/mtor signalling pathway that is involved in skeletal myogenesis. According to Western blotting analysis, APPH and a short peptide induced the phosphorylation of Akt, mTOR proteins and induced myogenic differentiation of C2C12 myoblasts in a differentiation medium

RESULTS: The phosphorylation myogenic transcription factor Foxo3A was also found to be increased in the cells treated with APPH and it's short peptide . In addition, reduction in cell viability caused by high glucose was also found to be reduced when treated with different doses of high glucose in a dose dependent manner. Moreover, number of myotybules in a differentiation medium reduced upon high glucose challenge, but treatment with APPH increased the number of differentiated myotubules. Further, the phosphorylations of AMPK and mitochondrial-related transcription factors such as PGC-1α were suppressed upon high glucose challenge but APPH treatment restored the protein levels.

CONCLUSION: We demonstrate for the first time that a specific potato peptide has a therapeutic effect against sarcopenia. In addition, APPH and it's short peptide improved the myogenic differentiation and their mitochondrial biogenesis and further improved mygenic protein and inhibited muscle protein degradation in C2C12 cells challenged under high glucose condition.

THE EFFECT OF THE ACE, ACTN3 AND PPARGC1A GENES POLYMORPHISMS ON HIGH-INTENSITY INTERVAL TRAINING OF ELITE CHINESE ROWERS

WEI, Q.

HUBEI INSTITUTE OF SPORT SCIENCE

INTRODUCTION: To identify molecular genetic markers in ACE I/D rs1799752, ACTN3 R577X rs1815739 and PPARGC1A Gly482Ser rs8192678 that predict initial aerobic capacity and training sensitivity in rowing athletes to improve athletic performance in high-intensity interval training.

METHODS: Methods: Fifty four athletes（33 males and 21 females） were selected from the national rowing group. The average age was 17.82±0.88 years, the average height was 180.46±8.04m, and the average weight was 77.53±12.48kg. Maximal oxygen uptake, functional conservation and 1000m/800m running were measured before and after a 4-week period of high-intensity interval training. DNA was extracted from saliva sample, genotype was identified by PCR-RFLP. A chi-square test was used to determine whether the SNPs met the Hardy-Weinberg equilibrium law. The association between genetic polymorphisms and the effects of high-intensity interval training was analysed by comparing aerobic phenotypes, training sensitivity between groups and pre- and post-training for each genotype.

RESULTS: 1. In male athletes, the ACE I/D polymorphism was associated with the initial value of RE/VO2 as II genotype > DD genotype; 2. In female subjects, the rate of change of RE/VO2 was significantly higher in the ID genotype than in the DD genotype (P=0.045); 3, ACTN3 XX genotype and RX genotype VO2max change rate was significantly higher than RR genotype (P<0.05); ACE II genotype VO2max change rate was significantly higher than the DD genotype and ID genotype (P<0.05); 4. In male subjects, PPARGCIA polymorphism was associated with RE/VO2 In male subjects, PPARGC1A polymorphisms were associated with RE/VO2 initial values, showing GG genotype > GA genotype and AA genotype.

CONCLUSION: 1. ACE I/D and PPARGC1A Gly482Ser can be used as genetic markers to predict the initial value of RE in males, and genotype II and GG carriers have RE higherly ; 2. ACTN3 R577X can predict the effect of high-intensity interval training intervention for maximal oxygen uptake in females, and XX and RX are the dominant genotypes. Sex differences and genotypic characteristics should be taken into account for the effectiveness of exercise training in superior rowers.

MUSCLE ACCRETION ACTIVITY OF ALCALASE®-ISOLATED SOY PROTEIN HYDROLYSATE IN SKELETAL MUSCLE C2C12 CELLS BY ACTIVATING PI3K/AKT/MTOR PATHWAY AND INHIBITING FOXO PATHWAY

CHIANG, W.

TUNGHAI UNIVERSITY

INTRODUCTION: Skeletal muscle development is strictly regulated process involving formation of mesodermal into myoblast, following the differentiation and fusion, finally changed into multinucleated myotubes. Myogenic regulatory factors play an important role in muscle fusion during differentiation (1). Among these factors, phosphoinositide 3-kinase (PI3K), protein kinase B (Akt) and mammalian target of rapamycin (mTOR) in protein synthesis PI3K/Akt/mTOR pathway as well as Forkhead Box O3 (FOXO3), muscle atrophy F-box (MAFbx) and muscle ring finger protein 1 (MuRF1) in protein degradation FOXO pathway, are plays critical role in muscle formation (2). This study aimed at evaluating the possible myogenic mechanism for enzymatic protein hydrolysate in C2C12 skeletal muscle cells.

METHODS: The C2C12 cells were cultured at 2.4 x 10 ∧ 5/12-well plate in the growth medium (DMEM containing 10% FBS) and differentiated in the C2C12 differentiation medium containing DMEM and 2% horse serum. Differentiated C2C12 cells were further induced atrophied by 5 uM dexamethasone (DEX) and then treated with or without selected protein hydrolysates. Protein expression of signaling factors associated with PI3K/Akt/mTOR pathway and FOXO pathway were analyzed (3, 4).

RESULTS: In preliminary study, four types of plant protein were hydrolyzed by three proteolytic enzymes, respectively. Alcalase®-isolated soy protein hydrolysate (AISPH) was selected due to its highest muscle accretion activity and product yield among hydrolysates. AISPH was prepared by hydrolyzing 6% ISP for 8 h with Alcalase® at 50 °C and pH 8.0. Based on simulated gastrointestinal digestive test, there was little effect of gastrointestinal proteases on muscle accretion activity for AISPH. Effects of AISPH concentrations on signaling factors in PI3K/Akt/mTOR pathway and FOXO pathway were also investigated after DEX-induced atrophied of C2C12 cells. The results indicated that AISPH was not only activating PI3K/Akt/mTOR pathway for muscle protein synthesis by upregulating the protein expression of PI3K, p-AKT and mTOR, but also inhibiting FOXO pathway for muscle protein degradation by downregulating the protein expression of FOXO3, MAFbx and MuRF1.

CONCLUSION: AISPH showed the effect of increasing muscle accretion in skeletal muscle cells, suggesting the application potential of AISPH in promoting the growth of skeletal muscle mass. The mechanism of muscle accretion for AISPH was to activate PI3K/Akt/mTOR pathway and inhibit FOXO pathway in skeletal muscle C2C12 cells.

EFFECTS OF HIIT AND MICT ON THE PROTEOMIC CHARACTERISTICS OF LIVER LIPID METABOLISM IN AGING RATS

SU, H.

BEIJING SPORT UNIVERSITY

INTRODUCTION: Current research has not fully understood the overall situation of liver lipid metabolism and related pathway changes caused by different exercise methods in the dynamic process of aging. Therefore, based on TMT proteomics technology, this study explored the effects of different exercise modes on the changes of liver lipid metabolism in rats during natural aging and the differences in pathway characteristics.

METHODS: Sixty 8-month-old SPF male SD rats were selected and randomly divided into groups B, C, H and M. Group B was sacrificed after 1 week of adaptive feeding; Group H used 90% VO2max and 65% VO2max running speed to alternate treadmill exercise, a total of 40 minutes/day, 3 days/week, HIIT exercise intervention for 24 weeks. Group M used continuous treadmill exercise with 70% VO2max, and the training time was the same as group H. Group C received no exercise intervention. Rat body fat percentage, body weight, serum LDL-C and HDL-C were collected every 4 weeks. Three rats from each group that had completely completed the intervention process were selected for liver TMT proteomics testing, and differential proteins were screened for bioinformatics analysis.

RESULTS: 24 weeks of HIIT and MICT did not significantly improve the increase in body fat content of rats caused by natural aging process, but they could significantly reduce the body weight of rats ($P<0.05$). 2. 24 weeks of HIIT and MICT can significantly reduce the increase of serum LDL-C content caused by natural aging ($P<0.05$), and promote the further increase of serum HDL-C content ($P<0.05$). 3. The results of proteomic functional enrichment showed that after 24 weeks, there were 117 proteins with significant differences between group C and group B; 52 proteins with significant differences between group H and group C; 38 proteins between group M and group C. There were significant differences in 25 proteins between group H and group M.

CONCLUSION: 1. The 24-week natural aging process will lead to the weakening of liver lipid metabolism, which is related to bile acid secretion and lipid absorption pathways. 2. 24 weeks of HIIT and MICT can significantly reduce the body weight and serum LDL-C of the rats, and significantly increase the serum HDL-C, and there is no significant difference in the intervention effect of the two exercise methods. 3. 24 weeks of HIIT can delay the decline of liver lipid metabolism through cytochrome P450 and linoleic acid metabolism. At 24 weeks, MICT can affect liver lipid metabolism through protein processing in endoplasmic reticulum, valine, leucine and isoleucine biosynthesis, cysteine and methionine metabolism, and tyrosine metabolism. In addition, both HIIT and MICT can affect liver lipid metabolism through linoleic acid metabolism and steroid hormone synthesis pathways. There were certain differences in peroxisome and endocytosis pathways between H and M groups.

LACTATE INCREASES FATTY-ACID OXIDATION BY TCA CYCLE AND MITOCHONDRIAL UNCOUPLING IN SKELETAL MUSCLE OF OBESE MICE

KOH, J.1, PARK, S.2, JUNG, S.2, KIM, J.2, KIM, Y.2, SUNG, H.3, PARK, S.2, DOH, K.2

YONSEI UNIVERSITY WONJU COLLEGE OF MEDICINE, YEUNGNAM UNIVERSITY COLLEGE OF MEDICINE, UNIVERSITY OF TORONTO

INTRODUCTION: Exercise training (Ext) is a productive way to reduce risk factors of metabolic disease. Lactate is largely increased by exercise, even when oxygen is sufficiently provided in muscle (1). Circulating lactate enters the muscle fiber and can stimulate the tricarboxylic acid (TCA) cycle for oxidative metabolism (1, 2), thereby suggesting the possibility of lactate's role as an efficient oxidative metabolic regulator for lipids. However, the molecular mechanism behind lactate's role in the oxidative metabolism in skeletal muscle (SKM) is not fully understood. Here we investigated the mechanism behind lactate-driven regulation of FAO in SKM, a process involved in the lowering of SKM lipids in subjects with diet-induced obesity (DIO).

METHODS: Animal exercise study, after 18 mice were fed high-fat diet (HFD) for 8 weeks, mice were randomized to three different groups (sedentary, exercise, and exercise + lactate administration). Lactate or saline was injected intraperitoneally (IP) immediately after moderate treadmill exercise for 3 weeks. For lactate and HFD study, mice were injected with saline or lactate under a normal chow diet (NCD) or HFD for 8 weeks. To understand metabolic pathways, gene silencing studies were performed using C2C12 myotubes. Fatty acid oxidation, mitochondrial oxygen consumption, enzyme activity, NADH/NAD+ assay, flow cytometry for fatty acid uptake, immunofluorescence staining, and other molecular biology assays were performed.

RESULTS: We found that increasing lactate levels enhanced energy expenditure mediated by fat metabolism during exercise recovery, decreasing triglyceride levels in SKM of DIO mice. To determine lactate-specific effects without exercise, lactate was administered to mice on a high-fat diet for eight weeks, and similar to our exercise condition, we found that lactate increases fatty acid (FA) uptake and oxidation in SKM. When FAs were provided as substrate to these same mice, TCA cycle activity and mitochondrial uncoupling-driven respiration is also enhanced. The increase in FAs promotes the movement of lactate into muscle cells, which in turn augments uncoupling protein-3 expression via enhanced NADH-NAD+ shuttling.

CONCLUSION: Exercise-induced lactate amplifies an adaptive increase in FAO capacity mediated by the TCA cycle and mitochondrial uncoupling in SKM when fatty acids are increased, and ultimately increases oxidative capacity.

LAMP : NEW DNA AMPLIFICATION TECHNOLOGY AS A POINT OF CARE TOOL TO HELP DIAGNOSTIC OF THEILERIA EQUI AND BABESIA CABALLI PATHOGENS CAUSING REDUCTION OF PERFORMANCES IN HORSES

VALOT, L., THIBAULT, T., SIMONNET, M., LACAZE, A., SCHIEB, D., THIERY, L.

ENALEES

INTRODUCTION: LAMP technology (Loop mediated isothermal AMPlification) is a NAAT technology (Nucleic Acid Amplification test) which can occur at constant temperature, unlike PCR which need thermal cycles. This allow the use of this technology near a sick animal and the obtention of the result in only 30 min. This technology can be really useful to detect highly contagious pathogens causing loss of performances, ie : detection of Theileria equi and Babesia caballi in horses causing loss of performances during a sportive competition.

METHODS: Specific LAMP primers for Theileria equi and Babesia caballi were designed and LAMP reactions were performed on viral genome and on blood samples extracted by our own specific quick extraction. Performances of these tests were evaluated in our lab and compared to PCR performed in an external lab.

RESULTS: The limit of detection of LAMP tests to detect Theileria equi and Babesia caballi of all method (quick extraction and LAMP test) is similar or better of the limit of detection of all method (extraction on column and PCR test) obtained in a conventional analysis laboratory. LAMP test which was designed are really specific for the target (>95% specificity) and are really sensitive for the target (>90% sensibility).This technology is really fast (<30 min) and can be performed near a sick animal.

CONCLUSION: LAMP tests are a new generation of DNA/RNA amplification test, really specific, really sensitive which can be performed near a sick animal and can give a result in only 30 min. These parameters allow the consideration to use this technology to detect pathogens infecting a sick horse causing loss of performances before a sportive event as a horse race.

EFFECTS OF SPRINT INTERVAL TRAINING ON SKELETAL MUSCLE FIBERS IN DEVELOPING RATS

NISHIZAWA, T., ANDO, K.

SIGAKKAN JUNIOR UNIVERSITY

INTRODUCTION: Many ball sports require higher performance in a shorter period of time. Therefore, sprinting ability and endurance at a higher level are necessary for athletes. Recently, it has been reported that rest time during interval training is important for training effectiveness.

We performed different types of running training in developing rats to investigate the effects of exercise intensity and rest time on skeletal muscle using histochemical methods.

METHODS: The experimental conditions were as follows. Twenty 13-weeks-old female Fischer 344 rats were used in the experiment. The rats were trained to run by different conditions on a treadmill for small animals. The Training began at 6 weeks of age. It was performed once a day, 5 days a week for 8 weeks.Rats were divided into four groups: Control (C), Sprint Interval Running training (SP), Interval Running training (IT), and Interval Uphill Running training (IU). The SP group consisted of 10 sets of 45-60 seconds of running at a speed of 35 m/min-40 m/min followed by 4 minutes of rest. The IT group consisted of 10 sets of 30 seconds of running at 30 m/min followed by 2 minutes and 30 seconds of rest, and the IU group consisted of the IT group training with a 15-degree uphill incline.

Gastrocnemius muscle (GAS) was used for histochemical staining, and ATPase staining and α-GDPH staining were performed to confirm the SDH staining results, and myofiber types (SO, FOG, FG) were determined. The analysis items were number occupancy, cross-sectional area, and myofibril optical density for each myofiber type. Fisher PLSD method was used for statistical processing. The significance level for all tests was set at 5%.

RESULTS: The composition ratio by muscle fiber type showed 13.60±7.54% for the C group, 21.32±14.42% for the SP group, and 19.56±6.12% for the IU group in FOG fibers at the superficial layer. The SP and IU groups showed an increasing trend compared to the C group. The muscle fiber cross-sectional area of superficial FOG fibers was 1318.8±232.8 μm2 in the C group, 1713.5±211.6 μm2 in the SP group, and 1688.2±171.3 μm2 in the IT group. SP group and IU group showed significantly higher values than C group ($p<0.05$).

CONCLUSION: In the SP group Changes in myofiber type composition, cross-sectional area, and oxidative enzyme activity concentrations were observed. In the FOG fiber of the training group showed higher values in myofiber type composition and cross-sectional area by myofiber type. These training-related changes occurred in the superficial gastrocnemius muscle (fast-twitch area).

In the present study, the SP group increased the oxidative capacity of fast-twitch muscle fibers while maintaining a fast contraction speed. That is, FOG fibers showed increased strength and FG fibers showed increased endurance. The results suggest that longer rest periods during intervals are effective. Therefore, sprint interval training is an effective training method to enhance athletic performance.

ELECTRIC PULSE STIMULATION OF DIFFERENTIATED HUMAN MUSCLE CELLS: THE MODEL FOR STUDYING EXERCISE-INDUCED ADAPTIVE RESPONSE IN VITRO.

KURDIOVA, T., GABRISOVA, K., UKROPEC, J., UKROPCOVA, B.

BIOMEDICAL RESEARCH CENTER OF SLOVAK ACADEMY OF SCIENCES

INTRODUCTION: In vitro methods are an important tool to study muscle related adaptations to exercise, especially on cellular and molecular level. Electrical pulse stimulation (EPS) of muscle cells in culture provides an in vitro model of exercise, where motor neuron activation of muscle fibers is replaced by external electric stimulation, resulting in repeated contractions of cultured myotubes (1). The aim of our work is to develop a protocol for electric stimulation that can mimic exercise more physiologically than the most frequently used continuous stimulation.

METHODS: Skeletal muscle cells were derived from vastus lateralis muscle of healthy, lean men (n = 4, age: 37 ± 12.7 years; BMI: 23.7 ± 1.4 kg/m2). Cells were differentiated for 5 days, and exposed to EPS (Ionoptix, USA), using two protocols: (i) continuous 24 h stimulation aimed at mimicking low-intensity exercise (frequency 1 Hz, pulse duration 2 ms), and (ii) intermittent 24 h stimulation where higher frequency stimulation was preceded and followed by subthreshold frequency stimulation (pulse duration 4 ms). After the 24 h stimulation, oxidation of radioactively labelled glucose and palmitate and incorporation of glucose into glycogen were measured. Exercise-related myokines released into the media (ELISA) and gene expressions (qPCR) were quantified.

RESULTS: Both types of electric stimulation (continuous and intermittent) resulted in visually detectable contractions of differentiated myotubes. Similarly, both protocols facilitated the incorporation of radiolabelled glucose into myotube glycogen store ($p<0.05$). However, an increase of glucose oxidation was observed only after the intermittent stimulation ($p<0.05$), where we have also observed a tendency to higher oxidation of palmitate (CO_2+ASP: +20%; $p<0.1$). Secretion of the contraction-regulated myokine, IL-8 was increased after the continuous ($p<0.05$), but not the intermittent stimulation. However, there was no uniform increase of IL-6 secretion with neither type of stimulation. The gene expression of these two myokines tended to increase only after the continuous stimulation ($p<0.1$), which has also led to a significant increase of Myh2 gene expression ($p<0.05$), the marker of fast intermittent fibers. There was no change in Myh7 gene expression, the marker of slow oxidative fibers.

CONCLUSION: Both EPS protocols led to the manifestation of specific adaptation mechanisms. However, the intermittent dosing of higher frequency EPS combined with low-frequency subthreshold stimulation elicited stronger response in the

myotube capacity to oxidase substrates, while continuous stimulation tended to have effect on the myokine expression in cultured primary human myotubes.

NOVEL HUMANIZED G6PD DEFICIENT MICE REVEAL MECHANISMS OF INCREASED TOLERANCE TO EXERCISE AS GLEANED BY MULTI-OMICS IN MODELS OF CRITICAL SPEED

CENDALI, F., TRAVIS, N., IRWIN, D., DZIECIATKOWSKA, M., DZIEWULSKA, K., ZIMRING, J., D'ALESSANDRO, A.

UNIVERSITY OF COLORADO ANSCHUTZ

INTRODUCTION: Glucose-6-phosphate-dehydrogenase deficiency (G6PD) is the most common enzymatic deficiency in humans, affecting ~500 million people or ~6% of mankind. G6PD is the rate limiting enzyme of the pentose phosphate pathway (PPP) that generates NADPH, an essential reducing equivalent for antioxidant metabolism that protects against intra- and extra-vascular hemolysis in response to oxidant stress. Impaired G6PD activity may cause hemolytic anemia due to exogenous stress. As such, individuals with G6PD deficiency are recommended to refrain from strenuous exercise as they are deemed to be at increased risk for hemolytic events in response to exercise-induced hemolysis. However, knowledge is limited regarding molecular impacts on exercise capacity in those who have the deficiency. While biochemically sound, this rationale has never been tested mechanistically, owing to ethical and technical limitations.

METHODS: Here we generated novel humanized mouse models carrying either (i) human canonical G6PD (normal activity), or the common G6PD variants (ii) African (V68M - < 10% residual enzymatic activity) or (iii) Mediterranean (S188F - <1% residual enzymatic activity). We leveraged these mouse models to assess critical speed (CS), a functional measurement of the speed-to-duration relationship. To expand the molecular resolution of genetically associated adaptations to exercise, CS tests were combined with multi-omics (mass spectrometry-based metabolomics, lipidomics and proteomics) characterization of plasma, RBCs, and multiple tissue matrices including liver, heart, kidney, lung, spleen, and muscle. All mice underwent hemodynamics tests to obtain cardiovascular data.

RESULTS: Unexpectedly, G6PD deficient mice showed ~10% faster CS compared to mice carrying the canonical human G6PD ($p<0.0001$ and $p<0.02$, respectively). Pathway analysis of metabolomics data generated from RBC and plasma fractions showed significant decreases in arginine metabolism, increased glycolysis, and elevated Krebs cycle intermediates, in addition to the expected differences in PPP. G6PD deficient mice had a significant ($p<0.02$) higher cardiac output. Multiomics analyses identified five major tissue clusters between heart, muscle, liver, kidney, and spleen, with G6PD function having the most significant metabolic impact on liver and soleus.

CONCLUSION: Novel humanized G6PD deficient mice maintain faster CS compared to mice without alterations to the PPP. Omics approaches afford the opportunity to identify metabolic correlates to measurements of performance in relevant animal models, such as the CS model, which offer expanded mechanistic understanding of molecular bases of CS and the associated impact of G6PD deficiency. Our results not only challenge the assumption that exercise-induced oxidant stress predisposes the ~500M individuals with G6PD deficiency worldwide to increased hemolytic propensity, but rather indicate a metabolic advantage of functional polymorphisms to G6PD with respect to exercise performance.

Motor Learning and Motor control

VISUAL REACTION TIMES OF PROFESSIONAL ESPORTS PLAYERS COMPARED TO UNIVERSITY ATHLETES

KIM, H.

GEORGIA STATE UNIVERSITY

INTRODUCTION: Interests in esports have surged these days, and esports players have shown superior performance in detecting a visual stimulus and reacting to it. Esports players are required to make decisions as quickly as possible. This ability is vital while playing esports as well as traditional sports. Previous studies revealed gaming activities could enhance reaction time, eye-hand coordination, and visual information processing skills. However, less is known about the differences in reaction time between traditional athletes and esports players. Luu et al. (2021) attempted to compare college football athletes visual, auditory, and tactile reaction times to esports gamers. Both groups showed faster reaction times than non-athletes but no significant difference in eye-hand reaction time. This study aimed to examine the reaction times of esports players, such as eye-hand and eye-foot reaction times, compared to athletes.

METHODS: Ten esports players (EP) aged 19.6 ± 2.0 and twenty-five university athletes (UA) aged 23.9 ± 1.7 from tennis, volleyball, and soccer teams participated voluntarily after signing informed consent. All participants are healthy young males who are ambidextrous. The Vienna Test System provided the eye-foot reaction time. Additionally, the conventional reaction timer measured the eye-hand reaction time in terms of simple and choice reaction time. A series of independent samples t-tests were performed at the significance level of 0.05.

RESULTS: There was no significant difference in simple and choice reaction times between the two groups for the eye-hand reaction times. The mean simple reaction time was 0.26 ± 0.03 seconds for EP and 0.28 ± 0.03 for UA. The mean

choice reaction time was 0.44 ± 0.07 seconds for EP and 0.44 ± 0.06 for UA, respectively. Interestingly, the foot reaction time took longer than the hand reaction time, and there was a significant difference in foot reaction time between EP and UA. The EP group showed 0.71 ± 0.07 whereas 0.62 ± 0.07 seconds for the UA. More specifically, there was a significant difference in the right foot. It might be that all the participants were right-handed and right-footed.

CONCLUSION: This study attempted to compare different types of reaction times between esports players and university athletes. There was a significant difference in eye-foot reaction time. University athletes showed a faster reaction time. The simple and choice reaction times showed similar values, and these results were consistent with the previous study of Bickmann et al. (2021) comparing esports players and traditional sportspeople. It is known that the ability of reaction time can improve with practice and experiences in sports as well as in esports. The difference in foot reaction time might be induced from that esports players use hands rather than feet while traditional sportspeople use hands and feet. In the future, it will be necessary to consider other influencing factors, such as the type of sports with an increased sample size.

RELATIONSHIP BETWEEN MOTOR SKILL AND RETENTION TRANSFER RACKET PERFORMANCE

SATO, T., NAKAJIMA, M., WATANABE, E.

JISSEN WOMENS UNIVERSITY

INTRODUCTION: A study of multivariable behavior naturally raise the question of which reference frames the central nervous system may use to coordinate motor actions. Previous studies were focused planar reaching movements and showed that translation and rotation of the start and target positions evoked joint kinematics. This investigation of the retention at highly skilled motor performance about tennis racket simple task by findings from arm hand motor behavior. Moreover, it were applied tennis and badminton educational program and extra lesson for acquired physical education in Japanese schools.

METHODS: Seven female university students with a mean ± SD, age 21.29 ± 0.89 years, volunteered to participate in the study. The protocol was explained and subjects gave the informed consent prior to the participation in this study. Two subjects were physically activity in additionally they had experiment tennis and badminton in childhood. All subjects had abstained from alcohol, caffeine and exercise for 24 hours preceding the investigation to ensure reliability. They had performed to put it basket which has distance 4m by same tennis racket until 2000 times trials. And the sensor device of three dimensional which recorded acceleration put on top their grip of their racket during swing.

RESULTS: There was significant difference between subject with retention and novice. It was observed clearly motion skills to control tennis racket by badminton player. Two retention player were rapidly increased encage goal by racket.

CONCLUSION: We examined three dimensions acceleration and true-false simple racket shot in tennis until 2000 times, major found that the retention has been acquired in two subjects. However all subjects had appeared learning-curve over 200 trials, especially in a short amount of time more than continued long-winded trails until 2000 times. It was appeared that once acquired similarity motor skills were retention as same as badminton and tennis. It was consider that motor control skills under age applied similarity retention of motor learning.

INTRACORTICAL INHIBITION AND EXERCISE: PAIRED-PULSE SOMATOSENSORY EVOKED POTENTIALS IN ATHLETES

MAUDRICH, T., RAGERT, P., KENVILLE, R.

LEIPZIG UNIVERSITY, FACULTY OF SPORTS SCIENCE

INTRODUCTION: Long-term exercise has been shown to modulate somatosensory excitability as assessed by single-pulse somatosensory-evoked potentials (SEP) in athletes (1). These neuroplastic adaptations appear to be use-dependent and limb-specific (2). Paired-pulse SEP (PP-SEP) are used to assess the intracortical inhibitory function of the somatosensory cortex known as paired-pulse inhibition (PPI). This study aimed at investigating the influence of exercise on PPI induced by tibial nerve stimulation in two groups of athletes, who primarily use 1) upper-extremities (UEX) and 2) lower-extremities (LEX).

METHODS: In total, 30 healthy athletes were enrolled in this study. Athletes were divided into 2 groups according to their respective sports disciplines: 1) UEX (n = 16 (12 female), age = 23.3 ± 3.8 yrs, training age: 12.4 ± 4 years, training per week: 4.7 ± 3 hours) & 2) LEX (n = 14 (1 female), age = 23.8 ± 3.8 yrs, training age: 12.6 ± 6 years, training per week: 7.4 ± 5 hours). Bilateral tibial nerve PP-SEP were applied at the ankle (3 Hz, 400 pulses, 0.2 ms square wave pulse, 60 ms ISI). SEP responses were recorded at the scalp with an Fz-Cz' EEG montage according to the international 10-20 system. PPI of short-latency peak-to-peak amplitudes (N30-P40, P40-N50, N50-P60) were calculated.

RESULTS: PPI was reliably induced for all SEP amplitudes (all $p < 0.001$). While no group differences in PPI could be observed between UEX and LEX (all $p > 0.05$), a significant negative correlation between PPI (N30-P40) and the amount of training hours per week could be observed ($rs = -0.516$, $p = 0.004$).

CONCLUSION: These results suggest that exercise modulates intracortical inhibition of the somatosensory cortex in athletes. Enhanced inhibitory function in athletes might provide performance benefits related to gating of task-relevant information in sports contexts (3). The lack of group differences could be explained by the fact that lower extremity information processing is also necessary for performance in UEX.

RELATIONSHIP BETWEEN A REACTION TEST AND HISTORY OR FEAR OF FALL IN OLDER PEOPLE

OYAMA, Y.1, SAKAI, T.2, NAKANO, T.3, HAYASHI, Y.4, KAMEOKA, M.5, MURAYAMA, T.6

1 TOIN UNIVERSITY OF YOKOHAMA, 2 NAGOYA GAKUIN UNIVERSITY, 3 CHUKYO UNIVERSITY, 4 HOSEI UNIVERSITY, 5 NIIGATA UNIVERSITY, 6 NIIGATA UNIVERSITY

INTRODUCTION: Fall prevention requires recognizing and reacting to disturbances and using strategies appropriate to the situation. Therefore, measuring and evaluating agility (i.e., quick reaction to disturbance) and equilibrium (i.e., postural control ability after the reaction) are essential because these two abilities comprise fall avoidance movements. Although studies have reported that agility and equilibrium were associated with falls in each measure used, they only examined these two abilities in relation to another specific ability. Evaluating fall avoidance ability in a sequence of movements is important because avoiding falls involves a sequence of two phases, namely, rapid body reaction and postural control, using appropriate response strategies. Although we have developed a reaction balance test (RBT) by combining agility and equilibrium and have confirmed its reliability and validity, we have not been able to examine its relationship to falls. Therefore, this study was designed to examine the relationship between the RBT and history or fear of fall.

METHODS: The RBT was conducted on 31 older people (9 males and 22 females). The RBT is a task in which the participants are instructed to quickly raise one leg when they feel a light stimulus on the stabilometer and then stand on the other leg for 10 s. Agility was evaluated using the single-leg reaction time to raise one leg, which is the time from when the red light flashed to when one leg left the ground. Equilibrium was evaluated using the center of pressure (COP) during the 10 s of single-leg standing after the participant raised one leg, and four parameters were evaluated: Max COP excursion, total length per second, stable time, and total length of stable time. An unpaired t-test was used to compare the RBT in the two groups with or without a history of falls and with or without fear of falls.

RESULTS: No differences in agility and equilibrium were observed between the fall and non-fall groups. In contrast, the fear of fall group tended to have a longer time to raise one leg and poorer COP parameters than the group without fear of fall. Particularly, a moderate difference was observed in the stable time.

CONCLUSION: The RBT, which evaluates agility and equilibrium during a series of movements, also suggests that both agility and equilibrium are impaired in people who have fear of falls. The fact that there was no association with history of fall, but only with fear of fall, should be further examined in detail.

TRAINING TO ENHANCE DRIBBLING AND PASSING PERFORMANCE IN FOOTBALL

TAGA, K.

NATIONAL INSTITUTE OF TECHNOLOGY, TOMAKOMAI COLLEGE

INTRODUCTION: The purpose of this study suggests the training to enhance a dribbling and passing performance in Football.

METHODS: Subjects were 32 junior high school soccer players; 17 in the training group, and 15 in the control group. Both groups did 2 hours of training three times a week for 16 months with the following drill: training group did dribbling training while control group did agility and pass & control training for the first 40 minutes. The dribbling tests and 11 vs 11 games with the third group were carried out before each group's training, after 3 months, 6 months, 10 months, and 16 months.

RESULTS: The results showed Time in the dribbling test greatly decreased more in training group than control group. At the 11 vs 11 game performance, the success and failure number of times on the ball keeping, Taking the opposite and breaking through in dribbling showed no significant in both groups as training progresses. However, the success number of times on carrying to space in dribbling showed significant improvement only in training group. The failure total number of dribbling showed significant decrease only in training group. Furthermore, the success number of times passing showed significant increase only in training group. The success rate in dribbling showed significant improvement only in training group. The success rate in passing showed decrease in both groups after 3 months, but it showed significant increase only in training group.

CONCLUSION: This study clarified the dribbling training intended for junior high school soccer players decreased Time in dribbling test, it improved dribbling skill, and it is suggested the improvement contribute to enhancing a game performance regarding dribbling and passing.

EFFECT OF TARGET CHANGE ON MOVEMENT TIME OF REACHING MOVEMENT

NAKAJIMA, K., YAMADA, N.
CHUKYO UNIVERSITY

INTRODUCTION: Sportspersons are required to perform their movements quickly and accurately according to the changing situations on the field. For example, during a soccer game, the pass course may be narrowed during a kick because of interference by an opposing competitor.

From this perspective, Fautrelle et al. (2011) examined a reaching movement task in which the size and distance of the target changes during the movement. The results showed that the movement time (MT) increased when the target changed during the movement. However, the timing of the target change was only at the start of the movement, and the target change up to the point of reaching the target was not examined. Therefore, a new experiment was developed with different timings to the target change and verified anew.

The study examined changes in reaching movement using a laboratory replication of a sporting situation in which the situation changes and a task in which the size of the target changes at the three timings during the reaching movement.

METHODS: Five right-handed males participated in this experiment. The experiment consisted of a reaching movement task in which participants moved from a starting to an ending point (target) on a tablet using a stylus. There were three conditions in which the target size changed from medium to larger or smaller or did not change during the movement from the starting point to the target (larger, smaller, and no change conditions). In addition, the target changed three times of which the target size change timings were (1) at 1/3 of the travel distance (early), (2) at the middle of the travel distance (center), and (3) at 2/3 of the travel distance (late). Data analysis was conducted from the time of the start of the pen tip movement until the target was reached (MT).

RESULTS: The MT for target change timing for early, center and late were as follows: (1) 582±125 ms for the larger, 651±254 ms for smaller, and 590±132 ms for no change conditions; (2) 585±108 ms for the larger, 631±187 ms for smaller, and 591±143 ms for no change conditions; (3) 577±110 ms for the larger, 660±287 ms for smaller, and 578±117 ms for no change conditions. The results indicate that the smaller conditions at all target change timings increased MT more than the larger and no change conditions.

CONCLUSION: The smaller target size is thought to have increased MT to improve accuracy. The results support the findings of Fautrelle et al. (2011). Their study revealed to tracking changes in target points at the start of movement, and this study shows the possibility for this using the coordinate position of a pen and changing the size of the target during movement.

EVALUATION OF THE EFFECTS OF STOCHASTIC RESONANCE ELECTRICAL STIMULATION OF SENSORY RECEPTORS AND NERVES ON POSTURAL SWAY

HIROKI, F.
RITSUMEIKAN UNIVERSITY GRADUATE SCHOOL

INTRODUCTION: Stochastic resonance (SR) electrical stimulation is used to improve postural sway in standing posture by applying weak noisy electrical signals that unable to be perceived by the somatosensory system. Previous studies have reported that SR electrical stimulation of sensory receptors in the feet and median nerve in the wrist improved in postural sway, but the mechanism by which SR electrical stimulation improves postural sway is not clear, and it is unclear whether it has a greater effect on sensory receptors or nerves. In addition, the effects of SR electrical stimulation on the body have been studied at the neuronal level, but the mechanisms of action have not been elucidated and there have been few studies on neural networks. Therefore, we have two hypotheses. First, we hypothesized that SR electrical stimulation would improve postural sway by exerting a significant effect on the nerves. Second, we hypothesized that the information enhanced by SR electrical stimulation would be integrated at the nerve junctions, further enhancing sensation. The purpose of this study was to test these hypotheses by simultaneous or single SR electrical stimulation of sensory receptors and nerves.

METHODS: The subjects were five healthy male adults (23±1.7 years old) in a static standing posture for 30 seconds with eyes closed, and postural sway was measured. The median nerve (MN) at the wrist, the axillary nerve (AN) behind the scapula, and the ventral thumb receptor (VTR) were the targets of stimulation (dominant hand). To evaluate postural sway, the standard deviation (SD) of the anteroposterior (AP) direction of the center of pressure measured with a force plate was calculated. The SR electrical stimulation applied to the subject was white noise, and a self-made SR electrical stimulator was used.

RESULTS: Single stimulation of VTR, MN, and AN tended to reduce AP SD more in VTR stimulation than in nerve stimulation. AP SD tended to be reduced by simultaneous stimulation of the VTR and MN, the VTR and AN, or the MN and AN, compared to no stimulation or single stimulation at one location.

CONCLUSION: Contrary to the first hypothesis, SR electrical stimulation seems to have a greater effect on the sensory receptors, since the effect on the sensory receptors was greater than that on the nerves, indicating that SR electrical stimulation has a greater effect on the sensory receptors. The second hypothesis of SR electrical stimulation seems to be valid, since simultaneous SR electrical stimulation of the two locations reduced AP SD. In addition, not only simultaneous stimu-

lation of nerves, but also simultaneous stimulation of sensory receptors and nerves reduced AP SD, suggesting that the effects of SR electrical stimulation may be superimposed regardless of the stimulation site. We will model the biological response to SR electrical stimulation of sensory receptors to elucidate the mechanism of postural sway in the future.

CHARACTERISTICS OF TWO PLAYERS' MOVEMENTS DURING A COUNTERATTACK

KAWABE, S., YAMADA, N.

CHUKYO UNIVERSITY

INTRODUCTION: Introduction

According to Bohrs law, movement time (MT) of a responder who moves in response to the leader is shorter than that of a leader who moves intentionally. This law holds true for (1) hand and (2) whole-body movements. Thus, the phenomenon of successful counterattacks frequently observed in sports such as kendo can be explained by the fact that the MT of the responder (counter attacker) is shorter than that of the leader (opponent). However, using a gun duel as an example, it was concluded that the leader wins even if the responder's MT is short, since the reaction time of humans is about 0.2 s (1). This suggests that the phenomenon of successful counter attacks in sports is not caused solely by differences in MT; however, previous studies were unable to experimentally confirm this. Therefore, it is necessary to focus on sports in which counterattacks can be confirmed and examine whether responders who move later win over leaders who move first. In this study, we experimentally reproduced a scene from a kendo match. Thereafter, we examined characteristics of the two players' movements when debananawaza (i.e., a counterattack) occurs and both players' striking times were examined.

METHODS: Methods

The players were paired up. They faced each other on a force plate, and after the experimenter had signaled hajime (start), the subjects played the game. After the signal, the players struck ("men") in their own time, and 10 trials were performed. Ground reaction force data were obtained from all trials using a force plate (1,000 Hz), and movement of the shinai was filmed using a high-speed camera (250 Hz) to determine the striking moment. The ground reaction force data helped identify the start of the two players' movement as they entered the striking motion (threshold set at ±10% of the body weight) and classifying them into two groups: the first mover (leader) and second mover (responder). Striking time (MT) from the start of movement to the striking moment was calculated for each group. The test's winner was the player who had struck first. One test that could not be measured correctly was excluded, and nine tests were included in the analysis.

RESULTS: Results

The leaders won 1/9 trials (a), the responders won 6/9 trials (b), and 2/9 trials ended in a tie (c). The MT was 0.46 s for the leaders and 0.37 s for the responders in scenario (a); it was 0.47±0.02 s for the leaders and 0.32±0.03 s for the responders in scenario (b); and 0.50±0.01 s for the leaders and 0.40±0.07 s for the responders in scenario (c).

CONCLUSION: Conclusions

This study showed that when debananawaza occurred, the responders won most trials. Although the relationship between two players' MTs supports previous studies, this study suggests that we can experimentally reproduce a phenomenon frequently observed in actual sports.

NEURAL CORRELATES OF SLACKLINE PERFORMANCE FOLLOWING A SINGLE TRAINING SESSION

KENVILLE, R., RAGERT, P., MAUDRICH, T.

LEIPZIG UNIVERSITY

INTRODUCTION: Previous studies demonstrate positive effects of long-term slackline training on static and dynamic balance ability 1. Neural correlates of balance improvements resulting from several weeks of slackline training have already been demonstrated at the structural and functional level 2. Critically, neural correlates of initial and acute slackline performance remain insufficiently explored. For this purpose, the present study aimed to investigate neural correlates of 1) initial slackline performance as well as 2) improvements in slackline performance following a single supervised training session.

METHODS: In total, 15 healthy participants (n = 10 (male), age = 25.4 □ 3.4 yrs.; n = 5 (female), age = 23 □ 1.7 yrs.) without prior slackline experience were enrolled in this study. Resting-state brain activity (5 min.) was recorded using a wireless 32-channel EEG system before (PRE) and after (POST) a 45-minute slackline training session. Slackline performance was evaluated by way of 6 standard dynamic and static balance tests on a Slackline. Power spectral density (PSD) was estimated across alpha (8-12 Hz), beta (13-30 Hz), and gamma (31-44 Hz) frequency bands for each electrode per condition (PRE and POST). Frequency-band specific PSD's were compared per channel between conditions using paired t-tests. Channels showing significant differences in PSD between conditions were further used for correlation analyses. Here, we correlated frequency-band specific PRE and POST PSD with initial Slackline performance (SPpre) and performance improvements following a single training session (SPpost-pre) using Spearman's rank correlation.

RESULTS: We found significant differences in PSD between PRE and POST for alpha and beta frequencies (all p-values were adjusted using FDR-correction). Correlation analyses revealed 1) significant positive correlations between occipital channels and SPpre (pooled rs = 0.6, p = 0.03) as well as SPpost-pre (pooled rs = 0.58, p = 0.04) for alpha frequencies and 2) significant positive correlations between parietal channels and SPpre (pooled rs = 0.64, p = 0.02) for beta frequencies (all p-values were adjusted using permutation-testing).

CONCLUSION: Our findings imply that resting state dynamics at alpha and beta frequencies relate to initial slackline performance as well as performance improvements following a single training session. These results further suggest that alpha and beta bands relate more to slackline performance and performance improvements compared to gamma bands.

DIFFERENT HURDLE CLEARANCE MOVEMENT PATTERNS BETWEEN YOUNG HURDLERS

PANTELI, F.1,2, SEIFERT, L.1, THEODOROU, A.2, KESOGLOU, I.2, ARGEITAKI, P.2, SMIRNIOTOU, A.2

1. UNIVERSITÉ DE ROUEN NORMANDIE 2. NATIONAL AND KAPODISTRIAN UNIVERSITY OF ATHENS

INTRODUCTION: Hurdling performance depends on the maintenance of an inter-hurdle accelerating running rhythm and hurdle clearance techniques. Hurdle clearance technique is related to the height of the centre of mass (CoM) during take-off and over the hurdle as well as with lead and trail leg joint angle characteristics (1). Different hurdle clearance techniques between elite hurdlers (1) and different locomotion patterns while negotiating the first two hurdles between novice hurdlers (2) suggests that each individual interact differently with the performance environment. Given the unique individual characteristics, hurdlers are expected to exploit hurdling parameters and adjust their movement pattern according to their needs, in order to satisfy interacting constraints during hurdling. The purpose of this study was to assess the manifestation of individual differences between young hurdlers while clearing the first two hurdles (0.76m) in a) knee joint angle configuration of the lead and trail leg, b) the trajectory of the CoM, c) horizontal velocity of the CoM during take-off and at landing.

METHODS: Five female hurdlers (under 16 years) were video recorded with three synchronised video cameras while clearing the first two hurdles during running, in practice conditions. The APAS software (Ariel Dynamics, 2010) was used for 3D movement analysis and data processing which included the calculation of lead leg and trail leg knee angle, CoM positional data as well as horizontal velocity of the CoM during take-off and at landing. The duration of each hurdle clearance stride was normalized in terms of percentages. Consequently individual athletes' data were analysed and expressed to a percentage of hurdle's phase total time.

RESULTS: Differences were observed between young hurdlers while clearing the first two hurdles in lead leg knee angle configuration and in CoM trajectory. Participants did not extend in a similar fashion their lead leg neither during flight nor at landing (for the last 70% of the hurdle clearance stride). Different values were also observed in raising the CoM during the first 20% of the hurdle clearance stride and in the position of the CoM during flight and at landing (the last 70% of the hurdle phase). Participants who maintained a higher position of the CoM at landing attained higher horizontal velocity after clearing both hurdles, indicating an accelerating running rhythm.

CONCLUSION: The manifestation of different hurdle clearance movement patterns, associated with the unique individual characteristics and the exploitation of different or variable execution parameters, indicates that each individual can vary motor behaviour and search for his/her own functional movement solutions which satisfy multiple, interacting constraints during task performance (3).

RELATIONSHIP BETWEEN SKILL PROFICIENCY AND SUBJECTIVE EVALUATION IN TRAMPOLINE ATHLETES

YAMAZAKI, K.

TOYO UNIVERSITY

INTRODUCTION: Previous studies have shown that changes in regional cerebral blood volume in the forehead during skill recall differ depending on the skill level of the athlete.

It is not possible to judge from these results whether it is due to the individual characteristics of the athletes or whether the difference in skill acquisition affect in brain activity.

Therefore, the purpose of this study was to examine the relationship between changes in brain activity during the skill acquisition process of trampoline players and subjective skill perfection from a longitudinal study to clarify issues mentioned above.

METHODS: The subjects were three female trampoline athletes at a university. The subjects were athletes who gave sufficient explanation about the experiment and obtained consent. An optical topography was used to measure brain function in the frontal lobe. Brain activity in the forehead was measured using optical topography. Measurements were taken once a month. At the time of measurement, we asked them to answer using the Visual Analog Scale about their subjective proficiency of the double twist, which they felt in the practice just before that. The brain activity data obtained was evaluat-

ed by the number of channels that showed a significant increase in blood volume when recalling the technique, out of the 47 channels that were measured.

RESULTS: The number of significant channels tended to increase as the skill became more difficult, and the results were similar to previous studies. However, there was no constant trend over the months, resulting in repeated increases and decreases. The Double Twist rose as the month progressed, but the tendency was not found and there was a period of stagnation.

CONCLUSION: This study showed that the simpler the trick, the lower the number of channels showing a significant blood rise, and the smaller the frontal lobe blood rise during recall.

It is known that when motor learning establishes movement automation, the brain activity area changes and shifts to memory-dependent brain activity areas. The results of this study also suggest that there was a similar tendency for the two skills already learned.

On the other hand, it was expected that brain activity would decrease as skill acquisition increased. However, in this study, despite the increase in subjective proficiency, there was no consistent trend in the number of significant channels.

The double twist technique that we focused on in this research is classified as a difficult technique even for athletes with a long competition history. It is thought that the technique was highly difficult even for the subjects who cooperated this time.

In this study, the subjective degree of perfection rose to 40 in about 5 months after starting practice, but considering the difficulty of the technique, it is possible that this evaluation was not appropriate. In the future, we will need to consider how subjective evaluations differ from objective evaluations by instructors and others.

THE RELATIONSHIP BETWEEN PEDALING EXERCISE PHASES AND PERFORMANCE FOLLOWING RESPONSE INHIBITION

TAKAYOSE, M., KOSHIZAWA, R., OKI, K.

NIHON UNIVERSITY

INTRODUCTION: Response inhibition of cognitive functions plays an important role during sports activities. Though there have been many studies on cognitive function during exercise, the results show little consensus. Furthermore, there have been few studies of response inhibition during exercise. In this study, we investigated the relationship between the performance following response inhibition and the muscle activities of the lower limbs during pedaling exercise.

METHODS: All participants were right-handed, healthy adult males. Participants were asked to perform a visual stop-signal task (SST) while pedaling (50%HRR) on a bicycle ergometer. During the SST, participants were required to respond by pressing a key on their right fingers in the Go condition and suppress the response in the Stop condition. Surface EMG signals were recorded from the vastus lateralis, vastus medialis, biceps femoris, and medial gastrocnemius. Event-related potentials (ERPs) were recorded from the scalp. The analysis period was divided into three periods: the lower limb muscle activities period on the ipsilateral side of the responding limb, the lower limb muscle activities period on the contralateral side, and the resting period.

RESULTS: The reaction time under the Go condition was the fastest for the resting period among the three periods (ipsilateral: 386.2±15.5 ms, contralateral: 402.7±40.6 ms, resting: 375.2±27.0 ms). In the Stop condition, the success rate of response inhibition was highest in the resting period (ipsilateral: 42.9±20.2%, contralateral: 25.5±18.4%, resting: 60.0±14.1%). In the P300 component of ERPs, the peak latency was shorter for the resting period than the other periods.

CONCLUSION: Participants exhibited better motor output responses and information processing related to response inhibition during the resting period. It is possible that information processing related to the pedaling activity of the lower limb muscles and upper limb responses formed a dual-tasking situation. Therefore, the allocation of limited attentional resources to each may have reduced performance in response inhibition during the lower limb muscle activities period.

Neuromuscular Physiology

RELATIONSHIPS BETWEEN COMPETITIVE ABILITY AND PRE-ACTIVATION TIME IN LEG MUSCLES DURING SPRINT RUNNING AND DROP JUMPING IN COLLEGE TRACK AND FIELD ATHLETES

YOKOTA, K., OGA, R., TAMAKI, H.

NATIONAL INSTITUTE OF FITNESS AND SPORTS

INTRODUCTION: Pre-activation (PA) of agonist/antagonist muscles prior to ground contact during running and jumping movements is one of the human motor control mechanisms, and according to previous reports, it has a positive impact on motor performance. There is, however, little information available regarding the relationship between the onset time of PA and subsequent motor performance in Japanese college track and field athletes. We investigated the relationships between the onset time of PA in the lower leg muscles during drop jumps (DJs), sprint running and jumping performance, and competitive ability in Japanese college track and field athletes.

METHODS: Fourteen male college track and field athletes performed both DJs from a 60 cm-high platform and sprint running for 20 m. We recorded surface electromyographic (sEMG) signals from their tibialis anterior, lateral gastrocnemius (LG), medial gastrocnemius, and soleus muscles during these tests. We calculated a DJ index by dividing the jumping height (m) by the ground contact time (s). The best International Association of Athletics Federations (IAAF) score of each runner was used as a variable representing individual running performance. The sEMG signals were normalized (ex-

pressed as a percentage of the maximum voluntary contraction) and the PA time for each muscle was measured as the interval between the onset of muscle activation and ground contact, assessed via sEMG.

RESULTS: There was no significant correlation between the DJ index and PA time for any of the muscles during DJs. However, PA time in the tibialis anterior during the sprint running was significantly correlated with IAAF score ($r = -0.68$, $p < 0.05$). There was also a strong, although nonlinear, relationship between the IAAF score and PA time in the LG during the 20 m sprint running ($R2 = 0.928$).

CONCLUSION: Our data suggest that the PA time in the LG during the 20 m sprint running and competitive ability can be modeled using a second-order regression, revealing a link between muscle pre-activation strategy in the LG and sprint-running performance in college sprint runners. The concept of pre-activation time in the leg muscles predicting the sprint-running performance of athletes may thus be worthy of further discussion.

MECHANICAL ACTIVITY AND INTERACTION OF ACTIVITY ON VASTUS LATERALIS AND VASTUS MEDIALIS OBLIQUE UNDER THE DECREASE OF KNEE EXTENSION TORQUE.

TANAKA, S.1, YOKOZAWA, S.2, IMAWAKA, T.3, HATASHIMA, K.1, HIRATSUKA, K.4

1 KOKUSHIKAN UNIVERSITY, 2 HEISEI INTERNATIONAL UNIVERSITY, 3 JAPAN INSTITUTE OF SPORTS SCIENCE, 4 RITSUMEIKAN UNIVERSITY

INTRODUCTION: Muscle function has been evaluated by electromyography method from viewpoint of physiological [1,2,3]. Recently, muscle contraction (MC) sensor is possible to evaluate the mechanical activity during muscle contraction [4]. It has been reported that muscle activity and MC signal was related to the elbow flexion force in isometric contraction [5]. However, interaction activity of knee extensor muscles with decrease of knee extension torque caused by a continuous knee extension task is not clear. In this study, the characteristics of the muscle activity and the interaction activity on knee extensor muscles under the decrease of knee extension torque caused by a continuous knee extension task were evaluated by electromyography and MC sensor methods.

METHODS: Eighteen males (age: 24.7±5.1yrs, height: 174.3±7.5cm, weight: 69.4±11.7kg) without disabilities to knee joint were participated in this study. The continuous task on 30 times knee extension and flexion isokinetic contraction (180 deg/sec) with maximal effort was performed by dynamometer (Biodex co.). And measurement of maximal knee extension torque under isometric contraction at knee angle 70 degrees was measured the pre and post continuous task. At the same time, the electrical muscle activity for vastus lateralis (VL) and vastus medialis oblique (VMO) were measured by surface electromyography (Nihon Koden co.). And also, the muscle deformation amount (FMC) for VL and VMO as a mechanical activity were measured by MC sensor (TMG. BMC). MC signals indicate the tension of muscle belly on contraction [4, 5]. These measurement parameters were calculated the mean value based on each 5% per maximal knee extension torque.

RESULTS: The knee extension peak torque reduced 10% by continuous knee extension task. In addition, the electrical muscle activity at VMO and VL in post showed higher values than pre. On the other hand, FMC in post were lower value than pre during over the 30% peak torque. Moreover, significant correlations were observed between VL and VMO for electrical activity in pre ($r=0.997$, $p<0.001$) and post ($r=0.998$, $p<0.001$). And FMC of VL and VMO were significantly correlated in Pre ($r=0.993$, $p<0.001$) and Post ($r=0.993$, $p<0.001$), respectively.

CONCLUSION: From these results, it was cleared that the electrical and mechanical information of the muscles differ in the muscle activity under the decrease of isometric knee extension torque. However, relative electrical muscle activity and relative FMC were significantly correlated between VL and VMO pre and post the continuous knee extension task, respectively. Therefore, the mechanical activity by the MC sensor method also observed interaction of muscle activity at VL and VMO as well as the electrical muscle activity.

TIME COURSE OF PERFORMANCE DECREMENT WITHIN 10 MAXIMAL SERIES PERFORMED ON A FLYWHEEL SQUAT EXERCISE

ALARCÓN, À., SALSE, J., TORRADO, P., MARINA, M.

UNIVERSITAT DE BARCELONA

INTRODUCTION: The flywheel squat exercise (FWsq) has become very popular thanks to its positive effects on the athletic performance (jumps, speed) and injury prevention. Proportion of force and power improvements depends on the duration of the task and the magnitude of the inertial load applied on the flywheel, thanks to diverse neurological and morphological adaptations (1). During eccentric contractions, there is an elongation because the external resistance exceeds the force produced by the muscle (2). This mechanical condition explains why the force is superior during the eccentric phase than in the concentric one, partially due to the inertia accumulated during the maximum concentric effort (3).

OBJECTIVES

The aim of this study was to characterize the loss of strength and power throughout the 10 repetitions performed within the 10 sets of a maximal flywheel squat protocol.

METHODS: 34 volunteers performed a 10x10 flywheel half squat exercise using a load of 1270 Kg/cm2. Preceding the 10 effective repetitions of each set, three additional repetitions were used to develop maximal momentum. Three minutes of rest between series was allowed. Force and Power were measured using the Chronojump Boscosystem® (Spain) and

averaged from three proportional sections (Sc1-3) of each set (1x set = 3x sections). Two-way Anova of repeated measures was used to analyse the time-course of change of these two parameters.

RESULTS: No significant decrements (P >1.00) in force and power were found in neither of the two phases (CON-ECC) within the first two series. Nevertheless, significant decrements (P≤0.001) were found in both parameters when comparing the three sections of each set from the 5th set onwards. Focusing on the first section (Sc1) of each set throughout the test, participants showed less force generation capacity (P≤0.011). Also, standing out that an interaction effect (F≥3.04; P≤0.02) confirmed that the relative decrement of force and power becomes increasingly more pronounced at the end of each set (Sc3) in comparison to their onset (Sc1).

CONCLUSION: Participants became less capable of maintaining their force and power within the successive sets as the FWsq progresses. Loss of performance is particularly dramatic from the 8th set. In earlier studies (4), we reported that participants could maintain their level of muscle activity throughout the 10 sets of the FWsq. According to Carmona et al. (5), we suggest that muscle contractile mechanisms can be negatively affected by this type of exercise.

EFFECT OF THE RESIDUAL TORQUE ENHANCEMENT ON ISOMETRIC SHOULDER ADDUCTION.

BUSQUETS, A.1, FERRER-URIS, B.1, HEILIJGERS, S.2, JENNER, J.2, RINCÓN-SARMIENTO, M.A.2, ANGULO-BARROSO, R.1

1 INSTITUT NACIONAL DEDUCACIÓ FÍSICA DE CATALUNYA, 2 THE HAGUE UNIVERSITY OF APPLIED SCIENCES

INTRODUCTION: Isometric action preceded by an eccentric action (ECC-ISO) can produced greater torques than purely isometric actions (ISO) at similar joint position and level of muscle activation [1]. This phenomenon is known as residual torque enhancement (rTE). At a similar level of submaximal torque, rTE can be observed as a muscle activation reduction compared to the ISO [2]. No studies focused on rTE have been conducted in complex joints like shoulders [3]. Our aim was to assess the rTE effect across submaximal and maximal intensities during a shoulder adduction.

METHODS: Seventeen male participants (23.8±6 years) were equipped with electrodes to measure the muscle activity of the pectoralis major, latissimus dorsi, trapezius, teres major, serratus anterior, and triceps brachii. Force output was recorded and displayed on screen for feedback purposes. At first, the 100% maximal voluntary contraction (MVC) in ISO followed by 7 trials (ISO: 40%, 60%, 80% MVC; ECC-ISO: 40%, 60%, 80%, 100% MVC) ordered randomly. During ISO trials participants had 3 s to achieve the requested force level and then 5 s to hold it; while for the ECC-ISO trials they were instructed to use 3 s to move arms in the frontal plane from the body side to 90° relative to the trunk (eccentric phase) and hold this position for 5 s. The isometric phase in both conditions was used to calculate the mean of the applied force (F) and the root mean square (RMS) for each muscle. Also, F and RMS values were normalized in relation to the 100% MVC in ISO. Repeated measures ANOVAs (Condition x MVC level) were conducted to establish muscle activation differences between the ISO and ECC-ISO in the different force intensities. Normalized values were used to assess muscle activation-torque relationship with linear regressions.

RESULTS: All muscles showed higher muscle activation for the ISO in contrast to the ECC-ISO. Planned comparisons indicated that this ISO higher muscle activation appeared in all the levels of force performed, except for the 40% MVC of the serratus anterior. The relative muscle activation and force level data across all MVC intensities had very good fit with the linear regression in both conditions. Comparing regressions and scatter plots from conditions, in all muscles values for the ECC-ISO conditions were rightward shifted (less RMS for similar MVC level) in relation to the ISO values.

CONCLUSION: The results suggest that rTE affected the shoulder muscles involved in the adduction when isometric actions were preceded by an eccentric action in a wide range of force intensities. In addition, it seems that the presence of the rTE improves muscle efficiency, seen as lower muscle activity at similar force intensities. These findings prove that rTE can be observed even in complex joints.

DOES PRIOR KNOWLEDGE OF SPRINT NUMBER AFFECTED ON PACING STRATEGIES DURING REPEATED-SPRINT SETS

SELMI, M.A., HAMMAMI, R., NAIMI, R., MORAN, J., VAN DEN TILLAAR, R., HAJ SASSI, R.

TUNISIAN RESEARCH LABORATORY "SPORT PERFORMANCE OPTIMIZATION," LR09SEP01

INTRODUCTION: The purpose of various different pacing strategies in training for sport is to ensure that maximal performance can be attained by a performing athlete (Baron et al., 2011). An athlete's performance can be affected by a number of different extraneous factors such as their prior level of experience, their competitive level and their knowledge of the demands of a particular task (Abbiss & Laursen., 2008, Swain et al., 2020). To this end, the extent to which an athlete

knows that they will engage in strenuous exercise appears to have an effect on their ability to optimize their performance during bouts of training. In addition to these strategies, coaches could also choose to deceive athletes with regard to the specific workloads that will be executed within a given session. However, to date, the effect of various different forms of deception on the in-session performance of athletes is unequivocal and so further study is required to determine optimal strategies. Therefore, this study explores the influence of prior knowledge of sprint number on mechanical work, surface EMG (RMS, MF), countermovement jump (CMJ) Heart rate (HR), feeling scale (FS) and RPE during repeated-sprint sets (RSS).

METHODS: Twenty-two athletes performed three RSS protocols in random order. In one trial, subjects were informed that they would perform 2 sets of 5×20 m with 15-second recovery between sprints and with 1-minute recovery between sets (control trial, CL). In a second trial, subjects were invited to perform 1 set of 5×20 m, but after the second set of 5×20 m, they were also asked to perform an additional five sprints (deception trial, DC). In a third trial, subjects were not told how many sprints they would be performing but were stopped after 2 sets of 5×20 m (unknown trial, UN). Performance measures recorded included total sprint time for the 5 sprints (TST), sum of sprint times performed during the two sets (SST) and best 20 m sprint time (BST) for each set. The CMJ, RMS, MF, HR, FS and RPE were recorded before and immediately after each RSS protocol

RESULTS: The BST and TST of first set were significantly better than in the second set of RSS ($F \geq 77.8$, $p \leq 0.001$, $\eta p2 \geq 0.79$). No significant effect of condition was found in the BST and SST in set 1, 2 or over the whole protocol with no significant interaction effect. In addition, the RMS, MF, HR, FS and CMJ performance recorded at the RSS protocol were not significantly different in the three conditions. However, the RPE was significantly higher ($F \geq 9.6$, $p \leq 0.001$, $\eta p2 \geq 0.31$) after the unknown trial and after the first RSS compared to the CL and DC trials.

CONCLUSION: The main findings of our analysis were that even though the best sprint times were observed in the second trial of each protocol, there was no actual significant difference between any of the protocols in overall sprint times. In this way, the level of prior knowledge that the study participants were provided with prior to sprint execution did not affect their performance of those sprints.

ACUTE EFFECTS OF A STATIC AND A NEUROMUSCULAR PROPRIOCEPTIVE FACILITATION STRETCHING PROTOCOL ON DIFFERENT STRENGTH PROFILES

VILA-CHÃ, C., GRAÇA, V., BOVOLINI, A., RÚA-ALONSO, M., MARQUES, M., BRITO, A., SERRA, N.

INSTITUTO POLITÉCNICO DA GUARDA

INTRODUCTION: A variety of stretching techniques has been widely used to enhance ROM, aiming to improve performance and prevent injuries [1]. However, several studies have observed adverse effects on maximal muscle strength and power after static and dynamic stretching modalities, raising interest in other stretching modes [2]. Neuromuscular proprioceptive facilitation (PNF) continues to be an effective practice, and its impact on neuromuscular performance is not well known. The purpose of this study was to evaluate the acute effect of two stretching protocols on different strength profiles and muscle activity (EMG) of knee extensors and flexors.

METHODS: Twenty volunteers (8 women and 12 men), amateurs trail amateurs (mean age = 28.7 ± 7.59 yrs.) participated in the study. They were submitted to a static and a PNF protocol in a random order on separate days. Each participant performed the sit and reach test, countermovement jump (CMJ), maximal isometric force (90° of knee flexion) and maximal isokinetic peak torque of the quadriceps and hamstrings (60°.s-1), pre-and post-stretching protocols. EMG of the femoral biceps (BF), vastus medialis (VM) and lateral gastrocnemius (LG) muscles were measured during the isometric and isokinetic tests.

RESULTS: After both protocols, sit and reach test performance increased (time effect: $P < 0.001$; + 12.93% after static and + 11.03% after PNF protocol), whereas CMJ performance decreased (-4.11% and -6.51%, after static and PNF, respectively; $P < 0.01$ for both protocols). The MVC of the hamstrings was significantly affected by the PNF protocol (-9.61%; $P = 0.02$), while peak torque increased after static stretching (+4.14%, $P = 0.056$). No changes were observed in the MVC and the peak torque of the knee extensors following both stretching protocols. Force-length relationship, hamstrings to quadriceps (H: Q) ratios and VM, BF and GL muscle activity were not affected by any of the stretching protocols.

CONCLUSION: Both protocols induced an increase in flexibility but decreased muscle power. During maximum force tests, the PNF protocol affected the performance of the hamstrings, reducing their capacity to produce isometric force but increasing their capacity in a dynamic situation. Depending on the force profile, the stretching protocols may have a distinct impact, but it does not alter the agonist/antagonist ratio nor the curve-force-length relationship.

Nutrition

EFFECTS OF ORAL GARLIC EXTRACT SUPPLEMENTATION ON CYCLING TIME TRIAL AND EXERCISE-INDUCED OXIDATIVE INFLAMMATION IN HEALTHY ADULTS

CHENG, I.S.

NATIONAL TAICHUNG UNIVERSITY OF EDUCATION

INTRODUCTION: Garlic extract has been shown to enhance antioxidant and anti-inflammation activities in humans. The present study investigated the effects of garlic supplementation on 40-km cycling time trial performance, exercise-induced oxidative stress, and inflammatory responses including blood biomarkers of oxidative stress, inflammation, and muscle

injury in healthy adults. We hypothesized that four weeks of daily garlic supplementation (1000 mg/day) would improve cycling performance by relieving systematic oxidative stress, inflammation, and muscle injury.

METHODS: Eleven physically active males (mean age: 22.0±4.8 years old, height: 174.9±7.7 cm, 77.0±13.3 kg, VO2 max: 45.3±5.5ml/kg/min) were recruited to perform this single-blind crossover study. Participants were randomly assigned to either garlic (garlic extracts 1000 mg/d for 4 weeks) or placebo trials. Following 4 weeks of supplementation, participants performed a 40-km cycling challenge and Total cycling performance time and respiratory exchange ratio (RER) were recorded. Blood samples were collected every 10 km to determine exercise-induced oxidative stress, inflammation, and muscle damage. A paired t-test was used to analyze the time recorded from participants during the 40 km time trial. Data for blood and gas samples collected at different time points were analyzed by repeated measure two-way ANOVA (trial × time). If a significant interaction was observed between treatments and time points, we further conducted a simple main effects analysis. In this regard, for post hoc analysis, Fisher's least significant difference (LSD) was used. The α value was set at $p < 0.05$.

RESULTS: The 40-km cycling time trial performance was not improved following 4 weeks of garlic supplementation. However, 4-wk garlic supplementation significantly increased whole-body antioxidant capacity (total antioxidant capacity, TAC), and subsequently attenuated MDA, TNF-α, and LDH during the 40-km cycling exercise period ($p < 0.05$). There were no significant differences among the blood biomarkers glucose, NEFA, IL-6, UA, and CK respectively. The respiratory exchange ratio was similar between garlic and placebo trials.

CONCLUSION: Four-week oral garlic supplementation attenuates exercise-induced oxidative inflammation and muscle damage during a 40-km bout of cycling. However, it appeared that 4-wk oral garlic had no ergogenic effect on cycling performance in healthy males.

THE RESEARCH OF ENZYME HYDROLYZED OKARA PROMOTE ENDURANCE EXERCISE PERFORMANCE AND RESIST EXERCISE FATIGUE IN MEN

YU-JOU, C., I-SHIUNG, C., CHIN-LIN, H.

CHUNG SHAN MEDICAL UNIVERSITY

INTRODUCTION: Exercise fatigue was a common problem caused by intense or prolonged exercise, that had adverse effects on health, and needed to be solved. Okara, a residue of soybean processing, was a good protein resource, and was full of branched-chain amino acid (BCAA) which were confirmed with benefits for reducing fatigue. Furthermore, the BCAA content of the protein was elevated after enzyme hydrolysis processing. Thus, the aim of this study was to access the effects of enzyme hydrolyzed okara (EHO) on endurance exercise and its anti-fatigue property.

METHODS: In this study, sixteen healthy men (20 to 40 years old) who exercise at least 2 times a week were recruited in this study. All participants received one dose of EHO supplement for 4 weeks and performed the same exhaustive exercise test before and after 4 weeks of intervention. The exercise time and the blood markers relative to fatigue (pre-exercise, during exercise, and at the end of exercise) were measured.

RESULTS: The results showed that the time to exhaustive was significantly increased after 4 weeks of EHO supplementation, and the lactate content was significantly decreased during exercise and the end of exercise. Furthermore, the level of insulin at the end of exercise was significantly lower after EHO supplementation.

CONCLUSION: Our research indicated that EHO supplementation could promote endurance in exercise, decrease the accumulation of fatigue substances, and increase insulin sensitivity, which showed an anti-fatigue function.

DIETARY INTAKE ANALYSIS FOR PERSONS WITH STANDARD LEVEL AND OVERWEIGHT LEVEL OF BMI

PLAVINA, L.

NATIONAL DEFENCE ACADEMY OF LATVIA

INTRODUCTION: Physically active persons could optimize physical functions by following to nutritional recommendation. Diet, which is adapted to energy expenditure, support physical health, welfare, and physical working capacities. Health status and body composition are indirectly related to dietary habits (Farina, et al., 2017; Dyal, et al, 2022). Nutritional knowledge level and readiness succeed to nutritional principles applicable to benefit physical activity and physical performance. Aim of the study evaluate differences in diet of young physically active person chord with standard BMI index and with overweight BMI before and after nutritional education course

METHODS: Participants of study group were men in aged from 22 to 35 years, the average age was 25.4 years, who had daily physical training. The study group participants were divided into two subgroups: respondents with standard level of BMI <25, the BMI level is into interval 18.5-24.9(N=20), and respondents with overweight level of BMI >25, when BMI is into interval 25.0-29.9(N=22). Dietary diary questionnaire developed according to standardized dietary epidemiology guidance (Willett, 2013). Daily dietary components % (proteins, carbohydrates, fat) as well total diet energy (in kcal) were calculated. We used nonparametric statistical analyses with Independent-Samples Mann-Whitney U Test summary, MS Excel and SPSS 27.0 version

RESULTS: Statistical tests analysis revealed no statistically approved differences between respondents' groups, the distribution of fat (p=0.624), carbohydrates (p=0.999), and proteins (p=0.521) in respondents` groups with standard BMI and overweight BMI in diet before nutritional education course. We revealed statistically significant differences of increasing of fat level (p=0.011) and decreasing carbohydrates (p=0.002) in study subgroups with standard BMI and overweight BMI

after nutritional education course, but there are no statistically approves differences in distribution of proteins (p=0.853), in respondents` subgroups after nutritional education course

CONCLUSION: Respondents from the study group showed a wide spectrum of individual habits of daily intake. The median of carbohydrates consumption energy level (%) was beneath compare to recommendation (till 60%) of carbohydrates consumption energy for general population, but above carbohydrates consumption energy level in recommendations (till 5%) of keto diet. The median value of proteins consumption energy level (%) was higher than recommended (till 15%) proteins consumption energy value for general population, but closed to recommended proteins consumption energy level in (till 20%) of keto diet. The fat consumption energy level median (%) was above fat consumption energy value in recommendation (till 25%) for general population, but below fat consumption energy value in recommendations (till 75%) of keto diet.Nutritional education has an impact on dietary intake of participants with standard and overweight level of BMI.

ACUTE EFFECTS OF RESISTANCE EXERCISE WITH DIFFERENT INTER-SET REST INTERVALS ON SUBJECTIVE APPETITE AND ENERGY INTAKE

LIU, H.

NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: This study examined the effects of resistance exercise (RE) with different inter-set rest intervals on subjective appetite and energy intake.

METHODS: In total, 12 healthy young men (age = 22.1 ± 1.5 years, body mass index = 22.7 ± 1.6 kg/m2) were included. Participants completed 3 moderate-load RE trials (3 sets of 70% 1RM) with different inter-set rest periods (60 sec, 120 sec, and 180 sec) and a control trial (CON; no exercise), in a randomized, crossover design. Subjective appetite ratings (hunger, satisfaction, fullness, and prospective food consumption) and levels of lactate were evaluated before exercise and 90 minutes after exercise. Ad libitum energy intake was determined 90 minutes after rest periods. Participants recorded over 3-day (the test day and one day before and after the test day) energy intake.

RESULTS: Recovery of appetite suppression was slower in the 60 sec trial ($p < 0.05$ vs. CON at post 0, 30, and 60 minutes). The area under the curve (AUC) of overall appetite was significantly lower in the 60 sec trial ($p < 0.05$ vs. 180 sec and CON). The AUC of lactate levels during the trial period was significantly higher in the 60 sec trial ($p < 0.05$ vs. 120 sec, 180 sec, and CON). There were no differences in energy intake responses, including ad libitum energy intake and 3-day food diary between 4 trials ($p > 0.05$).

CONCLUSION: These findings suggest that moderate-load RE with a short inter-set rest interval induces greater inhibitory responses on subjective appetite. RE with different inter-set rest intervals seems not to affect post-exercise energy intake.

EFFECTS OF SHORT-TERM ALTERNATE DAY FASTING ON WEIGHT LOSS AND BODY COMPOSITION

PANG, B., HUANG, C., SIM, D., NUR, R., YANG, Y.

NATIONAL INSTITUTE OF EDUCATION, NANYANG TECHNOLOGICAL UNIVERSITY

INTRODUCTION: Obesity is a public health epidemic. While many weight loss diets like alternate day fasting (ADF) have been shown to be effective in curtailing obesity, these diets typically require long durations to see positive results. The effectiveness of shorter-term ADF interventions in tackling obesity is less well studied. Another concern is that of muscle loss, which commonly occurs during weight loss. Therefore, this study investigates the effects of short-term (four weeks) ADF on weight loss and body composition.

METHODS: A total of 46 healthy young men were recruited, with 37 completing the intervention. Participants were aged 25 (3) years, with an average body mass index (BMI) of 26.7 (3.6) kg/m2. They completed 28 days of ADF, alternating every 24 hours between 'feeding' (ad libitum) and 'fasting' (400-600 kcal consumed between 12 to 2 PM). Body mass (BM), fat mass (FM), and fat-free mass (FFM) were measured using direct segmental multi-frequency bioelectrical impedance analysis (InBody 720). Within-subjects t-test was performed for repeated measures analyses.

RESULTS: There were significant reductions in all outcome measures post-intervention ($p < .001$). On average, the participants experienced a change of -2.4 [95% CI -2.9, -1.9] kg in BM (80.9 to 78.5 kg), -0.8 [95% CI -1.0, -0.6] kg/m2 in BMI (26.7 to 25.9 kg/m2), -1.6 [95% CI -2.0, -1.2] kg in FM (19.7 to 18.1 kg), -0.8 [95% CI -1.2, -0.3] kg in FFM (61.2 to 60.5 kg), and -1.4 [95% CI -1.9, -0.9] % points in percentage body fat, PBF (23.6 to 22.2%).

CONCLUSION: Short-term ADF over four weeks is effective in combating obesity through reductions in BM, BMI, FM and PBF. Expectedly, it also has a significant deleterious effect on FFM, an indicator of muscle mass. However, it should be noted that out of the total weight lost (2.4 kg), participants lost twice as much FM (1.6 kg) as compared to FFM (0.8 kg). These findings may have important implications for individuals who are looking to lose weight while preferentially losing more FM relative to FFM.

ASTAXANTHIN SUPPLEMENTATION IMPROVES CYCLING TIME TRIAL PERFORMANCE AND ATTENUATES EXERCISE-INDUCED OXIDATIVE STRESS AND MUSCLE DAMAGE IN HEALTHY ADULTS

TSAO, J.P., WANG, M.Y., CHIU, T.L.

CHINA MEDICAL UNIVERSITY

INTRODUCTION: The attenuation of exercise-induced whole-body oxidation stress, inflammation, and muscle damage are vital in sports competitions. However, astaxanthin (AST) is an oxygenated carotenoid and a ketocarotenoid, known for

its powerful biological antioxidant that occurs naturally in a wide variety of living organisms. Therefore, this experiment aims to investigate the effects of 4 days of high-dose AST supplementation (28 mg/day) on endurance performance, exercise-induced oxidative stress, inflammatory responses, and muscle damage in healthy adults.

METHODS: Ten healthy males (n=10, 22.5±0.90 yrs., body mass index (BMI) 22.9±0.83) were participating in this experiment and it was designed as a randomized, placebo-controlled, single-blind study. Participants were randomly assigned to either AST (28 mg/d for 4 days) or placebo trials with a 14-day washout period. On the fourth day of supplementation, a light-calorie breakfast (300 calories) was provided before the exercise challenge. After a one-hour rest, participants were required to perform a 75% maximal oxygen uptake (VO2max) time to exhaustion (TTE) cycling challenge. Blood samples were collected before, at the end of the TTE challenge, and every 20 mins during exercise to determine the physiology of exercise-induced oxidative stress, inflammation, and muscle damage.

RESULTS: The TTE under 75% VO2max cycling challenge has significantly increased after oral AST supplementation (AST: 5226.89 ± 273.493 (sec); Placebo: 4326.67 ± 150.196 (sec), $p < 0.05$). At the same time, the muscle damage marker (lactate dehydrogenase (LDH) and creatine kinase (CK)) were significantly lower at 20 min and at the end of TTE respectively in the AST treatment. The oxidation stress marker (malondialdehyde (MDA)) had a significantly lower response at 40 min and at the end of TTE respectively, compared to the placebo trial. However, no significant differences between AST and placebo trials were shown respectively among the blood biomarkers (glucose), anti-oxidation stress marker (total antioxidant capacity (TAC)) and inflammation marker (tumor necrosis factor-α (TNF-α)).

CONCLUSION: Bringing all the above evidence together, based study including the TTE cycling performance, physiology of exercise-induced oxidative stress and muscle damage, oral AST supplementation (28 mg/day) for 4 days can result in the attenuation in LDH, CK, and MDA indicators and also contain ergogenic properties, which is able to improve TTE cycling performance in healthy adults.

FLUOXETINE IMPAIRS MUSCULAR STRENGTH, POWER AND ENDURANCE PERFORMANCE PARTICULARLY WHEN IT IS CO-INGESTED WITH CAFFEINE: A CASE STUDY

GONZALEZ-AROCHA, A.1, MONTALVO-ALONSO, J.J.1, FERRAGUT, C.1, RODRÍGUEZ-MARTÍN, S.1, VALADÉS, D.1, PÉREZ-LÓPEZ, A.1

1. UNIVERSIDAD DE ALCALÁ

INTRODUCTION: The prevalence of depression among athletes is high due to several risk factors such as injuries, career termination, decline in performance, catastrophic performance or even as a consequence of the COVID-19 pandemic lockdown. Fluoxetine, a recurrent pharmacotherapy in depression, is one of the preferred treatment drugs in athletes since it does not seem to impair sports performance. Some athletes combine this drug with caffeine intake, a common nutritional supplement that improves muscular strength, power and endurance performance. Thus, the purpose of this study was to analyze the combined effect of fluoxetine and caffeine on muscular strength, power, and endurance performance.

METHODS: In this case study, a female participant (age: 25 years; body mass: 56.7 kg; fat mass: 13.4 kg) was recruited to visit the laboratory for five days to complete a familiarization day and four randomized experimental conditions: a) placebo (PLA); b) fluoxetine plus placebo (FLU+PLA); c) caffeine (CAF); d) fluoxetine plus caffeine (FLU+CAF). A total of 72h were allowed between experimental conditions to ensure recovery. Fluoxetine administration was conducted under medical consent and supervision, while 3 mg/kg of body mass of caffeine or maltodextrin (placebo) was provided 60 minutes after the test. The participant performed a muscular strength and power test for bench press and back squat exercises at 25%, 50%, 75% and 90% 1-repetition-maximum (1RM). Then, muscular endurance was assessed for both exercises at 65% and 85% 1RM performing one set until task failure.

RESULTS: FLU+CAF condition decreased mean velocity and power output in both exercises, bench press and back squat, at 75% and 90%1RM in the muscular strength and power tests. While the FLU+PLA condition decreased peak velocity as well as mean and peak power output at 25%1RM in the muscular strength and power. In addition, in the muscular endurance test, the FLU+CAF condition promotes a reduction in mean velocity and power output in both exercises at 85% 1RM. While the FLU+PLA condition stimulates a decrease in mean velocity and power output in both exercises at 65% 1RM.

CONCLUSION: Previous evidence support that fluoxetine administration did not alter sports performance. However, this case study indicates that fluoxetine could reduce muscular strength, power and endurance performance in isotonic exercise at low-to-moderate loads. Moreover, fluoxetine administration seems to counteract the ergogenic effect of caffeine and impair muscular strength, power and endurance performance when both drugs are co-ingested. Therefore, although further studies are needed, athletes diagnosed with depression on fluoxetine treatment should reconsider caffeine consumption as a nutritional supplement to enhance performance.

EFFECT OF LONG-TERM PRE-EXERCISE CREATINE INTAKE ON NON-INVASIVE MUSCLE DAMAGE MARKERS AFTER ECCENTRIC EXERCISE

INTRODUCTION: The intake of creatine has attracted attention as a means of preventing exercise-induced muscle damage (EIMD) caused by eccentric contraction exercise; however, there is insufficient knowledge on its effectiveness, including the duration of intake. On the other hand, although the use of repeatable non-invasive evaluation indices such as

imaging and urinary biomarkers for the evaluation of EIMD is expanding [1], the effect of creatine intake remains unclear. This study focused on long-term creatine intake with the aim of verifying how various markers change with EIMD based on 28 days' pre-exercise creatine intake.

METHODS: Twenty healthy young males (creatine group, n=10; placebo group, n=10) were stratified and randomly assigned to a group using the double-blind method and were instructed to take 3 g of either creatine monohydrate or placebo per day for 28 consecutive days. After the end of intake, the participants performed 50 repetitions of dumbbell exercises emphasising on eccentric contraction at 50% of the maximum lifting weight in the laboratory. Based on previous study [1,2], measurements were taken to verify the extent of EIMD at a total of 8 points: pre- and post-exercise, and 1, 24, 48, 72, 96, and 168 h after exercise. The measurement items were muscle shear modulus (SM) from ultrasound elastography images, urinary titin N-terminal fragments (UTF), maximum voluntary contractions (MVC), range of motion (ROM), upper arm circumference (50/75%), and subjective muscle pain (soreness: SOR)/muscle fatigue. Olink Target 48 Cytokine® was used for exhaustive analysis based on inflammatory markers, and exploratory analysis was conducted using urine samples collected at several timepoints. After the two-way analysis of variance, post hoc tests were conducted with the Bonferroni method, and the risk ratio was set as less than 5%.

RESULTS: The peak of change transitioned differently for each marker, as was seen in a previous study. An intergroup comparison revealed that the creatine intake group had significant differences in SM (96 and 168 h), MVC (post 48, 96, and 168 h), arm circumference (72, 96, and 168 h), and muscle fatigue (post 168 h) compared to the placebo group. Fluctuations in several inflammatory markers were also confirmed.

CONCLUSION: This study found that creatine exerted a notable inhibitory effect on the aforementioned markers, and the inhibitory effect was confirmed particularly several days after exercise. Creatine is expected to serve a role in accelerating the muscle recovery after exercise.

RELATIONSHIP BETWEEN BRANCHED CHAIN AMINO ACIDS AND INSULIN RESISTANCE IN WOMEN'S WATER POLO AND WOMEN'S SOCCER ATHLETES

ZHAO, D., WANG, C., WANG, B., FANG, M., HOU, B., ZHAO, H.

SHANGHAI RESEARCH INSTITUTE OF SPORTS SCIENCE

INTRODUCTION: To test the differences of branched chain amino acids(BCAA), insulin resistance and dietary intake index of female professional athletes and understand the occurrence of insulin resistance in female professional athletes. This study will provide research basis for the development of precise nutrition scheme for female professional athletes.

METHODS: The index of BCAA and insulin resistance in 54 female professional athletes were measured, and then the correlation between them was analyzed. The differences of serum branched chain amino acids between insulin resistance group and non-insulin resistance group were compared. The differences of serum branched chain amino acids, insulin resistance related indexes and dietary intake levels in different projects were analyzed.

RESULTS: Valine, isoleucine, leucine and BCAA were all positively correlated with blood glucose, HOMA-IR and skeletal muscle weight ($P < 0.05$). The levels of blood glucose, insulin, valine, isoleucine, leucine, BCAA and BMI in insulin resistance group were lower than those in non-insulin resistance group ($P < 0.05$). The BMI, skeletal muscle and blood glucose levels of young womens soccer were lower than that of adult womens soccer ($P < 0.05$), and the levels of total dietary energy, protein and carbohydrate intake were higher than that of adult womens soccer ($P < 0.05$). There was no significant difference between the two groups in insulin, HOMA-IR and HOMA-β ($P > 0.05$). The levels of insulin, HOMA-IR, HOMA-β, Valine, isoleucine, leucine and BCAA of female water polo players were higher than those of adult female soccers ($P < 0.01$). In addition, the levels of dietary total energy, protein, fat and carbohydrate were all higher than those of adult female soccer ($P < 0.01$).

CONCLUSION: Insulin resistance exists in womens water polo and womens soccer athletes who are engaged in high-intensity sports activities. The levels of branched chain amino acids are significantly correlated with insulin resistance. It is suggested that female professional athletes should pay attention to insulin resistance. Young athletes with high energy demands can be administrated with BCAA appropriately. Adult female professional athletes with high BMI and high dietary protein and fat intake should control BCAA intake to prevent the occurrence of insulin resistance.

EFFECTS OF CAFFEINATED COFFEE ON PHYSICAL AND COGNITIVE PERFORMANCE: DOSE, GENDER AND HABITUATION LEVEL

KARAYIGIT, R., KOZ, M.

ANKARA UNIVERSITY SPORT SCIENCE FACULTY

INTRODUCTION: Although effects of caffeinated coffee ingestion on physical performance is known, whether effects of different doses ingestion on physical and cognitive performance vary between genders and habituation is not known. The aim of this research is to investigate the effects of very low (1,5 mg/kg), moderate (3 mg/kg) and high (6 mg/kg) dose of caffeinated coffee ingestion on lower and upper body muscular strength, muscular endurance, sprint and cognitive performance in low, moderate and high habitually caffeine consumers male and female athletes.

METHODS: 69 athletes participated in this research, attended 4 test days in total by dividing 3 groups according to their habituation level: decaffeinated coffee (PLA), 1,5 mg/kg caffeinated coffee (LDOSE), 3 mg/kg caffeinated coffee (MODDOSE) and 6 mg/kg caffeinated coffee (HIGHDOSE) ingestion and performed skuat and bench press 1 repetition maximum (1RM) strength and 60% 1RM muscular endurance and sprint performance test. Cognitive performance (CP) was measured before coffee ingestion, after 60 min and after test protocol. Further, heart rate (HR) and ratings of perceived exertion (RPE) were measured at different time points.

RESULTS: As a results, caffeinated coffee did not increase muscular strength and upper body muscular endurance but 3 and 6 mg/kg doses increased lower body muscular endurance in only low and moderate habituation group and sprint performance enhanced with 6 mg/kg dose in all consumption groups. Additionally, in high consumption group, lower body muscular endurance performance increased only with 6 mg/kg caffeinated coffee but not with 3 or 1.5 mg/kg of caffeine. 6 mg/kg caffeinated coffee significantly improved cognitive performance but non doses affect heart rate and RPE.

CONCLUSION: This study partially supports the notion that ingest higher dose of acute caffeine than consume habitually to increase exercise performance in athletic population.

DIETARY CALCIUM INTAKE IN HEALTHY MEN AND ATHLETES: EFFECT ON FREE 25-(OH)D AND BIOAVAILABLE 25-(OH)D

ZAGRODNA, A.

UNIVERSITY OF HEALTH AND SPORT SCIENCES IN WROCŁAW

INTRODUCTION: An optimal supply of calcium is necessary for athletes to maintain bone health, skeletal muscle function, cardiac contraction and nerve conduction. Moreover, calcium and vitamin D are metabolically interrelated to serve endocrine functions. In some studies showed that calcium intake might be a significant determinant of serum vitamin D status. According to the "free hormone" hypothesis, current studies suggest that some functions of vitamin D may be more closely related to the free or bioavailable fraction of vitamin D than to total serum 25-(OH)D concentrations. Therefore, the aim of our study was to investigate whether different concentrations of habitual calcium intake influence serum free 25-(OH)D and bioavailable 25-(OH)D in healthy men and athletes.

METHODS: Sixty nine participants (healthy male [n= 27] and athletes – football players, judoists [n = 42]) took part in the study. Calcium intake was evaluated using a 7-days food record method. The subjects were divided into subgroups by dietary calcium intake (≥1000 mg/day versus <700 mg/day). Free (25-(OH)DF), bioavailable 25-(OH)D (25-(OH)DB) concentration were evaluated by calculation, using serum albumin and vitamin D binding protein levels. Total 25-(OH)D (25-(OH)DT) was assessed using LM-MS/MS. Two way analysis of variance, with healthy men/athletes as second variable was performed to analyse the effect of calcium intake on 25-(OH)DT, 25-(OH)DF and 25-(OH)DB. A statistical level of $p< 0.05$ was accepted. Analysis was performed in R for windows (version 4.2.2, Vienna, Austria).

RESULTS: Our study showed decreased 25-(OH)DF serum levels (12.19±5.72 pg/ml) in 33.3% of the healthy men group and the 40.5% (11.28±5.05 pg/ml) of the athletes group. There were no significant differences between groups (differing in calcium intake) in 25-(OH)DF, 25-(OH)DB, 25-(OH)DT. Subjects with low calcium intakes were compared with subjects with high calcium habitual intake, results showed that there was no significant levels of physical activity (healthy men vs athletes) x calcium intake grouping interaction effect on the mean serum 25-(OH)DF, 25-(OH)DB, 25-(OH)DT concentrations.

CONCLUSION: In summary, this study showed that 66.7% healthy men and 57.1% athletes did not covered the daily demand for calcium (RDA>1000 mg/d). It seems that healthy males and athletes with insufficient daily calcium intakes should receive a calcium – enhanced diet and in case of significant deficiency of calcium intake supplementation is necessary (apart from diet modification). Calcium intake grouping and the level of the physical activity had no effect on 25-(OH)DF, 25-(OH)DB, 25-(OH)DT concentrations. We found no evidence of a serum 25-(OH)DF, 25-(OH)DB sparing effect of high calcium intake, which has been referred to by some authors as "vitamin D economy."

THE EFFECT OF PHYSICAL EFFORT ON TOTAL- AND FREE FRACTION OF HYDROXYVITAMIN D IN THE NATIONAL TEAM MALE TRIATHLETES.

MALCZEWSKA-LENCZOWSKA, J.1, SURALA, O.1, GRANDA, D.1, SZCZEPANSKA, B.1, SITKOWSKI, D.2, LADYGA, M.2

INSTITUTE OF SPORT- NATIONAL REASEARCH INSTITUTE , WARSAW

INTRODUCTION: The standard indicator of vitamin D status is a total 25(OH)D concentration in the blood. Approximately 0.03% of this metabolite is the free form and remaining amount is bounded, mainly to vitamin D binding protein (VDBP). The major biologic function of VDBP is the regulation of both fractions of 25(OH)D in blood and the relationship between them [1,2]. Because only free fraction is able to exert their biological effects, it was hypothesized that this unbound form may be a better marker of vitamin D status than the classic measurement of a total 25(OH)D [1]. Recently, determination of free25(OH)D has also been proposed in physically active subjects [3]; however its usefulness in different physiological and pathological conditions has yet to be unequivocally confirmed in scientific studies [1,2].

The study aimed to investigate the direct effects of single, acute, and non-accustomed physical effort on serum of total- and free 25(OH)D concentration in male athletes.

METHODS: The study included 12 triathletes (members of the national team), aged 18.6 ± 2.1 years. They underwent maximal oxygen consumption (VO2max) test on a treadmill, and (1-3 days later) a 30-minute run (at 50% VO2max) on a 1.5-degree downhill treadmill (with an eccentric component), followed immediately by 3 x 3-min sprints at 100% VO2max

intensity, with a 1-min rests between them. Capillary blood was collected before, and 15 min, 3 and 24 hours after the exercise. The concentration of total- and free 25(OH)D (ELISA, DiaSource), VDBP (polyclonal antibodies ELISA, Immuniq), high sensitivity c-reactive protein (hsCRP - immunoturbidimetry, Roche), TNF-alfa (ELISA, R&D Systems) as well as phosphocreatine kinase activity (CK - enzymatic method, Roche), were determined. All post-exercise results were corrected for changes in plasma volume. Friedman's ANOVA with Dunn Bonferroni post-hoc test was used in the statistical analysis of the data.

RESULTS: Despite the lack of changes in hsCRP, significant post-exercise increase in CK activity in 3 and 24 h ($p<0.001$) and TNF-alpha ($p=0.005$) and VDBP ($p=0.002$) concentrations in 15 min were observed. Furthermore, the subjective severe muscle soreness the next morning was reported. At the same time, there were no significant post-exercise changes in the total- and free 25(OH)D concentrations, as well as in the total to free fraction ratio.

CONCLUSION: The presented results indicate that in healthy high-level athletes, acute non-accustomed physical efforts, had no effect on either of both vitamin D metabolites and the ratio of total to a free fraction. This suggests that a total 25(OH)D concentration in physically active subjects is an equally good indicator of vitamin D status as the free fraction.

ASSESSMENT OF ENERGY AVAILABILITY AND FACTORS ASSOCIATED WITH RED-S IN WEIGHT-SENSITIVE SPORTS AND WEIGHT CLASS ATHLETES DURING COMPETITIVE SEASON

HSU, Y.J., CHEN, M.Y., TSAI, J.S., LEE, M.C.

NATIONAL TAIWAN SPORT UNIVERSITY

INTRODUCTION: Relative energy deficiency in sport (RED-S) can negatively affect the health and performance of both male and female athletes. The underlying etiology of RED-S is low energy availability (EA), which occurs when there is insufficient dietary intake to meet exercise energy expenditure. The weight-sensitive sports and weight class athletes often having a high incidence of engaging in unhealthy nutrition and weight loss practices. Especially during the competitive season, weight-sensitive sports and weight class athletes reduce energy intake to achieve target body weight, changes in body composition occur due to fluctuations in energy expenditure and energy intake. LEA is when a higher training load is combined with low caloric intake so athletes are constantly in a state of calorie deficit. We aimed to assess dietary intake, energy expenditure, estimate EA, and assessed factors related to RED-S in weight-sensitive sports and weight class athletes during a competitive season.

METHODS: In a cross-sectional design study design, twenty athletes from judo (n = 10), weightlifting (n = 3) and rowing (n = 7) were included in this study. We measured dietary intake (24 h dietary-record) and exercise energy expenditure (EEE, accelerometry) over 4 days, including 2 weekdays (with training) and 2 weekend days (without scheduled training). Furthermore, we assessed body composition, and bone mineral density (dual-energy X-ray absorptiometry) and venous blood variables. Paired t-tests were used to compare dietary intake, EEE, macronutrient and EA between weekdays and weekend days. Other data expressed using descriptive statistics.

RESULTS: On weekdays, 90% of participants had an energy intake <30 kcal·kg·day–1, 20% had reduced EA (30-45 kcal·kg FFM·day–1), and 80% had low EA (<30 kcal·kg FFM·day–1). On weekend days, 69% of participants had an energy intake <30 kcal·kg·day–1, 62% had reduced EA (30-45 kcal·kg FFM·day–1), and 31% had low EA (<30 kcal·kg FFM·day–1). The EA was higher on weekend days (30 ± 15kcal·day–1) than on weekdays (18 ± 13 kcal·day–1; $p < 0.05$) because of the increase in EEE on weekend days. There were no differences in macronutrient consumption between weekdays and weekend days. Menstrual dysfunctions were reported in 22% of female participants. All participants had adequate bone health (Z-bone mineral density score: 1.6 ± 0.9), but 60% had concentrations of 25-OH vitamin D < 30 ng/ml, which is less than the levels of vitamin D deficiency.

CONCLUSION: There is still a prevalence of low EA in weight-sensitive sports and weight class athletes during competition season, have a high-risk of developing RED-S due to weight restrictions. High energy consumption resulting from sports training during the competition season requires athletes to increase their energy consumption to prevent the prevalence of low EA. Therefore, strategies to support the health of athletes and the energy availability of training are essential to optimize training results and prepare for competition.

EFFETS DE LA FEUILLE DE MORINGA OLEIFERA SUR LE TRAVAIL TOTAL LORS D'UNE EPREUVE D'ENDURANCE

GBEDINHESSI, D.G.E., MARY-POULIOT, M., RAYMOND, L., ST-PIERRE, D.H., DANIALOU, G., COMTOIS, A.S.

UQAM

INTRODUCTION: Moringa Oleifera is a plant found in tropical regions and whose different parts (leaves, seeds, root, bark) are used in food or in traditional medicine to treat different pathologies. Its nutritive, antioxidant, anti-inflammatory, analgesic, antimicrobial, vasodilator and ergogenic properties make this plant a candidate for improving sports performance. The objective of this study is to compare the total work during an endurance test before and after taking a Moringa Oleifera leaf tea.

METHODS: the total work done by 8 participants (5M, 3F, Age: 25.6□1.8 years, Weight: 68.6□5.6 kg, Height: 168.9□3.4 cm, VO2max: 44.1□3 ml/kg/min, SV2: 33.1□2.32 75 %VO2max) during a 20km time trial was measured. During the test, the load was set at a power (150□17.7 Watts) corresponding to the ventilatory threshold 2 (SV2) of the participants. In the back-

ground, the Heart Rate (HR) reached during the test, the perception of exertion (RPE) and the blood lactate level were also measured. We will use a paired-samples t-test to compare the mean of our different variables before and after the intervention. Significant difference will be defined as $p<0.05$. Analyzes will be performed using SPSS 27.0 statistical software for the social sciences.

RESULTS: The total work done by the participants during the endurance test was not significantly different (Δ 263.4□96.1 vs 261.7□100.7 kJ, p = 0.772, d=0.1). HR (Δ 176.9□11.9 vs 182.2□39.7 bpm, p=0.757, d=-0.1), RPE (Δ 14.9□3.5 vs 16.5□2.5, p=0.236, d= -0.5), lactate [La+] (Δ 11.8□2.8 vs 10.6□3.2 mmol/L, p=0.351, d=0.4) are not significantly different.

CONCLUSION: The preliminary study carried out showed that the Moringa Oleifera leaf does not improve the total work at SV2. Faced with this observation, we believe that the Moringa Oleifera leaf will have an effect on the total work at ventilatory threshold 1 (SV1). As the study is ongoing, the final result will be presented at the congress.

SELF-DECLARED PREVALENCE OF SLEEP AIDS USE IN POLISH ATHLETES

POKRYWKA, A.1,2, SURALA, O.3, BEREZOVSKA, D.1, KRZYWANSKI, J.4,5, RYNKOWSKI, M.2

1 MEDICAL UNIVERSITY OF WARSAW; 2 POLISH ANTI-DOPING AGENCY; 3 INSTITUTE OF SPORT – NATIONAL RESEARCH INSTITUTE, POLAND; 4 NATIONAL CENTRE FOR SPORTS MEDICINE, POLAND; 5 POLISH ATHLETIC ASSOCIATION

INTRODUCTION: The prevalence of sleep inadequacy is high among elite athletes. Sleep disturbances are observed in 50-78% of athletes, whereas 20-26% experience highly disrupted sleep [1]. Sleep inadequacy management requires a coordinated approach based primarily on non-pharmacological interventions, i.e. sleep education, screening and treatment [1]. Nonetheless, to optimize sleep, athletes and their medical practitioners often turn to supplements (despite the paucity of evidence regarding their efficacy) and pharmacological sleep aids [2], regardless of premises suggesting the side effect profile of some sleep medications, including overreliance and its addiction potential [2,3]. Available evidence regarding prescribed, over-the-counter sleep medication and sleep supplement intake among elite athletes is limited. Thus, the study aimed to assess the use of sleep aids, i.e. medications and/or dietary supplements, in athletes.

METHODS: Doping control forms (DCFs) were assessed to investigate the list of all medications and dietary supplements the tested athletes reported using across the seven days prior to doping controls. DCFs were collected by Polish Anti-Doping Agency between 2018 and 2021. Statistical analyses were performed using the non-parametric Chi-squared test applying a significance level of $p<0.05$.

RESULTS: A total of 3902 DCFs (females: 33.0%, n=1287) from athletes (mean (±SD) age of 25±7 years) representing 47 different sports were included in the study. In 298 DCFs (7.6%), the use of sleep medications (n=149, mostly melatonin (23.8%), zolpidem (4.4%), trazodone (4.0%)), and/or sleep supplements (n=163, multi-ingredient) was declared. There was no significant difference between the prevalence of sleep medication and sleep supplement use ($p>0.05$). Females more often than males reported the use of sleep aids (10.6% vs 6.2 %,$p<0.001$), both psychiatric drugs (5.8% vs 2.8 %,$p<0.001$) and supplements (5.4% vs 3.6 %,$p=0.0095$). The highest incidence of sleep aid use was declared by athletes aged 21-25 (42.3%,$p<0.001$). The difference between the prevalence of sleep aid use reported during in- and out-of-competition doping controls was not significant, $p>0.05$. All data refers to the number of DCFs and not to athletes.

CONCLUSION: Considering that even one in four elite athletes might suffer from highly disturbed sleep, the percentage of Polish subjects declaring using sleep aids seems relatively small. The females reported the highest incidence of sleep aid use, supporting the previous findings that the female gender is a general risk factor for sleep inadequacy. Irrespective of gender, the athletes declared the use of supplements as often as sleep medications. In addition, despite competition being a high-risk period for sleep disruption, an increased rate of sleep aids use was not observed during in-competition doping controls.

EFFECT OF 7-DAY POLYPHENOL POWDER SUPPLEMENTATION ON CYCLING PERFORMANCE AND LUNG FUNCTION IN AN OZONE-POLLUTED ENVIRONMENT.

MORTON, L.

UNIVERSITY OF AUCKLAND

INTRODUCTION: Polluted environments that are high in ozone can adversely affect lung function and limit exercise performance. Evidence suggests that some nutrient supplements may offset pollutions detrimental effects. This study aimed to determine the effect of supplementation of a polyphenol powder at a dose that provided 4.3 mg/kg bodyweight anthocyanins for seven days on exercise performance and lung function in a high ozone environment.

METHODS: The study was a randomised, double-blind, placebo-controlled crossover design. Ten trained cyclists (mean ± SD: age, 43.8 ± 12.38 years; height, 177.75 ± 7.1cm; weight, 76.02 ± 7.88 kg; VO2max 4.23 ± 0.79 L.min-1age) performed a maximal incremental test to determine peak power output (PPO) and a 4-km time trial (TT). Thereafter cyclists completed two experimental trials in an ozone environment (0.25 ppm) following 7-days of supplementation with either polyphenol blend (PB) or placebo (PL). The experimental protocol consisted of cycling for 10-min at 50 %, 10-min at 60 % and 5-min at

70% of incremental peak power output (PPO) achieved in the VO2max test. This was followed by 10 minutes of rest and then a maximal 4-km cycling time trial. Lung function (FVC, FEV1, FeNO) was measured pre- and post-exercise in the experimental trials.

RESULTS: VO'2 (L-1) was significantly higher in the PB group during the 4 km TT (p = 0.01), with significantly higher average power (Watts) in the first km of the TT (p = 0.01). Time to complete the 4 km TT was 4.3% faster following PB supplementation (406.4 ± 50.29 sec) compared to PL (426.2 ± 75.06 sec, p = 0.09, d = 0.31). PB supplementation significantly reduced the severity of cough experienced during ozone exposure (p = 0.03) but did not protect lung function (FEV1, FVC) following cycling in ozone.

CONCLUSION: Supplementation with a proprietary blend of polyphenols at an anthocyanin dose of 4.3 mg/kg bodyweight for 7-days may attenuate the decrease in exercise performance during cycling in an ozone polluted environment and reduce cough symptoms.

PROTECTIVE EFFECTS OF HIGH-FAT DIET AND AEROBIC EXERCISE TRAINING ON EXERCISE PERFORMANCE AND LIPID METABOLISM IN AGING FEMALE MICE WITH DIFFERENT INTRINSIC AEROBIC CAPACITY

HUANG, C.C.

NATIONAL TAIWAN SPORT UNIVERSITY

INTRODUCTION: Although aerobic endurance is generally considered an important factor in combating metabolic dysfunction, promoting health, and improving physical fitness and performance. However, there are few studies to investigate whether there is a significant difference in the severity of hyperglycemia, hyperlipidemia, hypertension diseases under high glucose between high- or low- intrinsic endurance capacity, and their possible mechanisms. We have successfully established (via artificial selection) tow mouse models with high and low aerobic endurance capacity, and are designated as the high-aerobic exercise capacity (HAEC) and low-aerobic exercise capacity (LAEC) lines for 22 generations. Through high fat diet (HFD) to simulate the metabolic syndrome caused, and the aim is current study was to investigate the effects of metabolic diseases and physiological and biochemical effects on aging mice with different intrinsic aerobic capacity under HFD and exercise training.

METHODS: We used female HAEC and LAEC mice naturally aged to 19 months, and assigned them to normal diet, high-fat diet (HFD), and high-fat diet combined with exercise training groups, respectively. After 6 weeks of HFD and aerobic exercise training, the exercise capacity and physiological metabolic indicators were tested.

RESULTS: We found that, although both HAEC and LAEC aging mice could cause significant weight gain under the induction of HFD, HAEC aging mice lose 5.56% of body weight and 57.18% ovary fat pad compared with LAEC aging mice, and exercise training was significantly reduced 10% body weight ($p<0.05$). Although both HAEC and LAEC aged mice had decreased muscle strength and endurance performance induced by a HFD, but HAEC aged mice still had better exercise performance maintenance and aerobic training for 6 weeks It has the effect of significantly improving sports performance ($p<0.05$). In addition, under the induction of HFD and the intervention of aerobic exercise training, HAEC aging mice significantly improved glucose tolerance, stable blood pressure, and the metabolism of total cholesterol and triglycerides in blood and liver compared with LAEC aging mice ($p<0.05$).

CONCLUSION: In conclusion, we found that although a HFD is one of the risk factors for metabolic diseases, intrinsic high aerobic capacity has a better protective effect. In addition, under aerobic exercise training, aging mice regardless of HAEC or LAEC have a protective effect on body composition and lipid metabolism, but the natural high aerobic capacity has better and more significant benefits.

CLASS, ORDER, AND FAMILY CHANGES OF GUT MICROBIOME BY AEROBIC EXERCISE

YUN, S., LEE, M., LEE, Y., PARK, J., WE, H., LEE, S., LEE, D.T.

KOOKMIN UNIV.

INTRODUCTION: The gut microbiome can be modified by disease, diet, and others affecting general health. This study aimed to explore whether aerobic exercise can change the Class, Order, and Family of the gut microbiome.

METHODS: Twenty four men were recruited and divided into two groups; Non-Exercise Group (NEG, n=8, 28.6±5.3 yrs, 176.0±7.8 cm, 81.3±14.6 kg, 26.1±3.3 kg/m2), and Exercise Group (EG, n=16, 28.6±5.1 yrs, 175.5±4.4 cm, 76.6±10.6 kg, 24.8±3.0 kg/m2). For the inclusion in the study, their physical activity level, intestinal health status, disease prevalence, medical history, and eating disorder were assessed. EG performed more than 30 min of aerobic exercise per day, 3 or more days per week, for 4 weeks at a moderate intensity predicted from the maximal aerobic capacity test. NEG did not participated in any exercise program during 4 weeks. Their basal level of gut microbiome was examined by stools collected one morning after a 10-hour fasting before and after 4 weeks. Data were analyzed using Wilcoxon. The one level of error was set to α=.05.

RESULTS: In the Class level, EG increased Bacteroidia (44.2±16.7 to 54.6±12.3%, p=0.002) and Deltaproteobacteria (0.09±0.16 to 0.25±0.33%, p=0.03) after 4 weeks, while Bacilli (0.31±0.41 to 0.09±0.09%, p=0.009), Clostridia (38.7±17.4 to 32.0±14.0%, p=0.008), and Negativicutes (9.6±7.1 to 7.1±4.3%, p=0.025) were decreased. In the Order level, EG increased Bacteroidales (44.2±16.7 to 54.6±12.3%, p=0.002) and Desulfovibrionales (0.09±0.16 to 0.25±0.33%, p=0.03) after 4 weeks, while Lactobacillales (0.31±0.41 to 0.09±0.09%, p=0.011), Clostridiales (38.7±17.4 to 32.0±14.0%, p=0.008), and Selenomonadales (9.6±7.1 to 7.1±4.3%, p=0.025) were decreased. In the Family level, EG increased Bacteroidaceae (22.3±13.4 to 28.9±14.9%, p=0.021), Prevotellaceae (19.8±25.7 to 22.6±25.7%, p=0.029), and Desulfovibrionaceae

(0.09±0.16 to 0.25±0.33%, p=0.03) after 4 weeks, while Streptococcaceae (0.21±0.28 to 0.06±0.07%, p=0.021), Lachnospiraceae (26.0±14.9 to 17.6±10.4%, p=0.002), and Veillonellaceae (6.03±8.04 to 3.94±4.78%, p=0.011) were decreased. No changes in any variables after 4 weeks in NEG were noticed.

CONCLUSION: Based on the results, the gut microbiome in the level of Class, Order, and Family strata were changes only in the aerobic exercise group. An additional research for the function and role of the microbiome is warranted.

CHLORELLA INTAKE COMBINED WITH SHORT-TERM HIGH INTENSITY INTERMITTENT TRAINING FURTHER ENHANCES AEROBIC AND ANAEROBIC CAPACITIES IN ATHLETES: A DOUBLE-BLIND RANDOMIZED STUDY

FUJIE, S.1, INOUE, K.1,2, TSUJI, K.2,3, HORII, N.2, OSHIDEN, M.1, MIZOGUCHI, T.4, OKUMURA, E.4, TABATA, I.1, IEMITSU, M.1

1>RITSUMEIKAN UNIVERSITY; 2>RESEARCH FELLOW OF JAPAN SOCIETY FOR THE PROMOTION OF SCIENCE; 3>HOSEI UNIVERSITY; 4>SUN CHLORELLA CORP.

INTRODUCTION: High intensity intermittent training (HIIT) enhances aerobic and anaerobic capacities in the athletes. Chronic intake of chlorella (CH), which is a type of unicellular green algae that contains various nutrients, increases aerobic capacity in young men. Our study using rats has demonstrated that chronic CH intake combined with HIIT further accelerated exercise performance as compared with HIIT alone. However, it is unclear whether the chronic CH intake combined with HIIT has more pronounced effects on aerobic and anaerobic capacities in the athletes. Therefore, we aimed to investigate the effects of chronic CH intake combined with short-term HIIT on aerobic and anaerobic capacities in the athletes using both laboratory and field tests.

METHODS: [Study 1: Laboratory test] Eleven female track and field athletes (100m-400m sprinters) were randomly divided into two groups; HIIT combined with CH intake (HIIT+CH) group and HIIT combined with placebo intake (HIIT+PL) group. They completed 4-week of exhaustive HIIT, consisting of 6-7 bouts of 20-second running on a treadmill with a 5% incline at an intensity of 170% maximal oxygen uptake (VO2max) with a 10-second rest between each bout, 3 days/week. They orally took CH or PL (15 tablets) after the breakfast and dinner between the 4-week in a double-blind, randomized, placebo-controlled trial. We measured the VO2max, and maximal oxygen deficit (MOD) before and after the intervention. [Study 2: Field test] Ten female lacrosse players completed 3-week of exhaustive HIIT, consisting of 7 bouts of running at full speed with a 10-second rest between each bout, 5 days/week. They orally took CH or PL between the 3-week in a double-blind, randomized, placebo-controlled, crossover design with a 5-week washout period. We measured the 20 m shuttle run as an index of aerobic capacity and sprint time for 50 m as an index of anaerobic capacity. All statistical analysis were performed using the paired Student's t-test or the unpaired Student's t-test. Significance was set at $P<0.05$.

RESULTS: [Study 1: Laboratory test] After each HIIT intervention, VO2max and MOD were significantly increased in both CH and PL groups ($P<0.05$). However, the changes in MOD were significantly higher in the HIIT+CH group than the HIIT+PL group (HIIT+CH: 6.5±3.0 ml/kg vs. HIIT+PL: 2.0±2.4 ml/kg, $P<0.05$). There were no significant differences of VO2max between the HIIT+CH and HIIT+PL groups. [Study 2: Field test] The 20 m shuttle run in the HIIT+CH group was significantly increased after the intervention (pre: 90.3±9.7 laps to post: 93.7±9.1 laps, $P<0.05$), but did not change in the HIIT+PL group. The sprint time for 50 m in the HIIT+CH group was significantly increased after the intervention (pre: 8.0±0.4 sec to post: 7.8±0.4 sec, $P<0.05$), but did not change in the HIIT+PL group.

CONCLUSION: These results suggest that the CH intake combined with short-term HIIT may further enhance aerobic and anaerobic capacities in the track and field athletes and lacrosse players.

EFFECTS OF SLEEP RESTRICTION AND CAFFEINE SUPPLEMENTATION ON RUNNING TIME-TRIAL PERFORMANCE

WANG, H.S., TSAI, Y.S., CHAN, Y.C., CHEN, T.T., CHEN, Y.C.

NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: Sleep restriction is a reduction of time in sleep under usual levels, which may impair endurance performance. Caffeine is a widely used supplementation for enhancing endurance performance but it is unclear whether caffeine intake after sleep restriction would be an effective way to maintain endurance performance.

METHODS: 10 physically active healthy young men (Age: 26.9 ± 5.8 years; Body mass: 64.2 ± 5.8 kg) were recruited and completed four trials in a balanced Latin square design. The four trials were sleep restriction + caffeine (SR-C), normal sleep + placebo (NS-P), sleep restriction + placebo (SR-P) and normal sleep + caffeine (NS-C). Sleep restriction was arranged during 03:00 to 06:00 (3 hours) while normal sleep was between 22:00 to 06:00 (8 hours). A 10-km treadmill time trial (TT) was conducted in the morning following SR/NS, and either supplementation of caffeine (6mg/kg body mass) or placebo in capsules was consumed an hour before the TT. Glucose, lactate and free fatty acid (FFA) were measured at post-sleep (Post-Sleep), pre-exercise (Pre-Ex) and immediately post-exercise (Post-Ex). Heart rate, rating of perceived exertion (RPE) and respiratory data were collected during the 10-km TT test.

RESULTS: The 10 km TT was improved by 4.9 % on NS-P (49.4 ± 6.9 min) compared to SR-P (52.0 ± 7.8 min), by 7.7 % on SR-C (47.8 ± 7.3 min) compared to SR-P, and by 2.8 % on NS-C (48.0 ± 6.4 min) compared to NS-P (all, $p < .05$). Respiratory exchange rate, % VO2max, lactate, and FFA were not different between four trials (all, $p > 0.05$), but heart rate was signifi-

cantly higher on caffeine trials (p<.05). RPE were significantly higher during SR-C than SR-P at 6 km and 10 km. Moreover, blood glucose on caffeine trials were higher than placebo trials at Post-Ex (131.5 ± 28.6 vs. 118.3 ± 25.0 mg/dL; p<.05).

CONCLUSION: Caffeine supplementation (6 mg/kg body mass) before exercise would offset the negative effects of sleep restriction on endurance performance.

EXPECTANCY IN CHARGE: AN UMBRELLA REVIEW OF THE PLACEBO EFFECTS IN MOTOR PERFORMANCE AND PERCEPTIONS

BRIETZKE, C., RIBEIRO, W.A., FRANCO-ALVARENGA, P.E., CANESTRI, R., VÍNICIUS, I., VASCONCELOS, G., CESARIO, J., JUNIOR, N.C., PAINELLI, V.S., PIRES, F.O.

SCHOOL OF ARTS, SCIENCES AND HUMANITIES. UNIVERSITY OF SÃO PAULO

INTRODUCTION: The placebo effect is a response from inert treatments supposedly eliciting a true treatment-like effect through a shared reward circuit mechanism [1,2]. Systematic reviews and meta-analyses (SRMA) from original studies have played an important role in scientific and clinical physical exercise scenarios, as they have confirmed the presence of a placebo-induced enhancement in strength and endurance performance. However, we are unaware of umbrella studies evaluating the quality of the SRMA approaching placebo effects in exercise settings. Therefore, we conducted a comprehensive umbrella review to assess the methodological quality and placebo effects summarized by SRMA.

METHODS: Peer-review literature was searched through PubMed, Embase, Cochrane Library, Virtual Health Library databases, while grey literature was accessed through Prospero and Open Access Theses and Dissertations databases. Reviews assessing placebo and nocebo effects on motor performance, pain, and fatigue outcomes were eligible if: Population: human participants from varied health and training status; Intervention: placebo effect elicited by any active treatment; Comparator: control condition with (i.e. positive control) or without active treatment; Outcome: motor performance (primary outcome) and perceptual responses such as perceived exertion and fatigue sensation (secondary outcome). The effect sizes reported by eligible reviews were presented. The methodological appraisal was assessed using the AMSTAR-2 checklist.

RESULTS: After an initial search retrieving 3.432 reviews, 9 reviews were considered eligible after 2-round screenings performed by 3 independent researchers. AMSTAR-2 checklist indicated that methodological quality varying from low (n = 3) to high quality (n = 2) and the median is moderate (60% of "yes"). Meta-analyses revealed that the the effect sizes varying from 0.02 (small) to 0.67 (moderate).

CONCLUSION: This review demonstrates that despite the placebo effect being widely investigated, the range of effect have a large variability and the quality of SRMA addressed to investigate it is only moderate.

COMBINED EFFECTS OF COCOA FLAVANOL INTAKE AND RESISTANCE EXERCISE ON EXECUTIVE FUNCTION

YUUKI, I.W.1, SUZUKI, A.1, DORA, K.1,2, MATSUMURA, T.1, FUKUZAWA, K.1, MURAKAMI, Y.1, NONOYAMA, S.1, TSUKAMOTO, H.1, HASHIMOTO, T.1

RITSUMEIKAN UNIVERSITY 1>, TOYO UNIVERSITY 2>

INTRODUCTION: Executive Function (EF) and Muscle Strength are important factors in performing sports. Resistance exercise is the best exercise program for maintaining and strengthening skeletal muscle and importantly is known to acutely/chronically improve EF. Generally, relatively higher intensity resistance exercise (HRE) might induce better muscle as well as cognitive function. However, HRE promotes the worsening of arterial stiffness. On the other hand, low-intensity resistance exercise improves arterial stiffness (1). Interestingly, the acute effects of resistance exercise on EF enhancement were comparable between HRE and high-volume and low-intensity resistance exercise (HV-LRE) (2), which is also an effective exercise for maintaining and strengthening a skeletal muscle. Additionally, high cocoa flavanol (HCF) intake has been reported to acutely improve EF. For instance, HCF intake enhances aerobic exercise-induced improvement in EF (3). Therefore, we hypothesized that HCF intake would further enhance resistance exercise-induced improvement in EF (inhibitory control; IC and working memory; WM). To test these hypotheses, we examined the combined effects of HCF intake and HV-LRE on IC and WM.

METHODS: Fifteen healthy young men received either an HCF or low cocoa flavanol (LCF) 1 hour before exercise. Exercise intensity for HV-LRE w 40% of one-repetition maximum for both conditions. HV-LRE was programmed for 5 sets with 25 repetitions per set. Stroop task (IC) and N-back task (WM) were evaluated before intake, 1 hour after intake (before exercise), and immediately after exercise. The data were analyzed by 2-way Repeated Measures ANOVA (Treatment × Time). In addition, a posterior test for significant differences between time points was confirmed by a paired t-test with Bonferroni correction. To compare the effects of HCF and LCF, the amount of change at each time point from baseline was confirmed by a paired t-test.

RESULTS: No significant interaction of HV-LRE and HCF on IC and WM was shown. IC was significantly higher immediately after exercise in HCF ($P < 0.05$) than LCF. In contrast, HV-LRE had no effect on IC. WM was significantly higher in HCF ($P < 0.05$) than LCF before exercise.

CONCLUSION: This study found that HCF enhances IC immediately after exercise and that HCF acutely enhances WM, while HCF intake did not further enhance resistance exercise-induced improvement in IC and WM.

THE IMPORTANCE OF THE ENDOCANNABINOID SYSTEM AND THE ROLE AND RISK OF CBD IN SPORTS NUTRITION

SHENKER-HORVÁTH, K.1, PÁLINKÁS, Z.1, BÁNYAI, B.2, BEDNÁRIKNÉ DÖRNYEI, G.3, SZEKERES, M.3, SZILÁGYI-UTCZÁS, M.1
1 HUNGARIAN UNIVERSITY OF SPORTS SCIENCE; 2 SEMMELWEIS UNIVERSITY; 3 SEMMELWEIS UNIVERSITY

INTRODUCTION: It has been revealed that the endocannabinoid system (ECS) plays an important role in several physiologic regulatory mechanisms, including neuronal development, nociception, inflammation, appetite regulation, digestion, energy metabolism, brain plasticity, learning and memory, and regulation of stress and emotions. The two major endocannabinoids, anandamide and 2-arachidonoglycerol (2-AG), interact with cannabinoid receptors, namely CB1 and CB2 receptors, resulting in similar effects to those seen after taking the psychoactive constituents of the cannabis plant. The cannabis plant contains more than 140 cannabinoids with the most notable being Δ9-tetrahydrocannabinol (THC) and cannabidiol (CBD). In addition to the involvement of the ECS and the cannabinoid signalling pathway in certain physiological and pathological functions, the therapeutic potential of legal CBD is becoming increasingly important. Evidence suggesting that CBD has the potential to be used as a part of the strategies to recover from fatigue and muscle damage related to physical and cognitive exertion in sports. Within the realm of elite sport, CBD use has increased exponentially, which is likely due to its removal from the World Anti-Doping Agency (WADA) prohibited list of banned substances. However, other natural and synthetic cannabinoids are still remained prohibited. Furthermore, since 2021 THC has been considered as a "Substance of abuse" by WADA. Therefore the analysis of dietary supplements (DS) and foods containing CBD is of huge importance.

METHODS: Our scope was to analyse DS and foods containing CBD with suitable and innovative chromatographic techniques (liquid (LC) and gas (GC)) coupled to mass spectrometry (MS). Our analytical methods were optimized to obtain low, but also practical limit of detection of the 10 most present cannabinoids. Two well-complementary and substitutive limit test methods were developed using LC-MS/MS and GC-MS/MS techniques prior to a common sample preparation (except for derivatization for GC). At the validation, detection limits of 100 ng/g and 100 ng/ml were determined.

RESULTS: Among 11 different analysed products with cannabis extract or CBD (e.g. chewing gum, chocolate, DS, oil) 4 of them contained almost one prohibited cannabinoid. At the same time in 3 cases the measured content of the desired active substances, CBD, was not detected.

CONCLUSION: The therapeutic potential of cannabinoids in a sporting context is particularly exciting given the ability to interact with the body's own endocannabinoid system. However the use of CBD products are likely to contain other cannabinoids which remain prohibited by WADA, thus the use of CBD at present remains a high risk for an anti-doping rule violation (ADRV). The developed methods can support the choice of safe DS used by elite athletes. It is crucial that practitioners and dietitians educate themselves on the science of CBD and fully understand the complexity of this product when it comes to the potential for an ADRV.

THE EFFECTS OF AN ACUTE DOSE OF NEW ZEALAND BLACKCURRANT EXTRACT ON 5 KM RUNNING PERFORMANCE

MOSS, S., BRINDLEY, E., ENRIGHT, K., HIGHTON, J., BOTT, R.
UNIVERSITY OF CHESTER; LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: This study investigated the effects of a large (900 mg) acute dose of New Zealand Blackcurrant extract (NZBC) on 5 km running performance and associated physiological responses.

METHODS: Sixteen trained male runners (age 26 ± 5 years, stature 173.4 ± 7.3 cm, body mass, 73.7 ± 6.9 kg, VO2max 55.4 ± 6.1 ml.kg-1.min-1) ingested either capsules containing NZBC (3 x 300 mg CurraNXTM, 315 mg anthocyanins) or a matched placebo (3 x 300 mg gluten free flour) 2 hours before exercise in a double-blind, randomised, crossover design. Performance time and physiological responses were assessed in a 5-km time-trial, preceded by 10 min steady-state exercise at the lactate threshold on a treadmill.

RESULTS: NZBC did not alter the physiological responses to steady-state exercise (VO2, RQ, VE, carbohydrate oxidation, fat oxidation, heart rate, blood lactate or Rating of Perceived Exertion, P>0.05). The 5-km time-trial was completed in a faster time in the NZBC condition compared to placebo (P=0.001, ES=0.30 ± 0.15; NZBC: 1308.96 ± 122.36 s, Placebo: 1346.33 ± 124.44 s). No differences in physiological responses were apparent between conditions for the 5-km time-trial (P>0.05).

CONCLUSION: Ingesting a large acute dose of NZBC improves performance in trained runners without altering cardiovascular or metabolic responses to exercise. Further research is needed to better understand the mechanisms underpinning improved performance following supplementation.

Philosophy and Ethics

Physical Activity Promotion

THE EFFECT OF THE HUMANITUDE CARE DANCE PROGRAM ON LIFE SATISFACTION OF THE ELDERLY.

LEE, J., KIM, H.

KOREA NATIONAL SPORT UNIVERSITY

This study was performed to examine the effects of the Humanitude care dance program on life satisfaction of the elderly. Twenty participants were divided into a experimental group (n=10, aged 77.6) and a control group (n=10, aged 77.3). The experimental group performed 12 classes of the Humanitude care dance program for two months(2 days per week, 50 min per session). As the result, life satisfaction score improved ($p<.05$), and changed by the program. These results show that this type of care dance program may help improve life satisfaction of the elderly as well as maintain their health condition.

COMPREHENSIVE ASSOCIATION BETWEEN THE NUMBER OF PEOPLE WHO EXERCISE REGULARLY TOGETHER AND VARIOUS FACTORS.

IKEDA, T.1, SAKAGUCHI, H.2, ANNOURA, T.2, NAGAMINE, K.3, AOYAGI, O.3

1 NISHI-KYUSHU UNIVERSITY, 2 JAPAN UNIVERSITY OF ECONOMICS, 3 FUKUOKA UNIVERSITY

Introduction

People engage in regular exercise in a variety of forms, some for health reasons and others for social interaction with the opportunity to exercise with others. Depending on the purpose of regular exercise, it is natural that the number of people who exercise on a regular basis and the purpose and environment of the exercise vary. Thus, this study examines the relationship between the number of people exercising together and various factors.

Methods

A questionnaire survey consisting of 12 items related to the number of people who exercise together was administered to 1,204 Japanese subjects in their late teens to middle age and older, covering sex, age, daily free time, self-evaluation of physical fitness, the purpose of the exercise, liking or disliking physical education as a child, involvement in non-sports activities, introversion and diplomacy, and expenditures for exercise and medical care. The respondents were also asked if they "Want to exercise alone;" "Want to exercise with a few people;" or "Want to exercise with a large number of people." In order to examine the comprehensive relationship between the frequency of the number of people exercising for each of the three patterns and the above factors, a canonical correlation analysis was conducted between the frequency of exercise by the number of people and the various factors, of which data are dummy-transformed.

Results

The canonical correlation coefficient obtained was 0.586 and significant at the 0.1% level ($Fo=2.92$, $df=[423, 10183]$, $P<0.001$). As for exercise orientation by the number of persons engaging together, the regression coefficient for the option "Want to exercise very much" was the largest for all groups and became smaller as the degree to which to want to exercise became less. In other words, it was not the case that only those who exercise with a specific number of people wanted to exercise more regularly, but those who were exercise-oriented tended to want to exercise in general, regardless of the number of people in the group. Among them, the regression coefficient for "Very much" for "With five or more people" was the highest at 0.963, and the structure coefficient was also the largest at 0.700, indicating that the canonical score in this model has a large exercise orientation with a large number of people. Based on this assumption, the structural coefficients for the association with various factors showed that higher values were obtained for the following factors: health benefits (0.600); elementary school physical education enthusiasts (0.537); exercising for health (0.520); boys (0.369); reducing medical costs (0.368); and being physically fit (0.319). In other words, those who exercise regularly tend to be boys, those who are health-oriented, and those who were confident in their physical fitness and had exercised since childhood. However, there was no association with age, free time availability, classes taken, or personality.

AN INVESTIGATION INTO THE EFFECT OF PLAY UPON THE DEVELOPMENT OF SOCIAL SKILLS AND ENGAGEMENT IN PHYSICAL ACTIVITY AMONG JAPANESE CHILDREN AGED 10–12

IKEDA, T.

FUKUOKA PREFECTURAL UNIVERSITY

Introduction

The objective of this study was to test the veracity of the contention that play is an important factor in child development and that a paucity of play may cause a decline in a childs physical strength and his or her inclination to engage in physical activity. To this end, the study investigated the relationship between the type of play, the development of social skills, and engagement in physical activity among Japanese children in the 5th- and 6th-grades of elementary school.

Methods

The research subjects were 794 children (boys: 391; girls: 403) aged between 10 and 12 years old. Each individual child was asked to assess themselves in response to a questionnaire consisting of (i) 25 items relating to the ability of their play (AP), (ii) 27 items relating to their social skills (SS), and (iii) 3 levels (light: LPA, middle: MPA, and heavy: HPA) relating to their physical activity. The survey was designed to be completed anonymously and to comply with ethical considerations. The resultant data was analyzed using IBM SPSS version 25.

Results

By subjecting the data to factor analysis using the principal factor method and promax rotation, three AP factors were extracted (F1: ingenuity in play, F2: internality and relationships, F3: consideration in play, factor contribution rate = 37.6%), with a further four factors being obtained for SS (F1: sense of responsibility and empathy, F2: aggressive and claim, F3: communication, F4: receptivity, factor contribution rate = 44.0%). As a result of applying the multi-dimensional unfolding (MDU) method and identifying relationships between factors, a correlation was observed between SS relating to a "sense of responsibility and empathy (SS-F1)" and each of the AP factors and, in particular, with "ingenuity in play (AP-F1)" and "consideration in play (AP-F3)". The ordered logistic regression analysis (chi-square value [9] = 44.3, $p < 0.001$) taking into account the effects of gender and age showed that children with more ability in terms of "ingenuity to play" were less likely to engage in LPA (b [1] = -0.517, $p < 0.001$). Meanwhile, and with respect to MPA, children with more ability in terms of "consideration in play" tended to spend more days engaged in physical activity (b [1] = 0.983, $p < 0.05$). For HPA, however, the data for play ability in "internality and relationships" (b [1] = -0.623, $p < 0.01$) and social skills in "communication" (b [1] = -0.509, $p < 0.05$) revealed that children with higher scores in these categories tend to engage in physical activity less.

Conclusion

The results of this study indicate that play does not necessarily enhance social skill or increase a child's inclination towards physical activity. Instead, the study suggests that, in order to facilitate the development of social skills and physical ability, a degree of ingenuity is required in order to determine the most appropriate type of play.

FROM HORIZONTAL TO VERTICAL, AN EXPERIENTIAL MOTOR PATH THROUGH A POST COVID OUTDOOR ACTIVITY

GAMBA, M., MANDOLESI, N.

HIGH SCHOOL/PLAY ACADEMY EDVIGE361°

28th ECSS Congress Paris 2023

INTRODUCTION: With a group of adolescents (13-18 years old), we intervened, after the pandemic period by creating an active motor and social experience immersed in nature localized in Umbria that has an enviable multiplicity outdoor activities, to return to a general balance that is the foundation of the life and well-being of each human. This experience already made in the past years, will repeated at the end of the school lessons, for three weeks,

METHOD: The horizontal dimension meets the vertical one to form a cross. Their intersection represents our individual story, with our limits and virtues, shadows and lights that always existed and will still exist. Daily monitoring through the socialization and cooperation of the various teams and personal questionnaires

RESULTS: Step by step through different paths: Walking orienting in a forest or following a new road with the mountain bike or climbing a rocky wall or Rowing between the rapids of a river to improve the self-esteem, the autonomy and initiative sense and to create collaboration with the group, to overcome our limits and fears.

DISCUSSION: A true active experience through a nature sport journey. A journey inside and outside of ourselves that allows to reach a goal, like a pilgrim and to go beyond our daily horizon, by putting ourselves into play. Promoting a healthier lifestyle should be an integral part of the adolescents overall education

WHERE IS RISKY PLAY OCCURRED AMONG ELEMENTARY SCHOOL CHILDREN DURING RECESS?

IMAI, N.

NIPPON SPORT SCIENCE UNIVERSITY

Background:

In recent years, "risky play," defined as "thrilling and exciting forms of physical play that involve uncertainty and a risk of physical injury", has attracted considerable attention. Such risky play practices have been positively associated with physical, mental, and social health. Furthermore, several studies have shown that the natural environment and the playground environment, including playground equipment, can influence risky play. For example, a previous study showed that the number of observed risky play was greater in natural playground than regular playgrounds among Norwegian children. However, limited evidence is available on where risky play is occurred among school-aged children during recess. The aims of the study were to 1) observe free play in various areas of a school and 2) identify where the risky play was occurred during recess among Japanese school-aged children.

METHODS: This study was conducted in November 2022 with elementary school children in grades 1-6 (aged 6-12 years) in Nagano Prefecture, Japan. The playground considered for this study was in the school premises. Using the event sampling method, we collected data on the types of play occurred during recess. We further categorized the observed play as either risky play (i.e., play with great heights, play with high speed, play with dangerous tools, play near dangerous elements, play involving risky elements, rough-and-tumble play, play where children go exploring alone, play with impact, and vicarious play) or non-risky play (i.e., play other than the above mentioned play). Moreover, to examine where the

observed risky play was taking place, we categorized the areas as follows: sandbox area, path area, natural area (trees and water), grass area, open area, fixed playground equipment area (swings, jungle gym, slide), and indoor area (gym).

RESULTS: Of the 42 types of play observed, 38.1% were grouped as risky play. The most common type of risky play was "play with high speed (11.9%)," followed by "rough-and-tumble play (9.5%)." However, "play with dangerous tools" and "play with dangerous tools" were never observed. The number of observed risky play was greatest in grass area compared to the other areas and the following activities were observed (e.g., tag, rolling on the side, sumo, playing fight, and picking grass and flowers). On the other hand, in the open space, traditional sports activities (e.g., dodgeball and football) were observed; however, no risky play was observed in this area.

Conclusions:

The occurrence of risky play varied depending on the play area; particularly, grass areas were likely to induce the occurrence of risky play among Japanese children.

THE EFFECTS OF THE FITNESS WALKING TRAIL APP ON PSYCHOLOGICAL WELLBEING AND PHYSICAL ACTIVITY LEVEL OF THE UNIVERSITY STUDENTS

LEUNG, E., YUEN, B.

THE CHINESE UNIVERSITY OF HONG KONG

Purpose: Regular physical activity is the prime way for prevention of numerous non-communicable diseases and has been associated with reducing risk of community-acquired infectious diseases (Chastin, et. al. 2021). Despite its beneficial effects on health, the PA levels of young people have been reported to be below the levels sufficient to gain the health benefits exercise can offer (Zimmermann-Sloutskis et al., 2010). Fitness walking is an easy and enjoyable way of doing exercise, especially in green outdoor environment. The purpose of the research was to evaluate the effect of a fitness walking mobile application (app) on the psychological wellbeing and PA level of the university students.

Methods: A fitness walking mobile app was developed to promote fitness walking for university students. A total of 2832 students from a university were volunteers who enrolled in the current study. Eligibility criteria included 1) current full-time undergraduate student; 2) absence of any physical conditions that would severely restrict the ability to be physically active. IPAQ-SF and PANAS Questionnaire were used to collect data of the PA level and psychological wellbeing of the participants. Data collections were conducted online before and after six months of the commencement of the intervention.

Results: At baseline, there were 64.6% females and 35.5% males and age averaged to 18.73 ± 2.16. To investigate changes over time, a sample of participants with repeated recordings were extracted; a valid pair of recordings for comparison has to be separated by a period of 6 months. A subsample of 153 (out of 2,838) participants remained for the pairwise comparison. Paired t-tests, Repeated Measures ANOVA, and GLM analysis were conducted for PA level, Positive Affect and Negative Affect. Most of these analyses did not find any significance ($p > 0.05$). The only significance was found in the Negative Affect for the total sample ($t = 3.14$, $df = 152$, $p = 0.002$) and the females ($t = 2.45$, $df = 106$, $p = 0.02$). The cross-tabulation analysis of PA category (High, Moderate and Low) of baseline and 6th month showed that 45.8% of participants had no change in PA category, while 21.5% got more active and 32.6% became less active.

Conclusion: The results showed that the fitness walking mobile app was not effective in promoting psychological wellbeing and PA level for university students. There were some possible reasons for non-significant results. Sample size was small due to the fact that limited number of participants reported their physical activities and psychological wellbeing after the 6-month period. Roughly speaking, half of the participants did not change in PA levels at all while the rest did change of which one half did better and the other did worst. So, the effect evened out. More efforts are needed to be made to promote proper use of this Walking App and more features have to be built into it so that more participants would get its benefits.

PHYSICAL ACTIVITY DURING PHYSICALLY ACTIVE LESSONS: EXPECTED LEVELS VERSUS REALITY.

JOHANSEN, J., MANDELID, M.B., REINBOTH, M.S., TJOMSLAND, H.E., THURSTON, M., RESALAND, G.K., BRATLAND-SANDA, S.

UNIVERSITY OF SOUTHEASTERN NORWAY; WESTERN NORWAY UNIVERSITY OF APPLIED SCIENCES; INLAND NORWAY UNIVERSITY OF APPLIED SCIENCES

INTRODUCTION

Levels of physical activity (PA) are declining in children and adolescents (1). Physically active lessons (PAL), which is conceptualized as combining PA with academic content (2), has been suggested as a strategy for both counteracting such a decline as well as improving academic outcomes in pupils (3). Although promising, little is known about the actual PA levels during PAL in schools that do not participate in a strict experimental intervention. Thus, this study investigates PA levels among pupils where PAL was already implemented into the schools teaching practice.

METHODS

Fifty-eight pupils were recruited across the 1st, 6th, and 8th grades. PA levels were measured by Actigraph triaxial accelerometers, worn by the pupils only during teaching where PAL was included. Measurements were collected during six months throughout the school year. All PA data were analyzed in one-second epochs. Evenson cut-off points were used to define minutes of sedentary time, light PA (LPA), and moderate-to-vigorous PA (MVPA).

RESULTS

In total, 37 PAL sessions were measured (12 in 1st, 15 in 6th and 10 in 8th grade) and the average duration of the sessions was 22.2 ± 7.2 min. On average, PAL sessions consisted of 57.8 ± 15.7% sedentary activity, 22.9 ± 7.5% LPA and 19.3 ± 10.3% MVPA. Each PAL session contributed an average of 9.8 ± 4.0 minutes with PA. The 6th grade proportionately had significantly higher ($p < 0.01$) sedentary time, and significantly lower ($p < 0.01$) LPA and MVPA compared to 1st and 8th grade, although not in PA minutes. No significant differences in any PA variables were revealed between 1st and 8th grade.

CONCLUSION

Sedentary time dominated the PAL sessions. Thus, PAL contributed a small amount of PA to the World Health Organization's recommendations of 60 minutes of daily PA for children and adolescents. The considerable variance in PA across PAL sessions could be a consequence of the organization of teaching, academic tasks, and selected type of PA. Despite the low amounts of PA, the actual amount may be of importance as a contributor to total PA in children and adolescents and thus in line with the updated PA recommendations that every move count. This may be especially true for those who are least active outside of school.

THE EFFECTS OF FIVE-DAY ADVENTURE-BASED PROGRAMME ON SELF-ESTEEM AND SELF-DETERMINATION NEEDS IN ADOLESCENTS IN TAIWAN

CHAN, W., CHI, L.K., MCGREGOR, E.

NATIONAL TAIWAN NORMAL UNIVERSITY, THE UNIVERSITY OF EDINBURGH

Introduction

Adventure programmes have been applied for educational purposes in the West with adolescents for some years. Adolescents are susceptible to low self-esteem and changing perceptions of their identity. However, adolescents increase their global self-esteem and improve their basic psychological needs of Self-Determination Theory following adventure-based programmes. In Taiwan, adventure programmes have expanded in recent years. There may be cultural factors influence programme outcomes. No research has explored the alteration of global self-esteem and the basic psychological needs in Taiwanese adolescents.

Method

Participants were adolescents aged 13-15. In Phase One, a survey examined the effects of adventure-based programme on 37 adolescents' global self-esteem using Rosenberg's self-esteem scale and the basic psychological needs using Basic Psychological Needs Scale at four time points. One-way Repeated measures ANOVA was used, with a P value set at less than .05. Phase Two comprised interviews with 24 participants to investigate their perceptions of self-esteem and basic psychological needs after the programme, and a possible relation between these variables. Content analysis was used, with trustworthiness processes.

Results

For Phase One, analyses showed no significant changes in participants' global self-esteem, overall basic needs scores, or in the scores for relatedness and autonomy at post-test compared to pre-test, although the competence was enhanced. A comparison of these measures across four time points showed no statistical differences after the programme or at one- and three-month re-test. In Phase Two, some participants reported increased confidence, competence and feeling of encouragement. Most participants regained their faith after the dilemmas, and perceived a sense of independence and self-determination during the activity, and an enhanced relatedness level.

Discussion

In quantitative findings, no significant changes showed at the four time points of comparison. Cultural factors such as modesty values, dialectical cognition, interpersonal relationship emphasis, or the importance of social hierarchy, may be one of main reasons to show the different results from the Western studies. The level of perceived competence increased after the programme. It is possibly because of breaking the comfort zone resulting in positive feedback. In qualitative findings, participants regained their self-confidence, encouragement and competence after dilemmas, and they perceived a sense of independence or self-determination during the activity. This may be due to risk sensation-seeking behaviour or an autonomy-supportive climate, different from the environment of hierarchical authority of custom. The need of relatedness is affected by cultural factors such as the importance of interpersonal relationship. Most participants felt supportive of and collaborative towards others.

POSTURAL EVALUATION OF YOUNG CHILDREN BY CHILDCARE WORKERS AND ITS RELATIONSHIP TO MEASURES OF YOUNG CHILDRENS PHYSICAL FITNESS AND MOTOR SKILLS, AND POSTURAL CONTROL FUNCTIONS

KAMEOKA, M.
NIIGATA UNIVERSITY

[Introduction] In childcare facilities (for 3-6 years), the number of infants who are unable to maintain posture is increasing. In daily life situations, some toddlers do not put their feet on the floor while eating, face to the side, or cannot maintain a sitting posture. In general, these abilities of young children are often evaluated subjectively by childcare workers. However, such evaluations may deviate from the actual abilities of toddlers. The purpose of this study was to clarify factors associated with the postural evaluation of toddlers by caregivers, using the postural evaluation of toddlers by childcare workers and measurements of physical strength and motor ability and postural control function.

[Methods] The subjects were 28 4- to 5-year-old children (14 boys and 14 girls) attending a nursery school. First, each of the 14 childcare workers evaluated the posture of the subject children on a 10-point scale. The total score of the 14 caregivers was used as the evaluation of each childs posture. Next, seven items of physical fitness and motor ability (shuttle run, standing long jump, softball throw, support one's body with straighten arms, repeated side steps, seated forward bend stretch, and grip strength) were administered, and the motor ability of the subject children was evaluated on a six-point scale. We also evaluated the subjects postural control function using a center-of-gravity sway meter. The length and rectangular area of the center of gravity sway trajectory were measured in the "open-eyed standing" posture using a center of gravity sway meter.

Correlation analysis and multiple regression analysis were used to examine the relationship between the child caregivers ratings and these measurements for males and females.

[Results] Correlation analysis revealed that there was a correlation between the standing long jump for boys and the rectangular area for girls. Multiple regression analysis using postural evaluation as the objective variable and postural control function and motor ability measurements as explanatory variables revealed a strong tendency for boys to be strongly influenced by the factors of standing long jump, softball throw, and support one's body with straighten arms, and for girls by shuttle run, repeated side steps, support one's body with straighten arms, and grip strength.

[Discussion] The results suggest that body support duration is related to postural assessment. Support one's body with straighten arms is said to be an indicator of muscular endurance, and this study suggests that "good posture" is also related to the ability to "maintain upper limb muscle strength. Future research is needed to elucidate the factors related to the evaluation of posture by childcare facilities children. In the future, we will examine ways to foster muscular endurance in young children while they play happily.

CHRONOLOGICAL EXERCISE BEHAVIOR CHANGES AND QUALITATIVE FACTORS IN FEMALE OLDER ADULTS ONE YEAR POST RESISTANCE EXERCISE CLASSES

IGARASHI, M.1, KOZAKAI, R.1, FUJITA, E.2, KAWANISHI, M.1
1 HOKUSHO UNIVERSITY; 2 NATIONAL INSTITUTE OF FITNESS AND SPORTS IN KANOYA

INTRODUCTION: Although many studies, including Picorelli et al (2014) and Room et al (2017), have quantitatively examined exercise behavior change in older adults before and after exercise intervention. Few studies have examined qualitative factors of exercise behavior change after the end of exercise intervention. The purpose of this qualitative study was to examine chronological exercise behavior changes and related factors of elderly women one year after the end of exercise classes.

METHODS: The exercise class consisted of self-weighted resistance exercise training devised by Tetsuo Fukunaga for maintaining muscle strength. Twenty eight senior women, the subjects of our study, participated in the exercise class for maintaining muscle strength for care prevention held in F Town, Hokkaido in 2019, 2020 and 2021. In 2020, 2021 and 2022, we used reminiscence method to conduct four semi-structured interviews of them at three months, six months, one year after the end of exercise class. Informed consent was obtained in advance from the subjects, and each interview lasted about 40 minutes. The qualitative factors of exercise behavior change were analyzed using the KH coder, a text mining method, on the text data of the interview contents, which were organized in chronological order. Correspondence analysis was used for time-series changes.

RESULTS: Nineteen subjects (64.3%) continued to exercise at least twice a week until one year after the end of the class. The top common network characteristics of qualitative factors as a set of commonalities in language throughout the one year were "self-efficacy," "social support," "simplicity of exercise," and "engagement status (time and continuation)." The characteristic qualitative factors from the correspondence analysis using the time series of the continuation group as an external variable were that "simplicity of exercise," "positive evaluation of exercise" and "self-efficacy," which were learned in the 3-month period immediately after the end of the class. While some "inhibiting factor" was observed at 6 months, reflecting "environmental barriers" due to the COVID-19 pandemic and "physical disease." At one year, there was "social support," from peers and instructors and "simplicity of exercise," and "positive evaluation of exercise" such as the enjoyment of exercise itself formed by the participation and continuation of exercise.

CONCLUSION: These qualitative factors suggested that the exercise program that are easy for the elderly to practice forms a positive attitude toward exercise, such as the enjoyment of the exercise itself, and that they continue to exercise even one year after the end of the class.

EFFECTS OF A 10-WEEK DUAL-TASK EXERCISE INTERVENTION ON COGNITIVE FUNCTION AND PHYSICAL FITNESS IN FEMALE ELDERLY WITH MILD COGNITIVE IMPAIRMENT

BO, Z.

SHANGHAI RESEARCH INSTITUTE OF SPORTS SCIENCE

Background and purpose:

As the risk of mild cognitive impairment increases with ageing in Shanghai, physical activity as a non-pharmacological intervention has been shown to have a positive effect on cognitive function in older adults with mild cognitive impairment in several studies. The present study was conducted to investigate the effects of a dual-task exercise intervention on the cognitive function and functional fitness of female elderly.

Subjects and METHODS: 85 female elderly residents in Shanghai were randomly selected and their baseline cognitive function (MOCA scale scores) showed a mean score ± standard deviation of 23.612 ± 3.764 (points). The subjects were randomly divided into 30 in the exercise group, 32 in the dual task group and 23 in the control group, with mean ages of 64.133±3.350 (years), 64.250±3.840 (years) and 65.957±4.743 (years) respectively, there are no significant differences between the groups ($p>0.05$). The exercise group was given 60 min/time, 2 times/week for 10 weeks, the dual-task group was given 60 min/time, 2 times/week for 10 weeks, and the control group was not given any exercise intervention. Cognitive function (MOCA) and functional fitness were tested in the three groups before and after the intervention. Within-group comparisons were analysed by paired t-tests and between-group comparisons were analysed by ANOVA.

RESULTS: (1) Compared with the pre-intervention period, the cognitive function (MOCA) of exercise group improved from 22.667±4.105 (points) to 24.067±4.077 (points) ($P<0.05$), and the performance of single leg standing with eyes closed, chair stand test, 2.44m rapid walking and 2-minutes step test improved ($P<0.05$).Compared with the pre-intervention period, the cognitive function (MOCA) of the dual-task group increased from 24.281±3.513(points)to 25.188±3.063(points),($p<0.05$), and the performance of grip strength, single leg standing with eyes closed, chair stand test and 2.44m rapid walking increased ($p<0.05$).Arm curl test decreased in the control group ($p<0.05$), and the rest did not change significantly ($p>0.05$).

(2) There was no significant difference in cognitive function (MOCA) between the exercise group and the dual task group compared to the control group after the intervention ($p<0.05$), and the performance was better in chair stand test and 2-minutes step test ($p<0.05$).

(3) No statistically significant differences were seen between the exercise group and the dual-task group in cognitive function (MOCA) and physical fitness indicators before and after the intervention ($p>0.05$).

CONCLUSION: The 10-week single exercise intervention and dual-task intervention both improved cognitive function (MOCA) and performance on several physical fitness indicators in female elderly with mild cognitive impairment.

EFFECTS OF AEROBIC EXERCISES WITH TRADITIONAL THAI DANCE ON CARDIORESPIRATORY SYSTEM

NEELAPAIJIT, N.

SILAPAKORN UNIVERSITY

Effects of Aerobic Exercises with Traditional Thai Dance on Cardiorespiratory System

NEELAPAIJI, N. NHUSAWI, K. KAESMAN, I. CHANTASORN, N. KLADKLEEB, S.

Silpakorn University

Abstract

INTRODUCTION: Aerobic Exercises with Traditional Thai Dance (ATTD) is a combination of Traditional Thai dance posture and movement with aerobic exercises. They were developed specifically to enhance Cardiorespiratory Systems

METHODS: The purpose of this research was to study and compare the effects of ATTD on Cardiorespiratory System. Of 80 female students between 18-24 years old, 30 students were selected by simple random sampling . They were divided into 15 students for a control group (engaging in normal daily activities), and 15 students for an experimental group (participating in ATTD). They were tested by Cardiorespiratory system testing before and after training. The program was 6 weeks in total, 3 days a week. The test results were analyzed by means of mean, standard deviation, and an independent t-test at the statistical significance level of .05.

RESULTS indicated as follows:

After the Cardiorespiratory system test, the results of the experimental group (ATTD) were 112.67 ± 5.602 and 121.13 ± 3.226, while the results of the control group were 112.47 ± 6.885 and 106.46 ± 6.770. The test was also conducted 6 weeks after training. The results showed that the differences between the control group and the experimental group was statistically significant at the .05 level.

CONCLUSION: Aerobic exercises with Traditional Thai dance (ATTD) showed a positive effects on the Cardiorespiratory system. It could be explained that when applying traditional Thai dance into aerobic exercises activities, both involved the

participants with continuous movement at moderate intensity. As a result, it caused the positive change in the body's cardiorespiratory system.

Key words : Aerobic Exercises, Traditional Thai Dance

Physical Education and Pedagogics

DEVELOPMENT AND VALIDATION OF MEASUREMENT FOR STUDENTS' PERCEIVED CONSTRAINT SUPPORT IN PHYSICAL EDUCATION

HSU, W., PAN, M.

NATIONAL DONG HWA UNIVERSITY

INTRODUCTION: Constraint-led Approach (CLA) is one of the trendy learning models in physical education. More and more researchers started to implement CLA in PE and pay attention to the outcomes of CLA-implemented PE. Nonetheless, most studies regarding CLA in PE stopped at developing CLA-based lesson plans for skill learning without trying to examine its alleged outcomes empirically. A reliable and valid measurement for students' perceived constraint support in PE would greatly benefit the examination of the effectiveness and outcomes of CLA-implemented PE. The study aimed to develop a conceptually sound and psychometrically robust measurement of perceived constraint support in physical education.

METHODS: In this three-phased study, interviews were conducted first to form initial items, and experts were then invited to further refine initial items. Exploratory factor analysis, confirmatory factor analysis, cross-validation, criterion-related validity, and test-retest reliability analysis were executed to test the validity and reliability of this measurement with samples of 866 and 792 middle and high school students respectively.

RESULTS: A psychometrically appropriate instrument titled the "Constraint Support Scale in Physical Education (CSS-PE) comprises one factor and five items. The CSS-PE passed the examinations of cross-validation, preliminary criterion-related validity, and test-retest reliability analysis, showing preliminary evidences of the reliability and validity.

CONCLUSION: This study furthered our knowledge of students' perceived constraint support and identified several constraint-supporting behavior from PE teachers, such as changing the difficulty of activities, representativeness learning design, and focusing on the movement outcomes rather than the movement itself. The study provides preliminary evidence of the reliability and validity of CSS-PE. Researchers and practitioners may use CSS-PE to evaluate students' perceived constraint support when adopting CLA teaching strategies. Furthermore, it would benefit researchers exploring the possibility of combining non-linear pedagogy or CLA with other non-skill learning models by conceptualizing constraint support and connecting it with other learning theories

EXPLORING THE EFFECT ON THE BADMINTON SKILL LEARNING IN PHYSICAL EDUCATION USING THE BADMINTON LEARNING TUTOR APP

LIN, K.C.1, KO, C.W.2, LEE, I.C.3

1.NATIONAL SUN YAT-SEN UNIVERSITY; 2.NATIONAL SUN YAT-SEN UNIVERSITY; 3.NATIONAL CHENG KUNG UNIVERSITY

Introduction

It has been the goal of physical education instructors to elevate learners learning efficiency significantly in a limited time. Thus, researchers have been constantly developing a badminton teaching system, which is expected to be supportive within the learners' badminton learning progress. Consequently, this study tends to develop a Badminton Learning Tutor APP which contains automatic grading, automatic feedback, and dynamic skeleton comparison video functions. Furthermore, this study compared the APP-assisted teaching method to the real-time recording-assisted method to observe whether the proposed APP could effectively help improve learners' learning efficacy toward serve and clear skills in badminton.

Methods

This study conducted the quasi-experimental design in eight weeks (1 week for the pre-test, 6 weeks for teaching, and 1 week for the post-test). The analysis was utilized by the mixed design ANOVA in SPSS ver. 17. The assumption of sphericity was examined by the Greenhouse-Geisser correction, an alpha of .05 was used to determine statistical significance, and the post-hoc tests were presented via the Bonferroni adjustment.

Results

On the serve skill learning, the results showed that the difference between groups was significant ($p = .006$). The within-subject effects, the scores of every testing week and the interaction effect of testing week and group were also significant (p-values were all smaller than .001). After the post-hoc analysis, it indicated that the differences between the two groups from the third week to the post-test were significantly different, and the scores of the experimental group were larger than those of the control group. On the clear skill learning, the results showed that the difference between groups was not significant ($p = .093$). The within-subject effects, the scores of every testing week and the interaction effect of testing week and group were significant (p-values were all smaller than 0.001). After the post-hoc analysis, it indicated that the differences between the two groups at the second, third, and sixth weeks were significantly different, and the corresponding scores of the experimental group were larger than those of the control group.

Discussion

Due to different characteristics, hitting time could be controlled without adjusting the position for serve skill. As for clear skill, it is required to master both the hitting time and moving position. Therefore, without time and spatial disturbance, the Badminton Learning Tutor APP can elevate learning efficacy significantly in the restricted time. Nevertheless, when the conditions of time and space are being considered in clear skill, the Badminton Learning Tutor APP can perform better learning efficiency initially but improve with a rather insignificant growth in the late stage. Overall, it is suggested that the learning progress toward clear skill could be extended in the future to further observe the learning effect.

RELATIONSHIP BETWEEN ELEMENTARY SCHOOL CHILDREN'S SPORTS AND PHYSICAL ACTIVITY HABITS, SELF-ASSESSED PHYSICAL FITNESS, AND GRIT SCORE

NAKANO, T.1, SAKAI, T.2, HAYASHI, Y.3, MURAYAMA, T.4, OYAMA, Y.5

1 CHUKYO UNIVERSITY; 2 NAGOYA GAKUIN UNIVERSITY; 3 HOSEI UNIVERSITY; 4 NIIGATA UNIVERSITY; 5 TOIN UNIVERSITY OF YOKOHAMA

[Introduction] Children are less likely than adults to engage in sports or other forms of physical activity to improve their health. Most kids enjoy participating in sports itself and engaging in physical activity with their friends. Parents expect sports and other physical activities to contribute toward improving their health and physical fitness as well as the sound growth of their children. In order to promote physical activity continuously, it is essential to do so in a way that is both socially and educationally beneficial. Of late, GRIT has emerged as an important measure of social competence. In addition, it is important as an educational goal as well. We believe childrens GRIT can be improved through sports and other physical activities. In view of this, the aim of this study was to examine the relationship between childrens habits related to sports and other physical activities, self-assessed level of physical fitness, and GRIT score.

[Methods] The subjects were 5,856 elementary school students. We administered a questionnaire to get information about the average daily sports and physical activity hours, self-assessed physical fitness level, sports and physical activity preferences, and the GRIT scale. (Duckworth & Quinn, 2009). We applied factor analysis to the GRIT scale data and verified the existence of two subfactors (persistence of effort and consistency of interest). Next, scores for the overall GRIT and each subfactor were determined by simple summation of the individual items. Furthermore, two groups were created using the average of GRIT scores for each gender as the boundary value. The differences in sports and physical activity hours were examined using the t-test. The differences in GRIT scores on the basis of self-assessed physical fitness level and sports and physical activity preference were examined using t-test and one-way ANOVA.

[Results] It was observed that children with better GRIT scores engaged in significantly more hours of sports and other physical activities. However, no significant difference was observed in the score of "consistency of interest" subfactor in terms of sports and physical activity hours on weekdays. GRIT scores were significantly higher among children whose self-assessed physical fitness level was 3 or higher on a 5-point Likert scale. Moreover, kids who had higher preference for sports and physical activity had higher GRIT scores.

[Discussion] It was suggested that children who engaged in more sports and physical activity during the day had better GRIT scores. As the differences in GRIT scores were also substantiated by preference for sports and physical activity and self-assessed physical fitness level, it was concluded that encouraging sports and physical activity and boosting physical fitness can help improve GRIT.

FACTOR STRUCTURE OF SITUATIONAL DECISION-MAKING ABILITY IN BASIC FACE-UP SITUATIONS IN BASKETBALL GAMES

OHYAMA, Y., AOYAGI, O., YAITA, A., KOMURE, I., TAGATA, S., NAGAMINE, K., ANNOURA, T.

NATIONAL INSTITUTE OF TECHNOLOGY, SASEBO COLLEGE

Introduction

In a basketball game, it is important to have the ability to assess the situation in order to instantly select the best play for the situation. The ability to make decision-making momentarily is naturally based on knowledge prior to games. Moreover, it is thought that not all individual situational judgments are made independently, but that there are some common situational judgment abilities underscoring these judgments that have been cultivated through experience and other factors. Therefore, this study aimed to examine the factor structure of the situational judgment ability in basic face-up situations, which is most often found in basketball games.

Methods

Eighty-one coaches were asked to answer the situational decision-making ability test in basic face-up situations, consisting of 68 questions developed by Oyama, et al. (2023). The test was conducted using an online test format (Google Forms). The scoring was based on the frequencies that the 16 coaches with advanced level S through B certifications chose as the correct answer, and the frequency as a score was given to the respondent who chose that option. Factor analysis was performed on the results of the scoring of that test to obtain the factor structure. Incomplete Principal Component analysis method was used for factor analysis, and the number of factors with a cumulative contribution of 50% or more was employed, followed by an orthogonal solution by Normal Varimax rotation.

Results

As a result, six factors were extracted showing a cumulative contribution rate of 50.52%. Factor 1 showed significant factor patterns for 13 items, including "Cognitive ability in attacking with a counter (factor pattern = 0.523)". Since these are all composed of cognitive ability, we interpreted this factor as "F1: Ability in recognizing a situation." Factor 2 showed significant factor patterns for seven items, including "Ability with prediction and decision-making when attaching the gap using driving and kicking (0.505)." Since these are composed of abilities related to drives, which are temporary numerical superiority situations, we interpreted this factor as "F2: Prediction and decision-making ability in momentary numerical superiority situations". In the same way, Factors 3 to 6 were interpreted as "F3: Prediction and decision-making ability before and after receiving a pass;" "F4: Prediction and decision-making ability in closed-out situations with the ball carrier;" "F5: Prediction and decision-making ability in facing-up and off-ball situations;" and "F6: Prediction and decision-making ability in driving situations with the ball carrier," respectively. In other words, the decision-making abilities in basic face-up situations in a basketball game consist of six factors, comprising one cognition and five prediction and decision-making abilities, with greater involvement of prediction and decision-making in the second half than cognition in the first half.

RESEARCH ON LEARNING CONTENT RELATED TO "COMPETITION" IN SCHOOL PHYSICAL EDUCATION: BASED ON EXAMPLES IN "THE COMMENTARY ON COURSES OF STUDY"

TAI, K.

GUNMA UNIVERSITY

Introduction

Previous studies provide a mixed view on "competition" in education, as some findings indicate that it may cause children to feel excessive exclusion others, and others consider it an effective means to increase the motivation to learn. (Kohn [1992], Suzuki [2005]). In Japanese school education, the word "competition" is used in "The Course of Study," indicating the learning goals and content of elementary and junior high schools. Furthermore, the only subjects that use the word "competition" are physical education and health and physical education subjects (Tai [2022]). However, it is still unclear what the description of the words related to "competition" in "The Course of Study" refers to as learning content.

In this study, we organized explanations and examples of the places where competition-related words were described in "The Commentary on Courses of Study for the Elementary School" and "The Commentary on Courses of Study for the Junior High School." We also considered the use of "competition" as teaching materials in school physical education.

It is expected that the results of this study will clarify the intention of handling "competition" in school physical education and contribute to the planning of teaching plans according to subject goals.

Methods

As a specific examination method, based on the explanations and examples using competition-related words in "The Commentary on Courses of Study," we organized each of the "subject goals," "elementary school," and "junior high school." We clarified the interpretation of "competition" and its use as teaching materials.

Result and Discussion

In junior high school physical education subject goals, "competition" was meant to be experienced with the intention of fostering "motivation" and "attitude."

In "The Commentary on Courses of Study for the Elementary School," "competition" was not only learning in itself but learning through "competition" ("acceptance of judgment," "fair play") was also shown as learning content. "Competition" in school physical education was used both as a learning objective and as a means of learning.

In "The Commentary on Courses of Study for the Junior High School," interpersonal competition by groups or individuals is recognized as a major characteristic of athletic events in the four areas where competition-related words are described. There is an understanding that enjoying "competition" means understanding the sports culture. The four areas of track and field, swimming, ball games, and budo (martial arts) are explained using phrases related to "competition." There is a characteristic of enjoying exercise in the form of games, matches, and so on, and it is important to consider this point in PE classes. At the same time, instructional examples are presented to prevent negative feelings from being competitive during exercise.

PEER VERBAL ENCOURAGEMENT ENHANCES OFFENSIVE PERFORMANCE INDICATORS IN HANDBALL SMALL-SIDED GAMES.

SAHLI, F., SAHLI, H., TRABELSI, O., JEBABLI, N., ZGHIBI, M., HADDAD, M.

QATAR UNIVERSITY

Effective teaching in physical education (PE) does not only rely on planning and implementing the best evidence-based didactic materials and pedagogical strategies to ensure students are making progress in their motor learning. There are times when PE teachers are required to address other intangible parameters in order to in-crease their students' motivation and, in turn, deeply engage them in the learning process.

This study aimed at assessing the effects of two verbal encouragement modalities on the different offensive and defensive performance indicators in handball small-sided games practiced in PE settings;

A total of 14 secondary school male students, aged 17 to 18, took part in a three-session practical intervention. Students were divided into two teams of seven players (four field players, a goalkeeper, and two substitutes). During each experimental session, each team played one 8-min period under teacher verbal encouragement (TeacherEN) and another under peer verbal encouragement (PeerEN). All sessions were videotaped for later analysis using a specific grid focusing on the balls played, balls won, balls lost, shots on goal, goals scored, as well as the ball conservation index (BCI) and the defensive efficiency index (DEI);

The findings showed no significant differences in favor of TeacherEN in all the performance indicators that were measured, while significant differences in favor of PeerEN were observed in balls played and shots on goal;

When implemented in handball small-sided games, peer verbal encouragement can produce greater positive effects than teacher verbal encouragement in terms of offensive performance.

RECEPTION OF ROGER CAILLOIS IN JAPAN

SASAKI, K.

KYOTO SANGYO UNIVERSITY

Introduction

Since the introduction and translation of his famous work "Man, Play and Games" (1958), Roger Caillois has been frequently referenced in the field of physical education and sports studies in Japan. Of particular interest has been the category of play, which is essential to definition of sports. In other words, sports are one of the categories of play characterized by competition. However, the scope of reading Caillois in this field has stayed about this point, and it seems that the understanding of Caillois is insufficient. This study reveals the limitations of these previous studies. It also aims to clarify the issues that should be approached.

Discussion(Methodes and Results)

We reread Caillois work following his logic with its subject in mind.

As is well known, Caillois divides play into four forms according to its inner qualities: Agôn, or competition; Alea, or chance; Mimicri, or role-playing; and Ilinx, or vertigo. According to Caillois, sporting activities are indeed classified as "Agôn." The competitive nature of sports is undeniable if we consider, for example, the Olympic Games or FIFA World Cup. Sports must be competitive games.

However, what does the taxonomy of play, to which only about one-fifth of his work is dedicated, tell us about Caillois idea of sports? Upon reading "Man, Play and Games," it is immediately apparent that the above four terms do not refer simply to the divisional limbs of play but rather the internal and essential properties that drive the activity of play itself. Their properties make possible the analysis of the society, which is the subject of his work. Caillois mentions sports because they are essential requirements for that.

Following Japans modernization, educational expectations have continued to be placed on sports (perhaps as the successor to athleticism). Even now, sports are part of the regular school curriculum, from elementary school to university. Sports in Caillois work are frequently referenced in relation to the educational significance of play, but what deserves more attention is that Agôn (and play types, i.e., Paidia and Ludus) is not a division principle but an internal properties, especially the relationship between its creative function in play and sports. This is the point that has been overlooked.

Conclusion

What must be clarified first is the meanings and roles of Agôn. Only after that, the meanings and significance of sports in Caillois work should become sufficiently clear.

ASSOCIATION BETWEEN PSYCHOLOGICAL NEED SATISFACTION, MOTIVATION FOR PHYSICAL ACTIVITY, MOTOR COMPETENCE AND PHYSICAL ACTIVITY IN YOUTH

SCHOSER, D., WILKE, C.

GERMAN SPORT UNIVERSITY COLOGNE

Introduction: Despite increased knowledge of positive health effects of physical activity, numerous studies have proclaimed a negative trend in the physical activity of youth. An important focus of research must be to identify the physical, psychological and social factors of this trends. The self-determination theory (SDT) including the sub-theory of psychological need satisfaction could give an important stimulus. To gain better understanding of the factors based on the SDT, this study explores the association between psychological need support (autonomy, competence and relatedness), their satis-

faction and motivation for physical activity. In a second step the association between motivation and motor competence as well as physical activity will be analysed.

Methods: Cross-sectional data from 332 fifth-grade children aged 9 to 11 years from four secondary schools in Germany were analysed. All subjects were measured on psychological need support, satisfaction and motivation for physical activity by questionnaire as well as tested on motor competence and physical activity. Correlation analyses using Spearman where conducted to obtain references about meaningful relationships.

Results: The results indicate statistically significant correlations between the psychological factors and physicals activity and motor competence. We found a positive correlation between psychological need support (r = .228 to .399) as well as satisfaction (r = .243 to .430) and level of intrinsic motivation. A negative relationship exists between amotivation and the support of competence (r = -.186) and relatedness (r=-.237) as well as satisfaction of autonomy (r=-.163). Extrinsic motivation shows a negative relationship with competence support (r=-.211). Furthermore, the intrinsic motivation is associated with motor competence (r=.217) and physical activity (r=.251). A negative correlation shows extrinsic motivation and amotivation with motor competence.

Discussion: To promote main forms of motor activity, the psychological factors could play an important role in youth's motor performance and activity in leisure time. The associations between intrinsic motivation, motor performance and physical activity on one hand, and the negative relationship of extrinsic motivation and amotivation on the other hand support this assumption. Moreover, the support of the psychological basic needs can influence the perceived satisfaction. These psychological factors embody potential tools for increasing motor competence and promoting physical activity. This is the basis for designing sustainable and effective countermeasures to decrease health risk factors which are associated with inactivity. Further research is needed to investigate the theoretically based assumptions.

DOSE THE BILINGUAL EDUCATION BRING NEGATIVE EFFECTS IN PHYSICAL EDUCATION?

CHANG, Y.C., LIU, C.C., TSENG, I.H., YANG, H.W., CHEN, Y.E.

NATION TAICHUNG UNIVERSITY OF EDUCATION

INTRODUCTION: In recent years, bilingual physical education has been gaining traction in Taiwan. Even if there are already many bilingual related references in various countries of the world [1], nevertheless, we have no way of knowing whether different countries and cultures have different outcomes. Based on the above, this study not only aims to explore the design of bilingual physical education activities in primary schools, but also to understand the language use of teachers and students physical activity in bilingual physical education in Taiwan.

METHODS: This study used qualitative studies. First, we design eight bilingual lessons in two teaching themes: gymnastics and dance, then we conduct public lectures and take the video. Through the observation of classroom behavior, the classroom behavior of teachers and students classroom participation were analyzed in depth. In the class observation, we use Mangold interact observation system as our tool. Furthermore, we use event recording method and Period recording method for encoding analysis. The index of this study is refer to the code list for classroom observation activities used in Coral's and Krüger's references [2].

Results and discussion:

1. In this study, we found that students physical activity in the classroom increased with the increase of teachers language use, which showed that the proportion of students physical activity was positively correlated with the proportion of teachers language use.

2. In bilingual physical education classes, the target language usage of each class is not fixed, there is no specific ratio standard, which shows that bilingual education is not taught entirely in English but should be promoted by on-site teachers who use the language flexibly according to the needs of the curriculum.

3. In terms of language use timing, the most common time for teachers to add language was during action demonstration (average use ratio was 17.48%). In the action demonstration due to the combination of body movements, even if the students do not understand what the teacher says, they still can understand the action skills that the teacher wants to convey through body language, which is the best time to join the target language.

VALIDATION OF THE FRENCH VERSION OF THE EDMCQ-PE (EMPOWERING AND DISEMPOWERING MOTIVATIONAL CLIMATE QUESTIONNAIRE IN PHYSICAL EDUCATION, MILTON ET AL., 2018)

SIMON, L., MASTAGLI, M., BOLMONT, B., HAINAUT, J.P.

UNIVERSITY OF LORRAINE

Context: The importance of the motivational climate created by the teacher has been continuously emphasized in recent years, especially in its role for the quality of the students experience in Physical Education (PE) (Duda et al., 2014). The ED-

MCQ-PE (Empowering and Disempowering Motivational Climate Questionnaire in PE) initially validated by Milton et al. (2018) is a questionnaire that aims to report the students perceived motivational climate in PE. This questionnaire has the advantage of being based on two major theories of motivation: the Self Determination Theory (SDT- Deci & Ryan, 2017), and the Achievement Goal Theories (AGT - Ames, 1992) which offer possibilities for a more detailed understanding of the motivational climate in PE with the notions of empowering and disempowering behaviors (Duda, 2013). Thus, this questionnaire is a useful tool for researchers but also for physical education teachers. Unfortunately, there is no validated French version of the EDMCQ-PE.

Objectives: Our objective is to translate and validate a French version of the EDMCQ-PE (Milton & al., 2018)

Method: Based on Vallerands method (1989), we attempt to translate and validate the EDMCQ-PE through 6 steps: (1) designing a preliminary version using a traditional translation, (2) assessment and possible modifications of the preliminary version with the help of a committee of experts including Milton, (3) assessment of the experimental scale by a clarity pre-test among 29 French high school students, (4) assessment of congruent and content validity among 27 bilingual students from the French high school of Chicago ,(5) assessment of fidelity and (6) assessment of construct fidelity were tested with 337 French high school students.

Results and discussion: Following translation by the expert comity (1&2), the clarity test (3) reveals that all items are fully understood. (4) Congruent and content validity analysis show that eight items should be treated with caution because one of the two statistical score is low. (5) Cronbachs alphas show satisfactory levels of fidelity, similar to those obtained by Milton, both at the level of the 5 subscales and at the level of the higher dimensions (empowering and disempowering). (6) The assessment of construct fidelity by the confirmatory factor analysis shows that French items have a similar correlation score with their subscale and their higher dimension to those obtained by Milton (included the 8 items questioned by the assessment of fidelity). Two items could be questioned by the confirmatory factor analysis but they remain good in congruent validity and fidelity in both subscales and higher dimension. Given all these results, we make the choice to propose a version retaining the 34 items of the EDMCQ-PE in the French version in order to remain as faithful as possible to the initially validated version.

Conclusion: Many indications show that the EDMCQ-PE is satisfactory with respect to Vallerands validation method

WATER SAFETY EDUCATION FOR COLLEGE STUDENTS

TORIUMI, T.

KEIO UNIVERSITY

Reasons for drowning are most commonly associated with failure to stay afloat or swim to safety. Some evidence suggests that victims drown because they cannot exit the water upon reaching the water's edge.

The purpose of this paper is to explore the real and perceived capacity of young adults to safely exit the water and ascertain what safety knowledge about exiting the water is promoted.

College-aged non-sports Japanese students (N = 62) completed a pretest survey of self-estimated capacity to exit the water under varied conditions. Participants were then tested in shallow water, deep water (flush edge), and deep water with a ledge (0.30 m) when fresh, after a 5-min swim in swimwear, in clothing, and while wearing a buoyancy vest.

Participants were Japanese young adults (N = 62) with a proven swimming capacity who were enrolled in an undergraduate Bachelor of non-Sports degree programs. Of these, 40 were male (64%) and 22 were female (36%), 80% were 19–20 years of age, 17% were 21–22 years of age, and the remaining 3% were 23 years and older. Before the commencement of an aquatics education program that focused on water safety, participants completed a pretest survey that was designed to provide a measure of self-estimated water competency and estimates of their capacity to exit the water under various conditions. Practical testing of exit skills was completed during 1.5 hr aquatics sessions/1 times per week over a 3-week period during the summer term (April–July 2021) in an indoor 50 m pool (water temperature 25 °C). Appropriate lifeguard supervision and safety equipment were available at all times. Ethics clearance for the study was obtained from Keio University Ethics Committee.

All data from the completed questionnaires were double entered into Microsoft Excel and data were transferred to SPSS version 24 for statistical analysis. Descriptive statistics expressed as frequencies and percentages were used to describe or characterize all numerical variables. These included four independent variables (gender, age, ethnicity, and self-estimated swimming competency) and four dependent variables related to previous experience, knowledge, perceptions of exiting task difficulty, and actual exiting competency. Chi-square tests of independence were used to test associations between the frequencies of the influences of age, gender, and ethnicity against the perceived and actual exertion required to perform the exiting tasks.

All participants were able to exit shallow and deep water when not fatigued, after a swim when wearing clothing or a buoyancy vest, but many failed to exit deep water over a 0.30 m ledge after swimming in clothing or in a buoyancy vest. Significantly more females than males found exiting deep water difficult. Most participants (especially males) underestimated the demands of exiting deep water. The value of situational learning via exposure to exiting difficulties in simulated

pool practices is discussed.

THE INFLUENCE OF

MATSUMOTO, A.
HIROSHIMA UNIVERCITY

[Background]

In recent years, attention has focused on extending healthy life expectancy in Japan, where the ageing population is advancing. The emphasis on primary prevention and improvement of the quality of life are fundamental concepts in the second phase of Healthy Japan 21 (Ministry of Health, Labour and Welfare, 2012). Moreover, recent social changes also involve youth life in disorder. Therefore, efforts for health and safety in school education are essential (Japan School Health Association, 2020). Especially health education, which plays a central role, aims to develop students' competency in making appropriate decisions and behavioural choices and implementing exercises actively (Ministry of Education, Culture, Sports, Science and Technology, 2020). However, due to teaching methods that lay emphasis on knowledge infusion, classes that approach the goal of health education have not been formed yet (Sugiyama, 2017). Thus, it is necessary to improve teaching methods. "Hands-on health learning", an innovative method, has shown various effects. However, introducing it to schools is complex due to the limitation of class periods. Considering this, "Hands-on Home Study Materials: My Body Record" is significant in achieving better health education and independent learning, enhancing students health awareness, cultivating competency of active practice and appropriate decision-making and behaviour choice. Accordingly, this study aims to clarify the effects of "My Body Record" on students health, lifestyle, and motivation for health learning.

[Methods]

This study was conducted among junior and senior high school students. Students did homework which included reflecting on their own lives, considering health issues and solutions, and filling in the handouts provided in advance. Each teacher collects the pre-prints and returns the pre-prints to students after checking the safety of the solutions. The students practised the solution for two weeks and recorded their work using practical prints and Google forms. Before and after the home study, a questionnaire survey was conducted using Google forms. The questionnaire items for the health and lifestyle survey were developed based on the previous study by Tokunaga (2005). The content of health learning was based on Sato (2015) and the report of the Health Learning Promotion Committee of the Japan School Health Association (2017).

[Results and Discussion]

Looking at the daily habits of the students, various problems can be seen, such as late bedtimes, shortened sleeping hours, and prolonged use of smartphones. By using the "Hands-on Home Study Materials: My Body Record" to practice what they have learned in health class, it is expected that these lifestyle habits will be improved. The details will be presented on the day.

COOKING PRACTICE FOR PARENTS OF HIGH SCHOOL ATHLETES: EFFECTS ON UNDERSTANDING THE QUANTITY OF RICE SERVED ON A PLATE

KOIZUMI, K.
JAPAN WOMENS COLLEGE OF PHYSICAL EDUCATION

Introduction

Female students who play sports need to eat grain dishes in order to consume the appropriate amount of carbohydrates in their diet. For example, they require approximately 200 g of rice per meal. Some students who are part of the cheerleading club and do not want to gain weight in positions that require them to be lightweight, or who want to maintain a slender appearance, make the mistake of losing weight by eating less. By choosing an appropriately sized bento and filling it with rice, main dishes, and side dishes, the bento can be cooked to provide appropriate levels of energy and nutrients. Therefore, in this study, we conducted cooking training using bento for parents of athletes to determine if it would affect their estimation of the amount of rice required.

Method

The participants were parents of students who were part of a high school cheerleading club (n=15). Parents first attended a brief lecture on food quantities, menus, and nutrients during cooking practice. Thereafter, in groups of four, they cooked the prepared ingredients as per the bento recipe. Next, they measured the portion size of their childs bento and served the rice, the main dish, and the side dish. A Google Forms questionnaire was then used to estimate the quantity of rice by looking at a picture of a bowl and a plate with 300 g of rice before and after cooking. Two groups were formed based on their ease of estimation; the D group (n = 4) found it difficult to estimate the amount of rice, main dishes, and side dishes before the cooking practice, while the ND group (n = 11) did not find it difficult. Statistical differences were determined using a two-way factorial analysis of variance. Differences were considered statistically significant at $p < 0.05$.

Results

Eight parents chose the appropriate bento size for the athletes, whereas seven parents chose a smaller bento than the appropriate amount. In the D group, 75% said they were not good at cooking, while 50% disliked cooking altogether. The amount of rice estimated for both plates and bowls were the same. There were no significant differences between the groups before and after the cooking practice. However, there was a significant difference between the two groups (dish

p=0.049, bowl p=0.012); the ND group estimated the dish and bowl to be approximately 200 g, while the D group estimated the dish to be approximately 150 g and the bowl to be approximately 120 g. Post-cooking practice, both groups answered that they could understand the guidelines for the amount of rice, main dish, and side dish.

Conclusion and discussion

Parents of students who are part of the cheerleading club were able to understand the amount of rice, main dishes, and side dishes in bento through cooking practices and lectures. However, when testing the ability to estimate the amount of rice, there was no change in either group; the estimated amount in the D group was less than the required measurement and lower than that in the ND group.

THE IMPACT OF CLASSROOM BASED PHYSICALLY ACTIVITY PROGRAM ON MATHEMATICS AND SUBJECT PREFERENCES ON 3TH GRADE PRIMARY SCHOOL PUPILS

TAMÁS, K.

ESZTERHÁZY KÁROLY CATHOLIC UNIVERSITY,

The impact of classroom based physically activity program on mathematics and subject preferences on 3th grade primary school pupils

Kertész Tamás 1,3 Szakály Zsolt 3, Bognár József 2

1 Eszterházy Károly Catholic University, Doctoral School of Education

2 Eszterházy Károly Catholic University, Institute of Sport Sciences

3 Széchenyi István University Faculty of Health and Sport Sciences

There is a growing body of literature on the impact of physical activity learning (PAL) on cognitive and psychological development. Research suggests that innovative classroom based PAL interventions have beneficial effects on academic performance. The introduction of coordination skills-based tasks in mathematics lessons demonstrates positive changes in task mastery and subject engagement. The purpose of this study was to demonstrate the effectiveness of an innovative sport tool and associated coordination-based methods on the learning of mathematics and subject preferences.The sample consisted of 3rd grade students (N=104) from two primary schools. Based on the PAL intervention, there were three experimental groups (1x a week; n=12), (2x a week; n=21), (3x a week; n=24), and also a control group (n=51). In addition, teacher interviews (n=2) were conducted to gain a deeper understanding of the experiences. An innovative coordination tool was utilized to support learning and during the 6-week program.

According to our results, significant improvements were observed between the pre- and post-measurements of the experimental group algebra and geometry variables and also in subject preferences ($p<0,05$). Repeated ANOVA analysis yielded significant differences for group, time and variables ($F=3.965$; $p=0.00066$). The interviews confirmed the positive impact of the innovations used in this study, not only in terms of students cognitive and emotional development, but also in terms of their adaptability to support the teaching-learning process. The results of this study suggests that it is a successful program and so it is worth extending in different classroom based physical activity programs.

STUDY PROTOCOL OF A PHYSICAL LITERACY BASED LONG-TERM ATHLETE DEVELOPMENT IN PHYSICAL EDUCATION CURRICULA FOR SECONDARY SCHOOL IN HONG KONG: A RANDOMIZED CONTROLLED TRIAL

HUANG, S.M.Y., SUM, R.K.W., CHOI, S.M., LEUNG, E.F.L., HO, R.W.K.

THE CHINESE UNIVERSITY OF HONG KONG

Background

Health and education-related organizations such as the United Nations and the Hong Kong Education Bureau continue to cultivate high expectations on quality physical education (QPE) curriculum and vast number of diversity strategies to ensure students develop physical literacy (PL) from an early age and build a solid foundation of movement from adequate physical activity (PA) guidelines. Barriers to meet this expectation such as lack of unique PE curriculum and long-term development programme for students, lack of time and greater emphasis on academic achievement are ongoing challenges to schools. Physical literacy based long-term athlete development (PLB-LTAD) curriculum for secondary school students, as a key intervention of this proposed project, is considered to be a pivotal role to enhance and support the quality of secondary schools PE in Hong Kong. The purpose of this study is to evaluate the effect of a PLB-LTAD programme in physical education curricula and how its routines can be associated with QPE at Hong Kong secondary schools.

Method

A randomized controlled trial (RCT) design was performed. One hundred twenty students aged 11 to 16 years participated in an eight-months of PLB-LTAD training programme (2 days a week, 45 minutes training per day). A total of 45-hours of PLB-LTAD training was conducted to students during this period. Qualified PE teachers implemented the PL intervention across two classes, and another two classes formed a control group as part of a RCT. Video recordings of PE lessons were used to check fidelity of the PLB-LTAD programme. Charting Physical Literacy Journey (CPLJ) Matrix, seven days of wearing accelerometers, and the LTAD stage four -"Training to Train" (endurance, strength, and speed) were used to collect self-report and objective data measures from baseline, post-intervention and follow-up phases. Repeated meas-

ure ANOVAs and MANCOVA, with time (baseline, after intervention, and follow-up) as within-subjects factor and intervention group (PLB-LTAD and CG) as between-subjects factors were used to evaluate the change of interventions on the students' PL, PA, and fitness levels.

Discussion

The study presents as an experimental study in Hong Kong to investigate the effect of a PLB-LTAD programme at the secondary school PE curriculum. Upon its completion, the study protocol may contribute to the field by providing evidence for the effectiveness of training programmes, for the manageability of students' PA levels and PL awareness in school settings. While it may affect students' athletics career and motivation to participate in various sports.

Physiology

MUSCLE OXYGENATION DURING THE MAXIMUM AEROBIC METABOLISM WORKOUTS IN WORLD CLASS KAYAKERS: A CASE STUDY

DADELIENE, R.1, NEKRIOSIUS, R.2, DADELO, S.3

1 VILNIUS UNIVERSITY, 2 LITHUANIAN SPORTS UNIVERSITY, 3 VILNIUS GEDIMINAS TECHNICAL UNIVERSITY

INTRODUCTION: In 1000-meter sprint kayaking events some muscle energy is generated through aerobic reactions and the other part of the energy comes from anaerobic reactions. Near Infrared Spectroscopy (NIRS) is one of the most informative methods for the analysis of aerobic metabolism in muscles. Although some researchers have analyzed the muscle oxygenation in different age kayakers by the NIRS method, there is little research evidence about the muscle oxygenation in world-class kayakers getting ready for 1000-meter sprint events.

The aim of this research work is to investigate muscle oxygenation of the world-class kayaker during workouts with different intensity efforts.

METHODS: A single case study was conducted with the kayaker who is the winner of Europe and World championships and who was the fifth at the Olympic Games. Athlete's data: height 184.5 cm, weight 89.4 kg, lean body mass 50,2 kg, vital capacity 7.7 l, grip strength 74 kg, VO2 max 5.24 l/min, maximum aerobic power on kayak ergometer 340 W, with VO2 at the anaerobic threshold of 3,90 l/min, capacity 220 W. NIRS monitors were fixed on the following muscles: Lateralis Dorsi (LD), Pectorlis Major (PM) and Vastus Lateralis (VL). The athlete performed two special workouts with explosive and high-intensity efforts. One workout was used to determine the VO2 max using a kayak ergometer. The other workout was rowing in water in a 1000-meter race (average 310 W, 3 min 38 sec.).

RESULTS: The VO2 max test revealed different oxygenation processes. Oxygen saturation reduced the most in VL muscle, whereas in LD and PM muscles the SmO2 dropped down to 20–30 %. During the racing workout, the SmO2 gradually reduced and reached the 0–10 % limit at the end of the distance. The heart rate was 184 bpm during both workouts.

CONCLUSION: Our study revealed that aerobic processes were very intensive in all world-class kayaker's muscles during both workouts involving high-intensity efforts. The greatest oxygenation changes were observed in VL muscle. These findings prompt the need for further research into aerobic metabolism in the muscles of world-class athletes.

EXERCISE TRAINING IMPROVES ERYTHROCYTE OSMOTIC DEFORMABILITY IN PATIENT WITH END STAGE RENAL DISEASE

HUANG, Y.

ASIA UNIVERSITY

INTRODUCTION: Erythrocyte injury and early senescence resulted in impaired deformability are important pathogenic features in end stage renal disease (ESRD), and which further disturb microcirculation. Moreover, the drastic changes in osmotic pressure also crucially affected osmotic deformability. This study investigated whether moderate intensity exercise training affect erythrocyte membrane and osmotic deformability in ESRD.

METHODS: Ten patients suffering from ESRD underwent moderate intensity exercise training for 30 min a day, 3 days a week for 12 weeks. The blood sample collection and graded exercise test (GXT) were performed 3 times at intervals of 12-weeks: baseline (T1), start training (T2), and after training (T3). All subjects were analyzed with osmotic gradient ektacytometry for assessing erythrocyte membrane stability and osmotic deformability before the GXT test.

RESULTS: The patients significantly improved their aerobic capacity, achieved a more symmetric erythrocyte shape, and heighten the levels of CD47 and CD147 after training. Furthermore, the osmolarity at EIhyper (Ohyper), elongation index values at low osmolar conditions (EImin) and the area under the osmolarity-elongation index curves were significantly higher after training compared to the baseline. Although no change was observed in the maximum elongation index (EImax), training for 12 weeks augmented the erythrocyte membrane deformability, represented by decreased SS1/2 and SS1/2/EImax. The erythrocyte count and hemoglobin were unchanged among three test timepoints.

CONCLUSION: A 12-week moderate intensity exercise training significantly improves erythrocyte membrane and osmotic deformability, and further enhanced aerobic capacity.

THE HIGH CARBOHYDRATE-INDUCED IMPAIRMENT OF ENDOTHELIAL FUNCTION IS SUPPRESSED BY THE FOLLOWING INTERMITTENT EXERCISE

FUKUBA, Y.1,2, KASHIMA, H.2, NISHITANI, N.3, MIURA, K.4, ENDO, M.Y.2

1: HIROSHIMA INTERNATIONAL UNIVERSITY, 2: PREFECTURAL UNIVERSITY OF HIROSHIMA, 3: UNIVERSITY OF TSUKUBA, 4: AICHI PREFECTURAL UNIVERSITY

INTRODUCTION: Aerobic exercise for the lower legs induces endothelial adaptation of the conduit artery in the inactive upper limbs, such as the brachial artery (BA). This favorable effect on the endothelium is derived from nitric oxide (NO) production, which is a strong endothelial mediator of vasodilation. NO production is mainly caused by the exercise-induced elevation of shear stress (SS) because of increased blood flow in the BA. However, ingestion of a carbohydrate-rich meal impairs endothelial function temporally. This damaging effect is caused by postprandial hyperglycemia, which increases oxidative stress and reduces endothelial NO bioavailability. Subsequently, repeated daily hyperglycemia would be associated with atherosclerosis development along with type II diabetes. However, the effect of exercise and its timing (e.g., pre- or postprandial exercise) on impaired endothelial function caused by high carbohydrate ingestion has not been extensively studied. Therefore, we evaluated flow-mediated dilation (FMD) of BA as a noninvasive standard measure of endothelial function after oral glucose ingestion. FMD was evaluated immediately before or after high-intensity intermittent exercise (HIIE), which is more effective than moderate-intensity constant exercise.

METHODS: Healthy young volunteers (n=11) participated in three protocols in random order. In the preprandial exercise protocol (preprandial Ex), 30 min HIIE was performed for 60–30 min before the ingestion of a 500 mL drink containing 75 g of glucose. In the postprandial exercise protocol (postprandial Ex), HIIE was performed for 15–45 min after ingestion of the drink. In the control protocol (Con), the subjects ingested the same drink without exercise. The leg cycling HIIE comprised a 2-min warm-up of 20 W and 28 min of main exercise. The main exercise consisted of 4 HIIE set repetitions: one 7 min set, approximately 80% of maximal heart rate (HRmax) corresponding to a work rate of 158 ± 41 W for 4 min, followed by a work rate of 20 W for 3 min. Before and at 60 and 120 min after glucose drink ingestion, FMD (%FMD = ([peak diameter−baseline diameter]/baseline diameter) × 100) and SS profiles (ante- and retrograde shear rates (SR) [an estimate of SS] = blood velocity/diameter) were evaluated by Doppler ultrasonography. Blood glucose (BG) and plasma insulin (PI) concentrations were measured at the same time schedule.

RESULTS: At 60 min after ingestion, postprandial Ex showed significantly higher % FMD compared with Con and preprandial Ex. The changes of antegrade SRs with time in three protocols were very similar to those in %FMD. The BG and PI responses with time in three protocols were mirror images of those in %FMD.

CONCLUSION: The postprandial high-intensity intermittent exercise effectively suppresses subsequent endothelial dysfunction via postprandial hyperglycemia suppression and antegrade shear stress elevation in the brachial artery.

EFFECT OF TRAINING ON URINARY N-TELOPEPTIDES OF TYPE I BONE COLLAGEN LEVELS IN MALE COLLEGE LONG-DISTANCE RUNNERS

FUJITA, S.1, WAKAMATSU, K.1, SAKURADA, S.2, WATANABE, S.1, TAKEDA, H.1

1 J.F.OBERLIN UNIVERSITY, TOKYO, JAPAN; 2 JUNTENDO UNIVERSITY, TOKYO, JAPAN

INTRODUCTION: A stress fracture is a bone injury tissue caused by chronic low-level stress activities such as running and eventually may lead to a complete fracture. This type of fracture is a serious complication with a long-term impact and affects athlete training status. The incidence of stress fracture has been shown to be high in long-distance runners, who may have two different types of training techniques: 1) long-running distances at a slow speed, and 2) short-running distances at a high speed. However, the effects of these types of training techniques on stress fracture are unknown. This study aims to determine the effects of these training methods on the levels of urinary N-telopeptides of type I bone collagen (u-NTX), a well-known biomarker for bone resorption, and Creatine Kinase (CK) enzyme in male college runners.

METHODS: In this study, we investigated the effects of different training contents on bone metabolism in long-distance runners. The participants were six male college students (mean age 19.5 ± 1.3 yr, mean body fat 12% ± 2.3%) of a university track team. The levels of u-NTX and CK were quantified during three different running periods: the "off" (at rest), the long-distance (LD), and the high speed (HS). The LD period involved high-training volumes and long distances, while the HS period involved high-quality training and short distances at faster speeds. The running speed and distance training were recorded each week using a smartwatch (ForeAthlete935, Garmin Corporation). The level of CK enzyme was assessed once each day after the finalization of the training period while u-NTX concentration

was continuously measured for seven days after each period.

The level of u-NTX is well-known to exhibit a large daily variation, and therefore the normal value was based on an average for seven consecutive days during the "off" period. Average values and fluctuations in the concentrations of u-NTX after LD and HS periods were compared to the normal value.

RESULTS: Results showed that the LD period (786.3 ± 218.4 U/L) had higher levels of CK than the "off" period (280.6 ± 73.5 U/L), $p < 0.05$). There was no change in the level of u-NTX after the HS period. After the LD period, the u-NTX values were lower on the 1st day (39.7 ± 9.5 nmolBCE/mmolCRE) and 5th day (37.2 ± 7.9 nmolBCE/mmolCRE) than the normal average value (47.6 ± 8.0nmolBCE/mmolCRE, $p < 0.05$). The average value 7 days after the LD period (40.2 ± 9.5 nmolBCE/mmolCRE) was also lower than the "off" period average ($p < 0.05$).

CONCLUSION: Our results support the idea that high-training volumes and long distances are associated with higher muscle damage than high-quality training and may also lead to the suppression of bone resorption.

COMBINED EFFECTS OF HYPERTHERMIA AND MENTAL FATIGUE IMPAIRS AEROBIC EXERCISE CAPACITY IN HIGHLY TRAINED ATHLETES IN THE HEAT.

NAITO, T.1, SAITO, T.2, MORINAGA, H.3, EDA, N.4

1> HOKKAI-GAKUEN UNIVERSITY, 2> TOTTORI UNIVERSITY, 3> NATIONAL INSTITUTE OF FITNESS AND SPORTS IN KANOYA, 4> DOKKYO MEDICAL UNIVERSITY

INTRODUCTION: Combined effects of mental fatigue by a prolonged cognitive task and exposure to heat stress would impair exercise capacity in the heat. However, in the focus of thermoregulatory responses, it is not unclear whether the effects of elevation in core temperature (hyperthermia) or heat exposure without elevation in core temperature during performed cognitive task induce to impair exercise capacity. The purpose of this study was to investigate the effects of differences in core temperature by exposure to heat stress in addition to a mental fatigue on aerobic exercise capacity in the heat.

METHODS: Seven highly trained athletes (age: 22 ± 1 years, height: 173.2 ± 2.4 cm, body mass: 67.11 ± 5.2 kg, maximal oxygen uptake: 63.7 ± 7.1 mL/kg/min) completed two experimental conditions: hyperthermia (HYP) and control (CON). Participants were conducted AX-Continuous Performance Task (AX-CPT) and Stroop tasks to induce mental fatigue during a warm water immersion at 40°C (HYP) or a seated in chamber at 35°C and 60% relative humidity (CON) for 45 min before exercise. Thereafter, participants performed running trial at 80% maximal oxygen uptake until voluntary exhaustion in the same chamber as the CON.

RESULTS: Exercise time to exhaustion was significantly lower in the HYP trial (8.9 ± 3.3 min) than that of the CON trial (12.6 ± 3.3 min; $p = 0.028$). Rectal temperature at the end of tasks in the HYP trial increased by 0.86 ± 0.26°C ($p = 0.001$) and was significantly higher (37.69 ± 0.18°C) than that of the CON trial (36.96 ± 0.13°C; $p = 0.001$), albeit no significantly differences in mean skin temperature ($p = 0.610$). Heart rate at the end of tasks in the HYP trial was significantly higher (98 ± 18 bpm) than that of the CON trial (76 ± 11 bpm; $p = 0.021$). Self-reported mental fatigue using visual analog scale was significantly higher after tasks in both trials ($p < 0.001$), but no significantly differences between trials (HYP: 5.3 ± 2.5, CON: 6.1 ± 2.2, $p = 0.349$). Throughout trial, salivary cortisol concentration and perceptual responses (perception of effort and thermal sensation) were not affected by hyperthermia.

CONCLUSION: This study demonstrated that combined effects of elevation in core temperature (hyperthermia) and mental fatigue in highly trained athletes causes to impair exercise capacity in hot environments compared to mental fatigue during heat exposure without elevation in core temperature. This observation suggests that athletes with mental fatigue should avoid elevation in core temperature equivalent to hyperthermia before exercise to attenuate impairment in subsequent endurance exercise performance in hot environments.

ESTIMATION OF LACTATE THRESHOLDS FOR MUSCLE OXYGENATION IN HEALTHY, NON-TRAINING INDIVIDUALS AND HIGH-TRAINED SPEED SKATERS

REBIS, K.1, KLUSIEWICZ, A.1, DLUGOLECKA, B.2, ROZANSKI, P.2, KOWIESKI, K.2

1INSTITUTE OF SPORT - NATIONAL RESEARCH INSTITUTE IN WARSAW, 2JOZEF PILSUDSKI UNIVERSITY OF PHYSICAL EDUCATION IN WARSAW, FACULTY OF PHYSICAL EDUCATION AND HEALTH, BIALA PODLASKA, POLAND

INTRODUCTION: In the last few years, the introduction of mobile oximeters to measure the oxygenation level of myoglobin in the muscle cytoplasm and hemoglobin in the blood vessels of the muscle microcirculation (muscle oxygen saturation, SmO2) has been particularly relevant to training practice [1]. SmO2 measurements provide valuable information about oxygen transport and utilization in muscles [2]. The main objective of the study was to determine lactated thresholds (aerobic and anaerobic) for near-infrared spectroscopy (NIRS) measurements in healthy, non-training individuals and highly trained athletes. It was important to answer the question to what extent muscle oxygenation at the anaerobic threshold level and after maximal exercise is dependent on the level of physical capacity.

METHODS: The study involved 29 untrained students (Female students n=13, 23.1 ± 1.0yrs, body mass index (BMI) 22.3 ± 3.7, Male students n=16, 23.8 ± 1.1yrs, BMI 25.6 ± 3.4) and 27 leading Polish speed skaters, members of the National Team of juniors and seniors, men and women (Female speed skaters n=13, 18.5 ± 2.0yrs, BMI 21.3 ± 1.0, Male speed skaters n=14, 17.9 ± 2.2yrs, BMI 22.3 ± 1.2). A graded-intensity exercise test on a bicycle ergometer was performed. The test consisted of 3-minute stages with graded load performed continuously. Based on blood lactate concentrations, the aerobic and 3 anaerobic thresholds (AT4 mmol, Dmax modf. and LT) were determined. During GXT test, a NIRS device (Moxy monitors; Fortiori Design LLC, Hutchinson, MN, USA) was placed on the vastus lateralis (VL) muscle that is active during cycling. The normal distribution of variables was examined using the Shapiro-Wilk test. The significance of differences was assessed using the Student test and Mann-Whitney U-test for variables with a distribution different from the normal distribution. The power of relationships between the variables was determined based on Pearson's correlation coefficients (r). The coefficient intervals for correlations were also presented. The level of statistical significance was set at $p \leq 0.05$.

RESULTS: Power values determined for all thresholds were significantly higher in female and male speed skaters compared to male and female college students. Muscle oxygenation (SmO2) at anaerobic thresholds was significantly lower in female speed skaters than in female students. In male speed skaters, the differences discussed were not statistically

significant. Both female and male skaters additionally showed greater decreases in SmO2 after the maximal test compared to students. The dependence of SmO2 on exercise load for all groups combined was polynomial. Although the time to achieve 50% SmO2 during recovery did not differentiate between the male and female groups studied, a higher rate of muscle reoxygenation (% / s) was found in female speed skaters compared to female students. This was also confirmed by a significant correlation in women between the rate of muscle reoxygenation and Peak Power. In speed skaters, although the mentioned rate of muscle reoxygenation was not significantly higher compared to students it showed a significant positive correlation with VO2max.

CONCLUSION: High diagnostic value characterized the assessment of differences in muscle oxygenation relative to resting value (ΔSmO2) both at anaerobic threshold (in females) and after maximal exercise (in females and males), with greater decreases in SmO2 observed in subjects with higher physical capacity. There was also a significant positive correlation between the rate of muscle reoxygenation after the maximal test and the level of physical capacity.

EFFECTS OF EQUOL SUPPLEMENTATION ON EXERCISE-INDUCED MUSCLE DAMAGE AND DELAYED-ONSET MUSCLE SORENESS IN YOUNG MEN: A RANDOMIZED, DOUBLE-BLINDED, PLACEBO-CONTROLLED CROSS-OVER STUDY

HAYASHI, K.

KOKUGAKUIN UNIVERSITY

INTRODUCTION: Estrogen has a protective effect on exercise-induced damage (EIMD) of skeletal muscle. Equol is a metabolite of dietary soy isoflavone daidzein by gut microbiome and has an anti-inflammatory and antioxidant effect like estrogen (Kim, 2021). Equol may be effective for attenuating the EIMD since inflammatory cytokines and reactive oxygen spaces are involved in the process of the EIMD. The purpose of the present study was to determine the positive and protective effects of equol supplementation on eccentric exercise-induced muscle damage and delayed onset muscle soreness in young men.

METHODS: Healthy young sedentary and recreational active men (n=12, 22±2 years, mean±SD) participated in the double-blind placebo-control cross-over designed study. All participants were tested for the equol producing status, and only the non-equol producers participated in the trial. Participants took the equol supplements (10mg/day) or placebo for 7 days before and 2 days after the 150 maximal eccentric actions of the quadriceps femoris muscle of one-leg on an isokinetic dynamometer (Cybex). At least 3 weeks later, participants performed an equivalent bout of eccentric exercise on the contralateral leg with consuming the other supplements. Maximum isometric torque and peak concentric torque during isokinetic knee extension (60 degree/sec), muscular stiffness of rectus femoris (handheld tissue hardness meter), range of motion of knee joints of the exercised leg, and pain scale of quadriceps (visual analog scale) were measured before and after 24h, 48h, and 72h the eccentric exercise.

RESULTS: Maximum isometric torque (-16.1%) and peak concentric torque (-22.9%) during isokinetic knee extension decreased at 24h after the eccentric exercise in the placebo condition ($p<0.05$) but apparent declines were not observed in the equol condition (isometric torque: -2.6%, peak concentric torque: -3.7%, interaction effect: $p<0.05$). The muscular pain scale of quadriceps increased at 24h following the eccentric exercise and returned to baseline at 48h in both conditions but no differences of trend were observed between the two conditions. Muscular stiffness of the rectus femoris and range of motion of knee joints of the exercised leg did not change in both conditions.

CONCLUSION: These results suggest that equol has a protective effect on the eccentric exercise-induced decline of muscular performance but not on delayed-onset muscle soreness in young men. Equol supplementation may be useful in maintaining muscular conditioning during the training and competitive periods.

EFFECTS OF EXERCISE INTENSITY IN HYPOXIA OR NORMOXIA ON EXPRESSION OF GENES INVOLVED IN MICE SKELETAL MUSCLE METABOLIC PATHWAYS

DROZDOVSKA, S.1,2, ZANOU, N.1, LAVIER, J.1, MILLET, G.1, PELLEGRIN, M.1,3

1 INSTITUTE OF SPORT SCIENCES, UNIVERSITY OF LAUSANNE, SWITZERLAND; 2 NATIONAL UNIVERSITY OF UKRAINE ON PHYSICAL EDUCATION AND SPORT. KYIV, UKRAINE; 3 DIVISION OF ANGIOLOGY, HEART AND VESSEL DEPARTMEN

INTRODUCTION: Exercise training performed in hypoxia may improve oxygen transport and skeletal muscle metabolism, and lead to greater benefits on physical performance, than similar training in normoxia. However, there are few studies comparing the molecular responses of skeletal muscle to different exercise intensities, superimposed to hypoxia. The aim of the present study was therefore to investigate the effects of low and supramaximal exercise intensities in hypoxia and normoxia on expression of genes associated with muscle energy metabolic pathways in healthy mice.

METHODS: A total of 36 8-week-old male C57BL/6J mice were randomly divided into six groups (n=6 mice/group): sedentary (SED) in normoxia and hypoxia, low-intensity training normoxia (LIT) in normoxia and hypoxia, supramaximal intensity normoxia (SIT) in normoxia and hypoxia. Exercise consisted in running on a mouse treadmill 3 times/week for 4 weeks, in a chamber with a fraction of inspired O2 (FiO2) of either 0.13 (hypoxia) or 0.21 (normoxia). Mice assigned to LIT groups ran continuously for 40 min at 40% of maximal aerobic speed, while mice in the SIT groups ran 4 sets of 5 × 10 s sprints at 150% of maximal aerobic speed, with 20s and 5 min of passive recovery between each sprint and each set, respectively.

At end of the study, maximal running distance was assessed with an incremental running test to exhaustion. Expression of genes involved in glucose, lipid and lactate metabolism, as well as mitochondrial biogenesis, was determined in the gastrocnemius muscle using real-time PCR.

RESULTS: Maximal running distance was not significantly different between the 6 groups of mice. HK2, PFK, LDHA, TFAM and HSL mRNA levels were significantly increased in SED in hypoxia compared to SED in normoxia, while no significant difference was reported in LIT and SIT in hypoxia in comparison with respective groups in normoxia. GLUT4 mRNA level significantly decreased in SIT in hypoxia versus SIT in normoxia. In normoxia, GLUT4, MCT1, MCT4 and NRF1 mRNA expression was significantly higher in SIT than in SED and LIT, when in hypoxia only MCT1 and MCT4 expression was upregulated in SIT compared to SED and LIT. Expression of PKm1, PDH, PDK4, PGC-1α, PGC-1β, mtDN1, mtND6, CytC, CytB, CD36 and UCP2 did not significantly differ between hypoxic and respective normoxic groups, and with exercise in any group.

CONCLUSION: The present study showed that 4 weeks of exercise training at low and supramaximal exercise intensities in normoxia and hypoxia have moderate effect on muscular transcriptional regulation of genes related to metabolic pathways in healthy mice. Despite previous reports that hypoxia induces a potent physiological stimulus and increases physical performance, due to the heterogeneity in response of LIT and SIT in hypoxia observed in the present study, we showed that the exercise intensity per se is paramount and induces different adaptations to hypoxic exercise.

IMPACT OF PHYSICAL ACTIVITY AND METABOLIC SYNDROME PARAMETERS ON THE RISK OF CAROTID PLAQUE INSTABILITY ASSESSED BY MRI.

THOMAS, A.

UNIVERSITY OF LYON

INTRODUCTION: Atherosclerotic disease is a complex multifactorial and systemic condition that affects coronary arteries, carotid arteries, and arteries of the lower limbs. Atherosclerotic plaque instability can lead to death, ischemic stroke, myocardial infarction, or acute lower limb ischemia and amputation. The pro-inflammatory and hypoxic environment of the atherosclerotic plaque promote the development of intraplaque neo-vessels that cause intraplaque hemorrhage (IPH). The most reliable in-vivo criterion for carotid plaque instability detection is presence of IPH, detected by magnetic resonance imaging (MRI) with gadolinium injection. Physical Activity (PA) decreases stroke's incidence and coronary arteries calcification. More precisely, PA has an impact on arterial stiffness and stenosis, but also on volume and instability of atheroma plaque.

The objective of the present study is to evaluate the impact of PA and sedentary behavior on IPH by MRI.

METHODS: This cross-sectional cohort study involves 57 patients with carotid atherosclerotic plaque with more than 50% stenosis, asymptomatic for more than 6 months, with no surgical indication for endarterectomy and no recent inflammatory intercurrent diseases. Characterization of carotid plaque instability was evaluated by magnetic resonance imaging (MRI). A score was defined for IPH (from 0: non hemorrhage to 3: large hemorrhage). PA and sedentary behavior were assessed by questionnaires (GPAQ) and physical fitness by 6-minutes Walking Test (6-MWT). The parameters of the metabolic syndrome (BMI, fat mass, hypertension, fasting blood glucose, dyslipidemia) known to promote atherogenesis have been analyzed as covariates.

RESULTS: We showed that the score of IPH quantified by MRI was increased in the glucose intolerant subgroup of patients (0.39 vs 0.84, p=0.04). This result was confirmed by a higher prevalence of hemorrhagic plaque in the glucose intolerant group (73 vs 41%, p< 0.05). Interestingly, the fasting blood glucose level is higher in patients with a hemorrhagic plaque than non-hemorrhagic plaque (5.6 vs 6.9 mM, p=0.04). Moreover, neither other known pro-atherogenic markers (LDL, cholesterol, TG) nor obesity seem to increase the degree of IPH. We also observed that the score of intraplaque hemorrhage quantified by MRI was increased in the sedentary non-physically active subgroup of patients (1.6 vs 0.8, p=0.08). This result confirms our previous observation3 showing a higher prevalence of hemorrhagic plaque in the sedentary non-active group compared to the physically active non-sedentary group (69 vs 31%, p< 0.01).

CONCLUSION: In conclusion, we demonstrated the major role of PA on the risk of plaque instability. Moreover, as we were able to reproduce by MRI imaging a result obtained by histology, we highlighted the importance of plaque MRI to detect unstable plaque in at-risk populations and to evaluate in-vivo beneficial interventional treatment including both PA and pharmacological treatment.

THE BILATERAL DIFFERENCE OF THE DEVELOPMENT ON LOWER LIMBS MUSCLE THICKNESSES IN MALE JUNIOR SPEED SKATERS.

KUMAGAWA, D.

KOKUSHIKAN UNIVERSITY

INTRODUCTION: The force and power generation capacities of the lower limb muscles are improved by speed skating training in speed skaters (Nemoto et al. 1990). Speed skating runs around a 400m ice rink. In curve skating, the body is tilted to the inside of the rink and the body is always pushed off to the right, so the kinetics of the left and right legs are different during curve skating. From these facts, it is expected that the load on the left and right legs is different during speed skating, and it is possible that there is a difference in the development of muscle morphology between the left and right legs. However, it is not clear whether the same specific hypertrophy in each site of lower limbs muscles occurs with competitive speed skating training in junior skaters. Therefore, in this study, we investigated that the effects of growth and

development on the bilateral difference of the development on lower limbs muscle thicknesses in male junior speed skaters.

METHODS: The subjects were 10 to 18 years old male speed skaters. They were divided into 9 groups according to chronological age every 1 year. All subjects had belonged to speed skating clubs and they performed training of speed skating all through the year. Body compositional parameters for body height, body mass, fat mass and fat-free mass of the whole body were measured using the body impedance analysis method. The muscle thicknesses on the thigh anterior, lateral and posterior, lower legs anterior and posterior in both legs were measured using the B-mode ultrasonic method.

RESULTS: As a result of two-way analysis of variance of age x left and right legs for muscle thickness, no significant difference or interaction between left and right legs was observed at all sites. The ratio of muscle thickness values in each age group to the 10-year-old group showed a greater rate of change in the thigh than in the lower leg. As a result of comparing the slope of the liner regression line in relationships between the left and right muscle thicknesses, the regression lines for the anterior and lateral thighs were gentler than those for the other regions. In other words, skaters with larger muscle size had greater muscle thickness on the left side.

CONCLUSION: From these results, the muscle thickness of the lower extremities in junior speed skaters is thought to be more remarkable in the thigh than in the lower leg. Furthermore, it was suggested that the muscle thickness on the left side is more developed than the muscle thickness on the right side in skaters with higher muscle thickness values.

EFFECTS OF DIFFERENT ENVIRONMENTAL ENRICHMENT ON SPONTANEOUS PHYSICAL ACTIVITY AND SPATIAL LEARNING.

SUDO, M., ANDO, S.

PHYSICAL FITNESS RESEARCH

INTRODUCTION: Environmental enrichment (EE) promotes a variety of positive effects on brain function. However, it is controversial whether EE remains beneficial in the absence of wheel running. The controversy may be the result of differences in spontaneous physical activity level. Nevertheless, in EE experiments where multiple rodents were housed in a cage, individual spontaneous physical activity level has not been measured due to the technical difficulties. PURPOSE: We tested the hypothesis that cognitive benefits arising from EE are associated with spontaneous physical activity level (wheel running and/or other locomotor activity). The purpose of the present study was to examine whether EE that enables facilitation of wheel running activity and physical activity (PA) changes spatial learning and memory and stress hormone.

METHODS: Wistar rats were divided into four different housing groups: EE (running wheel and objects: slope, tunnel, and hut), running wheel only (EE-R), objects only (EE-O), and standard environment (SE) (N=7-8/group). Physical activity level of each rat was continuously recorded using an embedded three-axis accelerometer. After exposure to each condition for 4 weeks, the animals were submitted to the Morris water maze (MWM) test. The MWM test was carried out on 4 consecutive days, and spatial learning and memory was assessed using time to find the platform. The concentration of serum corticosterone was analyzed using an electrochemiluminescence immunoassay method.

RESULTS: Physical activity level was higher in the EE (260,350 ± 9,203 a.u./week) and EE-R (205,018 ± 8562 a.u./week) compared with the SE (13,745 ± 945 a.u./week, Ps < 0.05). There was no difference in physical activity level between the EE-O (16,770 ± 1,200 a.u./week) and the SE. In the MWM, the time to find the platform was shorter in the EE groups (EE: 15.5 ± 3.0, EE-R: 11.4 ± 3.5, EE-O: 11.6 ± 4.5 sec) than the SE group (29.9 ± 3.0 sec, Ps < 0.05) on day 3. Physical activity level among the groups was not correlated with the time to find the platform (R2 = 0.22). The serum corticosterone concentration in the EE groups (EE: 399 ± 29.5, EE-R: 409 ± 46.5, EE-O: 420 ± 36.2 ng/mL) was significantly lower than that in the SE group (574 ± 33.1 ng/mL, Ps< 0.05).

CONCLUSION: The EE-O enhanced cognitive function despite lower physical activity level without increasing physiological stress. The present investigation suggests that spontaneous physical activity level alone does not determine hippocampus-dependent cognition in the environmental enrichment conditions.

COMBINED AEROBIC AND LOW-INTENSITY RESISTANCE EXERCISE TRAINING INCREASES BASAL NITRIC OXIDE PRODUCTION AND DECREASES ARTERIAL STIFFNESS IN HEALTHY OLDER ADULTS

OTSUKI, T., NAMATAME, H., UMINO, M., YOSHIKAWA, T., ZEMPO-MIYAKI, A.

RYUTSU KEIZAI UNIVERSITY

INTRODUCTION: Meta-analyses have concluded that combined aerobic and high-intensity or moderate-intensity resistance exercise training has no effects on arterial stiffness (1). However, a recent study demonstrated that combined aerobic training and low-intensity resistance training using rubber bands increases basal nitric oxide (NO) production and decreases arterial stiffness with marked reduction of body weight in obese adolescent girls (2).

METHODS: To investigate whether combined aerobic and low-intensity resistance training increases basal NO production and decreases arterial stiffness without body weight reduction in older adults, 27 healthy older individuals participated in a 6-week program as a part of the training group (mean body mass index, 21 kg/m2; walking and resistance training using one's body weight) or the control group (22 kg/m2, asked not to modify their lifestyle) (UMIN000034111).

RESULTS: The exercise intervention increased maximal oxygen uptake (aerobic capacity), score of the 10-time sit-to-stand test (muscle strength and endurance), and plasma concentrations of nitrite/nitrate (end products of NO) and decreased brachial-ankle pulse wave velocity (an index of arterial stiffness) without changes in body weight. In the control group, there were no differences in these measures before and after the study period.

CONCLUSION: These results suggest that combined aerobic and low-intensity resistance exercise training increases basal NO production and decreases arterial stiffness in healthy older adults.

THE BLOOD PRESSURE REGULATION AGAINST ACUTE CENTRAL BLOOD VOLUME REDUCTION IN ENDURANCE ATHLETES

HIRASAWA, A.1, HIRABUKI, K.1, HATA, N.1, SUDA, T.1, SUZUKI, R.1, FUKUIE, M.2, UECHI, T.3, MATSUDA, T.1, SUGAWARA, J.2, SHIBATA, S.1

1> KYORIN UNIVERSITY, 2> NATIONAL INSTITUTE OF ADVANCED INDUSTRIAL SCIENCE AND TECHNOLOGY, 3> YOKOHAMA ROSAI HOSPITAL

INTRODUCTION: The blood pressure is determined by the triple product of stroke volume (SV), heart rate (HR), and total peripheral vascular resistance (TPR), and thus maintained by adjusting these variables. It is necessary to increase HR and/or TPR to maintain blood pressure in response to SV reduction due to the decrease in central blood volume caused by a standing posture. It is known that orthostatic intolerance is lower in endurance athletes (Fit) as compared with non-athletes (UnFit). Therefore, Fit may have lower responses in HR or TPR than UnFit. We hypothesized that an increase in HR and/or TPR in response to the decrease in SV would be more impaired in Fit than UnFit. The purpose of this study was to test our hypothesis by comparing the SV, HR, and TPR changes during severe orthostatic stress by low body negative pressure (LBNP) between Fit and UnFit.

METHODS: Eleven male endurance athletes (Fit; 21±3 years old, VO2max 59.2±4.6 ml/kg/min) and 11 male non-athletes (UnFit; 25±7 years old, VO2max 35.6±8.1 ml/kg/min) underwent severe orthostatic stress test using gradient increase of LBNP. LBNP was gradually increased at -15 mmHg, -30 mmHg, and -40 mmHg for 5 minutes, and then incremented -10 mmHg every 3 minutes until pre-syncope (LBNPmax). HR (ECG), SV (3D echocardiography) and mean arterial pressure (MAP; Finometer) were assessed. TPR was calculated by MAP/(SV×HR). Changes in HR, SV, TPR, and MAP from baseline to the load of 85% LBNPmax (85% LBNPmax) were compared between Fit and UnFit.

RESULTS: There was no difference in delta decrease in SV between Fit and UnFit (P=0.277), while SV decreased at the 85% LBNPmax in both groups. However, delta increase in HR and TPR at 85% LBNPmax were smaller in Fit than UnFit (P=0.045 and P=0.024). As a result, delta decrease in MAP at 85% LBNPmax was larger in Fit than with UnFit (P=0.005).

CONCLUSION: The findings indicate that the responses of HR and TPR to an acute severe reduction in SV due to orthostatic stress was blunted in Fit as compared with UnFit, proposing one possible explanation for lower orthostatic intolerance in Fit.

EFFECTS OF SCIATIC NERVE AND CAPSAICIN-INDUCED SENSORY DENERVATION ON TRABECULAR BONE IN YOUNG RATS

NAKAGAWA, K., RYOYA, O., HIROYUKI, T.

NATIONAL INSTITUTE OF FITNESS AND SPORTS IN KANOYA

INTRODUCTION: Bone metabolism is regulated by neurogenic as well as mechanical and humoral factors. Both limb disuse induced by sciatic nerve denervation and capsaicin-induced sensory denervation cause bone loss in rat tibiae. In the present study we investigated the effects of the sciatic nerve and capsaicin-sensitive sensory neurons on the trabecular microstructure of tibial bone.

METHODS: We divided 32 twelve-week-old male Fischer 344 rats into four groups: control (C), capsaicin-administered (Cap), sciatic denervation (DN), and DN+Cap. The subcutaneous capsaicin injection was administered dorsally on three consecutive days. The sciatic denervation surgery was performed at the age of 12 weeks. At the age of 16 weeks, the tibiae were collected and subjected to three-dimensional micro computed tomography . The following parameters were measured: trabecular bone volume fraction , trabecular number, trabecular thickness, connection density, trabecular bone pattern factor, and structure model index (SMI). The SMI quantifies the plate versus rod characteristics of trabecular bone.

RESULTS: The connection density and the trabecular bone volume, number, and thickness were lower, by 25–70%, in the Cap, DN, and DN+Cap groups than in the C group. They were significantly lower in both the DN and DN+Cap groups than in the Cap group, but there was no significant difference between the DN and DN+Cap groups. In contrast, the SMI and trabecular bone pattern factor were significantly higher in the Cap, DN, and DN+Cap groups than in the C group.

CONCLUSION: These results suggest that in addition to reducing bone mass, selective sensory denervation through capsaicin treatment has negative effects on the maintenance of trabecular structure. This results in a shift toward the formation of a rod-like trabecular structure, although this effect is weaker than it is under sciatic denervation. These data also

suggest that capsaicin-sensitive sensory neurons have positive functions in the maintenance of bone mass and trabecular microstructure.

FUNCTIONAL, MOLECULAR AND STRUCTURAL EVENTS ARE NOT SYNCHRONIZED AFTER A PROTOCOL OF INTERMITTENT COLD EXPOSURE FOR MUSCULAR INJURY RECOVERY

TORRELLA, J.R., VISCOR, G., PAGÈS, T., SANTOCILDES, G.

UNIVERSITAT DE BARCELONA

INTRODUCTION: Musculoskeletal disorders are one of the main causes of requirement for functional rehabilitation in the world. In sports, musculoskeletal system injuries represent between 10-55% of all sustained injuries. Because of its high incidence and impact on health, skeletal muscle regeneration process has been extensively studied and characterized. However, still new therapeutic strategies need to be studied in order to accelerate the muscle regeneration process and ameliorate muscle tissue after injury. Due to its high plasticity, skeletal muscle can adapt and respond to different stimuli in order to maintain the homeostasis and improve its functionality. The main objective of our work was to study the effects of an intermittent cold exposure (ICE) protocol on the process of muscle regeneration in an animal model.

METHODS: Eighteen adult-male rats were surgically injured in the right gastrocnemius muscle (GM) and randomly divided into two groups: 1) Control (CON), that recovered at T=24ºC; 2) Intermittent cold exposure (ICE), that recovered for 4h/day at T=4ºC. Several parameters indicators of muscle recovery were measured in both GM (injured and contralateral non-injured) at two different time points after injury (9 and 21 days). Tetanic force (TF) was measured as a functional indicator. Capillary-to-fibre ratio (C/F), after muscle capillaries histochemical staining for eATPase, and VEGF expression, analysed by Western blot, were used as angiogenic indicators. Finally, expression of developmental myosin heavy chain (dMHC), quantification of central nuclei, and collagen I deposition at the injury site, assessed in histological slides, were used as markers of muscle regeneration.

RESULTS: Complete functional muscle recovery (TF) was achieved after 21 days of ICE (injured GM vs non-injured contralateral GM: $p=0.318$) but not after 9 days ($p<0.001$). Conversely, CON did not present any sign of recovery neither after 9 nor after 21 days ($p<0.05$). However, ICE increased VEGF expression after 9 days ($p=0.038$), which translated into angiogenesis at 21 days (C/F CON=2.6 vs ICE=2.9). After 21 days, ICE did not improve collagen I deposition ($p=0.243$) nor dMHC expression ($p=0.967$) and presented higher number of fibres centrally nucleated ($p<0.05$) at the injury site.

CONCLUSION: Our results indicate that ICE did not show a total muscle recovery, at the histological level, after 21 days from injury since fibrosis and molecular and cellular clues are still present after this period of time. However, total functional force recovery was evident from TF recordings which could be explained after an improvement in muscle angiogenesis leading to a good supply of nutrients and growth factors. These findings must be considered when taking decisions regarding the timing of return to play. A total functional recovery is not matched to histological structure repair, which could increase the risk of relapse after muscle injury recovery.

ACUTE EFFECTS OF MAXIMAL GRADED EXERCISE TEST ON CARDIAC AUTONOMIC NERVOUS ACTIVITY AND ARTERIAL BARORECEPTOR REFLEX FUNCTION IN ENDURANCE ATHLETES

SUZUKI, R., HIRABUKI, K., HATA, N., FUKUIKE, M., UECHI, T., HIRASAWA, A., MATSUDA, T., SHIBATA, S.

KYORIN UNIVERSITY,NATIONAL INSTITUTE OF ADVANCED INDUSTRIAL SCIENCE AND TECHNOLOGY

INTRODUCTION: It is known that endurance athletes (Fit) have a lower tolerance for orthostatic stress than sedentary adults (Sed). Autonomic nervous activity and arterial baroreflex function (BRS) play an important role for maintaining blood pressure during orthostatic stress. It has been reported that autonomic nervous activity and BRS are more functioning in Fit than in Sed in the resting condition. However, it is still unknown how the maximal graded exercise test (GXT) would acutely affect these functions in endurance athletes as compared with sedentary individuals. The purpose of this study was to examine whether the effects of GXT on cardiac autonomic nerve activity and BRS would be different based on a physical fitness level.

METHODS: Eight Sed and eleven Fit subjects underwent GXT. The resting RR interval (RR) and systolic blood pressure (SBP) were measured every heartbeat for 5 minutes before and after GXT. Power spectral analysis was applied for SBP and RR variabilities, and transfer functional analysis was applied between these variable. The speed of fluctuations in RR and SBP variabilities were divided into low frequency band (LF: 0.05~0.15Hz) and high frequency band (HF: 0.15~0.35Hz), and the power in each band was calculated. All parameters were compared before and after GXT between Sed and Fit using two way repeated ANOVA with post hoc test of Holm-Sidak.

RESULTS: SBP decreased only in Sed ($P<0.05$) and HR increased in both groups ($P<0.05$) after GXT as compared with before. HF-RR (a measure of parasympathetic activity) decreased only in Sed ($P<0.05$) and LF/HF (a measure of sympathetic activity) increased only in Sed ($P<0.05$) after GXT. LF-Gain (a measure of BRS) tended to decrease in both groups after GXT. LF-Gain was higher in Fit than in Sed after GXT ($P<0.05$).

CONCLUSION: Vagal withdrawal and sympathetic activation were observed in Sed but not in Fit after GXT. BRS was similarly attenuated in Sed and Fit after GXT even though different autonomic responses to GXT were observed between Sed and Fit.

ACUTE EFFECTS OF BLOOD FLOW RESTRICTION ON SPRINT INTERVAL EXERCISE IN COLLEGIATE ATHLETES

CHENG, C.F., CHEN, C., PAN, C.H., CHAN, K.H., WU, K.C.
NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: Blood-flow restriction (BFR) training combined with low-intensity aerobic or resistance exercise could increase aerobic capacity and muscle mass [1]. Preview studies [2, 3] reported that 4-wk of sprint interval training (SIT) combined with BFR might be a potent stimulus to enhance maximal oxygen uptake (VO2max) in well-trained individuals. This study examined the acute effects of BFR with different arterial occlusion pressures (AOP) on the 6 sets of Wingate-based cycling sprint exercise (SIE) performance and physiological responses in athletes.

METHODS: Twelve male collegiate basketball players familiar with SIT program were recruited in this randomized crossover-designed study. After performing the incremental cycling test, participants were asked to respectively perform three treatments, including BFR40 (40% AOP), BFR80 (80%AOP), and CON (passive rest), at rest intervals during SIE. The performance, i.e., peak and mean power, and percentage decrement score, were recorded during SIE test. The muscular deoxygenation and pulmonary oxygen uptake during SIE were measured by near infrared spectroscopy and gas analysis system, respectively. The blood lactate and pH levels were measured before and after SIE. The norepinephrine (NE), growth hormone (GH), insulin-like growth factor-1 (IGF-1), testosterone, nitric oxide (NO) and vascular endothelial growth factor (VEGF), were evaluated before, and immediately, 5, 15, 30, and 60 min after SIE.

RESULTS: No significant differences were found on the peak and mean power outputs among treatments during SIE test. There were also no significant differences on the percentage decrement scores of peak (BFR80 vs. BFR40 vs. CON, 7.8 ± 6.7% vs. 6.4 ± 2.8% vs. 6.7 ± 4.8%, $p > 0.05$) and mean (BFR80 vs. BFR40 vs. CON, 15.1 ± 5.9% vs. 13.7 ± 6.1% vs. 15.9 ± 6.9%, $p > 0.05$) power during SIE among treatments. No significant differences were found in the accumulated exercise time at ≥ 80%, 90%, and 100%VO2max during SIE among treatments. There were non-significant interaction effects on tissue saturation index, total hemoglobin, and deoxyhemoglobin (△HHb) during sprints. However, the △HHb at rest intervals in BFR40 (from the third to fifth rest interval) and BFR80 (from the second to fifth rest interval) were significantly higher than those in CON. No significant differences on blood lactate levels and pH after SIE among treatments. There were no significant interaction effects on the NE, GH, IGF-1, testosterone, NO and VEGF levels among treatments.

CONCLUSION: The BFR administrated at rest intervals might increase the oxygen extraction of muscles, however, different pressures of BFR might neither increase the SIE performance nor improve the muscle hypertrophic and angiogenic responses to SIE in collegiate athletes. VALIDATION OF A DOWNHILL RUNNING PROTOCOL TO STUDY THE EXERCISE-INDUCED MUSCLE DAMAGE (EIMD) AND DELAYED-ONSET MUSCLE SORENESS IN TRAINED ATHLETES.

HODY, S., SCHWARTZ, C., BURY, T.
UNIVERSITY OF LIEGE

INTRODUCTION: Exercise-induced muscle damage (EIMD) has largely been studied in sedentary subjects and/or in the days following maximal eccentric exercise on isolated muscle. However, a better understanding of the EIMD occurrence, prevention or intersubject variability resulting from a functional exercise as downhill running (DR) appears necessary to address this problem in endurance athletes. The purpose of this study was to investigate whether a 30min downhill running (DR) bout cause significant changes in EIMD indirect markers in trained athletes.

METHODS: Healthy well-trained males (n=12, 25±4.89yrs) underwent a VO2max test on a treadmill to determine their maximal aerobic speed (MAS). Then, they were submitted to a 30min DR protocol at 90% MAS (-15% gradient). The rate of perceived exertion (RPE) was assessed using a Borg scale. Indirect markers of muscle damage (plasma creatine kinase, muscle function, muscle extensibility and DOMS in lower limbs) were assessed pre, 24h and 48h after the DR. We also compared the stride parameters (using a 3D motion system) during level and downhill running at the same speed.

RESULTS: The athletes (VO2max: 51.84 ± 6.77 mlO2.min-1.kg-1) completed 30min DR at a speed of 15.53 ± 0.97km/h. Blood lactate increased from the start (2.58 ± 0.59mmol/l) to the end of the DR (5.06 ± 1.76mmol/l). A higher RPE score was found for the cardiovascular demand (13 ± 1.41) than for the muscular effort (14.92 ± 2.81). Plasma CK activity significantly increased from pre (226.08 ± 84.34UI/l) to 24h (1412.25 ± 579.16UI/l) and 48h (869.17 ± 573.11 UI/l) post-exercise ($p<0.01$). A significant decrease in maximal isometric strength of the knee extensors was observed at 24h (-16.12 ± 9.37%) and 48h (-11.61 ± 8.67%) post-DR compared to pre ($p<0.05$). Countermovement jump performance was also decreased at 24h (-5.28 ± 4.30%) and at 48h post (-3.18 ± 5.15%) compared to pre ($p<0.05$). Significant DOMS was observed ensuing the DR with the highest values found for the quadriceps (5.36 ± 2.27 a.u) and the gluteal muscles (4.63 ± 2.49 a.u) 24h post-exercise ($p<0.01$). The knee extensors' extensibility was decreased at 24h (-3.13 ± 4.03cm) and at 48h (-2.75 ± 2.39cm) post-exercise. A Pearson correlation analysis demonstrated a significant correlation between muscle strength loss and plasma CK activity measured 24h post-exercise ($r=0.71$; $p<0.01$). A lower stride frequency and a higher ground contact time was found during DR (-2.8%, $p<0.05$; -2.66% $p<0.001$, respectively) compared to level running.

CONCLUSION: Our data demonstrated that completing 30min downhill running (-15% gradient) at a speed corresponding to 90%MAS was effective to induce significant changes in EIMD markers in trained men, with higher changes observed at 24h post-exercise. This protocol represents an attractive model to deeper study the mechanisms underlying EIMD or its adaptation following DR in trained populations.

SEX DIFFERENCES IN MAXIMAL OXYGEN UPTAKE ADJUSTED FOR SKELETAL MUSCLE MASS IN ENDURANCE ATHLETES: A PRELIMINARY STUDY.

ANDRADE, M., AMADEUS, H., ASSIS, M., BARBOSA, J.G., ANJOS, V.R., VIVAN, L., SEFFRIN, A., VANCINI, R.L., DE LIRA, C.A.B.

FEDERAL UNIVERSITY OF SAO PAULO

INTRODUCTION: It is well known that male athletes perform better than the female athletes in several endurance sports. One of the main reasons for this sex difference in performance has been attributed to VO2max, more specifically to weight-adjusted VO2max, which is limited by the maximum cardiac output. It is estimated that male athletes presented VO2max about 20% higher than the women. However, the sex difference in aerobic performance in lower than 20%. For example, the sex difference in triathlon performance is about 10-12%. Therefore, other variables, apart to VO2max, also affect aerobic performance. Beside VO2max, the performance in long distance events also can be affected by muscle oxidative capacity. The latter can be estimated by lean mass adjusted VO2max. However, there are very little data in the literature on this variable, and little data about sex differences according to muscle oxidative capacity. Therefore, the aim of this study was to compare the aerobic muscle quality, accessed by VO2max adjusted by lower limbs lean mass, between male and female amateur triathletes.

METHODS: Thirty triathletes (15 men and 15 women) that are involved with triathlon training for at least 2 years underwent a cardiorespiratory maximal treadmill test to assess their VO2max (L.m-1), and a body composition test (dual-energy X-ray absorptiometry - DXA) to assess lower limbs lean mass. VO2 max was determined as the stabilization of O2 consumption (increase lower than 2.1 ml. kg-1. min-1), even after increasing treadmill speed. Body mass-adjusted VO2max (mL.kgBM-1.m-1) and lean mass-adjusted VO2max (mL.kgLM-1.m-1) were calculated.

RESULTS: The absolute VO2 max (4.9±0.2 vs. 2.9±0.2 L.m-1, $p < 0.001$, d = 10, 95% CI = 3.4 to 29) and body mass-adjusted VO2 max (61.9±7.1 vs. 52.6±7.1 ml. kg-1. min-1, $p = 0.001$, d = 1.3, 95% CI = 1.2 to 1.5) were significantly higher in male athletes than in female athletes. Conversely, the lean mass-adjusted VO2 max (186.5±14.5 vs. 199.0±23.5 mL.kgBM-1.m-1, $p = 0.092$, d = 0.6, 95%CI = 0.3 to 0.9) were not significantly different between sexes, but the effect size of the difference can be classified as moderate (higher values for the female athletes).

CONCLUSION: Although the sex difference in weight-adjusted VO2max values may explain, at least in part, the difference in performance, muscle oxidative capacity can attenuate the sex difference in performance, once the effect size of sex on lean mass-adjusted VO2max was moderate.

EFFECT OF HYPERCAPNIA ON OXYGEN UPTAKE KINETICS DURING MODERATE CONSTANT INTENSITY EXERCISE

KATO, T.

NATIONAL INSTITUTE OF TECHNOLOGY, TOYOTA COLLEGE

INTRODUCTION: Hypoxic gas (HP) inhalation increases the time constant of oxygen uptake (tVO2) in phase II during constant work-rate exercise (CWE) at moderate intensity [1]. Hypercapnic gas (HC) inhalation leads to increased pulmonary ventilation and decreased respiratory exchange ratio (RER) during CWE at moderate and heavy intensities [2]. Thus, it is hypothesized that HC inhalation alters VO2 kinetics during CWE. This study aimed to test the hypothesis that HC inhalation would alter tVO2 during CWE at moderate intensity.

METHODS: Six healthy males volunteered to participate in the present study. To set up the exercise intensity, the subjects performed incremental maximum exercise tests on three occasions; 1) breathing ambient air (Air); 2) breathing HC (21% O2, 3% CO2, N2=balance); 3) breathing HP (16% O2, N2=balance). Thereafter, each subject performed CWE at 45%VO2max intensity for 6 min on three occasions. Subjects breathed Air or HC or HP from 10 min before the start of exercise until the end of the exercise. The respiratory data were sampled by the automatic gas analyzer by the breath-by-breath system, and tVO2 in phase II was estimated with a nonlinear least-squares fitting procedure. Statistics analysis was performed by one-way ANOVA with a post hoc test.

RESULTS: The average value (baseline) of VO2 before the start of exercise for HC was significantly higher than in Air and HP (306±31 vs 265±35 vs 253±44 ml/min, respectively, $p<0.05$). The baseline VO2 was not different between Air and HP. The amplitude value (Amp) of VO2 for exponential fits for HP was lower than in Air and HC but not significantly statistically (1112±112 vs 1268±325 vs 1275±213 ml/min, respectively). Amp for VO2 was not different between Air and HC. There was no significant difference in the time delay (TD) of VO2 for the three conditions (HC:17.0±3.9, Air:13.3±4.3, HP:13.8±5.0 sec). tVO2 for HC was significantly less than in HP ($p<0.05$) and less than in Air but not significantly (20.6±6.2 vs 25.2±6.1 vs 23.3±8.0 sec, respectively). tVO2 for HP was higher than in Air but not significantly.

CONCLUSION: Our results showed that the increased pulmonary ventilation with HC led to an increase in the baseline VO2 at the resting period, but not in Amp VO2 during CWE at moderate intensity. Although not significantly different, tVO2 was less for HC than for Air, suggesting that HC may alter the dynamics of VO2 to saturation. However, this was for a small number of cases, and further experimentation is needed. In conclusion, VO2 kinetics during CWE at moderate inten-

sity change with HC inhalation, and while tVO2 during CWE at moderate intensity increases with HP inhalation, it may decrease with HC inhalation.

SEX DIFFERENCES IN INFLAMMATORY RESPONSES FOLLOWING ECCENTRIC EXERCISE

FUNAKI, A.1,2, ISHIKAWA, A.2, YAMADA, M.2,3, ICHIKAWA, K.2, KITAJIMA, A.2, NAKAYAMA, S.2, IKEGAMI, N.4, NISHIKAWA, Y.4, SAKAMAKI-SUNAGA, M.4

1. TEIKYO UNIVERSITY OF SCIENCE, 2. GRADUATE SCHOOL OF NIPPON SPORT SCIENCE UNIVERSITY, 3. RESEARCH FELLOW OF JAPAN SOCIETY FOR THE PROMOTION OF SCIENCE, 4. NIPPON SPORT SCIENCE UNIVERSITY

INTRODUCTION: Estradiol is a female hormone that inhibits inflammation following exercise. Increased blood neutrophil counts have been especially reported following eccentric exercise in males, but whether the same phenomenon occurs in females remained unclear. Furthermore, no studies have investigated the relationship between estradiol concentrations and inflammatory markers. Thus, this study aimed to investigate sex differences in the changes in blood inflammatory markers following eccentric exercise, including the relationship to estradiol concentration.

METHODS: This study included untrained 12 males (age: 22.3 ± 2.1 years; height: 175.1 ± 4.4 cm; weight: 65.4 ± 6.8 kg; and lean body mass: 57.4 ± 5.4 kg) and 12 females (age: 26.7 ± 6.7 years; height: 160.0 ± 3.4 cm; weight: 56.7 ± 3.4 kg; and lean body mass: 40.3 ± 1.9 kg). Participants performed 10 sets of 6 repetitions of eccentric exercises of elbow flexors with their nondominant. Blood samples were collected pre-exercise (PRE) and 4, 48, and 96 h postexercise (POST) to analyze serum estradiol concentration, serum creatine kinase (CK) activity, leukocyte count, leukocyte fractionation (neutrophils, lymphocyte, monocyte, and other leukocytes), and interleukin-6 concentration. The serum estradiol concentration was analyzed only PRE.

RESULTS: The serum estradiol concentration was significantly higher in females than in males (males: 27.0 [16.3–33.8] vs. females: 37.5 [30.8–50.8] pg/mL; $p < 0.01$). Significant time effects were observed for serum CK activity at PRE to 96 h POST ($p < 0.01$). PRE and 4 h POST CK activity were significantly lower in females compared to males, but the difference disappeared when normalized for lean body mass. Lymphocyte counts increased in 4 h POST compared to PRE only in females ($p < 0.01$), and the percent change in lymphocyte counts from PRE to 4 h POST was significantly higher in females than in males ($p < 0.05$). A significant negative correlation was observed between serum estradiol concentration and the percent change in lymphocyte counts from PRE to 48 h ($r = -0.640$, $p < 0.05$) and 96 h ($r = -0.735$, $p < 0.01$) POST in females. No sex differences were found in changes between neutrophil, monocyte, other leukocyte counts, and interleukin-6 concentrations.

CONCLUSION: These results suggest that the percent changes in lymphocyte counts from PRE to 4 h POST following eccentric exercise are higher in females than in males. Additionally, serum estradiol concentrations were negatively correlated with the percent change in lymphocyte counts following eccentric exercise in females. Therefore, females experience an increase in lymphocyte counts following eccentric exercise, which may be suppressed by estradiol.

INFLUENCES OF TRAINING IN THE COLD ON SKELETAL MUSCLE METABOLISM AND STRUCTURAL GENE EXPRESSION

GAGNON, D.D., HERZIG, K.H., STENBÄCK, V., KYRÖLÄINEN, H., PELTONEN, J.E., WALKOWIAK, J., TULPPO, M., MAGGA, J., KERKELÄ, R., MÄKELÄ, K.A.

UNIVERSITY OF JYVASKYLA

INTRODUCTION: Exercising under cold stress regulates muscle metabolism by increasing lipid utilization (1). Interestingly, lower muscle temperature may also impede post-exercise muscle protein synthesis following exercise (2). Whether acute metabolic and structural responses observed under cold stress regulate chronic adaptations to exercise in skeletal muscle during training in a cold environment remains unknown. This study investigated the effect of seven weeks of interval cycling training in thermoneutral or cold environment on the expression of selected metabolic and structural genes in skeletal muscles of healthy previously untrained volunteers.

METHODS: Thirty-four participants (age 24.7 ± 3.2 yrs, height 177 ± 12 cm, body mass 80.3 ± 17.9 kg, fat 27 ± 3%) with no training history took part in seven weeks of cycling interval training consisting of a short (100-130% of Watt max), a medium (90-95%), and a long (80-85%) session every week in either a thermoneutral (22°C [TN], n=19; 10F and 9M) or cold (0°C [CO], n=15; 8F and 7M) environment, wearing shorts and a t-shirt. Training sessions ranged from 10 - 45 min. Incremental VO2max testing was conducted before the training intervention and 72 hrs. post intervention, combined with muscle biopsies from the vastus lateralis muscle at both time points (6G Bergström needle). Real-time PCR was used to quantify metabolic and structural changes in muscle tissue. Two-way analyses of variance were used (temperature and time) to assess differences with a level of significance set at $p<0.05$.

RESULTS: Both groups exhibited increases in VO2max from 40.5±8.3 to 43.3±8.3 ml/kg/min in TN ($p<0.001$) and from 42.0±9.5 to 46±7.9 ml/kg/min in CO ($p<0.01$). In both groups, post training muscle analyses revealed an upregulation of peroxisome proliferator-activated receptor-gamma coactivator 1 alpha, glyceraldehyde 3-phosphate dehydrogenase, beta actin, and growth differentiation factor 11 (fold changes of 1.3, 1.3, 1.2, and 1.4, respectively, $p<0.05$), whereas myo-

statin was downregulated (fold change 0.6, p<0.01). Importantly, the effects of training in the cold did not lead to noticeable changes in gene expression compared to the TN group.

CONCLUSION: The present study explored the effects of training in a cold environment on metabolic and structural skeletal muscle gene expression. While acute exercise in the cold may alter energy metabolism and muscle remodelling pathways, these results suggest no meaningful impact of lower ambient temperature on key metabolic and structural gene expression in untrained young individuals following a 7-week training protocol.

EFFECTS OF SOLE CRYOSTIMULATION BETWEEN RESTING PERIODS ON PHYSIOLOGICAL RESPONSES AND EXERCISE PERFORMANCE IN A HOT ENVIRONMENT.

NAKAGAWA, Y., KANATANI, K., KAWABATA, T.

KANSAI UNIVERCITY

INTRODUCTION: Exercising in a hot environment causes hyperthermia, which reduce exercise performance(Gonzälez-Alonso et al.,1999, Parkin et al.,1999). It is important to maintain a low core temperature to maintain high exercise performance. Cooling mainly through arteriovenous anastomoses, such as palms and soles, is more efficient in lowering core temperature (Hirata,2016). The present study examined the effects of cryostimulation of sole after constant load exercise in a hot environment on subsequent endurance exercise performance tests and physical responses.

METHODS: Five trained subjects (age: 26 ± 2 years, height: 177.5 ± 4 cm, weight: 76.3 ± 5.8 kg) completed a submaximal (70% Vo_2max) constant load exercise test for 30 minutes (EX1) in a hot environment (Ta 35°C, RH 60%). The subjects After 10minutes rest completed a submaximal (70%vo2max) exercise (EX2) until it became impossible to continue exercise. Between EX1 and EX2, the subjects were at rest and the sole was cooled in an ice pack at -50°C for 2 minutes. Measurements were taken for esophageal temperature (Tes), skin temperature, heart rate (HR), cardio output (CO), stork volume (SV), forearm blood flow (FBF), muscle temperature. Every 2 minutes during the exercise, rate of perceived exertion (RPE) and thermosensory scale measurements were taken.

RESULTS: EX2 increased exercise time during cryostimulation of the sole. There was a decrease in Tes, HR, and FBF in rest cooling conditions between EX1 and EX2 compared to rest. SV increase was observed in cooling of the sole at rest. Cooling of the sole, there was a decrease in the thermosensory scale and RPE at the start of EX2.

CONCLUSION: Sole cooling decreased Tes and decreased the thermosensory scale and RPE from the start of exercise at EX2. Thermal discomfort and RPE may have influenced the duration of exercise. FBF decreased during sole cooling, which delayed the increase at the onset of EX2. Sole cooling also increased CO and SV at the start of EX2. These results suggest that the blood that should have been supplied to the skin from the start of EX2 was able to supply the active muscle blood flow. A 2-minute exposure to cryostimulation of sole improved thermoregulatory and cardiovascular function and prolonged the duration of EX2 exercise.

INFLUENCE OF EXPOSURE PERIODIC HYPOBARIC NORMOXIA ENVIRONMENT ON NIGHT SLEEP

WADA, T.1, SEKI, Y.1, HIRANO, T.1, HYODO, H.1, TOSHIYUKI, K.1, KASHIWAGI, Y.2, SHINTAKU, Y.3, KAWAKAMI, Y.4, KAWAKAMI, Y.4, MASHIKO, K.5, MASHIKO, K.5, YAMAMOTO, N.6, FUNATO, K.1, NISHINO, S.7

1 KOKUSHIKAN UNIVERSITY, 2 SENSHU UNIVERSITY, 3 WAKAYAMA PROFESSIONAL UNIVERSITY OF REHABILITATION, 4 SHINMEI-ROOM INC., 5 KYOWA KENSHO INC., 6 JRC HOKKAIDO COLLEGE OF NURSING, 7 STANFORD UNIVERSITY

INTRODUCTION: Sleeping in low-pressure environments at altitudes of 1,500 m and 2,000 m has been shown to shorten slow-wave sleep time and reduce sleep quality. A decrease in periodic respiration and slow-wave sleep was also observed in a low-pressure environment equivalent to an altitude of 2000m. It was clarified that there is a risk of inducing sleep disorders and lowering the quality of sleep while staying at high altitude. In addition, exposure to periodic hypobaric normoxia environment (PHNE) increases post-exercise VO2 and respiratory quotient (R), and has been shown to improve ventilation efficiency and promote lipid metabolism. The purpose of this study was to investigate how this PHNE affects sleep.

METHODS: Eighteen healthy university students participated in this study. Before the experiment, the content was fully explained and consent was obtained from the subjects. Subjects were exposed to PHNE room (NR-100E-3, Shinmei-room Inc., Japan) for 50 minutes (PHNE). As a control experiment, measurements were carried out in an environment (normobaric pressure) without changes in air pressure using the same equipment. After that, EEG measurement (EEG sensor ZA-X, Proassist, Japan) was performed during night sleep, and the sleeping state was analyzed. In addition, a sleep monitor (MTN-221, Acos, Japan) was attached to the waist to measure physical activity and body movement during sleep. Body temperature, SpO2, Visual Analog Scale (VAS), and POMS were measured before and after PHNE exposure. Statistical evaluation of the data was done by paired student's t-test. Significance level was set at the $p < 0.05$.

RESULTS: A decrease in heart rate was observed after the experiment both during PHNE and during normobaric pressure. The body temperature before the experiment and the body temperature after 30 minutes in the room tended to temporal increase in body temperature from the same level during both PHNE and normobaric pressure (36.7°C vs. 36.7°C: ns, 36.6°C vs. 37.0°C: p< 0.05). This suggests that the time zone after 30 minutes has passed is an environment that is likely to induce sleep like after bathing. There is a decrease in body temperature at the end of PHNE (37.0°C vs. 36.6°C, p<0.05).

Since some subjects were drowsy and asleep around this time, it was thought that the core body temperature decreased due to heat dissipation. Total sleep time did not differ between the two environments. EEG-measured sleep efficiency was increased in PHNE (73.4 vs. 90.6: p<0.05), and nocturnal awakening was shortened (21.3 min vs 5.7 min: p<0.05). In PHNE, both REM sleep (27.2 min vs. 66.5 min: ns) and NREM sleep (161.0 min vs. 219.1 min: ns) tended to increase.

CONCLUSION: Exposure to PHNE was associated with an increase in body temperature, suggesting the possibility of promoting sleep latency. In addition, EEG measurements suggest that sleep efficiency is improved, nocturnal awakening are reduced, and REM sleep and NREM sleep are increased.

ACUTE PHYSIOLOGICAL AND PERCEPTUAL RESPONSES TO WHOLE-BODY HIGH-INTENSITY INTERVAL TRAINING COMPARED WITH ERGOMETER-BASED INTERVAL AND CONTINUOUS TRAINING

POON, E.

THE EDUCATION UNIVERSITY OF HONG KONG

INTRODUCTION: Time-efficient, whole-body calisthenics exercise has gained worldwide popularity in recent years, especially during the COVID-19 pandemic. Previous studies have compared the physiological and perceptual responses of specialized, equipment-based high-intensity interval training (HIIT) with conventional, high-volume moderate-intensity continuous training (MICT), but relatively little is known about the impact of other more easily accessible forms of HIIT. This study aimed to compare the acute response to a single session of low-volume, whole-body HIIT (WB-HIIT), ergometer-based HIIT (ERG-HIIT), and MICT.

METHODS: Fourteen physically inactive adults (age = 28.4 ± 6.5 yr, VO2peak = 31.5 ± 6.3 ml· kg-1· min-1) underwent three exercise trials in a randomized order with 3-7days apart. During exercise, heart rate (HR), blood lactate (BLa) and rating of perceived exertion were measured. Level of enjoyment and task-specific self-efficacy were assessed after each trial.

RESULTS: The peak HR of WB-HIIT was significantly greater than MICT (p = 0.001). WB-HIIT induced significantly higher BLa concentration than ERG-HIIT (p < 0.05) and MICT (p < 0.001). WB-HIIT displayed the highest self-efficacy and elicited greater enjoyment than MICT (p < 0.05). Half of the participants prefer WB-HIIT to ERG-HIIT and MICT.

CONCLUSION: In conclusion, WB-HIIT appears to induce similar physiological and perceptual responses to ERG-HIIT but different from MICT. Our results indicated that low-volume, high-intensity whole-body calisthenics workout can be a viable, alternative exercise strategy when lacking time and accessibility of equipment, but further studies should address its safety concerns and long-term benefits for the general population.

WATER INTAKE INFLUENCE IN SWIMMING PERFORMANCE IN 100-M FRONT CRAWL IN WELL-TRAINED SWIMMERS

ESPADA, M.1,2,3, ALMEIDA, A.4, SANTOS, F.,1,2,5, REIS, J.3,5, FERREIRA, C.1,6, PESSÔA FILHO, D.7, ALMEIDA, T.3,7, PEREIRA, P.4, VICENTE, F.4

1INSTITUTO POLITÉCNICO SETÚBAL; 2CIEQV; 3CIPER, 4EGAS MONIZ SCHOOL OF HEALTH AND SCIENCE; 5FMH-UL; 6GOERD, UNEX; 7UNESP, BAURU AND RIO CLARO

INTRODUCTION: Swimming training can induce significant stress on various physiological systems and is distinctive since it is the only sport conducted entirely in a body weight–supported prone or supine position in water, featuring simultaneous use of arms and legs for propulsion with low eccentric and central nervous system demands [1]. Since many athletes experience fluid imbalances that can sabotage performance and even health [2], the purpose of this study was to evaluate hydration status and water intake during a simulated swimming competition influence on body mass (BM), sweat rate (SR), sweat loss (SL), % of body mass loss (%BML), heart rate (HR), urine pH and 100-m front crawl performance in well-trained swimmers.

METHODS: Twelve male competitive swimmers participated in the study (mean ± SD; 16.25 ± 1.66 years of age, 176.50 ± 6.35 cm of height, 66.13 ± 8.30 kg of BM. After a pretraining urine sample was collected for initial pH evaluation (pHi), each participant completed a validated food frequency questionnaire regarding the assessment of fluid intake during the day [3]. Afterward, BM was measured and considered initial BM (BMi), and later, athletes were provided with a 50 cl bottle of water. The first group (G1) were the swimmers with a water intake ≤ 340 mL, and the second group (G2), with a water intake ≥ 350 mL and ≤ 500 mL, in both cases immediately ingested before the 800-m aerobic swim of low to moderate intensity in-water warm-up. Then, in the middle of a 6-min rest period, initial heart rate (HRi) was measured, and after, 4 x 25 m maximal front crawl swimming were performed with 1-min rest in between, followed by another 6-min rest period before the 100-m maximal front crawl swimming trial (T100). Immediately after, end HR (HRend) was measured, and the same procedure was completed after a 5-min rest period for recovery HR assessment (HRr).

RESULTS: A total of six swimmers lost BM during the 45 minutes swimming training session, three integrated G1 (water intake ≤ 340 mL) and the other three G2 (water intake ≥ 350 mL and ≤ 500 mL). Five swimmers increased their BM (two in G1 and three in G2), and one swimmer presented no change in BM (G1). Correlations were observed in both groups between HR and urine pH data, water intake, and SL, but only in G1 was the HRend correlated to body mass loss (BML) and %BML (respectively, r=-0.81 and r=-0.82, in both cases p <0.05). Furthermore, also only in G1, T100 was strongly correlated to water intake and SL (in both cases, r=-0.85, p <0.05).

CONCLUSION: Our results suggest the measurement of individual needs to optimize fluid intake strategies and having an adequate hydration plan in place before, during, and after training can help not only swimming performance enhancement, but also aid in recovery of swimmers.

ASSESSMENT OF LEFT VENTRICULAR MASS USING DIFFERENT ECHOCARDIOGRAPHIC TECHNIQUES IN HEALTHY FEMALE ATHLETES

COTE, A.T., MORRISON, B.N., MASSAROTTO, R., CAMPBELL, A.

TRINITY WESTERN UNIVERSITY

INTRODUCTION: The application of three-dimensional (3D) echocardiography for the measurement of left ventricular mass (LVM) is considered to provide LVM quantification results similar to that of cardiac magnetic resonance imaging (gold standard) compared to two-dimensional (2D) echocardiographic techniques. We sought to assess the effects of two echocardiography techniques and training status on LVM in healthy female university students.

METHODS: LVM was assessed using the 2D American Society of Echocardiography linear method technique and 3D echocardiography was assessed using the volumetric technique. Training status was assessed through the comparison of LVM from female athletes (team sports and cross-country) (n=22) and normally active females (n=20).

RESULTS: Forty-three females (21.2±1.9) underwent echocardiography. There was no significant difference for age, heart rate or blood pressure ($p>0.05$) between the groups. Stroke volume did not differ between the groups using assessed by 2D or 3D echo. The relative wall thickness assessed by 2D echo was not significantly different between athletes and normally active (0.37±0.08 vs. 0.36±0.06; $p=0.536$). There was a significant difference in indexed LVM between the athletes (67.5 g/m2±14.9 vs. 56.8 g/m2±8.5; $p=0.005$) but not in the normally active females (56.9 g/m2±11.2 vs. 56.3 g/m2±9.6; $p=0.844$), for 2D echocardiography and 3D echocardiography methods, respectively. The distribution of relative wall thickness and indexed LVM using concentric and eccentric remodeling and hypertrophy cut-offs resulted in two athletes being identified to have concentric hypertrophy and one athlete having eccentric hypertrophy using 2D but not 3D echocardiography.

CONCLUSION: In female university students, indexed LVM assessed by 2D echo in female athletes may be overestimated, however, further analysis using these methods, including in male athletes and normally active males needs to be conducted.

EFFECT OF AN ACCLIMATION PROTOCOL TO ENVIRONMENTAL HEAT AND HUMIDITY STRESS ON PHYSIOLOGICAL AND INFLAMMATORY MARKERS.

TEIXEIRA, A.M.1, RUSENHAK, M.C.1, MENDES, A.1, ROSADO, M.F.1, DA SILVA, J.M.2, JIMÉNEZ, M.G., SANTOS, A.C.1,2

UNIVERSITY OF COIMBRA, 1.CIDAF-RESEARCH CENTER FOR SPORT AND PHYSICAL ACTIVITY. 2.LAI-LAETA- LABORATORY OF INDUSTRIAL AERODYNAMICS

INTRODUCTION: Exercise under environmental conditions of severe heat and humidity stress can lead to poor performance and many athletes experience exertional hyperthermia during training and competition. Due to the increase of competitions in countries with adverse climate conditions, acclimation of the athletes is becoming more frequent. However, little is known on the effects of acclimation training on the athlete's inflammatory response and health.

This study main objective was to determine the effect of exercise in classic laboratory environmental conditions (NC), as well as in conditions of environmental heat and humidity stress (HS), in physiological and inflammatory (IL-6, IL-15, IL-10, TNF-α, IL -β, IL-1ra, sCD14) markers in athletes, before and after a heat acclimation (HA) protocol.

METHODS: Eight endurance athletes, who compete at the Portuguese national level (37.5 ± 11.21 years) underwent an acclimation training protocol, in an indoor climate chamber, consisting of 2 weeks of training under 35°C and 55% humidity, with 3 sessions/week of increased duration (40, 60, 80, 90, 100 and 110 mins). The week before a progressive 4 min step VO2max test at 21ºC and 55% humidity and another one at 34ºC and 55% humidity were performed with 2 days interval. The same tests were repeated the week after the acclimation protocol. Physiological variables were evaluated during the VO2max tests at two intensities (moderate LAC= 2mmol/l and high LAC= 4mmol/l). Inflammatory markers concentrations were determined by ELISA (Thermofisher, UK) before and after the VO2max tests.

RESULTS: Although there were no significant differences in speed ($p = 0.58$), a small improvement in running speed was obtained for the HS environment at moderate intensity (2mmol/l), after acclimation (ES = -0.2). In the physiological variables, significant differences were found for VO2max, total energy expenditure and RPE ($p < 0.05$) (NC x HC at 2mmol/l). Important differences in effect sizes were identified for cardiovascular (HR; SBP; DBP), and thermoregulatory (body temperature; dehydration) adaptations. For the inflammatory markers, IL-6 and IL-15 showed decreases in their concentrations after HA compared to previous values under the same environmental conditions ($p < 0.05$). Significant differences in the sCD14 soluble endotoxin receptor ($p < 0.01$) were found in the HS environment after acclimation. A percentage of dehydration of at least 1.25% of total body weight can cause increases in IL-1β concentrations and, associated to this, an increase in endotoxin leakage from the gut, manifested by increases in sCD14 plasma concentrations.

CONCLUSION: Acclimation training was effective in promoting several physiological adaptations. Although IL-1β levels were increased in athletes at the time of HS after acclimation, IL-1ra levels were also higher at that time, suggesting a trend for athletes to maintain their inflammatory balance and immune system functionality.

ICE SLURRY INGESTION BEFORE AND BETWEEN EXERCISE ALTERS ENDURANCE EXERCISE CAPACITY AND COGNITIVE PERFORMANCE IN A HOT ENVIRONMENT

HASEGAWA, H.1, TAKIISHI, I.1, KUMAGAI, T.1, YANAOKA, T.1, ISHIYAMA, K.2, YAMADA, S.2, MORITO, A.2

HIROSHIMA UNI1: HIROSHIMA UNIVERSITY, GRADUATE SCHOOL OF HUMANITIES AND SOCIAL SCIENCES 2: R&D LABORATORIES, SELF-MEDICATION, TAISHO PHARMACEUTICAL CO., LTD., SAITAMA VERSITY

INTRODUCTION: Compared to temperate environments, the core and mean skin temperatures increase in the heat faster, resulting in increased cardiovascular, metabolic, and thermal perceptual loads and decreased endurance exercise performance. Cooling the body may be one such approach since this strategy can alleviate the physiological and perceptual strain in a hot environment. This study investigated the effects of ice slurry ingestion before and between exercise on thermoregulatory responses, endurance exercise capacity and cognitive performance in a hot environment.

METHODS: In a randomised cross over design, ten trained men (age, 22.1 ± 1.6 years; height, 1.72 ± 0.07 m; body mass, 63.5 ± 8.8 kg; VO2max, 60.6 ± 4.3 mL·min·kg-1) who were not acclimatized to the heat performed three 20-minute bicycle exercises at 50% watt max followed by an exercise at 80% watt max until exhaustion in a hot environment (32°C, 60% relative humidity). The subjects consumed frozen ice slurry (-4°C: ICE) or beverage of the same composition (32°C: CON) during a 8-minute of pre-cooling after warm-up (ingestion volume: 4 g·kg-1) and three 7-minute rests between exercise bouts (ingestion volume: 2 g·kg-1).

RESULTS: The changes in rectal, mean skin, deep-forehead, heart rate in the ICE condition during constant-load exercise was significantly lower than that of the CON condition ($p < 0.05$). Rating of perceived exertion, thermal sensation, and thermal comfort were significantly improved in the ICE condition. Exercise time to exhaustion at 80% watt max was significantly prolonged in the ICE condition compared with CON condition (79 ± 39 vs 232 ± 71 sec, respectively, $p < 0.05$). Cognitive performance (shifting attention test) was also improved in the late phase of constant exercise under ICE condition compared with CON condition. Sweat rate and rate of dehydration in the ICE were significantly lower than that of the CON condition.

CONCLUSION: Ingestion of frozen ice slurry before and between exercise bouts in a hot environment reduces increase in core and skin temperatures during constant-load exercise and improves perceptual thermal strain, exercise and cognitive performance. These improvements in ICE may be due to low thermal and perceptual strain during the constant exercise. The lower increase in core body temperature during constant exercise was suggested to be a cooling effect on the body due to the continuous intake of frozen ice slurry not only before exercise but also between exercises. This applied cooling method is an effective heat countermeasure for sports activities in a hot environment.

Physiotherapy

EFFECTIVENESS OF THE RSQ1 DEVICE RECUPERATION PROTOCOL IN THE TREATMENT OF SPORTS INJURIES

KOVACIC, I.1, BISIC, A.2, NEDOVIC, N.3

1DOCTORAL SCHOOL OF HEALTH SCIENCES, UNI OF PÉCS, HUNGARY 2SECONDARY SCHOOL FOR PHARMACY & PHYSICAL THERAPY, BELGRADE, SERBIA 3ACADEMY OF APPLIED STUDIES BELGRADE, COLLEGE OF HEALTH SCIENCES, SERBIA

INTRODUCTION: Injury during sports activities (sports injury) is common in case of insufficient preparation and warm-up before training, due to fatigue and too strenuous training, as well as during uncontrolled exercises on equipment in the gym. RSQ1 device (Physicare International B.V., Zaandam, The Netherlands) is a unique device for neuromuscular stimulation with a high-frequency signal of over 10kHz. Its advantages compared to other devices for electrotherapy: it accelerates circulation almost instantly, creates hypertrophy, increases saturation, engages a large number of motor units as well as a quick analgesic effect.

METHODS: Case study: Our subject is 24 years old female professional basketball player, with 14-16 hours spent on the court (including a game as well) per week. During one practice, while sprinting, sharp pain appeared on the lateral side of the quadriceps muscle. After positive (painful) palpation and slight strength testing, a radiologist specialist performed an ultrasound (US) diagnostic. It was confirmed muscle tear (grade II) of m. vastus lateralis and the size of the tear was 1,2 cm wide. Hemorrhage and liquid around the injured tissue were present as well. It was suggested 3 weeks of rest with physical therapy included and US control every 7 days.

First time during the rehab of sportsmen with muscle tear the RSQ1 recuperation protocol included 24hrs on the injured muscle. Only during the bathing and physical therapy sessions (cryotherapy, magneto therapy, laser, and interferential current therapy - which lasted one hour), RSQ1 was removed. Immediately after the therapy session, RSQ1 was put back on injured place and a recuperation protocol was set. During the RSQ1 session, electrodes are placed on the injured limb. The injured athlete is trained to use this device at home and keep it working on 24hrs per day.

RESULTS: After 3 days of being injured, the athlete felt capable to use muscle more without pain so the isometric exercises for the quadriceps muscle were included together with the RSQ1 device on it. Seven days after the injury, a US diagnostic was done with results of only a visible 0,8 cm muscle tear and almost complete disappearance of hemorrhage and local

liquid. Fourteen days after the injury, the US showed that there is not any tear noticeable on the injured area. RSQ1 device is now also included during the process of isometric and concentric exercises for quadriceps muscle. Recuperation protocol was still constantly included.

CONCLUSION: Three weeks after the injury, the US showed no signs of injury and the dynamometry testing showed only 15% less strength in the injured leg than before the injury. According to the manufacturer, this protocol results in an increased blood flow and a higher saturation of the blood in the treated area (goes up to 30%), which causes a faster recuperation of the muscle tissue. The athlete was able to return to the court earlier than expected.

RELIABILITY OF THE TRUNK FLEXOR ENDURANCE TEST USING DIFFERENT INCLINATION ANGLES

KOYAMA, T., KAWAI, R., MATSUDA, T., NITTA, O.

COLLEGE OF HUMANITIES AND SCIENCES, NIHON UNIVERSITY

INTRODUCTION: The sit-up has been used as a physical fitness test or a trunk flexor training. According to Axler et al. (1997), the internal pressure of the lumbar intervertebral disc during sit-up is approximately 3350 N, which means the same as the load for developing possible low back pain in hard labors reported by the National Institute of Occupational Safety and Health. The trunk flexor endurance test (TFET) has been reported as a safer endurance test than the sit-up, although previous studies have used various degrees of trunk inclination. Thus, it is not clear which inclination angle should be used in the TFET. For example, as a physical fitness test for health promotion in older age groups, an inclination angle of about 55 deg seems to be safer and less difficult. On the other hand, an inclination angle of about 45 deg seems to be more difficult and suitable for athletes. Therefore, the purpose of this study was to determine the reliability of the TFET using different inclination angles.

METHODS: The subjects were 15 physical education students (8 men, 7 women). The mean (standard deviation; SD) of age, height, and weight of the subjects were 20.7 (0.5) years, 165.3 (6.4) cm, and 59.3 (8.9) kg. The TFET was performed as following procedure; 1. Set the tilting table at randomly assigned angle (45deg, 50deg, or 55deg) and take a sitting position so that the whole back is in contact with the tilting table. 2. With the knees flexed at 90deg and the hands placed on the chest, The test starts by shifting the tilt table 10 cm backward, and the subject should keep the starting posture as long as possible. 3. When the posture becomes unmaintainable and the back touches the tilt table again, the test ends. The holding time of each angle was recorded twice (1st/2nd) one week apart in two weeks. All subjects performed the TEFT at 3 angles (total 6 measurements in 6 weeks). Intraclass correlation coefficient (ICC) was calculated to determine the test-retest reliability.

RESULTS: The mean value (SD) of the 1st / 2nd holding time in the TEFT were 160.3 (88.5) / 168.5 (72.4) seconds at 45deg, 263.7 (122.2) / 274.7 (129.7) seconds at 50deg, and 363.5 (208.9) / 385.5 (207.2) seconds at 55deg. As a result of the reliability test, ICC (1,1) was 0.907, 0.943, 0.970 and ICC (1,2) was 0.951, 0.970, 0.985 in the order of 45deg, 50deg, 55deg.

CONCLUSION: As a result of this study, very high reliability was observed for all three inclination angles. Reliable measurements could be performed at any angle in the TEFT. It will be suggested that one trial is sufficient so that the ICC (1, 1) was highly reliable. The holding time was the shortest at 45deg and the longest at 55deg. It may be too long to conduct this test at 55 deg as a physical fitness test. Further research will be needed to determine the validity of each angle.

EXERCISE, NEUROMUSCULAR ELECTRICAL STIMULATION AND THERMAL THERAPY COMBINATION EFFECTS ON PATELLO-FEMORAL PAIN

KIM, Y.K., WON, Y.C.

CHA UNIVERSITY

INTRODUCTION: Patellofemoral pain (PFP)is a common musculoskeletal disorder of the knee. PFP causes knee pain, quadriceps strength loss and impaired motor performance. Neuromuscular electrical stimulation (NMES) is currently used to improve muscle strength and rehabilitation medicine to restore muscle properties. Superficial heat treatment is one of the most widely used physical therapies for knee injuries. The aim of this study was to assess the efficacy of superimposed NMES, and heat therapy combined with strengthening exercises to improve the recovery of quadriceps strength and function in patients with PFP.

METHODS: A single-blind randomized controlled trial was performed with 10 patients who diagnosed with PFP. After baseline testing, patients randomized to two groups: group A; NMES with strengthening exercises, Group B; Combined NMES/Heat therapy with strengthening exercises. The patients in both groups were treated 3 times a week for 4 weeks.

The primary outcome measure was quadriceps muscle strength over 4 weeks. The secondary outcomes were physical function performance and knee pain. The primary analyses used repeated measures, linear mixed mixed-effects models with a random effect for subject, time as a continuous variable, group as a categorical variable, and a group and time interaction to test for differences in change over time among the groups.

RESULTS: Both groups improved in quadriceps muscle strength and forward step-down test in the PFP limb over the 4 weeks period. The group B (NMES/Heat therapy) improved to a greater extent than the group A in the quadriceps muscle strength, but no significant group differences in forward step-down test.

CONCLUSION: After NMES, Heat and strengthening exercises for 4weeks, we found improvements in quadriceps muscle strength and physical function performance.

EFFECTIVENESS OF A SOFTWARE-BASED REHABILITATION METHODOLOGY FOR SHOULDER INJURIES. A PRELIMINARY STUDY.

CASTAÑO DE EGUES, L., LATASA, I., SANZ, J.A., SETUAIN, I.
UNIVERSIDAD PUBLICA DE NAVARRA - ESPAÑA

INTRODUCTION: Sports-related shoulder injuries represent a challenge for clinicians because of the large variety of clinical entities involved and the broad anatomic structures that can be affected. Furthermore, commonly performed orthopaedic tests have demonstrated limited accuracy for diagnosing the injury despite considerable research efforts. Clusterization of tests has been demonstrated to improve diagnostic accuracy[1]. The aim of this study was to describe a comprehensive injury management software prototype integrating both a clinical- and functional cluster -based diagnostic and adapted rehabilitation prescription. Preliminary clinical effectiveness reports were also analysed.

METHODS: A longitudinal cohort study was performed recruiting up to 31 participants (18 male; 13 female). After the medical diagnosis and any requested supplementary evaluations (i.e., radiological examinations) were made, the participants were evaluated before and after the rehabilitation program by using a previously published evaluation model for shoulder injuries [2]. A comprehensive functional and clinical screening testing battery was recorded in the REHABI software prototype. Using an artificial intelligence decision-making scheme, the identified functional deficits were used to customize the individual rehabilitation plan of every participant. A deficit-based disability score was developed to monitor patient recovery rate. Descriptive statistics were calculated and paired (pre -post) T-Test executed in order to determine significance ($p< 0.05$) differences from pre to post rehabilitation evaluations. Phyton software was employed for statistical analysis.

RESULTS: The disability score was significantly reduced (7.5±3.6 points Pre; 3.6±2.2 points Post; $p<0.0001$) during the rehabilitation process. There was a mean of 31,7± 79.7 % reduction across all the patients.

CONCLUSION: It seems that the employment of a cluster based functional and clinical shoulder evaluation and rehabilitation prescription model by the use of the REHABI software is effective for sports related shoulder injuries. The wide SD value for the overall mean % of improvement may be related to the non-estructural injury specific profile of the patients recruited for this study.

T2 HAMSTRING MUSCLE ACTIVATION DURING THE SINGLE-LEG ROMAN CHAIR: IMPACT OF PRIOR INJURY

BAUTISTA, I.J.1,2, VICENTE-MAMPEL, J.2, PIQUERAS-SANCHIZ, F.2, BARAJA-VEGAS, L.2, VAN HOOREN, B.3
UNIVERSITY OF CHICHESTER

INTRODUCTION: The single-leg Roman chair exercise has recently been proposed as a hamstring exercise that may be effective for prevention and during the rehabilitation of hamstring injuries [1, 2]. However, the activation of the individual hamstring muscles during the single-leg Roman chair hold remains largely unknown. Knowledge about the preferential activation of different muscles during this exercise may help practitioners with more effective exercise prescription. Specifically, in case of previous injury, the BFlh has demonstrated to be subject to neuromuscular inhibition, leading to lower levels of activation during exercise compared to the non-injured status. This inhibition might be present up to up to 18 months post injury despite individuals training and competing at pre-injury levels [3 – 5]. Although this inhibition may initially be beneficial to protect the injured tissue from further damage, it might also reduce the force production and hence adaptations to training on the long-term, which in turn may compromise performance and increase the risk of re-injuries [5]. Previous studies have shown inhibition of previously injured hamstrings during eccentric exercises, but it is unknown whether this effect is also present during an isometric position-control exercise such as the single-leg Roman chair hold (SLRCH). This cross-sectional study therefore investigated muscle activation during the SLRCH in individuals with a prior hamstring injury. Muscle activation was assess using the transverse relaxation (T2) time for the biceps femoris long and short heads (BFlh, BFsh), semitendinosus (ST), semimembranosus (SM), and adductor magnus (AM) and compared within and between legs. Muscle cross-sectional area was also investigated. T2 times increased for all muscles, except for the AM in both legs.

METHODS: This study used a repeated-measures design to investigate hamstrings muscle activation during the single-leg Roman chair exercise. Muscle activation during the exercise was investigated by determining differences in the exercise-induced increases in the transverse (T2) relaxation time after the exercise. All tests were performed within a period of approximately 6 months in the MRI department of the Catholic University of Valencia.

RESULTS: In both legs, the ST showed a larger increase in T2 time compered to all other muscles. The BFlh showed a smaller increase in T2 time in the injured leg as compared to the uninjured leg, while there were no differences between legs for other muscles. Muscle cross-sectional area did not differ between the legs.

CONCLUSION: Overall, the ST is preferentially activated during the SLRCH in both the uninjured and injured leg, and the BFlh in the previously injured leg was activated less compared with the uninjured leg, despite no differences in muscle cross-sectional area.

ISOKINETIC STRENGTH PROFILE OF THE ROTATOR MUSCLES OF HIGH-LEVEL BOXERS

REVAULT, A.

INSEP

INTRODUCTION: The practice of high-level boxing repeatedly strains the shoulder [1,2] and few studies have explored the isokinetic profile of the rotator muscles of the boxer. Our objective was to describe and compare isokinetic muscle profiles of the shoulders of high-level boxers by laterality and gender.

METHODS: A total of 14 male (age = 21 ± 1.9 years, height = 180 ± 10 cm, mass = 68 ± 12 kg) and 5 female (age = 19 ± 0.7 years, height = 167 ± 7.1 cm, mass = 57 ± 5.1 kg) of the French Boxing Team took part to this cross-sectional study. A clinical examination and a bilateral shoulder isokinetic test were carried out for all the athletes of the French Boxing Team as part of the annual medical check-up. The muscle strength of the internal rotators (IR) and external rotators (ER) of the shoulder were measured on an isokinetic dynamometer (Biodex system 4, Biodex Medical Systems, New York, USA) in the concentric mode at 60°/s and 180°/s, and the eccentric mode at 60°/s. The ER : IR concentric ratio at 60°/s was also calculated

RESULTS: The statistical analysis of the data shows in males, a difference between the rear arm and the front arm only on the external rotators in the concentric mode at 60°/s (0.53 ± 0.08 vs. 0.50 ± 0.07, P = .03). For females, this trend is also apparent with a rear arm stronger than the front arm, but only at the 10% threshold. When comparing the ER : IR concentric ratio at 60°/s between men and women, significant differences were observed in the rear arm (0.63 ± 0.10 vs. 0.85 ± 0.14, P = .002) and the front arm (0.61 ± 0.09 vs. 0.80 ± 0.12, P = .005).

CONCLUSION: The isokinetic profile of high-level boxers, men and women, appears to be symmetrical between the rear arm (considered as the dominant one) and the front arm, with the possible exception of the external rotators peak force in the concentric mode at 60°/s, which is higher on the dominant side. On the other hand, there are differences in muscle profile between men and women, with a ER : IR concentric ratio at 60°/s, significantly higher in women than in men. This difference in muscle profile between male and female boxers should thus be explored in the context of certain shoulder diseases.

Psychology

DEVELOPMENT OF SPORTS TEAM GRATEFUL CLIMATE QUESTIONNAIRE

CHEN, L.H.

NATIONAL TAIWAN SPORT UNIVERSITY, TAIWAN

Gratitude has been conceptualized as an emotion, mood, or affective trait that has consistently positive effects on individuals thoughts and actions. Although most studies follow a conventional approach to studying gratitude at the individual level, gratitude can also be conceptualized at a level beyond individuals. Developing a measurement of grateful climate is an essential step to examining the function of a grateful climate in a team or group context. Accordingly, the purpose of this study was to develop a valid and reliable measure of the grateful climate of sports teams. This study used multilevel confirmatory factor analysis to evaluate the factor validity of the Sports Team Grateful Climate Questionnaire using a sample of 431 adolescent athletes from 56 teams in Taiwan. In addition, nomological validity and incremental validity were also examined in this study. The results indicated that the 9-item Sports Team Grateful Climate Questionnaire has good convergent validity, nomological validity, and incremental validity. This scale can be a useful tool for future empirical studies aiming to better understand the grateful climate and identify the role of the grateful climate in sports teams.

COMPARATIVE ANALYSIS OF BREATHING THROUGH BODY MOVEMENT

MANGEUN, K.

KOREA NATIONAL SPORT UNIVERSITY

Introduction

The hot issue these days, living in the age of 100 years of health, is about the body. Mental health is just as important as physical health. From this point of view, breathing, which connects the body and mind, is very important. This study aims to examine breathing through the movement of the body and what role it plays in human physical health and mind.

Methods

This study focuses on Pilates, which is popular as a rehabilitation exercise for the purpose of rehabilitation treatment and injury prevention, and attracts social attention from many people, and the breathing method of Korean dance, which is said to express Korean emotions. As for the research method, first, theoretical considerations were made by analyzing previous studies on respiration and health, and then the researcher directly observed the movements of teachers who teach Pilates and Korean dance to derive the results. The verification of the results was performed through triangular verification by 5 experts and research subjects.

Results and discussion

Pilates is an exercise method that relaxes and strengthens the body at the same time, helping you to accurately recognize and control your body. In particular, it strengthens flexibility and muscle strength around the spine, which is the center of

the body, and stabilizes the symmetry of the body up, down, left, and right with exercises that increase balance and stability of the body to maintain balance. Pilates breathes using the lower abdomen, and when exhaling, the lower abdomen must be strongly tightened to help prevent the face and spine from collapsing backwards. By doing so, the waist is not overburdened and the lower abdomen is pulled up to supply enough oxygen to the entire body and torso.

On the other hand, breathing in Korean dance takes the form of Danjeon breathing based on the principle of inhaling and exhaling to empty the lower abdomen. In Korean dance, most of the movements are by bending the lower body. When this movement is performed, breathing is exhaled, and the process of returning to the normal position is a state of breathing in.

Comparing these two exercises, Pilates makes the core muscles elastic and uses a breathing method that purifies the inside of the body to relax and release the tense state of the body. In addition, there are effects such as concentration, control, precision, stability, and body alignment through breathing, which are the basic principles of rehabilitation treatment.

In this way, if Pilates is more focused on maintaining the external health of the body, Korean dance can be seen as affecting mental health, which is an internal flow. In Korean dance, breathing determines the quality of dance movements and expresses the unique style and resentment of Korean dance. Breathing has the meaning of simple oxygen supply for humans to breathe and maintain life, but Korean dance helps peoples mental stability by expressing human thoughts and emotions as they are through breathing.

SELF-PRESENTATION MOTIVES, SELF-CONCEPT AND THEIR RELATIONSHIP WITH THE INTENTION TO BE PHYSICALLY ACTIVE IN HIGH SCHOOL STUDENTS

PINEDA-ESPEJEL, H.A., TREJO, M., MORQUECHO, R., GONZÁLEZ SOTELO, J., ESPINOZA COLLAZO, S., FLORES ZAMORA, J.

*UNIVERSIDAD AUTÓNOMA DE BAJA CALIFORNIA; *UNIVERSIDAD AUTÓNOMA DE NUEVO LEÓN*

Introduction

Knowing the main reasons why people start or choose to carry out a certain activity, such as physical exercise or sport, as well as the factors that determine the permanence or abandonment of this choice (Varela et al., 2011) is important to contribute to the creation of physical exercise programs that counteract sedentary lifestyle in the population. Leary and Kowalski (1990) theorized that self-presentation (or impression management) is the process by which people attempt to influence and control the impressions others have of them. The aim was to identify the relationship between self-presentation and self-concept with the intention of being physically active.

Methods

689 high school students aged 11 to 15 years old, and of both sexes participated. (307 boys and 319 girls), who answered the booklet of questionnaires that measure the variables in question.

Results

Spearmans rho correlation matrix showed that the intention to be physically active was significantly associated with impression motivation (rho= .44; p =.000), and with impression construction (rho= .27; p = .001), but it was not significantly associated with self-concept (rho= -.08; p = .06).

Conclusión

There are behaviors and motivations that drive young people to practice or abandon physical exercise; while the way in which young people perceive themselves does not have a significant influence. So the desire to create an impression in others that oneself performs physical exercise, as well as the behaviors used to affect the impressions that others have about them (eg, running faster when another sees them or accompanies them) makes the young people want to be physically active. It is supported that self-presentation is an essential part of interpersonal behavior, since self-image can influence how each person is valued and treated by others (Leary & Kowalski, 1990).

Leary, M.R., & Kowalski, R.M. Impression management: A literatura review and two-component model. Psychological Bulletin. 1990. 107(1), 34-47.

SYMPATHETIC AND PARASYMPATHETIC CHANGES IN ARCHERS AFTER A COURSE OF BIOFEEDBACK TRAINING

ESKANDARNEJAD, M.1, FEKRVAND LEILABAD, N.1, ZAMANLU, M.2

1. UNIVERSITY OF TABRIZ , 2. GOM UNIVERSITY OF MEDICAL SCIENCES

Introduction

The autonomic nervous system has two main branches: the sympathetic nervous system, which is responsible for preparing the human body for action in times of danger and stress, and the parasympathetic nervous system, which regulates the resting state of the body. In this regard, biofeedback training can adjust these systems.

Methods

The method of the present study was quasi-experimental with pretest-posttest design with control group. The participants of the present study were 15 of the best archers in Tabriz. Statistical samples were selected as available and randomly assigned to experimental (n = 8) and control (n = 7) groups. The amount of sympathetic and parasympathetic changes of participants in the test stages (pre-test, post-test 1 and post-test 2) were recorded and measured through a biofeedback device that included breath, heart rate, galvanic and skin temperature. The duration of biofeedback intervention in the experimental group was 20 sessions, which began with breathing exercises, then HRV training and then skin temperature and galvanic exercises were added, respectively. Both groups practiced archery and the experimental group did biofeedback training in addition to archery exercises. Research data were analyzed using descriptive and inferential statistical methods including analysis of variance with repeated measures and using SPSS software version 26.

Results

The findings in the two control and intervention groups were descriptively different and analytically they reached the significant limit in some cases, the results were in skin conductivity (P=0.07) and heart rate (P=0.1). Also, the mend of the intervention group after stress (recovery) reflected by the parameters of skin conductance response, high frequency of heart rate and low frequency of heart rate in the intervention group was more favorable than the control. For the skin conductance response, the reduction of about (0.11 Usiemens) and for the LF/HF ratio of the heart beat frequency values of about (1-1.5) were obtained.

Discussion

The results showed that the changes of the obtained parameters indicate sympathetic and parasympathetic activity, which were descriptively. It can be concluded that biofeedback training help the athletes to recover better from the sympathetic arousal caused by tensions, in addition, the combination of sympathetic and parasympathetic, especially in the cardiovascular scale, is more optimum in archers trained by biofeedback, so they Physical and mental physiological point of view will have better flexibility and restoration and all these things can lead to better performance of athletes.

INFLUENCE OF LOWER-LIMB MUSCLE STRENGTH ON NEURAL OSCILLATIONS DURING RESPONSE PREPARATION IN COGNITIVELY HEALTHY ELDERLY ADULTS

WANG, C.H., HO, M.C., FU, H.L., KAO, S.C., MOREAU, D.

NATIONAL CHENG KUNG UNIVERSITY, PURDUE UNIVERSITY, THE UNIVERSITY OF AUCKLAND

Introduction

Previous research has linked lower limb muscle strength to cognitive slowing in healthy elderly adults. However, it is not well understood whether this cognitive decline is related to the development of response preparation prior to motor execution. Therefore, the aim of this study was to explore the cognitive and neural mechanisms underlying the relationship between lower limb muscle strength and response preparation in elderly adults.

Methods

This study included 40 cognitively healthy elderly adults with higher (n = 20; male = 11; aged 70.40 ± 5.15 years) and lower (n = 20; male = 9; aged 71.50 ± 4.98 years) levels of lower-limb muscle strength. The muscle strength of the gastrocnemius and quadriceps femoris was assessed using manual muscle tests (MMT) conducted by experienced physical therapists. The participants completed a choice reaction time (RT) task with variable foreperiods (500ms and 1500ms) while their brain activity was recorded using electroencephalography (EEG). To measure their lower limb RTs, the participants were asked to press pedals with the corresponding foot in response to the task.

Results

The behavioral results showed that elderly adults with higher levels of lower-limb muscle strength had faster RTs than those with lower levels, regardless of the length of the foreperiod. Time-frequency analysis of EEG data revealed that those with greater lower-limb muscle strength had stronger beta power modulation in central brain areas during the preparatory period compared to those with lower muscle strength, particularly in the longer foreperiod condition.

Discussion

The results suggest that lower limb muscle fitness may be associated with faster motor execution of the lower-limbs under different levels of temporal uncertainty. The weaker beta oscillation observed in elderly adults with poorer lower-limb muscle strength may indicate less efficient preparation for a response during longer foreperiods. In conclusion, maintaining good lower-limb muscle strength may be important for establishing optimal processing for responding, particularly for speeded tasks, in elderly adults.

PREDICTORS OF COPING AMONG COLLEGE ATHLETES WITH CAREER CHOICE STRESS

CHAN, C.

NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: Due to college athletes' long-term focus on sports training and competition and their reliance on sports excellence-based programs to enter college without having to take the academic entrance exam, they generally have poor academic performance. Compared with college students, college athletes are often faced with learning difficulties, as well as a lack of career exploration and decision-making abilities. To maintain training effectiveness in sports, most college athletes take advice from their coaches and parents on decisions related to pursuing further studies. They have

relatively few opportunities to make decisions on their own, and their career decision-making experience is also insufficient. Due to the above-mentioned problems, many college athletes not only face more career decision stress but also choose to cope with the stress in a negative way, which adversely impact their subsequent career development. Coping refers to the cognitive and behavioral efforts of individuals in dealing with internal or external needs that exceed their own resources. The coping response that individuals adopt when they face external stress is regarded as one of the important elements influencing emotions and well-being.Past studies have investigated individuals' coping and influential factors from a holistic approach but have rarely explored the impact of specific stressors on the coping of individuals. Therefore, the results of the present study can expand the breadth and depth of academic research in the field of coping.

METHODS: This study explores the relationships between social support, career decision-making self-efficacy, negative mood regulation expectancies, and how college athletes cope with career decision stress. In total, 1,312 valid questionnaires were returned. The data obtained were statistically analyzed using structural equation modeling.

RESULTS: The results showed that social support was positively related to career decision-making self-efficacy(ß =.52, $p < .001$), negative mood regulation expectancies (ß =.35, $p < .001$), and coping(ß =.13, $p < .001$). Career decision-making self-efficacy was positively related to negative mood regulation expectancies(ß =.37, $p < .001$) and coping(ß =.71, $p < .001$). Negative mood regulation expectancies were positively related to coping(ß =.18, $p < .001$). In addition, The Sobel's test showed that career decision-making self-efficacy mediated an indirect relationship between social support and coping ($z = 6.94$, $p < .01$) and that negative mood regulation expectancies mediated an indirect relationship between social support and coping ($z = 5.72$, $p < .01$)

CONCLUSION: The findings indicated that social support, career decision-making self-efficacy, and negative mood regulation expectancies have direct or indirect relationships with college athletes' cope with career choice making stress. These findings suggest that career supports are required to provide athletes with assistance to improve their career decision-making self-efficacy, and subsequent career behaviors. In addition, enhancing career decision-making self-efficacy will help college athletes cope with career stress in a more positive way. Individuals with more positive negative mood regulation expectancies are more resistant when faced with and stress and will also adopt a more optimistic coping toward career decision making problems.

THE INFLUENCE OF ATHLETES IRRATIONAL BELIEFS AND PERFECTIONISM ON COMPETITIVE ANXIETY

TÓTH, R., TURNER, M.J., KÖKÉNY, T., TÓTH, L.

HUNGARIAN UNIVERSITY OF SPORT SCIENCE

Introduction

In this research, we investigated the influence of irrational beliefs (demandingness, awfulizing, low frustration tolerance, depreciation) and perfectionism (adaptive and maladaptive) on competitive anxiety (cognitive and somatic) in Hungarian amateur and professional athletes. Previous studies have shown that irrational beliefs are able to predict the emergence of competitive anxiety. Furthermore, greater irrational beliefs have been linked to greater perfectionism as well. The association between irrational beliefs and perfectionism and their combined effect upon anxiety has not been investigated in sport contexts. Hence, we hypothesized that the influence of irrational beliefs on competitive anxiety is mediated by perfectionism.

Methods

Competitive anxiety (CSAI-2), irrational beliefs (iPBI) and perfectionism (SAPS) were measured by questionnaires in 219 Hungarian athletes. We ran the descriptive statistics and Pearson intercorrelations of all the normal distributed variables using IBM SPSS program. Hayes model 6 was used to test the direct and indirect effects of irrational beliefs and perfectionism on competitive anxiety.

Results

In serial atemporal multiple mediation analysis, we found that both adaptive and maladaptive perfectionism have a significant partial mediator role in the relationship between irrational beliefs and competitive anxiety. Both the total irrational beliefs score and the four subscale scores have direct and indirect effects on cognitive competitive anxiety where adaptive and maladaptive perfectionism playing a mediator role. Depreciation beliefs had a direct, demandingness and awfulizing had an indirect effect on somatic competitive anxiety when both forms of perfectionism were mediators.

Discussion

These findings support our hypothesis that irrational beliefs and perfectionism are influence on the emergence of competitive anxiety in Hungarian athletes. Overall, athletes who set dogmatic standards for themselves and are not able to handle frustration, tend to awfulizing and disparagement themselves face greater competitive anxiety. The following process is influenced by perfectionist traits such as overly high expectations and a disproportionate focus on mistakes. The obtained findings have important practical application for sport psychologist because based on our results rational emotive behavior therapy (REBT) may be an effective intervention to reduce perfectionism and competitive anxiety in athletes, the specific effectiveness of this intervention with athletes requires further longitudinal research.

ANALYSIS OF PSYCHOLOGICAL EVALUATIONS IN ACADEMIES OF FOOTBALL ELITE

RÓDENAS, L., MEDINA-VILLANUEVA, S., VANEGAS-FARFANO, M., ESPINO, F.

UNIVERSIDAD AUTÓNOMA DE NUEVO LEÓN

Abstract

The use of science and technology applied to sports demands the investigation of effective methods and techniques that allow the increasingly necessary improvement of sports training and the inclusion and participation of the psychologist as a permanent demand and tool in team sports. Today the tactical preparation, its control and evaluation form in the sports training process is recognized as the first step to develop and improve in teams of 1st category in Mexico and the world, as well as the psychological preparation, imbued within the tactical preparation, that is why the great sports potencies in the world are currently striving to optimize this important process of preparing the athlete. Sports psychology has developed and consolidated its presence in the entire field of competitive sports practice. This science acts in the individual and group aspect, teaching the athlete to eliminate negative thoughts or to use concentration techniques, in addition to making the smartest decision at the most suitable moment. Sports Psychology nourishes from the sources of Social Psychology for the necessary explanation of these phenomena considering the background and development of social thinking (Predvechni and Sherkovin, 1986).

Method

The evaluation consisted in the application of a battery of psychological variables tests, which were applied in January and April 2019 to four categories of the Football Club. 11 psychological constructs were evaluated in total, its descriptive statistics were calculated according to category (U20 - U17 - U15 - II) and the moment of application (T1 and T2). Likewise, the changes in the psychological variables were analyzed according to the moment of application, the prediction of burnout and satisfaction with the life of T2 was analyzed based on the interpersonal styles of the coach generated in T1.

Results and Discussion

According to the results of the study both in the comparisons by variables, times (T1 and T2) and categories, it is important to act in a brief form in the sub-20 and second division categories, since they are at risk of truncating an adequate integral development of the soccer player, predicting a burnout and few intentions to continue with a physically active life as soon as he concludes his stage as professional soccer player.

THE MECHANISM AND PREDICTORS BETWEEN MINDFULNESS AND FLOW STATE IN ELITE ATHLETES

CHEN, J.

KEELUNG CHANG GUNG MEMORIAL HOSPITAL OF THE CGMF

Background: Mindfulness interventions have been proved a benefit to promote flow stated and competitive anxiety in elite athletes. However, few studies explored possible mechanisms between those factors and also less is known about if there is any baseline condition as predictors to predict the better outcomes.

Methods: 40 elite athletes of national level were recruited to participate 4 weeks workshop of Mindfulness Sport Performance Enhancement (MSPE). They were evaluated based on mental health condition (i.e., anxiety, depression, and sleep condition) and the outcome variables were flow state and competitive anxiety (i.e., confidence, somatic anxiety, and cognitive anxiety) at pre- and post-workshop.

Results: We found that trait mindfulness mediated the relationship between all three aspects of competitive anxiety with the flow state, and the cognitive anxiety among them has even reached a fully mediated effect. However, the baseline mental health condition did not reach significance to predict flow enhancement after MSPE.

Conclusion: Our findings suggest the mechanism that competitive anxiety negatively related to flow state via trait mindfulness. The baseline mental health is not a good predictor of MSPE intervention and future research should investigate possible predictors other than anxiety, depression, and sleep condition.

ACTIVE LIFESTYLES CONTRIBUTE TO MENTAL HEALTH IN HEALTHY YOUNG MALES

YOSHIDA, A.1,2, MORI, J.3

1 KYUSHU SANGYO UNIVERSITY; 2 SAGAMI WOMENS UNIVERSITY; 3 WASEDA UNIVERSITY

INTRODUCTION: Daily lifestyle habits play an important role in maintaining mental health. In order to improve quality of life in the future, it is necessary to identify the lifestyle habits that are essential for maintaining mental health. Adequate physical activity (PA) can contribute to the primary prevention of mental disorders. In this study, we investigated the characteristics of the daily habits of individuals with positive mood states, with a particular focus on PA.

METHODS: Twenty-two physically and mentally healthy young males (18-25 years, body mass index (BMI) 23.0 ± 2.7) participated in this study. They completed the Profile of Mood States (POMS) questionnaire before and after the 4-week

measurement period. The Total Mood Disturbance (TMD) score for the negative mood state was calculated from the POMS results. To measure daily PA during the period, subjects wore triaxial accelerometers every day. The measured PA was categorised by intensity as follows: sedentary behaviour (1.0 metabolic equivalent (MET) ≤ x < 1.5 METs), light-intensity PA (1.5 METs ≤ x < 3.0 METs), moderate-intensity PA (3.0 METs ≤ x < 6.0 METs), and vigorous-intensity PA (≥ 6.0 METs). Resting metabolic rate was measured by indirect calorimetry after an overnight fast. Habitual food intake was assessed by a brief self-administered diet-history questionnaire. Pearsons correlation analysis and stepwise multiple regression analysis were performed to examine the relationship between changes in TMD score and lifestyle habits over a 4-week period. A statistical level of $p < 0.05$ was accepted.

RESULTS: Fourteen of the 22 participants showed increased TMD scores over the 4-week measurement period. Daily PA was significantly associated with changes in TMD scores. Changes in TMD scores were positively correlated with energy expenditure during sedentary behaviour ($r = 0.506$, $p = 0.016$) and negatively correlated with energy expenditure during moderate-and vigorous-intensity PA ($r = -0.544$, $p = 0.009$), adjusted for total energy expenditure. These results suggest that individuals who are more physically active feel more mentally positive than individuals who are less physically active. Energy expenditure during sedentary behaviour and moderate-and vigorous-intensity PA independently influenced changes in TMD scores (adjusted $R2 = 0.444$, $p = 0.001$). Sleep duration and food intake were not associated with changes in TMD scores in this study, however.

CONCLUSION: Physically and mentally healthy young males with more sedentary behaviour experienced negative feelings, whereas those with more moderate-and vigorous-intensity PA experienced positive feelings. Replacing sedentary behaviour with moderate-to-high levels of PA may help to improve mental health. Given that the explanatory power of the regression model for changes in TMD scores was 44.4%, more detailed research on other lifestyle factors such as diet and sleep is needed.

DOES FEAR OF FAILURE CONSISTENTLY NEGATIVE? PSYCHOLOGICAL FLEXIBILITY INHIBITS THE NEGATIVE EFFECT OF FEAR OF FAILURE ON SPORTS PERFORMANCE.

CHANG, W.H., HSU, S.C., NI, Y.L., KUO, C.C., CHEN, L.H.

NATIONAL TAIPEI UNIVERSITY OF TECHNOLOGY

Introduction

Fear of failure is an aversive emotional response of fear or worry when an individual targets internal standards or goals and fails to achieve them (Conroy & Elliot, 2004). Existing studies take a negative view of fear of failure on performance because fear of failure causes athletes to overanalyze situations and drain individual cognitive resources, leading to lower performance. However, whether fear of failure is negative for all athletes or whether athletes with specific characteristics can attenuate this negative effect is unclear. Based on the Cognitive-motivational-relational (CMR) theory, we argued that psychological flexibility would inhibit the negative effect of fear of failure on sports performance because athletes with high psychological flexibility can keep their attention resources at the target even if they perceive the feeling of fear without getting caught up in it. Psychological flexibility, identified as willingness to contact undesirable thoughts and feelings while acting in a manner congruent with values and goals (Hayes, Luoma, Bond, Misuka, & Lillis, 2006). As such, we expect that only athletes with lower psychological flexibility would be more likely to feel insufficient cognitive resources and unable to respond to situational demands, thus reducing sports performance.

Methods

The present research used a two-wave longitudinal design to examine our hypothesis. We recruited 362 athletes (243 male and 119 female athletes) aged 16 to 18 years old (M age= 16.78, SD = 0.48). At Time 1, we administered the athlete questionnaires (The performance failure appraisal inventory, Personalized Psychological Flexibility Index, subjective performance, and demographics). Six months later (Time 2), the athletes were asked to complete the questionnaires on subjective performance a second time. The participants complete the survey in person. The time interval was chosen to accommodate the athletes' schedules.

Results

The result supports our hypothesis that fear of failure has negatively correlated with their subjective performance. To understand whether psychological flexibility would weaken the adverse effects of fear of failure, we examine the interaction between fear of failure and psychological flexibility. We found that while controlling for subjective performance at Time 1, fear of failure was negatively associated with subjective performance at Time 2 for low levels of psychological flexibility. We also found that fear of failure did not reduce subjective performance at Time 2 for high levels of psychological flexibility.

Discussion

The primary contribution of this study is identifying psychological flexibility as a moderator of associations between fear of failure and sports performance. Practically, coaches can therefore utilize different approaches to help athletes regulate their emotions to improve performance based on the athletes characteristics (i.e., psychological flexibility).

PREDICTING LEISURE-TIME PHYSICAL ACTIVITY (PA) LEVEL IN UNIVERSITY OF ZAGREB STUDENTS USING THEORY OF PLANNED BEHAVIOR (TPB) AND SELF-DETERMINATION THEORY (SDT) BASED CONSTRUCTS

BABIC, J.

UNIVERSITY OF APPLIED HEALTH SCIENCES

Introduction

Importance of physical activity in psychophysical health preservation is well established, and increasing physical activity level of insufficiently active student population should be goal of public health actions. For them to be efficient, it is necessary to determine all factors, including psychological, that are related with physical activity level.

The aim of this study was to determine relationship between theory of planned behavior (TPB) and self-determination theory (SDT) based constructs and student leisure-time physical activity.

Methods

Participants were 1304 University of Zagreb students (857 female, 447 male), average age 20,72 years. Croatian version of IPAQ (Pedisic et al., 2011), which measures adult PA, and Croatian version of EMI-2 (Vlasic et al., 2002), which measure 14 exercise motives, were used. Using factor analysis, 3 higher order factors were extracted (psychological, social and health exercise motives). Also, The Locus of Causality for Exercise Scale (Markland and Hardy, 1997), which consists of 3 items that assess the extent to which individuals feel that they choose to exercise rather than feeling that they have to for some reason, and Theory of planned behavior questionnaire regarding physical activity, created for the purpose of this research, were used.

Results

Regression analysis showed that predictor variables (psychological, social and health exercise motives, locus of causality for exercise, and TPB variables – intention to be physically active, attitudes toward physical activity, subjective norms of physical activity participation, perceived control of physical activity) explain 13,5% of student leisure-time physical activity variance ($p<0,01$). All predictor variables, except for attitudes toward physical activity and subjective norms of physical activity participation, proved to predict student leisure-time physical activity significantly.

Conclusion

Understanding students motivation differences with regard to their leisure-time PA is really important when it comes to creating intervention programs that aim to increase student population PA. The results show that different theory approaches to physical activity motivation should be considered when creating such programs.

Key words: physical activity, students, leisure.time, psychological factors

EXPLORING NEGATIVE EFFECTS OF STEREOTYPE THREATS FROM PERSPECTIVES OF SCHOOL BELONGING AND ACADEMIC AVOIDANCE STRATEGIES

HSU, Y.

NATIONAL CHIAYI UNIVERSITY

Introduction

Recent studies have demonstrated that negative stereotypes about the academic performance of athletes (e.g., the "dumb jock" stereotype) negatively affect their academic performance, attitudes, and career planning outcomes. In addition, preliminary intervention studies have reported that small-scale social psychological interventions (e.g., identity security intervention and self-complexity intervention) benefit student-athletes. In addition to impairing performance, stereotypes also deflate motivation prior to athletic performance. Thus, the present study aimed to explore the relationship among stereotype threat, school belonging, and avoidance strategies and to examine their influence on the academic values and career-related opinions of athletes. Furthermore, a subgroup analysis by age was conducted.

Methods

In total, 399 valid questionnaire responses were collected from a sample of student-athletes, including 174 senior high school students, 118 first- and second-year university students, and 107 third and fourth-year university students. The participants of the present study all completed a questionnaire that measured their perceptions of stereotype threat, school belonging, avoidance strategies, academic values, and career aspiration.

RESULTS: The results indicated that student-athletes in different academic stages had different perceptions. With regard to the participant's perception of stereotypes, the participants indicated that they were stereotyped more by their peers than by other individuals. Furthermore, senior students (i.e., third and fourth-year university students) were more prone than senior high school student-athletes to adopting avoidance strategies (self-handicapping, avoiding help-seeking, and

avoiding novelty). Finally, the regression results indicated that school belonging and avoidance strategies partially mediated the relationships of stereotype threat with academic values and career aspiration.

Discussion:

The results of the present study are consistent with those of other studies, suggesting that negative stereotyping can limit the self-confidence and future development of athletes or cause them to lose interest in exploring other careers. In addition, the negative effects of stereotype threats may influence athletes by reducing their level of school belonging and increasing their proclivity toward adopting avoidance strategies. A long-term application of such strategies harms academic performance and results in interrupted education. Through an investigation of the experiences of athletes, key insights that facilitate the development of academic and career consultation for athletes can be obtained. Future studies should focus on issues of school belonging and avoidance strategies to help schools foster more conducive environments for athletes.

FACTORS FACILITATING AND HINDERING THE MOTHER ATHLETES' SOCIALIZATION PROCESS

SHINODA, Y., TSUCHIYA, H.

OSAKA UNIVERSITY OF HEALTH AND SPORT SCIENCES

Introduction

The participation of women athletes in world-class competitions has increased significantly. Specific conditions other than pregnancy and childbirth might hinder mother-athletes' involvement in athletics. However, only a few studies have investigated mother athletes, especially their participation as elite athletes, unlike "father athletes." The purpose of this study was to explore systems supporting mother-athletes' socialization after pregnancy and giving birth.

Method

We conducted semi-structured interviews that asked two main questions: (1) What triggered you to be a mother-athlete? (2) What are the critical physical, social, and psychological episodes of this process? We selected two study participants based on the following criteria: (1) competed in the Japanese National team at international competitions or played as a Professional (2) returned to athletics after pregnancy, birth, and childcare. Participant A, who was in her 30s, had a planned pregnancy and birth and returned to athletics after giving birth. Participant B, also in her 30s, had a natural pregnancy and birth and returned to athletics after giving birth. We conducted interviews twice with each participant and analyzed all the responses by referring to Trajectory Equifinality Model (TEM). We anonymized the participant's sport, the age at pregnancy, and the interview date to protect their privacy.

Results

In the physical, social, and phycological processes of becoming a mother athlete, we identified eight shared facilitating factors and nine individual facilitating factors. In contrast, we identified three shared hindering factors and seven individual hindering factors. Examples of shared facilitating factors include (1) gynecologist, (2) family and partner, which is triple counted within the three criteria, (3) self-acceptance of physical change after birth, (4) pioneering, (5) kids, and (6) social role after birth. Moreover, examples of hindering factors include (1) lack of information after pregnancy, (2) physical change after birth, and (3) role conflicts. These findings suggest that multiple factors are related to becoming a mother athlete and remaining competitive in top-level athletics.

Discussion

This study explored factors related to mother-athletes' socialization during pregnancy, childbirth, and childcare as conditions specific to women and their life plans to remain competitive in their fields as women and athletes. We suggest that future studies include larger samples and develop more comprehensive support systems for mother-athletes' socialization. This study's limitations include not examining the broader context of mother-athletes' socialization and not investigating cultural aspects of socialization. We suggest that future studies compare support systems for athletes in Japan with that for working mothers because several studies have investigated support systems for working mothers.

CLASSIFICATION OF SOMATIC BODY NARRATIVES IN ATHLETES

SHIGEKI, A., DAISUKE, T., NAKAGOMI, S.

UNIVERSITY OF KOKUSHIKAN

Introduction

During counselling, athletes often complain about trouble they are having with movement, performance, and physical discomfort. These body-related complaints are equated (in this study) with the athlete's experienced-body ('body'). Therefore, in this study, 'body' seen as the mediator between mind and body. Classifying body-related narratives in terms of the relationship between mind and body will allow for a better grasp of an athlete's internal experience at a particular moment.

Purpose

The aim of this study was to classify the 'body', as experienced by athletes and described in counselling sessions, in terms of the relationship between mind and body.

Methods

In this study, the cases of two adolescent athletes whose counselling sessions had already been terminated were selected for detailed retrospective analysis. Somatic body complaints (narratives) were extracted from their counselling records and then classified by the first author. This tentative classification was then refined by a group of sport psychologists (triangulation).

Results and Discussion

After analysis, three main types of 'body'(narrative) were found.

1) Complaints suggesting that the conscious mind tries to direct the body, but the body disobeys. For example,

'When my feet hit the ground (while running), I don't want just my feet, but my entire body, including my upper body, to absorb the impact… but my body doesn't respond. My feet alone take the impact and push-off all on their own. To make things worse, my back feet lift off the ground but don't come forward as far as I'd want them to. My arms swing just fine, but my legs lag behind, and my body as a whole gets all out of sync.'

2) Experiencing the body moving as if it has the initiative, while the mind watches from the side lines. For example,

'(While running), my legs are like two sticks with no power at all. I don't even try to fix it... I just go with it. I think, "Oh no, I can't do anything" about it, but I don't stop. I just feel the sensation of not being able to do it, and there's nothing I can do to help. It's like my body is being moved along by some outside force .'

3) Experiencing somatic body symptoms that are treated as if they have nothing to do with the mind. For example,

'I try to get ready for practice and go from my room to the practice field. It's fine up to that point. But when I open the door, my body starts to feel strange. My legs become stiff, and I can't even stand. I start breathing faster and faster, and before I know it, I'm hyperventilating…'

Athletes' complaints about their bodies express their internal states (the relationship between their mind and body). Furthermore, the body, which is experienced at the image- level, intervenes with these complaints. Therefore, during counselling it is necessary to pay attention to the narrative presence of the body, which mediates between the mind and body.

EFFECT OF PROLONGED SITTING ON COGNITIVE FUNCTION: A RANDOMIZED CROSS-OVER TRIAL TO TEST THE MODERATING EFFECT OF INTERMITTENT EXERCISE

HORIUCHI, Y.1, STONER, L.2, POMEROY, A.2, HORIUCHI, M.3

1. KYUSHU SANGYO UNIVERSITY, UNIVERISTY , JAPAN; 2. UNIVERSITY OF NORTH CAROLINA, USA; 3. NATIONAL INSTITUTE OF FITNESS AND SPORTS IN KANOYA, JAPAN

Introduction

The limited number of studies investigating: (i) the effect of acute prolonged sitting on executive function; and (ii) the moderating effect of breaking-up prolonged sitting on the aforementioned have reported inconsistent findings[1,2]. Therefore, we tested the hypothesis that: (i) executive function will be reduced following 3 hours of uninterrupted sitting; (ii) executive function will be preserved when the 3 hour sitting is broken-up by performing 1 min of half-squat exercises every 20 min.

Methods

For this randomized cross-over trial, twenty inactive participants (45% women, 21±1 years) completed two 3 h sitting conditions: (i) uninterrupted (CON); and (ii) interrupted with 1 min bodyweight half -squats every 20 min (EX). Executive function was measured using the color word Stroop test (CWST) and Trail Making Test-B (TMT-B). The felt arousal scale was used to assess arousal level. Mental fatigue, concentration, and motivation were assessed using visual analogue scales, labeled from 0 mm (not at all) to 100 mm (extremely).

Results

For the congruent and neutral tasks, the interaction, time, and condition effects were non-significant ($P>0.05$). There was a significant interaction effect ($P=0.01$) for incongruent task, with completion time increasing (worse) by 4.2% for CON and decreasing (improved) by -3.5% for EX. There was a significant interaction effect ($P=0.04$) for TMT-B, with completion time increasing (worse) by 3.3 sec for CON and decreasing (improved) by 3.8 sec for EX. In both conditions, the arousal level significantly decreased by -21.7% for CON and by -4.9% for EX condition (time effect: $P=0.01$). The mental fatigue increased by 285% for CON and 157% for EX with a significant interaction effect ($P=0.04$). Similarly, the concentration decreased by -28.7% for CON and by -9.2% for EX with a significant interaction effect ($P=0.048$). Motivation also significantly decreased by -27.9% for CON and by -17.1% for EX in both conditions (time effect: $P<0.001$).

Discussion and conclusion

Compared to the uninterrupted condition, breaking-up prolonged sitting with intermittent half-squats had favorable effects on executive function, arousal, concentration and mental fatigue. The half-squat strategy was chosen because no equipment is necessary, and skill level requirements are minimal. Additionally, the activity can be performed in-place, meaning the environmental restructuring is not needed. Considering the promising findings, further study is warranted to determine whether this strategy can be feasibly implemented within home, schools and work settings.

EMOTIONAL INTELLIGENCE AND SELF-ESTEEM: UNIVERSITY STUDENTS WITH DIFFERENT CULTURAL AND SPORT CONTEXTS

MIRANDA-ROCHÍN, D., LÓPEZ-WALLE, J., CANTÚ-BERRUETO, A., GARCÍA-CALVO, T., RAMIS, Y.
UNIVERSIDAD AUTÓNOMA DE NUEVO LEÓN, FACULTAD DE ORGANIZACIÓN DEPORTIVA

Introduction: Emotional Intelligence (EI) has been understood as the set of responses to intrapersonal emotional information, identification, and management of ones own emotions; and interpersonal, recognizing emotions in others and relating to others (Salovey & Mayer, 1990). Self-esteem, understood as the appreciation that each person has about oneself, has been considered to be shaped by culture, emotions, thoughts and experiences (Rosenberg, 1989). The aim of this research was to describe EI in its factors of emotional attention, clarity and repair, and self-esteem in university students; and compare them based on the country (Mexico and Spain), gender and sports practice for competitive purposes. Methods: Participated 423 university students (49% Mexican, 51% Spanish; 66.5% women, 32.3% men, 1.2% non-binary; 17.5% practice competitive sport) with a mean age of 22.83 years. They completed the Trait Meta-Mood Scale (TMMS-24) and Rosenberg Self-Steem Scale (RSE) questionnaires. Results: The comparative analyses were: 1) significant differences in emotional repair, where the university students in Mexico present higher means (Beta = .28); 2) significant differences in emotional attention (Beta = .18) and repair (Beta = .04), when comparing by gender; and 3) when comparing according to the sport practice, significant differences were found in emotional repair (Beta = .43) and self-esteem (Beta = .30), with higher means in those who practice competitive sports. The MANOVA revealed significance in the crossover by country and sport [F(4) = 3.02]. Discussion: The practice of competitive sports seems to interact with the three EI factors and with self-esteem in a differentiated way by country, providing evidence for future lines of cross-cultural research on EI.

RELATION BETWEEN EXERCISE INTENSITY AND EFFECTS OF ATTENTIONAL FOCI ON PERCEIVED EXERTION

WAKATABE, S., HAYASHI, Y.
HOSEI UNIVERSITY

Introduction

Research has suggested that internal and external attentional foci influence perceived exertion during aerobic exercise. However, some studies have reported no influence of attentional foci on perceived exertion, and no study has taken account for the influence of exercise intensity on the effects of attentional foci. The present study examined whether differences in exercise intensity influence the effect of attentional foci on perceived exertion during aerobic exercise.

Methods

Seven healthy men (mean age, 22.0 ± 1.7 years) volunteered in this study. After an incremental cycling test, they performed 12 cycling tasks (three intensities: 40%, 50%, and 60% maximal oxygen consumption [VO2max] × four conditions; control, internal focus, auditory external focus, and visual external focus) spaced at least 24 h apart. The cycling task began with a warm-up (5 min), followed by the main cycling at 40%, 50%, or 60% VO2max (10 min), and ending with a cooling down period (5 min). In the internal focus condition, the participants were asked to focus on bodily sensations during cycling. In the audio external focus condition, they focused on auditory stimuli and were asked to count the number of times they heard "Dog." In the visual external focus condition, they focused on the front monitor and were asked to count the number of times they saw "Dog." In the control condition, the participants received no specific instructions and performed cycling as they typically did. During the cycling task, perceived exertion was measured five times using the Borg's RPE 6–20 scale: at the end of the warm-up, at 2 min 30 s, at 5 min, at 7 min 30 s, and at 10 min in the 10-min cycling. Two-way mixed linear model 4 × 5 (condition × measurement time) repeated-measures ANOVAs were computed for each exercise intensity to compare the effects of attentional foci on RPE.

Results

For each exercise intensity, the results showed a significant main effect of time ($P < 0.01$) but no significant main effects of condition (40% VO2max, $P = 0.06$; 50% VO2max, $P = 0.73$; 60% VO2max, $P = 0.85$) or interaction (40% VO2max, $P = 0.88$; 50% VO2max, $P = 0.99$; 60% VO2max, $P = 0.77$). Regardless of the attentional foci, the RPE increased during cycling.

Discussion

The results suggest that attentional foci have no effect on perceived exertion during moderate-intensity cycling exercises. This result is inconsistent with those of previous studies. One possible reason is that the cognitive load might be low in the auditory and visual external foci. Therefore, insufficient cognitive load may lead to a decrease in the effect of external focus on perceived exertion. However, considering the P value for 40% VO2max was 0.06, attentional foci might influence perceived exertion during cycling at 40% VO2max. Future studies need to increase the number of participants to clarify the relation between exercise intensity and the effect of attentional foci on perceived exertion.

THE PSYCHOLOGICAL CHARACTERISTICS OF PEAK PERFORMANCE IN TAIWANESE OLYMPIC ATHLETES: A QUALITATIVE STUDY

CHI, L., CHIEN, T.H., LEI, C.Y., WEN, T.Y., CHEN, J.Y., HUNG, H.W.

NATIONAL TAIWAN NORMAL UNIVERSITY

Introduction

The peak performance of athletes has always been expected to appear frequently by coaches and players and to clearly understand the nature, appearance, and development control strategies. Gardner (2009) suggests that the studies of athletes' peak performance can help athletes to achieve and maintain the feeling of 'in the zone' and the state of idea performance. In the past, most of the research on the psychological state of peak performance's data was studied by athletes in Western countries. In addition, only few studies recruited Olympic athletes as participants. The psychological state of athletes peak performance might be affected by different competitive levels and cultures, so it is necessary to establish local data to understand the psychological state and characteristics of peak performance of elite athletes in Taiwan, and then provide a basis for subsequent assistance in athletes psychological skills training.

Method

The qualitative research method was used in this study. Participants were 16 Taiwanese elite athletes and 10 coaches who participated either 2016 Rio Olympic Games or 2020 Tokyo Olympic Games. Sixteen athletes won 1 silver medal and 4 bronze medals in Olympic Games. The data was collected through the semi- constructed interview. After received the informed consent, participants were interviewed around 50 to 60 minutes.

Results

The results of the study found that Taiwanese Olympic athletes and coaches reported the following consistent psychological characteristics when athletes experiencing peak performance: high self-confidence, maintaining a normal mindset, full focus and engaging, enjoy the competition, and relax. The important factors affecting the peak performance of elite athletes are: Adequate preparation, support of significant others, completely execute the pre-competition planning, and pre-competition routine.

Discussion

In accord with the previous sport psychology theoretical and empirical literature, this study has found self-confidence, normal mindset, focus, enjoyment, and relax are the crucial elements of peak performance for Taiwanese Olympic athletes. In addition, this study also found the important factors such as preparation, social support, execution of pre-competition plan, and pre-competition routine affect athletes' peak performance. The results provide evidence for the idea that the optimal state for peak performance requires a highly developed ability to identify and then self-regulate a range of cognitive, emotional, and behavioral factors relevant to the individual athlete and the requirements of the competition environment.

THE RELATIONSHIPS BETWEEN MINDFULNESS, FLOW, CONCENTRATION, AND EMOTION REGULATION IN COLLEGE ATHLETES: A FMRI STUDY

CHI, L., CHUANG, H.Y., KUNG, Y., CHIEN, T.H., HUNG, H.W.

NATIONAL TAIWAN NORMAL UNIVERSITY

Introduction

Previous studies indicated that flow, concentration, and emotion regulation are important factors related to athletes' peak performance. In recent years, mindfulness has been used for athletes to improve their psychological skills (Gardner & Moore, 2012). The purpose of this study was two-fold. First, to examine the relationships of mindfulness to flow, concentration, and emotion regulation. Second, Functional Magnetic Resonance Imaging (fMRI) was used to examine the differences between high and low mindfulness college athletes on regions of interest (ROI).

Method

The participants were 201 the Division-I college athletes in Taiwan. They were asked to complete questionnaires which measured mindfulness, flow, concentration, and emotion regulation. In the second phase, 42 participants were recruited in the high mindfulness group (n=21) and the low mindfulness group (n=21) according to their score of mindfulness. All participants received a functional MRI scan after informed consent. The two groups of participants watched instructions and sports field pictures in different situations (motion, neuter).

Results

In terms of the relationships among college athletes' mindfulness, flow, concentration, and emotion regulation, mindfulness was positively related to flow and negatively correlated with anxiety. Mindfulness was not correlated to concentration. Regarding the differences between high and low mindfulness college athletes on regions of interest (ROI), there were no significant differences on ROI such as insula, anterior cingulate cortex, prefrontal cortex, and amygdala. Interestingly, the results of one-sample t test found that high mindfulness group athletes had higher activation on the area of cerebellum and thalamus in the motion condition than in the neuter condition. In addition, low mindfulness group showed higher

negative activation on inferior occipital gyrus in the motion condition. Compared to the motion condition, higher activation on Pre- and Post-central than neuter condition.

Discussion

In accord with the hypotheses, the findings revealed that college athletes' mindfulness trait was positively related to flow and negatively related to anxiety. However, no correlation between mindfulness and concentration. The results of this study did not support the hypothesis that the differences between high and low mindfulness college athletes on regions of interest (ROI). However, it was interestingly found that there were differences activation on different brain area in the motion and neuter conditions. high mindfulness groups athletes used more brain resources for the information integration in the motion condition than the neuter condition.

ASSESSMENT MOTIVES FOR ATTENDING AN ELITE SPORT SCHOOL (ESS) – QUESTIONNAIRE FOR 9 TO 10 YEARS OLD MALE AND FEMALE ATHLETES

STUCKE, C., SCHULZ, M.

OTTO-VON-GUERICKE-UNIVERSITY, ATHLETICS ASSOCIATION OF SAXONY ANHALT

Introduction

Psychosocial characteristics are given an essential role in the context of talent development. It is assumed that various motives determining the attendance of an elite sport school may have an impact on the later sports career. However, there are only few researches indicating young athletes´ reasons to learn and practise at an ESS. Therefore, our study aims to develop a questionnaire to assess explicit motives, based on the example of track and field athletes. Using explicit motives, individual dispositions and their long-term effects on elite sports performances, can be determined.

Method

Fundamental to developing the questionnaire was the 2 x 3 motive taxonomy by Gabler (2002). Four items each collect data about a person-centred and social-centred perspective classified in (1) motives related to performing sport practice (2) motives related to the results of sport practice and (3) motives related to sport practice as a means for other purposes. The factorial validity of the instrument was examined using exploratory factor analysis on data collected from 405 young athletes (f = 190, m = 215) at the age from 9 to 10 years old who applied for the ESS in Magdeburg and Halle (Saxony-Anhalt, Germany) in the period from 2016-2022. 138 athletes (f = 65, m = 73) have received a recommendation for the ESS.

Results

The exploratory factor analysis could not confirm the 2 x 3 motive taxonomy. After an item reduction a 2-factor solution with 8 items each was identified: factor 1 "gain recognition through practising athletics" and factor 2 "goal and purpose of practising athletics". Both factors make up 44.17% of the total variance. The KMO-coefficient is .903 (Chi2 = 1,834.65; df = 120; $p < .001$). Internal consistency analysis revealed acceptable Cronbachs alpha coefficients (factor 1 $\alpha = .804$, factor 2 $\alpha = .826$). Athletes with a recommendation for ESS tend to show higher values of the two factors, but the results are not significant. A higher level of both factors correlates, more than coincidentally, with better performance in throwing, running and jumping disciplines as well as in the combined events. However, a higher value in factor 1 is associated with a decrease in confidence and self-efficacy after one year of training.

Discussion

The adapted questionnaire is an appropriate instrument for measuring young athletes´ explicit motives for attending an ESS. The trainers will receive an assessment of the later ESS students. The results indicate that the motive "recognition" initially requires higher physical and athletic performance. However, in the long term it can also lead to unfavourable expression of psychological characteristics, resulting in negative performance development. Appropriate pedagogical-psychological support should therefore be given to young athletes, especially during the first years at the ESS, in order to promote appropriate personality development.

PHYSICAL ACTIVITY AND ANXIETY SYMPTOMS IN COLLEGE STUDENTS: THE ROLE OF INTENSITY AND DOMAIN

HUANG, T.

SHANGHAI JIAO TONG UNIVERSITY

Background

There has been an increase in college students physical inactivity over the past decade, and college students engage in a higher sedentary time than the general young adult population. This is not only associated with an increased risk of chronic disease but also leads to mental health problems. Anxiety disorders constitute a major part of the disease burden in mental health. A growing body of evidence supports the role of physical activity in maintaining mental health and preventing anxiety symptoms. However, due to the heterogeneity of previous studies, there is a lack of knowledge regarding effective physical activity intensity and domain in relation to anxiety prevention. We aimed to examine the association

between physical and anxiety symptoms among college students and whether it can be modified by the role of intensity and domain.

Methods

Nine hundred and twenty-seven college students (mean age = 19.42) were recruited from Shanghai, China. Physical activity was assessed using the 24-hour Movement Behaviours Questionnaire, through which the intensity and domain of physical activity were reported. Anxiety symptom was evaluated using the Self-Rating Anxiety Scale. The cross-sectional association of physical activity with anxiety symptoms was examined using multiple linear regression.

Results

Associations between intensity and domain-specific physical activity and anxiety symptoms were not uniform. Within the leisure domain, light (β = -0.10, 95%CI, -0.20 ~ -0.01, $p < 0.05$) and moderate (β = -0.19, 95%CI, -0.35 ~ -0.03, $p < 0.05$) intensity physical activity was inversely associated with anxiety scores ($p > 0.05$), whereas vigorous intensity physical activity was not associated with anxiety scores in college students ($p > 0.05$). Within transport and household domains, physical activity was not associated with anxiety scores regardless of intensity ($p > 0.05$).

Conclusions

The findings indicated that leisure-time physical activity of light and moderate intensity was associated with anxiety among college students. The associations of physical activity with anxiety symptoms varied by the intensities and domains of physical activity.

ROOM FOR IMPROVEMENT: A MIXED STUDY OF LIFE SKILLS DEVELOPMENT IN HIGH SCHOOL STUDENT-ATHLETES

TROTTIER, C., TOUPIN, J., DRAPEAU, V., PÉPIN, M.A., FRENETTE, E., GOULET, C., FALCÃO, W.R., BILLAUT, F., PELET, S., TRUDEL, P., VEILLETTE, R., LAVOIE, S.

UNIVERSITÉ LAVAL

This study examines the experiences of student-athletes and school sport stakeholders (e.g., coaches, teachers) concerning student-athletes' needs in terms of life skills development through high school sport programs in Québec. A mixed design was used to analyze participants recruited from 10 high schools offering sport-study programs. Student-athletes (n = 854) completed questionnaires on their experiences of sport participation and the life skills they had acquired. Semi-structured interviews were held with 14 focus groups of student-athletes (n = 79) and 14 focus groups of school sport stakeholders (n = 77). Quantitative data were analyzed descriptively and qualitative data were analyzed thematically. Results showed that not all student-athletes had optimal life skills in four areas: (a) mental skills (i.e., time management, goal setting, emotional regulation, self-confidence); (b) healthy eating habits (i.e., fruit and vegetable's consumption, body image satisfaction, nutritional supplements); (c) physical and mental recovery (i.e., stress and performance anxiety management, sleep quality); and (d) safety behavior (i.e., safe behaviors, concussion awareness, knowledge of potentially dangerous ergogenic substances, positive climate). The findings highlight specific needs of student-athletes that should be targeted in future multidisciplinary support programs for school sport stakeholders to better equip them to foster life skills and positive development in student-athletes through high school sport.

THE EFFECT OF PUTTING PERFORMANCE OUTCOMES ON EEG MARKERS DURING THE PREPARATION PERIOD OF SUBSEQUENT PUTTS

HUNG, E., CHUEH, T.Y., HUNG, T.M., CHANG, Y.K.

NATIONAL TAIWAN NORMAL UNIVERSITY

Introduction

When a skilled athlete makes a mistake, the athlete will refer to previous experiences in their working memory to make adjustments in subsequent trials. As the three stages of motor learning point out, when a skilled athlete needs to allocate attention for their motor performance, their initial procedural movement process will rely on declarative knowledge and their behavioral process also shifts from an automatic process to a controlled process according to the dual-process theory. However, the psychophysiological mechanisms underlying this motor adjustment have rarely been explored. Therefore, this study intends to use EEG markers to explore these mechanisms. Specifically, we examine whether the elevated left temporal (T7) α2 (An EEG marker for verbal-analytic and language processing) is the main process for motor adjustment, instead of the right temporal (T8) or other frequency bands (α1 and β1).

Methods

Eighteen right-handed skilled golfers (handicap < 18) were recruited for this study. The participants were requested to perform 60 putts while EEG was recorded. Theα1 (8-10 Hz), α2 (10-12 Hz), and β1 (12-15 Hz) from T7 and T8 were compared between previous successful and unsuccessful trials. A 2 (Performance: after holed, after unholed) × 2 (electrode: T7, T8) × 3 (Frequency band: α1, α2, and β1) three-way repeated measure analysis of variance (ANOVA) was employed to examine the performance effects. A statistical level of $p < 0.05$ was accepted.

Results

The 2 × 2 × 3 three-way repeated measure ANOVA showed an approaching significant main effect on performance [$F(1, 17) = 3.457$, $p = .08$, $\eta 2p = .169$]; subsequent trials to failed putts showed higher α1, α2, and β1 power in both temporal electrodes. Neither the three way interactions of performance × electrode × frequency band $F(1, 17) = .074$, $p = .798$, η2p

= .004, nor the two way interaction involving performance [performance × electrode F (1, 17) = 1.810, p = .196, η2p = .096, performance × frequency band F (1, 17) = 1.003, p = .331, η2p = .056] reached significance.

Discussion & Conclusion

This study examined whether skilled golfers, following a putting failure compared with putting success, engaged in more verbal analysis as attentional reinvestment in movement adjustment during the preparation period for their next putt. Results showed that trials after a failed putt were preceded by higher EEG power in α1, α2, and β1 in both T7 and T8 sites. Although this performance main effect only approached statistical significance, this finding suggests that the performance could be affected by previous performance outcomes and a reinvestment for movement adjustment likely explains changes in EEG markers.

STRATEGIC SELF-TALK FOR ANXIETY REGULATION: COMPETITION TIME.

HATZIGEORGIADIS, A., PROSKINITOPOULOS, T., TZORMPATZAKIS, E., MYLONOPOULOS, A., GALANIS, E.

UNIVERSITY OF THESSALY

Self-talk interventions have proven effective in lowering anxiety levels in young athletes in field experiments, however, such experiments cannot resemble real competitive conditions. The purpose of the present study was to explore the effects of a strategic self-talk intervention on pre-competition anxiety and self-confidence in young swimmers. Fifty-five competitive swimmers initially agreed to participate in the study. Eventually, 38 (22 females) with a mean age of 14.72, training on average 5.86 times per week for an average of 14.02 hours, completed the requirements of the study. Swimmers competed in two qualifying for the national championship competitions that took place at an 8-week interval. Hence, the self-talk intervention was implemented over the 8-week period in-between these competitions. During this period, participants of the experimental group received a tailor-made intervention based on an opening need assessment session. The purpose of the intervention was to assist swimmers to develop specific self-talk plans for the competition but also to change unproductive self-talk. The importance of the competition was assessed one day before the competition, whereas pre-competition anxiety and self-confidence were assessed approximately 15 minutes before the start of each swimmer's main race. Preliminary analyses showed no differences in baseline anxiety and self-confidence between the intervention and the control groups; in addition, no between or within-group differences were recorded for competition importance. Two-way (2x2) mixed model MANOVA showed a significant multivariate group by time interaction, F(3, 34)= 3.00, p< .05, partial η2= .21. Examination of the pairwise comparisons revealed that for the intervention group cognitive and somatic anxiety were reduced and self-confidence was increased, whereas no significant differences were recorded for the control group. The findings of this pragmatic intervention study may lack the methodological rigor of controlled lab experiments due to the dynamic and unpredicted competitive environment, however, they hold important ecological validity, thus complementing previous findings from field experiments.

EFFECT OF VOLUNTARY EXERCISE ON DEPRESSION IN HIGH-FAT-FED MICE

OYANAGI, E., WATANABE, C., HAMADA, H., KAWASHIMA, M., AOKI, T., YANO, H.

KAWASAKI UNIVERSITY OF MEDICAL WELFARE

Backgrounds: Regular exercise has been reported to prevent not only obesity, but also mental disorders. In humans, a reduced risk of depression was reported in individuals engaged in high activity and moderate activity as compared with those at low activity (Paffenbarger, et al., 1994). Additionally, the voluntary wheel running induces an antidepressant-like effect in some behavioral tests of rodents (Duman, et al., 2008). On the other hand, previously published studies have shown that obesity or high-fat diet (HFD) related cognitive impairment, depression and anxiety (Lof, et al., 2022). However, the details of the effect exercise on depression in HFD-fed-mice are unknown. Therefore, the purpose of this study was to determine the effect of voluntary exercise on the antidepressant-like behavior in HFD-fed mice.

Materials and methods: Four-week-old C57BL/6 male mice (n=48) were used for the experiment and all mice were treated voluntary wheel running for 10 weeks. Diets were either normal dietary intake (CD) or HFD. Body weights were measured weekly. Half of the mice on each diet were then loaded with or without social defeat stress (SDS) for 10 days, followed by a sucrose preference test (SPT). Organs (body fat, adrenal glands, and thymus gland) were removed under anesthesia. This study was approved by the Animal Experimentation Committee of Kawasaki University of Health and Welfare (#19-005).

Results: No changes in wheel running activity were observed with different diets, but body weight in HFD mice during the voluntary wheel running period was significantly higher than that in CD mice. In both dietary groups, voluntary wheel activity was decreased during SDS loading (p<0.01). Furthermore, the HFD induced lower voluntary wheel activity in mice regardless of SDS loading (p < 0.05). The assessment of depression-like behavior by SPT showed significant differences between diets (p<0.01). Also, significant differences in thymus, adrenal, and body fat mass were observed by diets and SDS loading.

Discussion: HFD intake induced the decreasing SPT, which indicates depression-like behavior, and atrophy of the thymus gland. These results indicate that the depression-preventive effect of voluntary exercise habits is strongly influenced by HFD intake. Thus, dietary composition influences the effect of exercise. Furthermore, the response to a 10-day SDS load also resulted in atrophy of the thymus, that exercise habits do not necessarily lead to resistance to stress. These results suggest that a combination of exercise and diet is important for the prevention of depression.

REAL-LIFE STRESSORS AND RECOVERY EXPERIENCES OF SPORTS STUDENTS - AN AMBULATORY ASSESSMENT STUDY

KRUMM, C.1, DÜRSELEN, J.1, HEINRICH, N.W.2, KLEINERT, J.1, VON HAAREN-MACK, B.3

1. GERMAN SPORTS UNIVERSITY COLOGNE, INSTITUTE OF PSYCHOLOGY, 2. TECHNICAL UNIVERSITY BERLIN, 3. KARLSRUHER INSTITUTE OF TECHNOLOGY

Students of all disciplines report various stressors during their daily lifes, such as exam periods or financial problems (Hurst et al., 2013). Recovering from stress is important to prevent ill health. The extent to which these real-life stressors influence recovery experiences of sports students, has not yet been investigated. Thus, the aim of this study is to investigate how to which stressors over the day are associated with recovery experiences in the evening. Compared to other subjects, studying of sports science is characterized by specific conditions (e.g., sport practical courses and examinations), which may also lead to negative health consequences (e.g., injuries; Bastemeyer et al. 2021). Therefore, the second aim of this study is to examine whether the context (e.g., study-related) of a perceived stressor predicts recovery experiences.

A total of 86 sports students (m = 33, w = 46, d = 1) were examined on five consecutive days within the exam period of the 2021 summer semester. Students were surveyed six times a day approximately every two hours via smartphone app (LifeData LLC). They were asked if they had perceived a negative event in the last two hours (yes/no) and, if "yes," in what context (leisure, study-related) (Almeida et al., 2020). Recovery experiences (e.g., relaxation, control, psychological detachment and mastery) were recorded every evening, using the Recovery Experience Questionnaire (Sonnentag & Fritz, 2007). To examine the extent to which daily stressors were associated with recovery experiences at the end of the day, multilevel analyses were computed in SPSS.

When any stressor was present, we found significant associations between stressor and relaxation (ß = -.491, SE = 0.16, p = .002) and between stressor and control (ß = -.395, SE = 0.16, p = .011). With the onset of a stressor, these recovery experiences decreased in the evening.

While the results showed that the occurrence of a stressor predicted less relaxation and less control in the evening, this was not observed for detachment and mastery. To explain these results, future studies should investigate which stressors and how the intensity and the appraisal of a stressor predict recovery experiences in the evening. Within sports students´ education, recovery strategies should be addressed to prevent ill-health and maintain study-related performance. Especially in stressful phases (e.g., exam periods) it is important to recover well. However, the results of this study show that stressors may hinder recovery.

RELATIONSHIP AMONG PERCEIVED PHYSICAL COMPETENCE, GROSS MOTOR SKILLS, AND PHYSICAL ACTIVITY LEVELS IN A SAMPLE OF ITALIAN 9 TO 11-YEAR-OLD CHILDREN

NICOLOSI, S.

KORE UNIVERSITY OF ENNA

This study analyzed the relationship among Perceived Physical Competence, Gross Motor Skills, and Physical Activity Levels in a sample of 119 Italian 9-11-years old-Children (M=55; F=64; Mage=10.09; SD=0.57).

The instruments administered were: (1) the Italian version of Ulrichs (1992) Gross Motor Development Test (TGMD), to assess Gross Motor Skills (Locomotion and Object Control Skills); (2) the Italian version of the Self-Description Questionnaire (SDQ; Marsh, 1988) for children and pre-adolescents (Camodeca et al. (2010), to measure the perceived physical appearance, perceived physical competence, self-esteem, and self-concept; and (3) the Physical Activity Questionnaire for children and pre-adolescents (PAQ-C-it; Gobbi et al., 2016), to assess physical activity levels.

Mediation analysis showed that perceived physical competence (independent variable) affects gross motor skills (dependent variable), with the mediation of physical activity levels (mediating variable) (R2=.21; Total ES=2.33 p<.001; PA levels Ind. Eff.=.14 p<.001). Gender is a significant covariate in the relationship between perceived physical competence and gross motor skill, but not between perceived physical competence and physical activity levels.

Results emphasized the key role of perceived physical competence in understanding PA-related behaviour in children. Furthermore, levels of physical activity had significant positive effects on perceived physical competence and the latter, in turn, affects physical activity levels.

Gross Motor skills are not uniform and there are significant differences between genders in gross-motor skills (locomotion and object control), therefore, from an educational perspective, teachers and educators should offer a wider range of activities such that all children can exercise all gross-motor skills. For those skills in which children are less able, activities that allow them to improve are advised, starting from their interests and their perceived self-efficacy. A game-based approach (GBA) should be considered in order to make the activities attractive to boys and girls (TGfU SIG, 2021).

Sociology

THE SOCIOLOGY OF CHILDHOOD AND THE LEARNING OF MOVEMENTS IN TRADITIONAL CHILDRENS GAMES

MELLO, A.M.

UFRJ - UNIVERSIDADE FEDERAL DO RIO DE JANEIRO

Introduction

Childrens culture, object of study of Sociology of Childhood, covers various forms of play, among which are the traditional games practiced by groups of children in the streets, squares and schoolyards such as hopscotch, jump rope, kite, marbles, hide-and-seek, etc. In a dialectic articulation between action and thought, children need to master body movements that require a certain level of learning. Traditional games are activities that provide an exceptional set of motor experiences through which the child learns new moves and bodily possibilities (Mello, 2006).

The objective of this study was to analyze the learning process of children in their attempt to master the existing complex motor skills in traditional games. The theoretical framework comprised a trans-disciplinary dialogue between the Sociology of Childhood (Corsaro, 2005; Sirota, 2006) and the historical-cultural theory (Vygotski, 1997).

Methods

The study followed a qualitative approach of ethnographic orientation. Fieldwork was conducted in a public elementary school located in the city of Rio de Janeiro, with children ranging from 6 to 10 years of age who freely played traditional games in the schoolyard.

The tools used included observations of the children during their games, records in field journals, audio, photographs, personal interviews and interviews with groups of children.

Discussion of Results

Following the theoretical and methodological orientation of the Sociology of Childhood according to which children are actors of social processes (Sirota, 2001; 2006), we collected the children's testimonial statements on how their learnings of motor skills take place in the practice of traditional childrens games, being these data central to our research.

The observations and statements indicated that the learning of motor skills of traditional games occurs initially by imitation in the group to which the child belongs. The child observes and tries to reproduce the movement made by another child. However, the observation and movement reproduction are not enough for the child to fully master the necessary movements of the games, especially those which are more complex.

It is fundamental to have the mediation of peers with a deep knowledge of the movements required by the game so that the child can make progress in his learning. The learning of movements in traditional games occurs under conditions predisposed by the zone of proximal development (Vygotski, 1997) through collaboration and guidance among peers.

SOUTH CHINA UNIVERSITY OF TECHNOLOGY

Introduction: 18-year-old Eileen Gu is the undoubted spotlight of the world with a three-medals debut in 2022 Winter Olympics, and as the host country, China has crafted overwhelming media coverage towards the naturalized skier to boost national pride. Therefore, by making a comprehensive text analysis of coverage of Eileen Gu, this paper aims to figure out how Chinese media build up a perfect female athlete that's totally different from those in the past on its home-hosted Beijing Olympics and thereby boost national pride through a series of innovative media narratives.

Methods: 341 news pieces from June 1, 2019, to April 14, 2022 were downloaded from Wisers News Database with the keyword "Eileen Gu" and used for in-depth text analysis through KH-Coder, a text data mining software developed by Japanese scholar Koichi Higuchi. The software generates a list of key words by frequency and a keyword co-occurrence bumble network is developed, which exhibits the and reveal the media narrative behind.

Results: Eileen Gu, as a new female athlete icon, emerged as a perfect puppet for Chinese propaganda due to a combination of her transferred citizenship, her historical achievements in winter sports and her family background and personal charm. Based on these conditions, China has kicked off its propaganda machine three years old and its media strategies could be boiled down to three perspectives, namely patriotism, feminism and Olympic spirit. Gu is shaped as a naturalized athlete passionate about traditional Chinese culture, a Gen-Z feminist with dual success in terms of academics and her sport career and a Chinese sportsmanship ambassador exhibiting friendliness, modesty and generosity to her competitors and teammates.

Discussion: The three narratives above are proved to be really effective and well absorbed by the Chinese audience with all age ranges as most of them are isolated from the global Internet with a long-standing firewall and the stated-own media would never write about controversies about Gu due to strict censorship. Thus, in the cocoon of information created by the Chinese authority, Gu dominated the trending topics on both news media outlets and social media platforms during the whole Winter Game period. However, the flawless image of Gu collapses soon after her return to America alongside tempting fame and financial rewards as a viral celebrity. It is such a shameful lesson for the Chinese to come to know via news imported from western countries via VPN that the hero and idol they admired seem to be a fence-sitter trying to behave in the way people like in China and America respectively. Illusory as Gus media image is, the years-long cam-

paign yielded satisfying results since Gus completed her mission and win big with her dual nationality while the authority managed to achieve their propaganda goals and win more gold medals in the home-hosted Winter Olympics.

Sport Management and law

THE ENGAGEMENT OF LOCAL COMMUNITY TO IMPROVE A BRANDING OF HOST CITY THROUGH SPORTS EVENT: A CASE STUDY OF INDONESIA AND MALAYSIA

AMALI, Z., CASTYANA, B., RAHAYU, T., JUNAIDI, S.

MINISTRY OF YOUTH AND SPORTS, REPUBLIC OF INDONESIA; FACULTY OF SPOTS SCIENCE, UNIVERSITAS NEGERI SEMARANG, REPUBLIC OF INDONESIA

Since the successful of Indonesia as host country of Asian Games 2018, many sport events have been prepared by the government, such as Moto GP in 2022 and FIFA World Cup U-20 in 2023. On the other hand, Malaysia as a neighborhood country also uses sports event as an effort to increase the economy and provide opportunities for its citizens to take part in it. In tourism literature, it has been claimed that sports mega-events are a steadily growing tourism segment which directly attracts significant numbers of tourists and generates substantive tourism receipts, while also improving the host country's market position, and changing the image of the associated tourist destination. Based on data from the Malaysian Central Statistics Agency in 2020, sports events are the top five reasons for local residents to visit an area. However, the success of sports events as marketing tool cannot be separated from the participation of the local community. This qualitative research aimed to identify and analyze the role of local community to improve a branding of host city used two major sports event in Indonesia and Malaysia, namely the MesaStila 100K Ultra Marathon and Tour de Langkawi. By using an open survey method that can be filled out online via the Google Form application, 45 informants came from participants agree to fill the questionnaire that has seven indicators, consisted of 1) Brand Salience, 2) Brand Association, 3) Brand Resonance, 4) Brand Loyalty, 5) Service Experience, 6) Journey Experience, and 7) Sharing Value through Event. After data collected and analyzed using NVivo 12 Pro, we found that as many as 68.88% participants in sports event pushed to visit a certain place and gain new experience. That condition makes a good place for local community to introduce local culture through cultural festival or entertainment stage. Apart from having side events, the services provided to the participants are also important, where as many as 37.78% of the participants stated it. The local community is hoping to give the best service there and through sports event, it was the best way to give a local hospitality. With the best quality service to participants, they will spread the positive image they get and can make them come back in the future. Participants also said that they would like to visit the area again because of the attractive location and beautiful scenery. This is shown by the presence of 43.18% of participants who said the location and scenery were an important part for them to come back. On this part, local community has a major duty to take care and maintain the attractiveness of tourism destination. Based on those statements, it can be concluded that new experiences, attractive locations, activities that can introduce local culture, and services are an important part that can be done by local community to improve branding of sports events host city.

HOW CAN GREEN ADVERTISING ELICIT SPORTS TOURISTS SELF-CONTROL TO EXHIBIT GREEN TOURISM BEHAVIOR? THE ROLE OF CONSTRUAL-LEVEL THEORY

NI, Y.L., KUO, C.C., HSU, S.C., CHANG, W.H., CHEN, L.H.

NATIONAL CHIAYI UNIVERSITY

Introduction

Environmental protection and conservation have become one of the highest priorities for the tourism business (Kim & Stepchenkova, 2019). Following these trends, sports tourism researchers also start to consider how to elicit tourists self-control and exhibit green tourism behavior. Based on the strength model of self-control (Baumeister et al., 2007), we argue that sports tourists with self-control might line with the social standard to exhibit more green tourism behavior. That is because they might consider the long-term benefits to the natural environment and then regulate their behavior to engage in green tourism behavior. Furthermore, high-level construal would lead individuals to focus on long-term or distal perspectives rather than short-term outcomes and exhibit goal-directed behavior (Fujita et al., 2006). As such, we argue that the high construal-level green advertising would elicit the sports tourists' self-control to concern about environmentally friendly in the future and then exhibit green sports tourism behavior.

Methods

The study participants were 361 tourism participants (232 females and 129 males) who were recruited in college in Taiwan and volunteered for the study. Among the 361 participants, the mean age was 22.19 years (SD = 8.37), who had sports tourism experience in the past month. An experimental study was conducted to test the proposed hypotheses. A 1 (self-control) × 2 (fewer pictures and more words advertising claim vs. more pictures and fewer words advertising claim) between-subjects design was employed. The participants first read a brief description of the procedures and instructions and then were asked to complete a questionnaire that consisted of demographic items and questions about self-control and Chinese social desirability. Next, the participants were exposed to one of the two green tourism behavior advertising messages used in this study.

Results

The result supports our hypothesis that sports tourists' self-control was positively correlated with their green tourism behavior. To understand whether the different advertising claims would enhance the relationship between participants self-control and green tourism behavior, we examine the interaction between self-control and ad manipulation. The result indicates that participants with greater self-control produced a higher level of green tourism behavior when they reviewed the high-level construal design advertisement.

Discussion

This study expands our understanding of individuals self-control in green sports tourism and highlight self-control acts an important role to guide sports tourists to exhibit green tourism behavior. In addition, we advance the current understanding of self-control and the construal level of environmental psychology literature by identifying the interactive effect between self-control and the construal level theory on how to influence environmentally friendly behavior in sports tourism.

A STUDY OF SPORT INDUSTRY FORECASTING AND MANAGEMENT BY POLITICS IN TAIWAN

LIN, W.

TAIPEI NATIONAL UNIVERSITY OF THE ARTS

Introduction

Deep learning drives many services of artificial intelligence that improve automation, performing analytical and physical tasks without human intervention. An Artificial Neural Network (ANN) model that can predict future sports industries in Taiwan was developed. Through the governments public information, to advance sport management and brief sport policy, this study captured the development and current situation of the sports industry in Taiwan by analyzing the domestic sports industry and the literature and then constructing the sports industry management system consistent with the government unit and the industry.

Methods

According to the public information disclosure of Gross Domestic Product (GDP), Gross National Product (GNP), general income, the Number of Firms, and the employed population of 12 sports industries, we planned to explore and discuss the construction model and forecasting sports industry during 2008-2018. In the first stage, we utilized the neural network analysis to evaluate and forecast for the "industrial forecasting model." of consulting for the government and sports business. In the second stage, Considering the application of the BCG matrix is a powerful means of simplifying complex issues regarding sport policy. The BCG matrix is a 2 × 2 matrix initially used to compare sports industries based on the total value of all the goods and services produced within Taiwan and all the income generated by nationals of Taiwanese sports industries made within or outside Taiwan. Based on the results of deep learning analysis, sports industries are classified into the quadrants Stars, Dogs, Cash cows, and Question marks.

Results

In the first stage, we figured out predictions with GDP and GNP in 2019 of 12 sports industries. In the second stage, we classified Stars stands for increasing GDP and GNP as "sports stadium or construction industry."

Cash cows stand for increasing GNP, and decreasing GDP, as "rental of sports products or equipment." The question mark represents decreasing GNP but increasing GDP, and no industry match in the study. The dog represents both decreasing GNP and GDP as "educational services for leisure sport," "wholesalers and retailers of sports products or equipment," "sports performances," "health care for sports," "sports tourism," "sports wagering," "sports media or information publishing," "sports agent, management consulting or administration industry," "eSports Industry," and "professional sports or amateur industry."

Discussion

We planned to figure out the research gaps between government departments and the sports industry, the advantages of research in the field of sport management, "data specialization" and "data rarity," and the academic research and connects the physical education and sports policy and development issues, and connects the sports industry with the practical contribution and benefit of the academic and practical integration of the sports industry.

RELATIONSHIP QUALITY AND WELL-BEING FOR EMPLOYEES' PARTICIPATION IN SPORT AND RECREATIONAL CLUB ACTIVITIES

TENG, P.Y., TENG, P.C., CHEN, M.Y., CHEN, H.H.

ASIA EASTERN UNIVERSITY OF SCIENCE AND TECHNOLOGY; NATIONAL TAIWAN NORMAL UNIVERSITY

Relationship quality and well-being for employees' participation in sport and recreational club activities

Teng, P-Y 1, Teng, P-C 1, Chen, M-Y 2, Chen, H-H2

1 Asia Eastern University of Science and Technology, Taiwan

2 National Taiwan Normal University, Taiwan

Abstract

INTRODUCTION: Relationship quality are focused on trust, adaptation, communication, cooperation, promise, and satisfaction. Moreover, employee well-being is a type of individual experience, which is related to the time line when individuals engage in activities that match with value pursuits and comprise the instant experience related to temporary emotion-

al or sensory feelings and accumulated experience related to continuous mind or spiritual feelings (Diener, Suh, Lucas, & Smith, 1999). Nevertheless, the effects of relationships outside work on employee well-being mainly consider the relationships with teammates (Sweetman, Luthans, Avey, & Luthans, 2011) or group members (Holzgreve et al., 2020). The purposes of this study were: (1) to explore the correlation between relationship quality and well-being of employees' participation in sport and recreational club activities, and (2) to examine linear relationship among the employees' participation in sport and recreational club activities on relationship quality and well-being.

METHODS: The data consisted 250 valid questionnaires were completed by C Financial Holding Co., Ltd. throughout their internal sport and recreational club members (131 males, 119 females), age ranged 41-50 years old for all participants. Measures included relationship quality and well-being scales. Data analysis methods included the descriptive statistics, Pearson correlation analysis, and linear regression analysis.

RESULTS: The results reveal the positive correlation among relationship quality, life satisfaction, and positive emotions ($p < .05$). Satisfaction and commitment to life explained a significant proportion of the variance of positive emotions (Adjusted $R2 = .46$, $p < .05$). Commitment has a significant proportion of the variance of subjective well-being(Adjusted $R2 = .29$, $p < .05$).

DISCUSSION:

Based on this study, it concluded that companies should invest in community activities actively as the linkage with relationship quality in the future and to improve employee satisfaction and enhance well-being. Consequently, a brief discussion suggests that the theoretical perspectives of these significant variables need to be considered for further implications and study.

RESEARCH ON ATHLETE WELFARE SYSTEM IN CHINA

WANG, Y.

CHINA SPORT INFORMATION CENTER

Introduction

The athlete welfare work is mainly carried out by various levels of sport administrations and sport associations in China. A support system for athlete development is very essential for athletes to strike a balance between sport and work/education.

Methods

The methods of literature review, expert interviews and statistical analysis are applied in this research. Face-to-face interviews were conducted with some government officials and athletes.

Results

The General Administration of Sport of China has issued several guidelines aiming to strengthen athletes' education and career planning. A variety of seminars and training sessions have been organized to help retiring athletes to go through transition period smoothly.

In recent years, a lot of investigations into athletes' welfare have been conducted in different provinces and municipalities, and new athlete liaison working groups have been formed to know more about athletes' needs. The Beijing Sport Administration established an information platform for retired athletes in 2019. The Tianjin Sport Administration cooperated with related education departments and social security departments in formulating athlete welfare policies.

China Sports Foundation has been providing Disability Mutual Aid Insurance for elite athletes all over the country, and multiple entrepreneurship grants for retired athletes who want to start a business.

Discussion

To further enhance the support system for athlete development in China, it is suggested that we diversify the development pathways for our athletes and make full use of the athlete welfare departments, so as to care for athletes through the whole process from enrollment into sports teams to retirement. It is also advised that commercial insurances should be offered to athletes as a lifetime guarantee, and new information technology should be utilized more efficiently to facilitate athletes' career transition.

IT'S NOT JUST FOOTBALL: TESTING A SPILLOVER EFFECT OF SATISFACTION WITH FOOTBALL TEAM PERFORMANCE ON FAN'S EMOTIONAL EXHAUSTION AT WORK

KUO, C.C.1, NI, Y.L.2, HSU, S.C.3, CHANG, W.H.4, CHEN, L.H.5
TUNGHAI UNIVERSITY1, NATIONAL CHIAYI UNIVERSITY2, CENTRAL POLICE UNIVERSITY3, NATIONAL TAIPEI UNIVERSITY OF TECHNOLOGY4, NATIONAL TAIWAN SPORT UNIVERSITY5

Introduction

Football is one of the world's most popular sports and is beloved by 265 million sports fans worldwide. The affective state of sports fans was significantly affected by the winning or losing results of the team they support. Although a number of studies have demonstrated that sports fans' emotional reactions are likely to influence the attitudes and behaviors towards their teams, whether and when such subsequent affective states spill over to fans' lives outside sports, such as work lives, is rare to be explored. Guiding by an integrated perspective of affective event theory (Weiss & Cropanzano, 1996) and the Work-Home resource model (ten Brummelhuis & Bakker, 2012), we proposed that sports fans have higher satisfaction with football team performance might reduce the experience of emotional exhaustion at work. Because watching a sports game may constitute a vital event for sports fans, people who assess a sports event of as satisfactory tend to develop positive affective states. Such positive affective states are served as a contextual resource that replenishes in the non-work (home) domain and might prevent the depletion of personal resources and experience emotional exhaustion in the work domain. Further, research suggests that team identification involves emotional ties and a sense of belongingness toward a focal team, strongly influencing fans' thoughts, attitudes, and behaviors (Delia & James, 2018). As such, we expect that those sports fans with higher team identification would be more likely to respond to the favorable affective event and experience less emotional exhaustion at work.

Methods

Ninety-one satellite football fans in Taiwan who support various European professional football teams (e.g., Paris-Saint German, Borussia Dortmund, Real Madrid, or Tottenham Hotspur) were recruited. Participants provided weekly survey data two times a week over a period of four work weeks. Multilevel modeling was adopted to test research hypotheses.

Results

The results indicated that satisfaction with football team performance did not significantly predict fans' emotional exhaustion at work. However, satisfaction with football team performance significantly reduced fans' emotional exhaustion at work for those with higher team identification. Overall, our hypotheses were partly supported.

Discussion

This study provides several implications. First, by examining the role of satisfaction with football team performance, our study expands the understanding of leisure-work facilitation, that is, the spillover effect from leisure to work. Second, with respect to the literature on recovery and sport management, our study goes beyond the factors regarding sport participation (physical activity) and identify the beneficial role of sports spectatorship, which also provides practical implication to practitioners in promoting occupational health through sports.

PARTICIPANTS SATISFACTION AND EVENT ATTACHMENT: AN ONLINE INTERNATIONAL MARATHON IN TAIWAN

CHENG, T.C., CHEN, H.W., CHEN, M.Y.
NATIONAL TAIWAN NORMAL UNIVERSITY

Introduction

The global sports industry has lost more than US$ 60 billion due to the COVID-19 pandemic; the sports industry has lost revenue from event attendee fees, media broadcasting, and corporate sponsorship of sporting events (CNBC, 2020). Thus, innovative strategies and the development of new sporting event opportunities are crucial for event organizers to maintain profitability. Taiwan's Rice Heaven Tianzhong Marathon, the most hospitable marathon in Taiwan, was held online in 2021 due to the COVID-19 pandemic. The event attracted more than 9,000 participants and featured charitable activities such as rice donations and tree planting. Based on previous studies, a strong attachment enhances event participants' cognitive, emotional, and behavioral responses toward events (Iniesta-Bonillo et al.,2016; Fu et al.,2019). Therefore, the aim of this study is to understand the perceived satisfaction of participants by evaluating the event attachment toward the online marathon event.

Methods

This study evaluated participant satisfaction, event attachment, and participant demographics for the 2021 Taiwan's Rice Heaven Tianzhong Marathon, which has been held every year since 2012. Through purposive sampling, a total of 374 valid completed questionnaires were obtained. Analysis of variance, correlation analysis, and moderated hierarchical regression analysis were performed.

Results

The findings indicated that gender ($t(372)=4.053$, $p<.05$) and marriage status ($t(372)=-3.218$, $p<.05$) were significantly associated with event attachment. In addition, attendance history was significantly associated with event attachment, and event attachment was significantly associated with event satisfaction. Furthermore, functional knowledge, emotional importance, and symbolic expression had significant explanatory power for event satisfaction with a total of 20.8 % variance explained. A significant interaction effect between event attachment and attendance history toward participant

satisfaction was observed with a total of 18.5 % variance explained through hierarchical regression analysis; attendance history moderated the effect of event attachment on event satisfaction (F(1,370)=29.249, p=.018).

Discussion

Participants' perceptions of event attachment influenced their satisfaction with this online sporting event. Male participants had more agreement in event attachment than did female participants. Additionally, married participants had more agreement in event attachment than did unmarried participants. These findings emphasize that event attachment is crucial for online sporting events. Other sporting event organizers may wish to develop strategies that encourage event attachment, such as virtual interaction with participants or other online activities to sustain the events. Future research could expand upon this framework by examining other variables, such as repurchase behavior, to explore actual participant behavior during online sporting events.

THE DETERMINANTS OF CROSS-BORDER SPORT CONSUMPTION IN GUANGDONG-HONG KONG-MACAO GREATER BAY AREA(GBA)

ZHOU, L.

GUANGZHOU SPORT UNIVERSITY

Purpose – The purpose of this study was to examine the relationships between product or service, catering, accommodation, shopping, sightseeing, transportation, ease of customs, currency exchange and behavioral intentions, as well as whether individual attitudes have mediation effects on these factors toward behavioral intentions in the context of cross-border sports consumption in Guangdong-Hong Kong-Macao Greater Bay Area.

Design/methodology/approach – A structural equation model was used to analyze the mediation effect of individual attitude on the influencing factors toward behavioral intentions. The group comparison was used to compare the different effects of various factors on the citizens in the three places.

Findings – Results showed positive impacts of (a) individual attitudes on behavioral intentions, and demonstrated (b) individual attitudes mediate relationships between catering, accommodation, shopping, ease of customs, currency exchange and behavioral intentions, (c) individual attitudes partially mediate relationship between product or service and behavioral intentions, and that (d) individual attitudes do not mediate the relationship between transportation and behavioral intentions. Compared with Hong Kong and Macao citizens, the ease of customs has greater impact on Guangdong citizens. Catering, shopping, sightseeing and currency exchange have greater impact on Macao citizens than those in Guangdong and Hong Kong.

Practical implications – The current research is aimed at contributing to practical applications by identifying the drivers of consumer attitude and behavioral intention in sport consumption in Guangdong-Hong Kong-Macau Greater Bay, and hence proposing effective strategies to improve consumer-perceived service quality and promote the development of sport industries in bordering cities.

Originality/value – The findings contribute to the literature in several ways. First, it tests the relationships between product or service, catering, accommodation, shopping, sightseeing, transportation, ease of customs, currency exchange and behavioral intentions with emphasis on the mediating effect of individual attitude in the context of cross-border sports consumption in Guangdong-Hong Kong-Macao Greater Bay Area. Second, the study broadens the knowledge in the context of cross border sport participation. Third, this study confirms that it is much different between cross border shopping and sport participation.

Keyword: cross-border sports consumption, sports industry, Guangdong-Hong Kong-Macao Greater Bay Area, behavioral intentions

CLINICAL EXERCISE PHYSIOLOGY ACCREDITATION: AN AUDIT OF EXISTING STANDARDS

REEVES, N.

GRIFFITH UNIVERSITY

Health professions such as clinical exercise physiology (CEP) are founded on a set of standards that outline base level knowledge, skills and competencies to define the roles and scope of practice of the profession. Despite the practice of CEP having many common features regardless of the country in which it is conveyed, a harmonised set of international standards does not exist.

PURPOSE: To systematically audit the professional standards for the five countries recognised as having existing national certification systems for CEP. METHODS: The audit process was conducted using a modified scoping review protocol based on the documentation provided by the American College of Sports Medicine (ACSM), Exercise & Sports Science Australia (ESSA), British Association of Sport and Exercise Sciences (BASES), Canadian Society for Exercise Physiology (CSEP), and Sport and Exercise Science New Zealand (SESNZ). Two reviewers independently extracted data from the standards documents and results were cross checked by relevant experts from each jurisdiction. RESULTS: There was commonality of themes for 60% of all content extracted. The overall coverage of themes was 60%, 67%, 76%, 88% and 98% from New Zealand, Canada, USA, UK and Australia respectively. CONCLUSION: There is a common core of themes covered by all current national standards for CEP across the five nations audited, but there is variable coverage in the remaining 40%. These findings are important for understanding the differences in current training and certification of CEP professionals, and how this might influence the internationalisation of the profession.

THE VERIFICATION OF THE ISOLATION BUBBLE SYSTEM FOR OLYMPICSCAMP -ETHNOGRAPHY OF THE FRENCH NATIONAL TEAM-

MIZOGUCHI, N.
JAPAN WOMENS COLLEGE OF PHYSICAL EDUCATION

In February 2021, amidst the spread of the new coronavirus (Covid 19), the Tokyo Organising Committee for the Olympic Games published a set of rules and regulations that adopted an isolation bubble system. The bubble system is a bubble system in which the Games are operated in such a way as to envelop the host city in a giant bubble, blocking athletes and officials from contact with the outside world. In addition to regular PCR inspections before and after entry and during the Games, strict curfews are imposed at the Games venue to ensure isolation. This bubble system is now becoming established as the new modality for international sporting events. A concrete example of the bubble system for infection control at the Tokyo Olympics is that athletes will be tested for Covid19 within 72 hours before leaving the country and will continue to be tested regularly during the Games. They must then download a health management app called COCOA or O C H A . The scope of activities is also limited to the athletes village, competition, and practice venues, and public transport is not allowed for travel. After entering the country, the athletes activities are restricted to the competition and training venues and the athletes village. Furthermore, as a rule, they must leave the country within 48 hours of the end of the Games. Nevertheless, while such strict and thorough infection control measures reduce the risk of infection, it can be imagined that athletes placed in a bubble (external isolation) will experience increased stress. Under the extreme tension of the Olympics, what kind of stress will athletes place inside the bubble face, and how will they accept the isolation of the bubble environment for the Games? I was appointed by the French Olympic Committee as the local head co-ordinator of the Taekwondo team and spent time with the team in isolation. As a sociologist, I was motivated to accompany the team to the pre-camp and observe the normative awareness of the living environment of the Olympic team in the bubble and the governance within the organization.

In this research, I accompanied the overseas team to the teams pre-camp as a local attendant and spent time with the team in the pre-camp, and observed them in the same bubble, eating the same life, conducting interviews in French, and recording their behavior and words using the ethnographic method. Regarding living in isolation, we found that the lawns as a relaxation zone, ice baths, and the provision of Japanese food served as a stress buffer for the athletes. To ensure that they felt protected rather than isolated, weekly online meetings were held for two months before the camp to promote communication. Thanks to the various considerations by the pre-camp host municipality and facilities, the players did not feel so burdened. The athletes did not feel any discomfort because they had already been using the bubble system for more than a year for their training camps in France.

THE RELATIONSHIP AMONG CONSUMPTION VALUE, EMOTIONAL ENJOYMENT, SOCIAL ATTITUDE, INTENTION TO CONTINUOUS PARTICIPATION AND INTENTION TO LEAVE OF GOLF PARTICIPANTS: FOCUSING ON THE MZ GENERATION

KIM, I.G.1, PARK, J.1, CHOI, Y.1, KIM, J.1
KOREA NATIONAL SPORT UNIVERSITY

Kim, I.G.1, Park, J.1, Choi, Y.1, Kim, J.1*

1: Korea National Sport University (Seoul, South Korea)

Introduction

Along with COVID-19 pandemic, as the preference for outdoor sports increased, golf population in South Korea, including the MZ generation(born between 1980 and 2010), has increased(Seo, 2022). The MZ generation in Korea enjoys golf as part of their consumption value. However, stablising COVID-19 is leading to an increase in other outdoor activities, causing a decrease in golf participants. In particular, the MZ generation is increasingly giving up continuous participation in golf due to the cost burden. As such, the MZ generation's participation in golf decreases, leading to a slowdown in the overall growth of the golf industry in Korea. Therefore, the purpose of this study is to investigate the relationship among consumption value, emotional enjoyment, social attitude, intention to continuous participation and intention to leave of golf participants in the MZ generation. This study would be meaningful in contributing to the development of the Korean golf industry by leading the MZ generation to continuous participation in golf.

Methods

Data were collected from 493 MZ generations with golf rounding experience by using convenient sampling method. After removing 184 cases of incomplete questionnaires, 309 were used for data analysis. For the study, frequency analysis, reliability analysis, Confirmatory Factor Analysis (CFA), correlation analysis and Structural Equation Model (SEM) were conducted by using SPSS 20.0 and AMOS 20.0.

Results

The overall validity and fit did not seem acceptable, $\chi 2(df) = 492.812$ (224, $p<.001$). Nevertheless, CFI = .937, TLI = .922, RMSEA = .062 and SRMR = .057 exceeded fit index recommended by Bagozzi & Dholakia (2002), and therefore overall validity and fit can be considered a good model for the study. As a result, emotional value positively affected emotional pleasure, $\beta=.784$, $t=8.131$, and social value significantly influenced social attitude, $\beta=.891$, $t=9.418$. Also, emotional pleasure and social attitude have a positive effect on intention to continuous participation, respectively, $\beta=.719$, $t=10.529$ and $\beta=.247$, $t=4.397$. However, emotional pleasure was not significant for intention to leave, $\beta=-.386$, $t=-5.108$.

Conclusion

The findings found that emotional and social values were important for forming positive emotion, attitudes and continued participation in golf. In addtion, it was confirmed that emotional pleasure was essential to prevent the MZ generation from participating in golf. Therefore, stakeholders in the golf industry should revitalise the golf community which can enhance interation between the MZ generations. Lastly, it is necessary to pay attention to satisfying the joy between participants rather than the intrinsic joy of golf.

THE RELIABILITY AND VALIDITY OF THREE COMMERCIAL DEVICES IN MEASURING THE MOVEMENT VELOCITY IN UNILATERAL RESISTANCE EXERCISES

CHEN, Z.1, LIAO, K.1,2, BISHOP, C.3, BIAN, C.1, LI, Y.1,4

1SHANGHAI UNIVERSITY OF SPORT, CHINA; 2GUANGDONG VOCATIONAL INSTITUTE OF SPORT, CHINA; 3LONDON SPORT INSTITUTE, MIDDLESEX UNIVERSITY, UNITED KINGDOM; 4CHINA INSTITUTE OF SPORT SCIENCE, CHINA

INTRODUCTION: Velocity-based training (VBT) is a novel resistance training method that uses instant feedback of each repetition (e.g., mean or peak velocity) to manipulate training load [1]. In the field, optimal implementation of VBT relies on the use of valid devices in order to prevent the natural variation in training from being masked by measurement errors in the device itself [2]. Several studies have explored the reliability and validity of many commercial devices in bilateral exercises [3-5]. However, given the prevalence of unilateral movement patterns in many sports and the fact that many unilateral exercises are commonly programmed [6,7], we recommended more information is needed relating to VBT during unilateral resistance training. Therefore, the aim of this study was to evaluate the reliability and validity of three commercial devices in measuring mean velocity (MV) and peak velocity (PV) during unilateral resistance exercises.

METHODS: Nineteen strength-trained young men completed two sessions consisting of one set of 2-3 repetitions against 6 sub-maximal loads (40, 50, 60, 70, 80, and 90% of one repetition maximum [1RM]) during the Bulgarian split squat and lunge, respectively. The PV and MV were recorded simultaneously by linear transducers (GymAware), accelerometer (Push), smartphone application (My Lift) and compared to a 3D motion capture system (Vicon) for all repetitions. For reliability, the coefficient of variation (CV) and the interclass correlation coefficient with 95%CI (ICC, two-way random, absolute agreement) were used to evaluated the absolute and relative reliability respectively for devices in this study. For validity, linear regression analysis, Bland-Altman limits of agreement (LoA), standard error of the measurement (SEM), mean absolute percentage error (MAPE) and Hedge's g effect sizes were used to evaluate the validity of each device compared to the 3D system.

RESULTS: GymAware was the most reliable (CV < 10%) and most valid (r = 0.920 to 0.960, r2 = 0.847 to 0.922, SEE = 0.029 to 0.037m/s; bias = -0.02 to 0.00m/s, 95% LoA = -0.08 to -0.07m/s, ES < 0.2) in MV measurement, but would overestimate in PV measurement (bias = 0.02 to 0.06m/s, 95% LoA = -0.15 to -0.26m/s, ES = 0.06 to 0.35). Push was the less reliable especially at higher intensities (> 80% 1RM) and valid with substantial differences and 95% LoA well above the acceptable levels (95% LoA: MV = ± 0.07m/s; PV = ± 0.11m/s) both in MV and PV measurement. My Lift was reliable but limited in validity of MV measurement (bias = -0.03 to 0.04m/s, 95% LoA = -0.08 to 0.15m/s).

CONCLUSION: GymAware can confidently be used as an alternative to 3D motion capture systems if measuring MV in unilateral resistance exercises, with some caution given to estimations of PV. However, the reliability and validity of Push and My Lift in measuring movement velocity during unilateral resistance exercises were questionable. We suggest against the utilization of Push and My Lift for velocity-based resistance training, when using unilateral resistance exercises.

ASSESSMENT OF WELLNESS AND FATIGUE IN COLLEGIATE SOFTBALL PLAYERS

FIGUEROA, Y.

SAM HOUSTON STATE UNIVERSITY

INTRODUCTION: The purpose of this study was to investigate wellness and fatigue throughout an off-season resistance training program in collegiate softball players using objective and subjective methods.

METHODS: Seventeen (n = 17) female collegiate softball players participated in off-season resistance training sessions as part of team training. Resistance training sessions took place two to three times per week over six weeks for a total of 13 sessions. Objective measures of fatigue were obtained for each resistance training session using vertical jump and handgrip strength. Vertical jump height was assessed using a jump mat in which participants performed three trials, and the best attempt was recorded. Handgrip strength was measured using a handgrip dynamometer with participants performing three trials using their dominant hand. The best attempt was recorded as the session's handgrip strength. Subjective measures of fatigue were collected using a wellness questionnaire prior to each resistance training session. The wellness questionnaire consisted of questions related to hours slept, sleep quality, nutrition, soreness, academic stress, and sport practice difficulty based on a scale of one (lowest) to five (highest) for applicable questions. Spearman's rho was used to analyze correlations among variables. Alpha was set at 0.05.

RESULTS: Over the six weeks, participants reported an average of 6.67 (SE = 0.077) hours slept, ratings of 3.45 (SE = 0.069) for sleep quality, 2.96 (SE = 0.049) for nutrition, 2.47 (SE = 0.074) for soreness, 3.09 (SE = 0.059) for academic stress, and 1.60 (SE = 0.064) for sport practice difficulty. Vertical jump height average was 52.22 cm (SE = 0.149). The average for handgrip strength was 39.0 kg (SE = 0.871). Positive correlations were found between hours slept and sleep quality (r_s = 0.280, $p < 0.001$), sleep quality and vertical jump (r_s = 0.196, $p = 0.005$), nutrition and grip strength (r_s = 0.175, $p = 0.011$), soreness and academic stress (r_s = 0.185, $p = 0.007$), and soreness and practice difficulty (r_s = 0.456, $p < 0.001$). Negative correlations were found between hours slept and academic stress (r_s = -0.162, $p = 0.019$), sleep quality and nutrition (r_s = -0.172, $p = 0.013$), sleep quality and soreness (r_s = -0.202, $p = 0.003$), sleep quality and academic stress (r_s = -0.213, $p = 0.002$), nutrition and vertical jump height (r_s = -0.242, $p < 0.001$), soreness and vertical jump height (r_s = -0.172, $p = 0.014$), and soreness and handgrip strength (r_s = -0.156, $p = 0.024$).

CONCLUSION: Monitoring wellness and fatigue uncovered numerous areas impacted in the overall wellbeing and performance of collegiate softball players. Athletes and coaches should emphasize the importance of sleep quality and nutrition for mental and physical performance. Soreness also plays a role in athlete performance as evidenced by the corresponding vertical jump height and handgrip strength. Further investigation is necessary to understand the causes of these relationships.

ANALYSIS OF METAVERSE APPLICATION IN PHYSICAL EDUCATION

CAO, Y.

BEIJING SPORT UNIVERSITY

INTRODUCTION: Since 2021, the concept of the Metaverse has gradually become a hot topic in the world. The development of information technologies, such as VR, AI and blockchain, provides a solid technical guarantee for the realization of the Metaverse. In addition to the need for educational reform, Metaverse empowering physical education will become a typical feature of educational informatization.

METHODS: Literature reviews and expert interview

RESULTS: From the perspective of teachers, firstly, Metaverse will promote the role transformation of physical education teachers. Second, Virtual physical education teachers will appear. Virtual teachers not only have low cost, but also can serve students in different regions and schools which will greatly promote education equity. Third, Metaverse will assist the professional development of physical education teachers. Teachers or researchers from the whole world can become creators and owners of high-quality physical educational resources in the Metaverse world.

From the perspective of students, first, Metaverse will provide ubiquitous and verifiable intelligent learning paradigm. Through ubiquitous and verifiable learning, students can use flexible human-computer interaction on the Metaverse sports training platform to verify the accuracy of sports actions on the premise of minimizing the risk of sports injury. Second, Metaverse will provide an experiential learning process of deep immersion. It can break through the space limitations of traditional physical education, students can conduct real-time smooth interaction and intelligent feedback during sports learning. Whats more, Metaverse will promote the realization of individualized physical education. In the era of the Metaverse, students will have a Metaverse pass in addition to his/her ID card and passport, they can enter any virtual sports space for learning and training according to their personal interests and needs.

From the perspective of sport universities, Metaverse is a new generation of Internet based on blockchain. the process data and final data of physical education activities can be truly recorded based on blockchain, therefore, not only will realize the precise educational management and evaluation based on data, but also it can provide the possibility for the establishment of university credit bank. The graduation certificate will be digital, carrying more detailed learning information, so the establishment of the Metaverse sport universities will become a reality and provide new motivation for the development of high-quality sports education.

CONCLUSION: Physical education is an important component of education, Metaverse will provide a new platform for modern physical education, the concept, strategies, management and evaluation of it will be greatly developed by Metaverse, these changes will play a key role in the development of future physical education.

DEVELOPMENT OF ICT PLATFORM SERVICE MODEL TO ACCELERATE DIGITAL TRANSFORMATION OF TENNIS INDUSTRY IN SOUTH KOREA

KIM, C.R., LEE, J.H.

DONGEUI UNIVERSITY & KOREA MARITIME AND OCEAN UNIVERSITY

INTRODUCTION: Since Steve Jobs iPhone debut, the use of mobile media has created an optimal environment in which users can directly generate, store, and share data on the Internet. In terms of market capitalization, 7 out of 10 major IT companies are leading the world. Major platform companies such as Amazon, Google, Facebook, and Apple are building their own platforms, allowing users to stay there, and using them as the core strength of their businesses. As a result, the importance of platforms has risen throughout the industry, and the platform has changed the paradigm of the industry and even the value chain [1]. ICT (Information Communication Technology) based platforms also play a very important role in the distribution and distribution channel of cultural content. Even so, this ICT platform technology must be applied to the analog sports scene in line with the trends of the times. Even though many people enjoy sports and the implementation of platform services where suppliers and consumers meet has come technically enough, there are still no platform services being used at actual sports sites, furthermore, there is not enough of insightful prior research on how to provide them.

Therefore, this research would like to develop an efficient platform services model to develop and disseminate in the Tennis industry market of South Korea, which is rapidly increasing with young people.

METHODS: To carry out this research, we would like to develop a platform service model using the business model canvas strategy [2]. In addition, to analyze the problems in the Korean tennis industry market and develop a platform service model, we conducted focused interviews and in-depth interviews with 10 people involved in the tennis industry.

RESULTS: The research stage is 1) macro and micro environment analysis of the tennis industry market, 2) Tennis industry stakeholders analysis, 3) differentiating factors and user-customized core value analysis based on competitive product analysis of the existing market, 4) to develop a platform service design model that utilizes the business strategy canvas.

CONCLUSION: The findings of this research are as follows; first, segmentation of the market of tennis industry stakeholders, second, how to solve the problems of tennis industry stakeholders, third, how to communicate with tennis industry stakeholders, 4th, what kind of relationship will be formed with tennis industry stakeholders, 5th, how to generate revenue from tennis industry stakeholders, 6th, how to control physical and human resources to execute the business model, Seventh, what are the core activities of the platform service, Eighth, how to form core partners, Ninth, what are the costs required to operate the business. Finally, we would like to suggest an efficient platform business model of O2O, B2B, B2C, and B2G based on this.

THE MEASUREMENT OF INTERNAL AND EXTERNAL LOAD IN BADMINTON SINGLE AND DOUBLE GAME

LIN, Y.C., CHEN, W.H., LIU, T.H., CHANG, S.S., SHIANG, T.Y.

TUNGHAI UNIVERSITY

INTRODUCTION: The local positioning system (LPS) with the inertial measurement unit (IMU) can measure the players external load such as movement distance, speed, position, and Player Load (PL). The internal load of the players can be measured by heart rate (HR) monitors and rating of perceived exertion (RPE) (1). This study used LPS and HR monitors to record the cumulative load of badminton players during the simulated games, and observed the relationship between external and internal load.

METHODS: Fifteen mens college badminton players (age: 21.2 ± 1.6 years, training experience: 7.5 ± 3.7 years) participated in this study. Each player wore a LPS sensor (Goalgo T1, Tromin Technology Co., Ltd., Taiwan) (2) on the left shoulder and a HR monitor (Polar H10) on the chest and played a simulated single and a simulated double game in badminton. Total distance covered (TDC), triaxial (PLTotal) and uniaxial PL (anteroposterior [PLAP], mediolateral [PLML], and vertical [PLV]) (3), Banister's TRIMP, and session RPE (sRPE) were collected and calculated.

RESULTS: The results of this study showed that the Banister's TRIMP (21.09 ±9.21 a.u.) in the single game were higher than the Banister's TRIMP (13.12 ±7.09 a.u.) in double game. External load measured showed that TDC (594.73 ±119.33 m) and PLTotal (71.40 ±23.11 a.u.) in the single game were higher than the TDC (486.99 ±79.89 m) and PLTotal (54.51 ±18.21 a.u.) in double game. Significant Pearson's correlations between the sRPE and the TDC ($r = .75$, $p < .01$) and between the sRPE and the PLTotal ($r = .48$, $p = .07$) were observed in the singles game. In the double game, the sRPE was significantly related to the PLV ($r = .70$, $p < .01$) and the sRPE was related to the PLTotal ($r = .68$, $p < .01$).

CONCLUSION: The physiological load (Banister's TRIMP) and external load (TDC and PLTotoal) of mens single game was higher than double game. The factors affecting the subjective load of singles and doubles players are different. The main factor affecting the sRPE for singles players is horizontal movement distance, while for doubles players, it is vertical movement. Movement distance and vertical movement load may be the suitable load indicators for evaluating singles and doubles players load.

RELIABILITY OF COEFFICIENT OF DETERMINATION OF LINEAR REGRESSION MODEL BY ANGULAR VARIATION OF ACCELERATION DATA OF EACH PART OF THE BODY

KOMATSU, T., KOMAYA, Y., ONISHI, J.

NIHON UNIVERSITY

INTRODUCTION: The Acceleration sensors have been attached to various parts of the body, and have come to be widely used not only for posture analysis but also for occupational kinematical analysis. The aim of this research is to minimize the feeling of wearing the sensor and to measure the physical load by a simple measurement method based on highly accurate posture examination and individual properties of kinematical analysis.

METHODS: In this study, three subjects were asked to wear accelerometers (manufactured by HITACHI) in seven locations on their both thighs, both lower legs, both wrists, and back in a work environment that imitating regular cleaning room. The average of unit data per hour (min.) was calculated. Due to the characteristics of the sensor, the value of the vertical (Z) component is set to 1G, and the number of squats per unit time (min.) and the operation time (sec.) were measured.

Each parameter was then examined from a linear regression model. In addition, we also re-verified the data this time with a simple gyro acceleration sensor (WitMotion Shenzhen Co., Ltd.).

RESULTS: The objective variable was the squatting time, and the explanatory variable was the value of the acceleration sensor attached to each part of the body. As a result, a relatively high accuracy result was obtained ($r2 = 0.712$) even when the device was worn on the right lower leg in the identically as the four locations extracted from the sensor ($r2 = 0.777$).

In addition, the acceleration x, y, and z were converted to the angle θ using the acceleration sensor and the number of squatting per unit time (sec.), and the relationship between the angle θ (Y) and the squatting time (sec.) was clarified. From these results, it was found that the greater the angle, the longer the squatting time. Therefore, it was suggested that a squatting state can be estimated.

As in the past, we also obtained knowledge that supports the results with a simple gyro accelerometer.

CONCLUSION: We used squatting time as the objective variable, and examined the correlation coefficient, which is the reliability of the joint angle (θ) extracted from the acceleration sensor. This result suggests that it is possible to detect actual squatting with a small number of accelerometers for discern squatting motions.

In the future, it will be a basic material for calculating more precise movement characteristics and physical load from the relationship with each joint angle such as vertical acceleration changes and crouching posture (θ).

INVESTIGATING THE AGREEMENT BETWEEN FORCE PLATFORM AND PLANTAR PRESSURE INSOLE DATA IN BAREFOOT AND SPORT-SPECIFIC FOOTWEAR CONDITIONS ACROSS FOUR DIFFERENT MOVEMENT PATTERNS

LOCKWOOD, K.1, DUNNE, C.1, TSU, T.1, HOLMES, M.1, WAGNAC, E.2, CLÉMENT, J.3

BROCK UNIVERSITY

INTRODUCTION: Conducting applied sport research in real-world settings is challenged by the lack of portable instrumentation that produces valid and reliable data that is collected without interfering with the athletes movement and is meaningful to sport performance. The purpose of the study was to compare and contrast data collected simultaneously from a force platform and a plantar pressure insole to provide support for the use of the XSENSOR® pressure insoles in a sport-performance environment.

METHODS: Data was collected in two conditions. The barefoot condition consisted of the insole on a force platform in isolation and the in-skate condition consisted of the insole inside a speed skate boot on a force platform. A single-participant design was conducted whereby an injury-free female completed multiple trials in both conditions. A P6000 Force Platform (BTS Bioengineering Corp., MI, Italy) was used to collect force data and a X4 Foot and Gait Measurement Systems plantar pressure insole (XSENSOR® Technology Corporation, AB, Canada) was used to collect pressure data in the two conditions across four movement patterns; static stance (SS), anterior-posterior sway (AP), medial-lateral sway (ML), and lateral jump (LJ).

RESULTS: Intraclass correlation coefficients (ICC) and Bland-Altman plots revealed excellent agreement between the cumulative centre of pressure (CoP) path length (mm) measured from the force platform and insole in the barefoot condition across the four movement patterns. Moderate agreement was revealed between the cumulative CoP path length (mm) in the in-skate condition across the SS and LJ patterns and poor agreement between the cumulative CoP path length (mm) in the in-skate condition across the AP and ML sway patterns. Bivariate Pearson product-moment correlations revealed significant positive correlations between time-series force (N) data and time-series pressure (psi) data in both conditions across the four movement patterns ($p < 0.05$).

CONCLUSION: Results confirmed that the XSENSOR® insoles were capable of collecting data comparable to a gold-standard force platform. The level of agreement could be attributed to the high resolution (233 sensels/insole) and high sampling frequency (150 Hz) of the insoles. These results are consistent with a recent study comparing insole plantar pressure data to known pressures and contact areas applied by an inflatable bladder in a non-human model [1]. The current study further investigated the use of XSENSOR® insoles in a human-model under two conditions; a human foot in isolation and a human foot inserted into sport-specific footwear, namely speed skates. Outcomes provided researchers and practitioners with empirical support and confidence to employ the X4 Foot and Gait Measurement Systems plantar pressure insoles (XSENSOR® Technology Corporation, AB, Canada) outside of a laboratory setting in a real-world sport environment to collect and analyze in-skate plantar pressure data during on ice performance.

VALIDITY AND INTERUNIT RELIABILITY OF CATAPULT VECTOR S7 10HZ GLOBAL NAVIGATION SATELLITE SYSTEM UNITS FOR ASSESSING ATHLETE MOVEMENT PATTERNS IN HOCKEY

KONERTH, N., CRAMB, R.

DURHAM UNIVERSITY

INTRODUCTION: Global Navigation Satellite System (GNSS) receivers, most commonly Global Positioning System (GPS) receivers, are frequently used to monitor external training load, which informs training decisions, substitutions, and athlete recovery in elite-level hockey. Since no peer-reviewed research has considered Catapult Sports' newest GNSS device, the Vector S7 10 Hz, the aim of this study was to determine the validity and interunit reliability of this device for tracking athlete movement patterns in hockey.

METHODS: A repeated measures and validation design was utilized with 10 national level hockey athletes (5 male, 5 female) completing 14 laps of a 487 m sport simulation circuit designed to mirror movement patterns in a hockey match. Each participant wore two Vector S7 GNSS units, and, during each lap, completed 4 short shuttles with change of direction (COD). The primary outcomes for validation and reliability were speed and distance, measured via the GNSS units and criterion measures (timing gates, stopwatch, and measuring tape). Validity was evaluated via t-tests, percent standard error of the estimate (%SEE), and Pearson correlations, and interunit reliability was assessed via paired sample t-tests, coefficient of variation (CV) and interclass correlations.

RESULTS: The Vector S7 units had an overall mean bias of 2.8% ($p<0.001$), which increased to 14.3% on a 13 m T-shaped shuttle. Percent SEE was < 2.25% for all but the shortest two (13 m T-shaped and 8.5m V-shaped) COD shuttles where %SEE increased to 7.0% and 10.3%, respectively. Interunit reliability was very good, with an overall CV of 0.3% and all CV values < 3.1%.

CONCLUSION: The mean bias of the Vector S7 units was larger than that measured in previous Catapult devices; however, bias over the shuttles and %SEE was comparable to previous results. The interunit reliability was notably better than earlier models. As the Vector S7's bias was very consistent, it could be easily corrected for, with a multiplicative factor of 1.0286, making these devices a valid and reliable measure of athlete movement patterns in hockey.

TENNIS SERVE VOLUME, DISTRIBUTION AND ACCELEROMETER LOAD DURING TRAINING AND COMPETITION FROM WEARABLE MICROTECHNOLOGY.

PERRI, T., REID, M., MURPHY, A., DUFFIELD, R.

TENNIS AUSTRALIA

INTRODUCTION: This study investigated serving volume, frequency and accelerometer loads of elite female tennis players via machine learning algorithms for stroke even detection developed from global positioning systems (GPS) and micro-electro-mechanical systems (MEMS) devices. Specifically, these wearable technology metrics were analysed across session type (practice vs. match-play) and drill type (e.g., serving vs. point-play) during training and tournament blocks to inform coaching decisions and serve training prescription.

METHODS: Five elite female tennis players (18.8 ±2.9y) wore a commercial GPS and MEMS device (Catapult Vector S7) during a tennis season. Training and tournament blocks were determined from individualised athlete schedules. Monitoring occurred during practice sessions and official singles and doubles matches. Within practice sessions, drills that involved the serve were classified as "serving drills" or "point play drills". Prototype machine learning algorithms were used to detect serve strokes at 98-99% precision alongside measures of intensity from the accelerometer and gyroscope. Three key variables of the serve were analysed and included absolute and relative; 1) serve volume, 2) serve load (arbitrary units [AU]) and 3) rotation magnitude (revolutions per second [rps]). Due to the small sample size, effect size analyses were performed using Cohen's d statistic with 95% confidence intervals across and within block type, session type and drill type.

RESULTS: Large effects were observed for greater serve load during official matches compared to training and tournament practice sessions (d = 0.97-1.07 [95% CI = 0.69-1.30]). Further analysis of session-level data showed trivial differences in rotation magnitude per serve across all conditions (d = 0.03-0.06 [95% CI = -0.01-0.09]). Within training blocks, large ES existed for higher cumulative serve volume (d = 0.82 [95% CI = 0.54-1.10]) and serve load (d = 0.85-1.10 [95% CI = 0.33-1.34]) during point-play drills. However, serving drills involved greater serve frequency (n.min-1) (d = 1.10-1.87 [95% CI = 0.59-2.19]) and relative serve load (AU.min-1) (d = 1.35 [95% CI = 1.06-1.65]). Serving drills had a small ES for increased rotation magnitude during tournament blocks (d = 0.43 [95% CI = 0.02-0.88]), whilst trivial ES were observed for point play drills (d = 0.19 [95% CI = -0.14-0.53]).

CONCLUSION: Serve volume remains highest in official match-play compared to individual practice sessions. Further, this study presents initial evidence that serving during official match-play demonstrate greater accelerometer demands compared to practice. This could indicate the usefulness of wearable technology metrics for serving practice in tennis to ensure training outcomes are replicating competition outcomes. An increased focus on serving frequency within tennis monitoring strategies may also have important implications for adolescent athletes that require careful training prescription.

VALIDATION OF PREDICTED JOINT ANGLES BASED ON INERTIAL MEASUREMENT UNITS AND AUTOMATED LANDING ERROR SCORING SYSTEM

DENG, Y.J., HSU, W.C., LIN, Y.J.

NATIONAL TAIWAN UNIVERSITY OF SCIENCE AND TECHNOLOGY

INTRODUCTION: The landing error scoring system (LESS) [1] and unilateral landing error scoring system (ULESS) [2] can be used as screening tools for sports injuries. However, it is time-consuming to use these systems for evaluating the landing pattern, and the scoring process required well-trained expertise such as therapists or trainers, which prevented the system to be widely used [3]. We aimed to utilize the inertial measurement units (IMU) sensor to develop an automated LESS/ULESS.

METHODS: Nineteen participants performed bilateral (BJL) and unilateral (UJL) jump-landing. By using a 3D motion capture system, camera and IMU, different analysis methods (3D motion analysis, 2D image, and IMU's prediction model) were used to obtain knee, hip, and trunk angles collected at initial contact (IC), maximum knee flexion (MKF) and range of mo-

tion (ROM) from IC to MKF during BJL and UJL. Intraclass correlation coefficient (ICC) was obtained to assess inter-method reliability. Bland-Altman plots was used to compare the angle obtained by each analysis methods with the 3D motion analysis for concurrent criterion validity. Wilcoxon signed-rank test was used to examine mean differences. Finally, participants' movement quality was evaluated by expert LESS raters (2D image) using the LESS rubric and by self-developed code that automates LESS scoring (3D motion analysis, and IMU's prediction model).

RESULTS: In the BJL and UJL tasks, the variables obtained from the IMU model showed moderate to excellent inter-trial correlations (ICC > .5) for the measured angles at all movement events, except for the trunk angle at the IC in UJL task which showed poor inter-trial correlation (ICC < .5). In Bland-Altman, both the predicted angle obtained from IMU and measured angles obtained from 2D image were within 1.96 times the standard deviation compared to the values calculation from 3D motion analysis, except for the hip and knee angles at MKF and ROM in BJL and for the knee angles at IC in UJL. There were significant differences (P < .05) in hip angle at IC, hip and knee angles at MKF, knee angle ROM in BJL, hip and knee angles at IC, hip, knee, and trunk angles at MKF, and hip, knee, and trunk angles ROM in UJL.

CONCLUSION: The joint angles estimated from the IMU model showed moderate to excellent reliability during BJL and UJL tasks of LESS. These preliminary results may allow further study to embaddd the predicted model in an automatic scoring system in practice. In addition, the automated LESS/ULESS developed in the current study can be used for most items except for knee valgus, standing width, and overall impression which cannot be scored based on joint angles. Finally, future works should address the challenges in defining events in the real-world scene not from the three-dimensional motion capture system but from a practical kits which consist of fusion of different devices.

ARTIFICIAL INTELLIGENCE-BASED GOLF SWING ANALYSIS SYSTEM

HONG, E.

WASHINGTON UNIVERSITY IN ST. LOUIS

INTRODUCTION: We propose an artificial intelligence-based software system that analyzes the dynamics of a golf swing and provides targeted suggestions to help golfers improve their swing and reach their full potential. In our proposed system, a machine-learning model is applied to a large dataset of golf swings to identify patterns and relationships between the shoulder trajectory and ball flight. The system then uses computer vision techniques to track the movement of the golfers shoulder during the swing. The data collected from the tracking is then used to make predictions about the quality of the swing. Based on the predictions, the system automatically generates suggestions to help the golfer improve their swing. To be specific, the rotational angles from the player provide valuable information about the dynamics of the golf swing and can help to identify areas for improvement.

METHODS: The tool detects two key frames: the setup position where the player holds the golf club in front of them, and the follow-through (FT) position where the golf club head is farthest toward the front. Based on the two key frames, the coordinates of the shoulder joints in each frame are identified by a machine-learning based computer vision tool, MediaPipe. Then, the rotational angles of the shoulder during the swing are computed by our algorithm which involves finding the difference between the initial and final coordinates of the shoulder joint, and then using trigonometry to convert this difference into angles in the horizontal and vertical plane as follows.

RESULTS: In our experimentation, we analyzed golfer's swing and the outcomes especially focused on ball flight after swing. Our experimental results indicate a strong correlation between the shoulder rotation angle and the ball flight, with an increase in the shoulder rotation angle leading to a greater distance of the ball. This suggests that a complete shoulder turn is essential for generating power and maximizing the balls distance. By measuring the rotational angles and analyzing the correlation with the distance and angle of the ball, we can provide suggestions for improvement to help golfers improve their swing and reach their full potential.

CONCLUSION: In addition to providing guidance, the system can also track the golfers progress over time by comparing the results from multiple swings. This allows the golfer to see how they are improving and what areas they need to continue to work on. The use of the angles of the shoulder turn in our proposed system provides a more comprehensive and effective analysis of the golf swing, leading to more targeted and effective suggestions for improvement.

Overall, our proposed system can provide valuable insights into the dynamics of the golf swing and help golfers achieve their goals, making it a useful tool for golf coaches and players alike. Our proposed machine-learning based golf swing tutor can provide personalized and effective guidance to golfers of all skill levels.

PHOTOGRAMMETRY AND HOW TO MAKE BACKCOUNTRY SKIING SAFER

KREINER, J., HOLLAUS, B.

MCI - ENTREPENEURIAL SCHOOL

INTRODUCTION: Mountains are becoming more and more the playground of athletes and adventure seekers. In Germany, the number of ski tourers has doubled to 500.000 in the last 10 years bringing along many injuries and deaths. There can be multiple reasons for injuries but downfall (2%), impact against obstacles (4%), getting lost (2%) and avalanches

(10%) can result from insufficient route planning and terrain judgement (DAV 2021, ÖKAS 2019). In this approach, the potential of photogrammetry and its enhancement of safety in the alpine are being analysed.

METHODS: Photogrammetry is the process of computing 3D environments based on images captured with conventional cameras or drones. Within about 40 minutes of drone flight, 550 images of different angles of a mountain were captured and rendered to a fully textured 3D model with 45 Million triangles. Then a team descended a very exposed and complex side of this mountain face first without and then with the option of planning their route using the 3D Model.

RESULTS: With the additional details from the 3D model, the team decided to ski a different line down the mountain as the model revealed 2 couloirs that had less exposure and therefore significantly less risk of downfall or high consequence avalanches. On the first approach ropes, harnesses and anchoring equipment were brought along as emergency tools for dead ends. With the detailed 3D model, it was clearly visible, that such tools would not be necessary as a safer route could be determined and followed easily by studying and screenshotting some of the relevant landmarks.

CONCLUSION: This approach clearly shows an improvement in terrain knowledge and route planning possibilities, while the advantages of using a photogrammetry model for ski touring will further be analysed in a separate study. Visual analysis is only the starting point of what this can be used for. The 3D models also allow the use of further data analysis and create filters based on factors such as snow coverage, steepness of terrain or calculating and simulating avalanches. In other sports athletes train the repetition of ever repeating movements based on anticipation and reaction. Bringing the surroundings of an athlete into a Virtual Reality simulator as accurately as possible will set the basis for developing such simulators. Those simulators are especially useful for sports with limited or costly access or to study athletes inside a lab while exercising their sports.

Sports Medicine and Orthopedics

WEARABLE SENSOR TECHNOLOGY TO PREDICT CORE BODY TEMPERATURE: A SYSTEMATIC REVIEW

DOLSON, C., HARLOW, E., CALCEI, J., VOOS, J., SESHADRI, D.

SPORTS MEDICINE INSTITUTE, UNIVERSITY HOSPITALS CLEVELAND MEDICAL CENTER

INTRODUCTION: Exertional heat-related illness (HRI) is increasing in incidence as global temperatures rise, with heat-related deaths increasing by 74% globally from 1980 to 2016[1]. Despite the frequency and potentially fatal consequences of undetected HRI, coaches, trainers, supervisors, and employers currently rely on visible cues and subjective assessments of their athletes and employees for early detection, such as malaise, confusion, thirst, ataxia, or excessive sweating. The measurement of core body temperature (CBT) using existing rectal, esophageal, or pill thermometers has been shown to predict HRI and its severity, but these measurement methods are excessively invasive, obstructive, or costly for high acuity and high motion settings. Noninvasive prediction of CBT using wearable technology and predictive algorithms offers the potential for continuous CBT monitoring and early intervention to prevent HRI in athletic, military, and intense work environments.

1. Fernandez, M. Extreme Heat-Caused Deaths Have Jumped 74% in the Last 30 Years Available online: https://www.axios.com/2021/08/20/extreme-heat-killed-nearly-400000-people-globally (accessed on 1 December 2022).

METHODS: A systematic literature search was conducted in the Web of Science Core Collection database to identify works from 1 January 2000 until 31 December 2021 in which predicted CBT was compared to measured CBT in actively exercising subjects.

RESULTS: This systematic review identified 20 studies representing a total of 25 distinct algorithms to predict core body temperature using wearable technology. The unweighted average RMSE after removal of an outlier was 0.28 ± 0.14 °C. Clinical validity standards of RMSE less than or equal to 0.5 °C were met by 17 out of 18 algorithms. However, few algorithms incorporated individual and environmental data into their core body temperature prediction algorithms, despite the known impact of individual health and situational and environmental factors on CBT, thus limiting the population and settings in which these algorithms can be considered valid. High accuracy across variable conditions and subjects was observed in the two algorithms in this review that reported the use of ML methods.

CONCLUSION: Robust machine learning methods offer the ability to develop more accurate, reliable, and personalized CBT prediction algorithms using wearable devices through increased data processing abilities. The integration and interoperability of CBT prediction algorithms with existing HRI prevention and treatment tools, including heat indices such as the WBGT, athlete management systems, and electronic medical records, will further prevent HRI and increase the availability and speed of data access during critical heat events, improving the clinical decision-making process for athletic trainers and physicians, sports scientists, employers, and military officers.

PHYSICIAN-PATIENT SEX CONCORDANCE AND ABILITY TO CARE FOR ATHLETES

TSUKAHARA, Y.

TOKYO WOMENS COLLEGE OF PHYSICAL EDUCATION

INTRODUCTION: The effect of physician-patient sex concordance in medicine has been reported in many studies. However, agreement on whether physician sex has an effect on their ability to care for athletes of concordant or different sexes in sports medicine is not fully understood, and differences between surgeons and nonsurgeons has not been investigated.

METHODS: An anonymous survey was distributed to sports medicine physicians around the globe. Participants (n = 1,193) were asked to decide whether sex of the physician made them better suited to care for athletes of concordant or different sexes along with their personal background. Participants were sports medicine physicians trained in orthopedics (n = 472 [39.6%]) and nonorthopedics (n = 721 [60.4%]).

RESULTS: Chi-square analysis revealed that 35% of the orthopedics trained sports medicine physicians answered "strongly agree" or "agree" to the statement, "MALE sports medicine physicians are better suited that their female counterparts to care for MALE athletes," which was significantly higher than the non-orthopedic-sports medicine physicians ($p < 0.001$). Moreover, 6.2% of the orthopedic- sports medicine physicians answered "strongly agree" or "agree" to the statement, "MALE sports medicine physicians are better suited that their female counterparts to care for FEMALE athletes," which was significantly higher than the non-ortho-SM group ($p = 0.003$). Regression analysis revealed that orthopedic-sports medicine physicians agreed less than nonorthopedic-sports medicine physicians regarding the agreement on male physicians more suitable to care for male athletes (odds ratio = 0.61. $p < 0.05$).

CONCLUSION: Sex of the physician and athlete may have an effect on treatment but focusing on it too much may not be suitable for patient care

INJURIES IN INTERNATIONAL MEN'S SIXES LACROSSE: INJURY SURVEILLANCE OF THE BRITISH LACROSSE MEN'S NATIONAL TEAM DURING A NINE-MONTH TRAINING CYCLE LEADING UP TO AND INCLUDING THE WORLD GAMES 2022.

COLLIER, M.

UNIVERSITY OF LEICESTER

INTRODUCTION: International lacrosse is expanding into new variants, including World Lacrosse Sixes (Sixes). Currently, no data exits on injury surveillance in this new, shortened version of the sport, which is currently under review for Olympic Games inclusion in 2028. The purpose of this descriptive epidemiology study is to analyse injury data in a Men's National Sixes lacrosse team across training and competition.

METHODS: This study prospectively observed injuries that occurred within a training and competition cycle of the British Lacrosse Men's National Lacrosse team in the build up to the World Games 2022. The data was collected by the team physiotherapist, injury incidence was calculated based on exposure and data categorized into injury type, body part, and mechanism.

RESULTS: 43 injuries were observed as a result of playing Sixes. Injury incidence rates varied between practice and tournaments. 11.6% of the injuries were time-loss injuries, 67.4% of the injuries were able to continue following treatment and 20.9% of the injuries were able to continue without any treatment. Injuries most frequently occurred in competitive matches (65.1%). The lower limb was the most commonly injured area (62.8%), with the lower leg predominantly being the most affected part of the lower limb (63.0%). Most injuries were sustained through a contact mechanism (48.8%) or an overload mechanism (37.2%). The most frequent injuries were contusions (25.6%) and muscle injuries (25.6%).

CONCLUSION: To our knowledge, this is the first epidemiologic study of Sixes lacrosse injuries. Injury rates differed to those of field lacrosse. Further research is required in epidemiology and risk factors for injuries of Sixes lacrosse.

RUNNER'S PERCEPTIONS OF MEDICAL COVERGE DURING THE 33RD « TOUR OF FASO »

CISSE, A.

INSTITUTE OF SPORTS SCIENCES AND HUMAN DEVELOPMENT

INTRODUCTION: The enthusiasm of African populations for cycling is growing. The medical coverage of the 33rd « Tour of Faso » was a great challenge due to insecurity issues. One of the major indicators of the quality of medical care is the satisfaction of runners. The aim of this study was to report the perception of medical service offered to riders who sustained injuries during the 33rd « Tour du Faso ».

METHODS: This was a cross-sectional descriptive study. We have included in this study all riders who sustained accidental traumatic injuries and treated during the 33rd « Tour of Faso ». A questionnaire was established to collect demographic data and perceptions of the 33rd « Tour of Faso » medical service.

RESULTS: The peloton of the 33rd International Cycling Tour of Burkina Faso was made up of 82 riders from Europe and Africa. A total of 24 cases of fall were recorded, representing 29.26% of the peloton. The mean age was 26.48 ± 4.40 years. They came from sub-Saharan Africa in 62.5% of cases. They had more than one Tour participation in 75% of cases. The identification of the medical team was easy for 87.5% of the victims. The same value was obtained for the assessment of the quality of care. Five cases of self-medication were reported. Among them, 4 gave personal reasons. The main suggestion was to strengthen communication about the medical service of the Tour.

CONCLUSION: Riders perception and knowledge of the « Tour of Faso » medical service need to be improved. Raising awareness is necessary.

ACUTE EXERCISE AND EXECUTIVE-RELATED OCULOMOTOR PERFORMANCE IN INDIVIDUALS WITH PARKINSON'S DISEASE

TSAI, C.L.1, PAN, C.Y.2, TSENG, Y.T.3, CHANG, Y.C.1, WANG, T.C.1

1: NATIONAL CHENG KUNG UNIVERSITY , 2: NATIONAL KAOHSIUNG NORMAL UNIVERSITY , 3: NATIONAL TSING HUA UNIVERSITY

INTRODUCTION: There is limited information available on which type of aerobic exercise is optimal for improving impairments in executive function and oculomotor control in individuals with parkinson's disease (PD). In the present study, we explored the effects of interventions involving acute bouts of aerobic exercise of varying intensity on executive-related oculomotor performance in individuals with PD.

METHODS: Twenty-three individuals with PD completed an acute bout of each of continuous moderate-intensity exercise (CMIE), high-intensity interval exercise (HIIE), and a rest session in counterbalanced order using a balanced within-subject cross-over design. Their neuropsychological and oculomotor performance parameters in the saccade paradigm at baseline and following each session were assessed.

RESULTS: There was no significant effect of acute CMIE or HIIE on the coefficient of variation of the reaction time (RT) in individuals with PD. However, HIIE induced significantly shorter RTs in the antisaccade condition ($p = .001$), and CMIE did so in both the prosaccade and antisaccade conditions (both $ps < .036$). In oculomotor performance, a change in saccade peak velocity only following CMIE ($p = .003$), not HIIE, was observed. However, the two acute aerobic exercise modes failed to significantly affect saccade amplitude and latency.

CONCLUSION: The present results suggest that acute HIIE and CMIE protocols may have various beneficial effects on executive-related oculomotor performance in individuals with PD.

EPIDEMIOLOGY AND SEVERITY OF MEDICAL EVENTS FOR MOUNTAIN BIKERS AND HIKERS TRANSPORTED BY AMBULANCE IN WESTERN AUSTRALIA 2015-2020

BRAYBROOK, P.J., TOHIRA, H., BRINK, D., FINN, J., BUZZACOTT, P.L.

CURTIN UNIVERSITY

INTRODUCTION: Outdoor activities offer physical and mental health benefits. However, incidents can occur requiring ambulance transport to hospital. This study aimed to describe the epidemiology and severity of traumatic and medical incidents for mountain bikers and hikers transported by ambulance within WA.

METHODS: This was a retrospective cohort study of ambulance-transported mountain bikers and hikers within WA from 2015-2020. Data were extracted from ambulance patient care records. Multivariable analyses were undertaken to identify variables associated with higher patient severity based on the National Early Warning Score (NEWS2)

RESULTS: A total of 610 patients required ambulance transport to hospital whilst mountain biking (n=329, 54%) or hiking (n=281, 46%). The median age of mountain bikers and hikers was 38 (24-48) years and 49 (32-63) years, respectively. Overall, 339 patients (56%) were male, and 271 (44%) were female. Most mountain bikers were male (n=274, 83%), whereas more females were hikers (n=166, 59%). Paramedics reported a fracture in 92 (28%) mountain bikers and 78 (28%) hikers. The predominant injury locations for mountain bikers were upper limbs and for hikers lower limbs. A total of 245 (74%) mountain bikers received analgesia and 190 (67%) hikers. Cases were trauma-related in 92% of mountain bikers and 55% of hikers. Around 23% of mountain bikers had NEWS2 scores above low risk compared with 30% of hikers. Unadjusted analysis showed a significant association ($p<0.05$) between the primary outcome (presence of more clinical severity) and the activity being undertaken with hikers being more likely than mountain bikers to have higher severity NEWS2 scores (OR = 1.5, 95% CI 1.02-2.1, p=0.037).

CONCLUSION: We found that both mountain bikers and hikers experienced incidents requiring transport to hospital by ambulance. Mountain bikers were younger and more likely to be male, with hikers older and more likely to be female. Mountain bikers sustain predominantly upper limb fractures and hikers typically sustain lower limb fractures. These findings show the importance of correct protective clothing for both mountain bikers (arm guards and shoulder pads) and hikers (well-fitted, suitable-soled, high ankle boots). Trauma-related incidents were more common in mountain bikers, but hikers had a higher level of clinical severity, as indicated by the NEWS2 scores. Hikers had a greater proportion of their vital signs outside of normal range according to the NEWS2 classification and overall, mountain bikers and hikers who were transported to hospital were more likely to have a higher NEWS2 if it was for a medical aetiology than a trauma-related one. Hikers new to the sport should consult with their general practitioner about their current fitness to undertake such an activity. Additionally experienced hikers should consider pre-existing health conditions before setting out on a hike in remote areas.

COMPARISON OF BONE METABOLISM MARKERS (BAP AND TRACP-5B) : ELITE VERSUS NON-ELITE IN COLLEGIATE MALE LONG-DISTANCE RUNNERS

WAKAMATSU, K.1, FUJITA, S.1, SAKURABA, K.2, SANOMURA, M.3, WATANABE, K.1, YANAGITA, K.4

1 J.F.OBERLIN UNIVERSITY, TOKYO, JAPAN; 2 JUNTENDO UNIVERSITY, TOKYO, JAPAN; 3 TEIKYO UNIVERSITY, TOKYO, JAPAN; 4 DOTABATA CO., LTD., TOKYO, JAPAN

INTRODUCTION: The effect of exercise on bone health has received much attention in recent years. Overuse injuries, including stress fractures, are serious problems faced by athletes. Track-and-field athletes have the highest incidence of stress fractures than the other athletes (1). A stress fracture is a break in bone tissue caused by repeated minor external mechanical stress caused by activities, such as running, that can occasionally lead to a complete fracture. Stress fracture is a serious injury because it takes a long time for complete healing and prevents athletes from training (2). Bone strength is associated with bone density and quality (bone metabolism and collagen cross-linking). Low bone density has been reported to increase the risk of stress fracture. Nonetheless, as results based on bone density reflect nutritional condition and mechanical stress over several previous months, they are not suitable for early detection of stress fractures. This study aimed to examine the usability of some bone metabolism markers to prevent overuse bone injuries in collegiate male long-distance runners.

METHODS: The subjects included 18 elite collegiate male long-distance runners ([ER] height, 172.6 ± 5.5 cm; weight, 57.4 ± 4.9 kg; body fat percentage, 6.0% ± 2.0%) and 9 non-elite collegiate male long-distance runners ([NER] height, 169.0 ± 4.4 cm; weight, 57.4 ± 7.1 kg; body fat percentage, 11.5% ± 2.6%). Bone metabolism markers, such as bone alkaline phosphatase (BAP) and bone-specific tartrate-resistant acid phosphatase (TRACP-5b), were measured in both the groups. Body fat percentage was measured by bioimpedance analysis.

RESULTS: No significant differences were observed in the levels of BAP (ER 16.4 ± 3.9 vs. NER 15.5 ± 6.5 U/L) and TRACP-5b (ER 574.3 ± 162.6 vs. NER 656.4 ± 195.7 mU/dL) between the elite and non-elite collegiate male long-distance runners. However, the body fat percentage was significantly different between ER (6.0% ± 2.0%) and NER (11.5% ± 2.6%) ($p < 0.001$).

CONCLUSION: In this study, targeting 18 elite and 9 non-elite collegiate male long-distance runners, we conducted a questionnaire survey on physical characteristics and measured bone metabolism marker with the serum samples. The finding is as follows: In non-elite collegiate male long-distance runners, body fat percentage was significantly higher than that in the elite collegiate male long-distance runners ($p < 0.001$).

A COMBINED INFRARED METHOD WITH THERMAL IMAGING AND RASTERSTEREOGRAPHY TO ASSESS BACK CHANGES IN HEALTHY INDIVIDUALS: A CROSS-SECTIONAL STUDY

ROGGIO, F., PETRIGNA, L., TROVATO, B., MUSUMECI, G.

UNIVERSITY OF CATANIA

INTRODUCTION: Musculoskeletal disorders in the healthy population are increasing as the assumption of incorrect posture is recurrent during daily activities. Non-invasive methods are spreading to overcome the need to screen many people without harmful effects. Rasterstereography provides information on changes in back posture; infrared thermography investigates body temperature reactions to different stimuli. These methods can identify specific changes before individuals experience pain or posture alteration. Therefore, we propose a combined infrared method with thermal imaging and rasterstereography to assess back changes and provide normative data for this method.

METHODS: In this cross-sectional study, 175 healthy individuals (85 men and 90 women) were analyzed, 29.25 ± 5.95 years old, weight 62.66 ± 7.4 kg, and 170.18 ± 7.20 cm in height. Spine 3D® evaluated the morphological structural aspect of the FLIR E54 back; the infrared camera measured the temperature of the back. The Student's t-test determined any significant differences between male and female rasterstereography and thermal images; Cohens effect size (d) showed significant differences between groups, while Pearson's correlation (r) highlighted the relationship between the two methods.

RESULTS: In the sagittal plane, the depth of the cervical region (males= 43.67 ± 9.99 mm vs. females= 31.74 ± 7.76 mm, d = 1.33) and the angle of lumbar lordosis (males= 36.39 ± 8.70 ° vs. females= 47.56 ± 8.47 °, d= -1.30) have a large effect size. In the coronal plane, shoulder obliquity (males= -7.23 ± 10.16 mm vs. females = -2.91 ± 9.93, d= -0.43) and vertebral deviation RMS (males= 3.01 ± 1.61 vs. females = 2.57 ± 1.48, d= 0.28) show a small effect size. In the transversal plane, the shoulder torsion has a small effect size (males= -0.25 ± 2.41 ° vs. females = -1.02 ± 2.43 °, d= 0.32). The back temperature shows gender differences in the cervical area (males= 33.84 ± 0.63 ° C vs. females= 34.29 ± 0.86 °C, d= -0.58) and the dorsal area (males= 33.14 ± 0.70 ° C vs. females= 33.64 ± 0.95 °C, d= -0.60). Furthermore, males showed a moderate correlation between the surface rotation of the vertebrae RMS and the cervical (r= -0.42), dorsal (r= -0.57), and lumbar (r= -0.48) regions. The female lumbar temperature is moderately correlated with the angle of lumbar lordosis (r= -0.43) and the dorsal temperature with shoulder torsion (r= 0.43).

CONCLUSION: The combined infrared method highlights an interesting correlation between the two suggested methods in the postural analysis of the back. Further studies in a pathological population may elucidate the mechanisms of spinal alteration and the thermal response of muscles.

USE OF SOCIAL MEDIA FOR SPORTS INJURY PREVENTION AND MANAGEMENT BY RECREATIONAL ATHLETES

MUKHERJEE, S., PNG, J.W.

NATIONAL INSTITUTE OF EDUCATION, NANYANG TECHNOLOGICAL UNIVERSITY, SINGAPORE

INTRODUCTION: The progressive growth of social media and its increasing engagement potential as a sports medicine information resource [1] together with the consistent prevalence of sport injuries suggests the possibility of social media as an effective platform for sport injury information provision [2]. This relatively new scope of study yields limited literature on social media for sport injury information and hence comprehensive insights are yet be drawn for applied practice.

METHODS: A descriptive cross-sectional study was conducted. 267 recreational athletes volunteered and completed a self-reported online 45-item questionnaire. The questionnaire included sections on demographics, sports participation and training, injury history, if medical advice was sought, preference of information sources to identify and manage the injury, information on social media usage and perceptions on its effectiveness in injury prevention and management.

RESULTS: Internet was the most preferred source of information (53.4%). 60.6% of recreational athletes reported to use social media as an information resource for sport injury awareness and management. 63.7% of these were below 25 and 17% above 50 years age. 82.1% participants self-explored the social-media options for information. Majority (35.8%) explored the social media for new injuries followed by those with chronic injuries (27.1%). Those with knee, ankle and lower back injuries more frequently resorted to social-media search. While 44% self-diagnosed the injury using information on social media, <50% of them found the information to be useful enough for injury awareness and management. Information presented by professionals (e.g., doctors & physiotherapists) were more commonly accessed. 55.1% participants found social-media to be convenient, allowed them to discuss and interact with those with similar problems, 70% intended to continue to use social-media for injury management and 90% believed that social-media can be a useful information resource for sports injury awareness and management.

CONCLUSION: Social media has the potential as a platform for sport injury awareness and management-related information, and recreational athletes seem to benefit from it for their injury treatment and rehabilitation. Given that information by professionals is more frequently accessed and perceived to be of higher credibility, practitioners and professionals may consider social-media platforms as a facilitator of information and service to the athletic population.

RETURN-TO-SPORTS TRAINING AND LATE-STAGE REHABILITATION AFTER ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION AND FORMAL TREATMENT COMPLETION: A MULTICENTRE RANDOMISED CONTROLLED TRIAL

NIEDERER, D., KELLER, M., SCHÜTTLER, K., SCHOEPP, C., PETERSEN, W., BEST, R., MENGIS, N., MEHL, J., KRAUSE, M., JAKOB, S., WIEßMEIER, M., VOGT, L., PINGGERA, L., GÜNTHER, D., ELLERMANN, A., EFE, T.

GOETHE-UNIVERSITY FRANKFURT/MAIN, ET AL.

Groneberg, D., Behringer, M., Stein, T.

INTRODUCTION: At the completion of the formal, medically prescribed rehabilitation following an arthroscopic anterior cruciate ligament reconstruction, only a minor share of athletes resolve their functional capacities. The end of the formal rehabilitation is, thus, not the end of the functional rehabilitation. Objective: To compare the intervention adherence and effectiveness of a specific, late-stage rehabilitation to usual care after anterior cruciate ligament (ACL) reconstruction.

METHODS: Design: Prospective, double-blind multicentre parallel groups randomized controlled trial (RCT). Participants aged 18-35 years after formal rehabilitation completion (on average 241 days post-reconstruction) were block-randomised to a 5-month neuromuscular performance intervention (Stop-X group) or to the Usual care (medically prescribed and individual formal rehabilitation) group. All outcomes were measured therapists- and assessor-blinded once a month. The knee separation distance at landing a drop jump was the primary outcome. Linear mixed models were calculated using the change scores.

RESULTS: N = 112 participants (Stop-X: 57; Usual care: 55) were analysed. Initially, the intervention frequency was higher in the Stop-X than in the Usual care group: 2.65 (standard deviation 0.96) units per week versus 2.48 (1.14) per week, respectively, in the first and 2.28 (1.02) versus 2.14 (1.31) per week, respectively, in the second month. No adjusted between-group*time(*baseline)-differences were found for the primary outcome. Baseline-adjusted between-group*time-effects favour the Stop-X-group at two months for knee problems during sport (KOOS-SPORT) (estimate = 64.3 [95% CI = 24.4 to 104.3] for the Stop-X), for confidence to return to sport (ACL-RSI) (62.4 [10.7 to 114.2]), for pain-associated knee problems (KOOS-PAIN) (82.8 [36.0 to 129.6]), during everyday activities (KOOS-ADL) (71.1 [6.4 to 135.7]), and for the limb symmetry index in the front hop for distance at months 3 and 4 ((0.34 [0.10 to 0.57]; 0.31 [0.08 to 0.54])). No between-group*time-effects occurred for kinesiophobia, symptom-associated knee problems or the Balance hops performance. Until the end of the intervention, 79% of the Stop-X and 70% of the Usual care participants ($p < 0.05$) have successfully returned to their pre-injury sport type and level.

CONCLUSION: In our multicentre RCT, we found that a 5-month, late-stage rehabilitation and return-to-sports training programme after an anterior cruciate ligament reconstruction and formal treatment completion programme to be slightly

superior to usual care. The intervention led to superior effects when compared to usual care in certain neuromuscular functions within the initial 3 months of the intervention as well as in return-to-sporty rates and time spans until return-to-sport. The low costs and the small benefit may justify its usage after formal rehabilitation completion.

FROM INJURY PREDICTION TO INJURY RISK ASSESSMENT, CAN WE MODEL REAL-TIME ACTIONABLE INSIGHT FROM HETEROGENEOUS TRAINING AND HEALTH DATA?

GOMAZ, L.1,2, VAN DER MEULEN, F.3, VERHAGEN, E.2

1 DELFT UNIVERSITY OF TECHNOLOGY, 2 VU UNIVERSITY MEDICAL CENTER, 3 VRIJE UNIVERSITEIT AMSTERDAM

INTRODUCTION: Overuse injuries occur without a specific, identifiable event that is responsible and, as such, still represent a substantial problem in many sports disciplines. Due to the gradual appearance of symptoms in the early injury phase, athletes are likely to continue to train and compete despite overuse conditions. The typical presentation and characteristics of overuse injuries make them difficult to capture. The process of sports injury occurrence depends on many factors and constraints that interact in ways that are often unknown [1]. Preventive routines are part of many training programs. Still, they are often based on subjective measures or periodical medical assessments that lack the warning sign of injury risk level at the moment of measurement. Combining medical evaluation with real-time performance and health output from wearables represents a potential for a real-time injury risk assessment and creates a need for a novel approach. This study developed a framework that incorporates heterogeneous training and health data from wearables and self-reported questionnaires to estimate the risk of injury.

METHODS: The simulation study was performed based on longitudinal data assessed weekly with the OSTRC questionnaire [2] in Dutch Olympic athletes. The data set included 11 participants followed over 52 weeks with dichotomous injury outcomes encountered within the data set. This approach assumes that an athlete is transitioning between different injury states over time depending on observable covariates. Such an approach considers that each athlete can change injury state many times over the course of follow-up. The latent Markov model [3] was used to model the probability of transitions between injury states for an individual athlete, depending on the simulated training load and gender.

RESULTS: The model provided the current injury state and the probability of transitioning to another state. We retrieved model accuracy between 88% and 95% in the model's ability to predict future injury states.

CONCLUSION: Probabilistic graphical models, such as those employed in this study, show promising results in injury risk assessment based on training and health data. The model's outcome may be used as a guideline in rehabilitation and to support practitioners in making real-time risk management decisions.

COMMON RISK FACTORS FOR SPORTS INJURIES IN AMATEUR FOOTBALL MALES

XIAO, Q., SU, X.Y., ZHAI, J.Y., LI, X.M.

BEIJING SPORT UNIVERSITY

INTRODUCTION: Football is a confrontational sport with high intensity and fast rhythm, so it is easy to happen sports injuries in football. The occurrence of sports injury is closely related to the characteristics of sports events, sports venues, fatigue, age, and other factors, which are called the risk factors of sports injury. At present, there are relatively few studies on the risk factors of sports injury for ordinary male sports enthusiasts. Therefore, this study aims to identify the common risk factors of sports injury in amateur football men according to the questionnaire information.

METHODS: Based on expert interviews, a questionnaire was designed to investigate the risk factors of sports injury. The subjects were adult males who exercised regularly, professional training background and chronic diseases were not considered. Adult amateur football men are the target group for this study. Questionnaires are released through the Netease positioning and Questionnaire Star platform, and the questionnaires are collected in the form of electronic files. Trap questions, manual screening, and other techniques were used to evaluate the quality of the questionnaire. All data were analyzed using SPSS 26.0. Through descriptive statistics, mean±SD, the exploratory factor analysis ($KMO > 0.6$, $P < 0.05$), the contribution rates of different factors to sports injury risk of male football players were obtained.

RESULTS: A total of 10866 valid questionnaires were collected, among which 1018 data from the male who were amateur football were extracted and included in statistical analysis. According to the data from the questionnaire, the injury incidence rate of amateur male football players was 93.5% (965/1032). KMO=0.672 was obtained by exploratory factor analysis, and $P<0.01$ was obtained by Bartletts spherical test, indicating a significant correlation between variables. Factor analysis principal component method extracted 5 common factors, a total variance contribution of 73.6%. According to the characteristics of risk factors, five common factors were named, namely, strength quality (m1), exercise habits (m2), morphological characteristics (m3), fatigue recovery (m4), and sports grounds (m5), among which m1 contributed the most (24.3%). The aforementioned criteria provide a clearer explanation of the risk factors for sports injuries among amateur football men generally.

CONCLUSION: (1) the sports injury risk factors questionnaire designed in this study can effectively collect relevant information about sports injury risk factors of amateur male football players; (2) Strength training, exercise habits, morphologi-

cal characteristics, fatigue recovery, and sports grounds have significant effects on the risk of sports injury in amateur football men, the exposure frequency of risk factors should be considered to avoid sports injuries.

COMMON RISK FACTORS FOR SPORTS INJURIES IN AMATEUR BASKETBALL MALES

SU, X.Y., ZHAI, J.Y., XIAO, Q., LI, X.M.
BEIJING SPORT UNIVERSITY

INTRODUCTION: Basketball is a sport with great intensity and fierce confrontation, so sports injuries are easy to occur. There are many amateurs due to various internal and external factors, resulting in different sports injuries. Few pieces of research on the risk factors of sports injury in amateur males. So this study aims to extract information from a designed questionnaire, determine the risk factors that may predict injuries for amateur basketball males, and give advice on preventing injuries.

METHODS: A questionnaire was designed to investigate the risk factors of sports injury. It was distributed using NetEase positioning and Questionnaire Star platforms, aiming at regular exercise adults. The quality of the questionnaire was checked by means of trap questions, finishing time and manual screening, et al. Internal reliability was measured through the calculation of Cronbachs alpha coefficient. Exploratory factor analysis was used to evaluate construct validity by the Kaiser-Meyer-Olkin (KMO) and Bartletts sphericity test, cumulative variance contribution rates were obtained. Chi-square test was performed to estimate the odd ratios of risk factors. The data were statistically analyzed through SPSS 26.0; the significance level was 0.05.

RESULTS: A total of 18316 valid questionnaires were collected and 2431 questionnaires were amateur basketball males. The total Cronbachs alpha coefficient was calculated 0.705. Exploratory factor analysis (KMO=0.657) and Bartletts test of spherical ($p<0.01$), indicated a significant correlation between the variables. The principal component factor analysis produced four common factors: strength quality, exercise habits, fatigue recovery and exercise cognition. The total variance contribution rate was 71.1%. Chi-square test showed that strength training($p<0.001$, OR 0.548), "always"($p<0.001$, OR 0.347) and "often"($p=0.002$, OR 0.533) strength training with professional guidance, wearing professional sports shoes ($p=0.005$, OR 0.106), "always" warm-up($p=0.015$, OR 0.358), "always" ($p=0.006$, OR 0.315) and "often" ($p=0.003$, OR 0.300) relax were protective factors; machine load-bearing($p=0.001$, OR 2.258), free load-bearing($p=0.008$, OR 1.995) and tired or illness ($p=0.001$, OR 1.868) were damage factors.

CONCLUSION: The study results confirmed the validity and reliability of the questionnaire to evaluate injury risk factors in amateur basketball males. To evaluate the risk of sports injury, four aspects should be included: strength quality, exercise habits, fatigue recovery and exercise cognition. We suggest amateur basketball males follow advice including strength training , strength training with professional guidance, wearing professional sports shoes, warm-up and relaxation; avoid machine and free load-bearing training and do not exercise when tired or illness. The frequency of exposure to risk factors should be considered for basketball males to prevent sports injuries.

BIOIMPEDANCE ANALYSIS IS A NEW INDICATOR OF EXERCISE-INDUCED MUSCLE DAMAGE

YAMAGUCHI, S.1,2, INAMI, T.1, ISHIDA, H.3, MORITO, A.2,4, YAMADA, S.4, NAGATA, N.1, MURAYAMA, M.1, KOHTAKE, N.2
1,2,3 KEIO UNIVERSITY, 4 TAISHO PHARMACEUTICAL CO., LTD.

INTRODUCTION: Bioimpedance analysis (BIA), which measures the electrical resistivity of a living body by applying a weak electric current, has been used primarily to estimate body composition. In addition, BIA may be useful in assessing the degree of exercise-induced muscle damage (EIMD) resulting from intense eccentric contractions. Indeed, previous studies have reported a significant increase in extracellular water (ECW) content after the onset of EIMD. However, these studies only evaluated intracellular and extracellular water content and did not investigate other BIA parameters such as impedance, reactance, and resistance. Therefore, the purpose of this study was to analyse BIA parameters not reported in previous studies.

METHODS: Twenty-two healthy young men with limited exercise experience performed 50 dumbbell exercises at 50% of the maximum lifting weight, with a bias on eccentric contractions. All subjects performed the dumbbell exercise with the left arm. Measurements were performed to assess the degree of EIMD at 8 points on both arms before and immediately after, and at 1, 24, 48, 72, 96, and 168 hours after exercise. BIA parameters (impedance, reactance, and resistance), subjective muscle soreness (SOR), and maximal voluntary isometric muscle capacity (MVIC) were analysed. BIA was measured using InBody. After a two-way analysis of variance (left arm vs. right arm) was performed, BIA parameters were post-hoc tested using the Bonferroni method. A one-way analysis of variance was used to assess other EIMD measures followed by post-hoc testing using the Bonferroni method. The significance level was set at $p < 0.05$. All statistical analyses were performed using Predictive Analytics Software (PASW) version 26.0 for Windows (SPSS Japan Inc., Tokyo, Japan).

RESULTS: Results showed that SOR was significantly higher after 24 hours of eccentric exercise; MVIC was significantly lower immediately after exercise, and total body water (TBW), ECW, and intracellular water (ICW) were higher in the left arm than those in the right arm at all time points. Impedance, reactance, and resistance were lower in the left arm than those in the right arm at all time points.

CONCLUSION: Generally, histamine and kinins cause vasodilation and increased vascular permeability, which induce swelling at the site of injury. Therefore, the changes in intracellular and extracellular water content found in this study may be attributed to vasodilation and increased permeability. In addition, impedance reflects the amount of membrane proteins, resistance reflects the amount of body water as a conductor inside and outside the cell, and reactance reflects the

resistivity of the electrical capacitance of the cell membrane. In the present study, all BIA parameters were significantly altered, suggesting that EIMD may have caused changes in the amount of membrane proteins, the amount of body water as a conductor, and damage to the cell membrane.

TEMPORARILY INSUFFICIENT SLEEP DOES NOT NEGATIVELY INFLUENCE ON CAROTID ARTERY STIFFNESS RESPONSE TO CARDIOPULMONARY EXERCISE IN YOUNG ADULTS

PARK, S., LEE, E., SON, J., KIM, D., HWANG, M.

INCHEON NATIONAL UNIVERSITY

INTRODUCTION: Insufficient sleep is a prevalent global health issue and associated with cardiovascular disease (CVD) risk. Carotid artery stiffness, a clinical index of CVD, can be improved through regular physical activity. However, there has been a limited number of studies to investigate the combined effect of insufficient sleep and exercise on carotid artery stiffness. Therefore, this study aimed to assess the combined effects of cardiopulmonary exercise and insufficient sleep on carotid artery stiffness in healthy young adults.

METHODS: In a randomized cross-over design, six young adults (4 females & 2 males; 22.2±0.3 yrs) visited our laboratory at both insufficient sleep (IS; 3.0±0.1 hrs) and normal sleep (NS; 7.5±0.1 hrs) condition. All participants performed moderate intensity treadmill exercise for 30 minutes at 70% of peak heart rate. To compare and analyze any differences in changes in carotid artery stiffness measures in response to the exercise between two different sleep conditions, we assessed carotid artery compliance, distensibility, and β-stiffness index using an Aloka Prosound α7 ultrasound system and Cardiovascular Suite analysis software.

RESULTS: At baseline, there was no significant difference in carotid artery compliance, distensibility, and β-stiffness index between IS and NS conditions ($P \geq 0.72$). There was no significant condition by time interaction on carotid artery compliance, distensibility, and β-stiffness index between two different sleep conditions ($P \geq 0.56$).

CONCLUSION: Temporarily insufficient sleep does not negatively affect carotid artery stiffness indices at rest and their responses to cardiopulmonary exercise in healthy young adults.

CONSERVATIVE TREATMENT OF CAPITELLAR OSTEOCHONDRITIS DISSECANS IN YOUNG BASEBALL PLAYERS: IS ANNUAL ULTRASOUND ELBOW SCREENING EFFECTIVE?

HOJO, T.1, KIDA, Y.2, KOTOURA, Y.2, UMREDA, T.1, TAKATSUJI, K.2, KOBAYASHI, Y.2, SUKENARI, T.2, MINAMI, M.2

1> DOSHISHA UNIVERSITY, 2> KYOTO PREFECTURAL UNIVERSITY OF MEDICINE

INTRODUCTION: Capitellar OCD is a typical sports disorder that occurs in the elbow joint of young baseball players and often requires surgical treatment. Reportedly, the prevalence of OCD is 2-3% among baseball players, and it is known that the earlier the stage of the disease, the better the outcome of conservative treatment. Capitellar OCD can be diagnosed by ultrasonography, and we have been recommending annual ultrasound (US) elbow screening for young baseball players in our community since 2008. The purpose of this study was to compare the results of conservative treatment of OCD detected by US elbow screening with those of OCD diagnosed only after a direct visit to a hospital and to investigate the usefulness of US elbow screening for young baseball players.

METHODS: During 2009-2019, 263 baseball players were diagnosed with capitellar OCD at our institution and satellite hospitals and 250 cases were followed up longer than 12 months were enrolled in this study. The patients were divided into a US screening group and a hospital group according to whether the diagnosis of OCD was made by US elbow screening or direct hospital visit. Age at the time of initial visit, stage of the OCD (stage I, II, or III), results of conservative treatment (complete healing, partial healing, or surgery), and period for return to sports were studied. The results were statistically compared between the two groups. A p value of <0.05 was considered significant.

RESULTS: There were 158 patients in the US screening group and 92 patients in the hospital group. The age at first visit was 12.0±2.1 y.o. in the US screening group and 13.9±2.1 y.o. in the hospital examination group. In terms of the stage of the OCD at the time of initial examination, percentage of the patients in the US screening group of the stage I, II and III were 60.8%, 31.0%, and 8.2%, respectively, while 21.5%, 41.9%, and 35.5% of the patients in the hospital group were in the stage I, II, and III, respectively.

The results of conservative treatment showed that 60.8% of patients in the US screening group had complete healing, 12.0% had partial healing, and 27.2% had surgery. On the other hand, 18.5% of patients in the hospital group resulted in complete healing, 10.9% resulted in partial healing, and 70.7% underwent surgery. Complete healing was significantly more common in the US screening group. There was no significant difference in the period to return to sports between the two groups.

CONCLUSION: Capitellar OCD is often asymptomatic or minimally symptomatic at the early stage when conservative therapy is effective. However, by the time the patient presents to the hospital directly with symptomatic OCD, the stage of the disease has often progressed. In this study, the US screening group was significantly younger and had more stage I lesions, and 72.8% of them were able to return to play conservatively. On the other hand, patients in the hospital group were significantly older and had fewer stages I lesions, and only 29.4% were able to return to play conservatively. The efficacy of US elbow screening is that it can detect capitellar OCD at an early stage with fewer symptoms and lead to conservative healing of the lesion and return to sports in a higher percentage of patients. US elbow screening had a positive impact on the outcome of conservative treatment of capitellum OCD.

STUDY OF STRATEGIES FOR STRESS FRACTURES IN RECRUITS BASED ON THE MALE ATHLETE TRIAD.

HE, J., BAO, D., JIANG, G.

BEIJING SPORT UNIVERCITY

INTRODUCTION: A stress fracture (SF) is a non-traumatic injury that occurs in the weight-bearing bones of the lower limbs and is mainly caused by a sudden increase in repetitive motion. A variety of internal and external factors can increase the risk of stress fractures, but previous studies have focused more on external factors. As the fitness of recruits changes, there is a need to consider the internal factors that cause fractures.

METHODS: This paper is a review of the causes of stress fractures in recruits at the present time, with reference to the national and international literature.

RESULTS: Stress fractures are incomplete fractures not caused by trauma. Extrinsic risk factors include previous footwear discomfort, inadequate vitamin D/calcium intake and poor environment. Athletes and military trainees, who may experience periods of increased physical activity during training that exceed their energy intake, often have this metabolic state. In athletes and military trainees, inadequate energy intake leads to disturbances in reproductive hormones. A prolonged decline in reproductive health will affect bone health, leading to stress fractures. Tenforde et al. define the clinical signs of relatively low energy intake (eating disorders), reduced testosterone levels (decreased libido) and low bone mineral density (osteoporosis) as the male athlete triad. This may be associated with an increased risk of stress fractures. Most studies on the "male athlete triad" have focused on male athletes. However, these signs are also common in military training for recruits.

CONCLUSION: The "male athlete triad" is an objective and complex syndrome in sports medicine that exists during military training and has a relationship between its three symptoms and stress fractures in recruits, and is an important internal factor contributing to stress fractures in recruits. There are gaps in the epidemiological features, clinical characteristics and treatment options for the "male athlete triad". A multicentre prospective study should be conducted to determine the internal and external causes of stress fractures in recruits, with a focus on the internal causes of the male athlete triad.

THE CLINICAL EFFECTIVENESS OF THE COMPLEX UPPER EXTREMITY LOW-INTENSITY RESISTANCE TRAINING COMBINED WITH BLOOD FLOW RESTRICTION IN THE TREATMENT OF TENNIS ELBOW

WU, C.C., YOU, Y.L., YANG, C.C., YANG, B.S., GUO, L.Y.

KAOHSIUNG MEDICAL UNIVERSITY

INTRODUCTION: Tennis elbow was known as the lateral epicondylitis or lateral elbow tendinitis, such as inflamation of the origined site of common wrist externsors due to overuse. The symptom includes chronic pain, decrease muscular strength and reduced functional ability. Thereafter, mucular stenethening for wrist entensor within pain tolerance is important. However, few study investigated the effect of blood flow restriction (BFR) for muscular strengthening for clients with tendinopathy.

The purpose of this study was to investigate whether there is pain relief and painless grip strength and functional improvement in clients with lateral tendinopathy by combining low-intensity resistance training with or without BFR for 4 weeks, three times a week.

METHODS: A total of 11 clients were divided into two groups randomly; 5 subjects in the low-intensity resistance training combined with blood flow restriction group (LI-BFR), 6 subjects low-intensity resistance training groups (LI). Before and after training, the assessment and measurement tools include Visual Analogue Scale (VAS), Patient-Rated Tennis Elbow Evaluation Questionnaire (PRTEE), and pressure pain threshold (PPT) maximum painless grip strength (PFG) as the outcome measure.

RESULTS: After 4 weeks of training in the two groups(LI-BFR、LI), for within-group comparison, the VAS, PRTEE, PPT,PFG were significantly improved afer training($P < 0.05$). In the comparison of the changes between groups, the PFG and PPT improved significantly in the LI-BFR group compared with those in the LI group ($P < 0.05$) .

CONCLUSION: This study shows that the two groups (LI-BFR, LI) at 4 weeks can effectively improve pain, painless grip strength, tenderness threshold and function inclients with lateral elbow tendinopathy. Combined with blood flow restriction (LI-BFR) can provide better clinical rehabilitation training effects especially for improvements on pressure pain threshold and maximum painless grip strength.

GENETIC POLYMORPHISMS INFLUENCE ON SPORTS INJURIES AND MUSCLE DAMAGE

DELFORGE, E., BOISSIÈRE, J., IMBERT, S., DINE, G., DAUSSIN, F.

UNIVERSITÉ DE LILLE

INTRODUCTION: The practice of sports or physical activity has been acknowledged to be beneficial for health. However, the physical practice may also induce injuries related to the sport. Indeed, when related to 1000 hours of practice, injury incidence in training is 3.7 in football and 3.0 in rugby union whereas it increases to 36.0 and 81.0 (respectively) during matches. Injuries negatively affect the players' performance and health, and may have financial implications for the athletes and/or their clubs. Therefore, avoiding players' injuries became a priority and strategies are developed to limit them. Training workloads focused trainers' and researchers' attention as their monitoring allows to maximize the training processes and performance, and limit the occurrence of injury. Internal and external outcomes are used to characterize the

training and competition load. For the same external workload, the internal responses differ for each people leading to different levels of fatigue or exercise-induced muscle damage. While a high training load and a certain amount of muscle damage are necessary to induce adaptations and performance increase, excessive muscle damage favor injury occurrence. Great inter-individual variations have been observed following a same external training load. Scientific evidence support that several factors are involved in the occurrence of injury or exercise-induced muscle damage. Besides exercise characteristics, individual risk factors, such as genetics, seem to be a component to take into account in injury mechanisms. Particularly, single genetic polymorphism, an alteration in DNA sequence, may alter the protein structure and its function within the cell. Studies support that genetic polymorphisms may be considered as a predisposing factor. In this context, identifying injury-predisposing polymorphisms is of interest to improve training load prescription.

METHODS: A review was achieved to identify genetic polymorphisms which increase injuries and muscle damage susceptibility.

RESULTS: Several genetic polymorphisms have been identified during the last decade involving muscles, ligaments, or tendons-related genes. These genetic polymorphisms can impact, positively or negatively the risk, the incidence, and the severity of injuries. Among them, the major genes identified were ACE, ACTN3, COL5A1, IL6, MCT1, MMP3, and HGF.

CONCLUSION: The present study supports the interest to assess genetic polymorphisms in athletes to better individualize training strategies.

EFFECT OF VP CURRENT STIMULATION ON BONE HEALING IN A RAT TIBIA INJURY MODEL

NAO, Y., HIRAI, S., WATARU, M., SIQIN, X., MASAFUMI, O.

TOYO. UNIV

INTRODUCTION: Fractures are traumatic injuries that can occur in all age groups, from children to the elderly, and it is desirable to shorten the duration of treatment to prevent a decline in quality of life. On the other hand, a device that can energize a living body without contact has recently been developed. This device is characterized by the use of vector potential (VP) energization (VP energization stimulation), and its preventive and therapeutic effects on various musculoskeletal diseases are currently being investigated. However, the effect of VP current stimulation on bone healing after fracture has not yet been verified. Therefore, we aimed to investigate the effects of VP electric current stimulation on bone healing.

METHODS: Six 6W male Wistar rats (12 rats) were used as material. All rats were pre-reared for 1 week (at 7W rats), and then the tibia was injured by a 2.0 mm diameter drill to create a bone injury model, assuming a fracture. The VP intervention condition was 60 min/day, 7 days/week. At the end of the experimental period, rats were euthanized by carbon dioxide inhalation and tibiae were removed. Tibiae were subjected to various treatments and analyzed histologically and genetically.

RESULTS: Using μCT, the new bone formed at the site of bone injury in each group was analyzed. The results showed that bone mass and bone density were higher in EX than in CO. We also analyzed gene expression of bone formation markers in the bone injured areas using qPCR. both Col1a (gene name of type I collagen) and BGLAP (gene name of osteocalcin) were highly expressed in EX.

CONCLUSION: It is thought that the amount of bone formation by osteoblasts was increased in the bone injured area of EX compared to CO, and as a result, the formation of new bone was promoted. Thus, it was suggested that VP electrical stimulation may accelerate the healing of bone damage.

LOW BACK PAIN STATUS OF COLLEGE ATHLETES IN RELATION TO DIFFERENT MUSCULOSKELETAL PROBLEMS

HUANG, H.C., LIANG, J.M., WU, W.L.

KAOHSIUNG MEDICAL UNIVERSITY

INTRODUCTION: As sport specialist clinicians, it is important to recognize reasons of low back pain in order to implement appropriate rehabilitation programs to reduce the risk of injury, thus finding athlete's problem faster and precisely is important. Biomechanically, hip muscles (hip extensors, gluteus muscles and tensor fascia lata) playing importance role in lumbo-pelvic stability during trunk rotation, jumping, and running. Report showed that hip musculoskeletal weakness, tightness, or discomfort associated with lumbar movement and/or change the ground reaction forces to the lower back. Therefore, the aims of the study were to clarify the prevalence and the characteristics of the low back pain in college athletes and find out the potential musculoskeletal problems of athletes with low back pain.

METHODS: A questionnaire survey and medical check-ups of college athletes competing at a national level in 10 universities in Taiwan was conducted. Eligibility criteria for this study were: age between 18~30 years old college students; active athlete; weekly training volume (at least 10 hr); a certain competition level (at least national events). The self-completed questionnaires form was distributed to all participants before the physical examinations and was collected on the day of the check-up. Each participant was asked to complete 5 orthopaedic tests on the day of the check-up.

RESULTS: 701 college athletes were included in this study, 563 male and 138 female. LBP on the day of the check-up was confirmed in 327 (46.6%), the mean VAS was 3.14 ± 1.82. The prevalence of LBP in last 4 weeks, 6 months, and 12 months were 343 (48.9%), 423 (60.3%), and 471 (67.2%), respectively. For demographic data, it showed that sports experience (OR 1.07, 95%CI 1.03-1.10, $p < 0.01$) and training load (OR 1.03, 95%CI 1.01-1.05, $p < 0.01$) slightly increased risk of low back pain. For previous injury history, the highest hazard value is on the pelvis (OR 2.52, 95%CI 1.25-5.08, $p = 0.01$). For muscu-

loskeletal examinations, Bonnet's Sign (OR 1.50, 95%CI 1.10-2.04, p = 0.01), Faber-patrick test (OR 1.39, 95%CI 1.02-1.92, p = 0.04), and Ober's test (OR 2.01, 95%CI 1.27-3.18, p < 0.01) were associated with LBP, but Thomas test and Ely's sign were not significantly associated with LBP.

CONCLUSION: The current study confirmed that Bonnet's Sign, Faber-patrick test, and Ober's test have significantly higher odd ratio in experiencing LBP athletes compared to no LBP athletes. This suggest that orthopeadic test is very helpful for sport health physicians to approach LBP athletes quickly and precisely, and it might help LBP athletes get better sooner, set up individual training program, and avoid future injury.

EXPLORING BARRIERS AND FACILITATORS TO DELIVERING INJURY PREVENTION TRAINING IN YOUTH SOCCER FROM GRASS-ROOT COACHES' PERSPECTIVES: A EUROPEAN STUDY

BARDEN, C.1, WING, K.1, ROBERTS, W.2, DE STE CROIX, M.1, AYALA, F.3, LEHNERT, M.4, HUGHES, J.5

1UNIVERSITY OF GLOUCESTERSHIRE; 2UNIVERSITY OF WAIKATO; 3UNIVERSITY OF MURCIA; 4PALACKY UNIVERSITY; 5CARDIFF METROPOLITAN UNIVERSITY

INTRODUCTION: It is widely proposed that coach education in injury prevention could reduce injury rates in youth sport, with targeted workshops showing significant improvement in knowledge, understanding, attitude and confidence to deliver such injury prevention programmes [1]. There is strong evidence that injury prevention programmes can reduce injury risk and improve physical characteristics, yet programme awareness, uptake and adherence are often poor [2]. The aim of this study was to investigate perceived barriers and facilitators to adopting, implementing and maintaining an injury prevention programme through an inductive, qualitative lens.

METHODS: A total of 269 grass-root soccer coaches from 3 European countries (UK, Spain, Czech Republic) were recruited and completed a 2-hour injury prevention workshop. Data was collected using a validated questionnaire exploring knowledge, understanding, confidence to deliver and attitudes towards youth injury prevention A six-phase thematic analysis framework [3] was employed to identify and describe patterns of meaning.

RESULTS: Three predominant themes were identified: perceived challenges/barriers, facilitators and socio-environmental contributors. Perceived barriers included constraints (time), inadequate facilities/resource and athlete attitude sub-themes. Within the attitude sub-theme barrier, there was also a sense that lack of awareness from parents often isolates the coach. Facilitators included coach motivation and receptiveness, stakeholder support and perceived intervention effectiveness. Socio-environmental contributors particularly influenced coaches' perceptions of logistical or institutional barriers. Coaches were concerned that introducing another 'programme' would impact on training load targets and technical development, despite acknowledging the benefits of the programme., Coaches also felt more confident delivering when they had autonomy/freedom to make content-based decisions regarding their coaching sessions.

CONCLUSION: Stakeholders buy-in and coaches' receptiveness are key to successful adoption and implementation of injury prevention programmes. Future interventions should focus on organisational buy-in as well as up-skilling coaches. Continued coach education would empower coaches to make decisions regarding session content; reinforce their ability to deliver preventative programmes without extensive resource; whilst improving knowledge and confidence to educate youth athletes about the importance of injury prevention. Time should not be seen as a constraint to implementation and adding movements within technical sessions, rather than seeing them as a separate element at the start of sessions, would help reduce this perceived barrier.

ACTIVITY DURING REST BREAKS, FITNESS LEVEL AND INJURIES IN PROFESSIONAL BALLET DANCERS

RAKOVAC, M.1, SAJKOVIC, D.1,2

1: UNIVERSITY OF ZAGREB, FACULTY OF KINESIOLOGY, 2: SESTRE MILOSRDNICE UNIVERSITY HOSPITAL CENTER

INTRODUCTION: Working days of professional ballet dancers are characterized by long working hours and significant physical demand (Twitchett et al., 2010). Morning classes are followed by rehearsals and evening performances, with usually short breaks in between. Physical fitness is crucial for performance and injury prevention and many dancers undertake supplemental training to improve their fitness level (Dang et al., 2022). Less is known about the effects of rest-break activities. The aim of the study was to evaluate the difference in physical fitness and injury occurrence between dancers based on their activity during rest breaks.

METHODS: Participants were members of a professional ballet ensemble (n=40, 26 females; age (mean±SD) 31.3±7.7 y; height 170.2±7.2 cm; body mass 58.5±10.1 kg). Data on rest-break activity (active/inactive) during a working day was collected via questionnaire. Injury incidence and related time loss from dance was monitored during a one-year period. Muscular fitness was tested by curl-up repetition test, back extension, push-ups, plank and Sargent jump test. Aerobic fitness was assessed by Astrand-Rhyming cycle ergometer test. Balance was tested by single-leg 30s balance test and flexibility by sit-and-reach test and bilateral plantar flexion ROM. Dancers were tested in high-demand period of mid-season.

The differences in physical fitness and injury-related time loss between the active and inactive group were tested by Student's t-test. The relationship between rest-break activity and injury occurrence was tested by Chi-square test for independence.

RESULTS: Curl-up repetition test was the only test in which active and inactive group differed significantly (47.9±26.3 vs 33.0±16.8 (n; mean±SD), respectively, t=-2.2, p=.035). In all other tests, except Astrand-Rhyming and Sargent tests, there was a trend of better average results in the active group, although without significant difference. Age, supplemental training and ensemble position were accounted for. There was no significant association between rest-break activity and injury occurrence (Pearson Chi-square=0.61, p=.44). Eighteen participants were injured during the monitored period. There was no difference between active and inactive dancers in time loss duration due to injury (p=.21).

CONCLUSION: The only fitness component significantly better in dancers who choose active rest breaks was trunk muscular endurance. This could be attributed to the preferred activities reported by dancers. Although there was no significant difference in other tests, there was a trend of better results in the active group. The potential of implementing rest break activities aimed to improve particular fitness components should be further explored, keeping in mind the overall daily workload (Kozai et al., 2020).

SERUM LEVELS OF BONE FORMATION AND RESORPTION MARKERS IN RELATION TO VITAMIN D STATUS IN PROFESSIONAL ATHLETES AND PHYSICALLY ACTIVE MEN DURING UPPER AND LOWER BODY HIGH-INTENSITY EXERCISE

WALDZINSKI, T., WALDZINSKA, E., MIESZKOWSKI, J., NIESPODZINSKI, B., STANKIEIWCZ, B., DURZYNSKA, A., BRZEZINSKA, P., KOCHANOWICZ, A.

LOMZA STATE UNIVERSITY OF APPLIED SCIENCES

INTRODUCTION: Several reports on the effect of single exercise and regular training on bone marker levels have been published; however, the data are not consistent. Without a doubt, exercise intensity and its nature, in conjunction with dietary factors, determine the bone marker response. Of note, many indoor athletes who practice certain sports are vitamin D-deficient. Vitamin D plays an important role in bone metabolism. It also influences skeletal muscle strength, reduces muscle atrophy and parathyroid hormone concentration, and exerts many other effects . Despite of these positive effects, to the best of our knowledge, the acute effect of exercise on bone formation and resorption markers in relation to vitamin D status had not yet been assessed. Hence, the primary aim of the current study was to evaluate the effects of vitamin D status on changes in the serum PINP and CTX levels induced by Wingate anaerobic test (WAnT) in highly trained athletes and untrained young men.

METHODS: Sixteen elite male artistic gymnasts (EG; 21.4 ± 0.8 years-old) and 16 physically active men (the control group, PAM; 20.9 ± 1.2 years-old) performed lower and upper body 30-s Wingate anaerobic tests (LBWT and UBWT, respectively). For biomarker analysis, blood samples were collected before, and 5 and 30 min after exercise. Samples for vitamin D levels were collected before exercise. N-terminal propeptide of type I collagen (PINP) was analysed as a marker of bone formation. C-terminal telopeptide of type I collagen (CTX) was analysed as a marker of bone resorption.

RESULTS: UBWT fitness readings were better in the EG group than in the PAM group, with no difference in LBWT readings between the groups. UBWT mean power was 8.8% higher in subjects with 25(OH)D3 levels over 22.50 ng/ml and in those with 24,25(OH)2D3 levels over 1.27 ng/ml. Serum CTX levels increased after both tests in the PAM group, with no change in the EG group. PINP levels did not change in either group; however, in PAM subjects with 25(OH)D3 levels above the median, they were higher than those in EG subjects

CONCLUSION: Vitamin D metabolites affect the anaerobic performance and bone turnover markers at rest and after exercise. Further, adaptation to physical activity modulates the effect of anaerobic exercise on bone metabolism markers.

HOW DOES ACHILLES TENDON RUPTURE AFFECT SPORTS PERFORMANCE AFTER RETURN TO PLAY? A MEDIA-BASED, MATCHED-PAIRS ANALYSIS IN MALE ELITE BASKETBALL ATHLETES.

WILKE, J., MOHR, L.

UNIVERSITY OF KLAGENFURT / GOETHE UNIVERSITY FRANKFURT

INTRODUCTION: Achilles tendon rupture (ATR) represents one of the most devastating musculoskeletal injuries in sports. Most affected athletes require surgery and return to competition only after downtimes of about six to twelve months [1, 2]. It may hence be assumed that pre-injury performance levels cannot be fully restored during the complex rehabilitation process. This study aimed to compare both, simple and complex performance indicators in male NBA basketball players with and without a history of ATR.

METHODS: A total of n=42 NBA athletes with an ATR sustained between 1970 and 2022 were identified using official databases (e.g. NBA.com) and media-based registers. Both simple (e.g., points scored/rebounds/assists/blocks/steals/turnovers, all normalised per 36 minutes of playing time) and complex (e.g., player efficieny rating, points per possession, offensive/defensive rating) indicators of performance were extracted for the injured athletes as well as for a sample of n=42 controls, matched based on age, career duration, height, weight, pre-injury performance, and position. For both groups, differences were calculated between the reference season (pre-injury in ATR group) and the (consecutive) post-injury season. Mann-Whitney-U tests and related effect sizes were computed for group comparisons.

RESULTS: While both groups were not different with regard to 12 out of 17 performance indicators (p>.05), systematic differences with moderate effect sizes were observed for the remaining variables. Individuals with a history of ATR had a lower field goal (-1.5 %, p=.03, r=.27) and true shooting percentage (-2,9%, p=.006, r=.34), additionally achieving fewer blocks (-0.2, p=.005, r=.36), fewer points per possession (-0.09, p=.002, r=.40), and a lower game rating (-1 point, p=.02, r=.30).

CONCLUSION: Following ATR, performance can be restored with regard to most indicators of performance in elite basketball athletes. However, coaches and therapists need to be aware that some deficits continue to exist, requiring focused attention.

CONCUSSION AWARENESS IN KARATE CHILDREN INTERNATINAL COMPETITORS

ARRIAZA, R., MARTÍNEZ DE QUEL, O., AUGUSTOVICOVA, D.

UNIVERSITY OF A CORUÑA

INTRODUCTION: There is a paucity of information about the awareness of young adolescents and children on concussions.

METHODS: A survey was conducted during the 2022 Cadets and Juniors World Karate Chamionships about concussions epidemiology and awareness in 14-15 year old children

RESULTS: Ninety percent of the registerede competitors answered the survey. they belong to 97 different countries

24.9 5 of the children stated that they did not know what a concussion is. ·5.75 believed that a concussion is a loss of conciousness

CONCLUSION: In light of the results, it is mandatory to increase the effort to teach the young karate players what a concussion and their risks are

DEVELOPMENT OF A STANDARDIZED QUESTIONNAIRE TO REPORT MECHANISMS OF FALL-RELATED INJURIES IN SPORT CLIMBING

LUIGGI, M.

AIX-MARSEILLE UNIVERSITY

INTRODUCTION: Sport climbing is rapidly growing in popularity. While falls are frequent and mostly harmless given the recommended positioning during a fall, the most severe and very severe injuries in sport climbing have been caused by a fall. However, the respective contribution of fall mechanisms to the burden of fall-related injury (FRI) in sport climbing is little understood. In case of FRI, mechanisms are primarily asked to the climber and the belayer by sport climbing responsible or rescue teams, but no standardized tool exists to report the fall mechanisms that led to injury. The main purpose of this study was thus to develop a reliable standardized self-report tool of fall mechanisms.

METHODS: Fall mechanisms were compiled from a previous empirical study (1). A total of 40 fall mechanisms were divided into three fall temporalities dimensions: 1) the reasons that lead to the fall (FR; n=12); 2) the climber's or belayer's behaviors during the fall (FB; n=19); 3) the details concerning the end of the fall (FE; n=9). A questionnaire was developed with four boxes. The first three boxes included items representing FE, FB and FE. The last box included the location of the body hit in case of collision during the fall. A pilot study was conducted between January, 30th, 2023 and February, 13th, 2023 in a french sport climbing gym to assess the internal validity of the tool. A researcher observed climbers ascents, and in case of a fall, reported FE, FB and FE using the developed questionnaire. The same questionnaire was subsequently filled by the climber and the belayer without having prior knowledge of the exact content of the questionnaire. The (i) researcher and climbers and (ii) researcher and belayers levels of agreement were compared using Gwet's AC1 agreement coefficient, overall and by fall temporalities (2).

RESULTS: A total of 50 falls were recorded. The overall agreement between researcher and climber was very good (0.88, 95% CI=0.86-0.89). The researcher and climber had a very good level of agreement for fall reasons (0.89, 95% CI=0.85-0.92), fall behaviors (0.81, 95% CI=0.77-0.85) and fall end (0.90, 95% CI=0.85-0.94). A very good level of agreement was also found concerning the location of the body that hit the wall (0.97, 95% CI=0.95-0.99).

The overall agreement between researcher and belayer was very good (0.89, 95% CI=0.87-0.81). The researcher and climber had a very good level of agreement for fall reasons (0.89, 95% CI=0.85-0.93), fall behaviors (0.84, 95% CI=0.80-0.87) and fall end (0.92, 95% CI=0.88-0.96). A very good level of agreement was also found concerning the location of the body that hit the wall (0.96, 95% CI=0.94-0.98).

CONCLUSION: The level of agreement of fall mechanisms reported by the researcher, the climbers and the belayers were very good. This standardized questionnaire could be used to report fall mechanisms that led to an injury in sport climbing. Further studies are needed to compare its validity according to the climbers' level of experience and climbing

MUSCLE OXYGEN SATURATION AS A DIGITAL BIOMARKER TO GUIDE THE RETURN TO PLAY OF ATHLETES FOLLOWING ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION

VANBIBBER, H.1,2, MOYAL, A.1, HARLOW, E.1, GELETKA, B.1, CALCEI, J.1,2, VOOS, J.1,2, SESHADRI, D.1

UNIVERSITY HOSPITALS CLEVELAND MEDICAL CENTER, CASE WESTERN RESERVE UNIVERSITY

INTRODUCTION: Return to play (RTP) protocols for anterior cruciate ligament (ACL) injuries involve full motion, strength, psychological readiness, GPS monitoring, isokinetic testing, and functional testing. However, current RTP criteria lack ob-

jective, internal, and continuous data necessary to complement current assessments. The majority of evidence suggests > 9 months is required to regain neuromuscular function and allow for appropriate osseointegration and vascularization of the neoligament into the native environment. Monitoring muscle oxygen saturation (SmO2) levels utilizing wearable sensors enables the collection of objective and internal data to monitor oxygen delivery and consumption in surgical and contralateral limbs during the RTP process. Crum et al. validated the reliability of the SmO2 sensor at low to moderate exercises among 10 healthy cyclists. Statistical analysis showed strong correlations of r=0.842-0.993 for the Spearman's Rank-Order Correlation and r=0.773-0.992 for the Intraclass Correlation between the trials of all participants [1]. We hypothesize that muscle atrophy in the surgical leg following ACL reconstruction (ACLR) results in changes in SmO2.

METHODS: Currently ongoing is a multi-arm IRB approved study assessing SmO2 levels in the legs of healthy subjects aged 14-22 years (arm 1, n=50) and aged matched patients after ACLR (arm 2, n=50). A standardized workout was created for testing at 6, 9, and 12 -months post ACLR. Sensors are placed on the vastus medialis bilaterally to record SmO2 throughout the study duration. Healthy patients undergo testing once, while surgical patients undergo the testing at 6, 9, and 12 -months post-operatively.

RESULTS: At present, continuous SmO2 data has been collected on seven healthy subjects and nine patients. The healthy cohort shows no difference in SmO2 levels between the two limbs. Results of the longitudinal trial for ACL patients show the convergence of SmO2 levels during air bike interval sprints, 1-minute air bike sprint, and isometric squat hold exercises over the 6, 9, and 12 -month time periods. ACLR SmO2 levels at the 12 -month trials resemble the healthy cohort.

CONCLUSION: The change in SmO2 in ACLR patients is likely due to a combination of altered hemoglobin-oxygen unbinding, altered blood delivery, detraining, and muscle atrophy. These changes in SmO2 in the ACLR subjects correlate with improvement in other RTP testing. SmO2 data offer complementary objective data in RTP criteria. Future work will measure key biomarker and physiological data along with patient reported outcome measures on this critical age group. This data will enable an integrative algorithm that physicians and physical therapists can employ to gauge athlete readiness following ACLR with broader implications to other musculoskeletal injuries.

THE RELATIONSHIP BETWEEN THE AMOUNT OF KNOWLEDGE IN SAILING COMPETITIONS AND THE FACTORS OF GENDER, AGE, COMPETITIVE AGE, POSITION, AND BOAT TYPE

SAKAGUCHI, H.1, IMAMURA, K.1, AOYAGI, O.2, NAGAMINE, K.2

1> JAPAN UNIVERSITY OF ECONOMICS., 2> FUKUOKA UNIVERSITY.

INTRODUCTION: In Sailing competitions, decision-making is more important, which is based not only on a correct assessment of the situation but also on a great deal of correct knowledge. However, how do sailing competitors acquire the correct amount of knowledge? It would be interesting to know whether it is acquired simply by reading books or it is naturally acquired through the experience of sailing a boat under various conditions. Therefore, this study examines the relationship between the amount of knowledge required for sailing competitions and the factors of gender, age, competitive age, position, and boat type.

METHODS: The knowledge required for sailing competitions is assumed to be: (1) Outfitting (56 items); (2) Sailing (28 items); (3) Racing (16 items); (4) Strategies (10 items); (5) Tactics (14 items); (6) Weather (19 items); and (7) Safety (5 items). Corresponding to these factors, a total of 149 written tests were administered to 165 participants in the 74th National Athletic Meet Sailing Competition in Japan. Apart from that, a) Gender, b) Age, c) Competitive years, d) Boat type, and e) Position were also asked. Multiple regression analysis was performed on the data obtained with dummy transformations for a) Gender, d) Boat type, and e) Position. In addition, explanatory variables were selected using the forward-backward variable selection method.

RESULTS: As a result of variable selection, a regression equation consisting of b) Age, d) Boat type, and e) Position was chosen, with the multiple correlation coefficient of .259 (F0=3.61, df=[3, 151], p=0.0147), which was a significant correlation at the 5% level. The regression coefficients were 0.038 for Age, 0.848 for Position (skipper; fixed at 0.0 for crew), -1.306 for Boat type (single-seater; fixed at 0 for two-seater), and the constant term was 11.535. The regression coefficient for Boat type was significant at the 1% level (p=0.005). In other words, Boat type contributed the most to the acquisition of sailing knowledge, followed by Age and Position.

CONCLUSION: First of all, the results indicating that two-seater boats contribute the most to the acquisition of sailing knowledge compared to one-person boats can be explained by the fact that participants in two-person boats are more competitive and more knowledgeable than those in one-person boats. Second, it is thought that older participants acquire more sailing knowledge than younger ones possibly because they are able to acquire knowledge in a shorter period of time and in a more theoretical way, due to their higher level of comprehension. Third, skippers contribute the most to the acquisition of sailing knowledge as opposed to their crews because skippers hold the rudder and steer the boat.

Boat type contributed the most to the acquisition of sailing knowledge, followed by Age and Position.

LONGITUDINAL CHANGES IN BASKETBALL DRIBBLING SKILLS BY SPORTS EVENT USING LINEAR MIXED MODEL

AOYAGI, O.1, KOMURE, I.1, NAGAMINE, K.1, TAGATA, S.2

1.FUKUOKA UNIVERSITY, 2. HITACHI HITECH COUGARS

INTRODUCTION: Skill tests are used also in PE basketball classes of Physical Education majors to measure basic skills. However, it is possible that each of the students in the Physical Education majors specializes in sports events other than basketball, and this may affect the measurements of the skill tests. At the same time, it may affect their effectiveness in PE classes. For example, those who specialize in basketball or similar sports events would be less effective in the PE class, while those who do not would be more effective. Therefore, this study examines longitudinal changes in dribbling skills. However, since there are those who have experience in the same sports event practice similar to each other while considering these associations, this study aimed to examine the associations using a linear mixed model.

METHODS: 244 students of Physical Education major (71 male and 73 female students) taking basketball PE classes at F-University were asked to perform the basketball dribbling skill test twice each. Subjects dribble in a zigzag manner between 12 chairs (= 2 rows of 6 chairs) arranged with 6 feet apart, and the time required is measured. Then, the change over a six-month period by the following sports event group is examined: "Basketball," "Ball games other than basketball," "Non-ball games," "No affiliation," and "Faculty other than physical education." Since these individual repetitions (individuals), sports events (SE), and groups of sports events (GSE) are nested, their association was analyzed using a linear mixed model with these as random effects and with timing (before and after the class), gender, and their interaction as fixed effects.

RESULTS: The results of the deviance analysis for the models with only random effects (Null model, AIC=4521.9) and the model including gender and time as fixed effects (Full model, AIC=4442.3) showed significant goodness of fit (Chi-squared =85.54, df=3, $p<0.001$). Furthermore, the likelihood ratio test was used to select independent variables, and a model was selected that excluded the fixed effects of the interaction between time and gender and the random effect of the slope of the GSE (Selected model, AIC=4439.1). The intraclass correlation coefficients for the random effects were the highest for the individual intercept at 0.591 and the interaction (slope) between time and individuals at 0.541, followed by the intercept for the GSE at 0.389 but were the lowest for the SE intercept at 0.184 and its interaction with a time at 0.177. In other words, the development of dribbling skills was largely influenced by individuals and GSE, with little influence among the SE. For the fixed effects, the partial regression coefficients for males and time were -2.70 and -1.56, respectively, and the interaction effect between males and time was not significant.

CONCLUSION: Males were originally better in dribbling skills than girls, and the overall effect of the classes was uniformly effective for both genders.

COMPARISON OF ATTACK INDICATORS OF NÕMME KALJU FOOTBALL CLUB IN THE PREMIUM LEAGUE IN SEASONS 2018 AND 2021

STAMM, R., STAMM, M., EHASTU, M.

INSTITUTE OF HEALTH SCIENCES AND SPORTS

INTRODUCTION: In football, attack indicators can help to explain the reasons why one team is more successful than another. The aim of the current study was to compare the seasons of 2018 and 2021 of Nõmme Kalju FC who plays in the Premium League of Estonia and to find which differences in attack indicators caused the weaker results of the team during the second season.

METHODS: In the second, 2021 season, the team lost more points and finished at a lower position in the table. A total of 68 league games were analysed. The analysis included the following parameters: goals scored, total number of passes, percentage of precise passes, key passes, number of precise key passes, centrings, percentage of precise centrings, kicks towards the goal, precise kicks to the goal, situations created for scoring a goal, standard situations, goals scored from standard situations, percentage of possessing the ball, number of position attacks, goals scored from position attacks, number of counter-attacks, goals scored from counter-attacks.

RESULTS: In the 2018 season, the number of goals, the number of precise kicks, and number of kicks towards the goal by the team was statistically significantly greater than in the 2021 season. In the 2018 season, the number of centrings by the team was statistically significantly greater than in the 2021 season, but no statistically significant difference was found in the indicators of pass and possession of the ball. The comparison of attack types revealed statistically significant differences in favour of the 2018 season in both standard situations and counterattacks.

CONCLUSION: The reason why fewer centrings were performed in the 2021 season might be that during attack the team could not possess the ball on the opponent's side long enough. A study conducted in the English Premier League revealed that if a team performed more centrings, this did not bring about an increase in the percentage of wins [2]. The reason why the indicators in standard situations and counterattacks were lower in 2021 may have depended on the tactics of the game – too one-sided, misunderstandings between players during attack, timing of passes and openings. A study of goals scored from counterattacks revealed that teams that were at higher positions in the table performed more counterattacks and scored more goals from them [1]. It can be concluded that the differences in standard situations and counterattacks between the two seasons can help to explain the reason why Nõmme Kalju FC lost too many games in the 2021 season and finished at a lower position.

POS-PANDEMIC ERA INQUIRY TENDENCY FOR SUBSTANCES PROHIBITED IN SPORTS: DATA ANALYSIS OF TAIWANESE ANTI-DOPING SERVICES.

CHEN, C.C., LIN, T.Y., CHEN, C.H., WANG, C.Y., WU, Y.T., HSU, M.C., CHANG, W.C.W.

KAOHSIUNG MEDICAL UNIVERSITY

INTRODUCTION: World Anti-Doping Agency (WADA) updates its prohibited list(1) annually according to the latest research and reports, making it difficult for sports and medical professionals to keep track of all the latest information and memorized which healthcare products contain substances prohibited in sports. To assist Taiwanese athletes and people concerned, anti-doping authorities in Taiwan provide services utilizing website search tools, APP, and online professional consultation. Analysis data collected from these services allow us to identify the population in need and the types of issues or substances that athletes may encounter in daily life, improving the efficiency of sports-prohibited substance misuse prevention.

METHODS: The study collects over 30,000 data from the search history of anti-doping APP and inquiries submitted for prohibited substances consultation from 2021 to 2022 which contain the identity (i.e. occupation or relationship to athlete) of anonymous users. The prohibited substances in the data were categorized according to WADA's prohibited list(1) and routes of administration. The information on the users' population and healthcare products was also calculated and categorized.

RESULTS: The majority of users are athletes (44.0%), much more than any other group in the user population (all below 20%). For healthcare products in the database, 60.4% are western medicine (21.9% containing prohibited substances), 28.2% are traditional Chinese medicines (35.9% contain prohibited substances), and 11.4% are nutritional supplements (58.3% high risk of containing prohibited substances). Prohibited substances in modern medicine include S1 anabolic agents (1.6%), S2 peptide hormones (0.5%), S3 beta-2 agonists (6.7%), S4 metabolic modulators (1.7%), S5 diuretics (3.1%), S6 stimulants (52.4%), S7 narcotics (4.9%), S9 glucocorticoids (25.3%), P1 beta-blockers (3.8%); prohibited substances in traditional Chinese medicines include S3 beta-2 agonists (44.4%), S6 stimulants (51.4%), S8 cannabinoids (4.2%).

CONCLUSION: Athletes are the population most likely to utilize anti-doping services to search for information about whether healthcare products contain substances prohibited in sports. Approximately 50% of prohibited substances in inquiries are from category S6, this might contribute to that substances listed in this category are often used for the treatment of common cold and Covid-19 symptoms. Inquiries about traditional Chinese medicines and nutritional supplements products have a higher percentage containing prohibited substances than western medicines. This may be attributed to the complexity of the composition, manufacturing process, and source material within products of the above two categories.

ANALYSIS OF THE COMPETITION PATTERN OF CHINESE COLLEGE STUDENTS TAEKWONDO COMPETITION IN 2022

SUN, J.

CHINA UNIVERSITY OF GEOSCIENSE

INTRODUCTION: Taking the winning data of Chinese college students taekwondo competition in 2022 as a sample, this paper analyzes and summarizes the geographical distribution of the winning schools, the proportion of winning gender, the difficulty of winning the small events, and the participation proportion of each group, and explores the current competitive pattern of Chinese college students taekwondo competition, with a view to providing a certain reference basis for the future development of Chinese college students taekwondo project from a macro perspective.

METHODS: Literature Method, Mathematical Statistics method, Logical Analysis Method

RESULTS: 1. The competition difficulty of individual project is higher than that of group project

2.The competition difficulty of grade Poomsae is higher than that of Dan Poomsae

3. The award-winning degree of economically developed regions is higher than that of other regions

4. The winning ratio of men and women is similar

CONCLUSION: The popularity of taekwondo in Chinese universities is very high. A total of 129 universities in 24 provinces participated in the 2022 Chinese college student taekwondo competition. The participants are mainly from South China, Central China and East China. The degree of regional economic development is related to the number of participants and the level of athletes skills.

ADDITIONAL MEASURES IMPROVE HRV BASED VENTILATORY THRESHOLD ESTIMATION ACCURACY COMPARED TO STATE-OF-THE-ART DFA-A1 ALGORITHM

ERONEN, T., LIPPONEN, J.A., HYRYLÄ, V., TIKKANEN, H., TARVAINEN, M.
UNIVERSITY OF EASTERN FINLAND

INTRODUCTION: Short-term Detrended Fluctuation Analysis scaling exponent (DFA-a1), a parameter of non-linear heart rate variability (HRV) analysis, has been used to determine organismic transition zones (aerobic and anaerobic threshold) during exercise. DFA-a1 has shown good agreement with traditionally used ventilatory thresholds (VT1 and VT2) (1). We hypothesized by adding meaningful measures to the DFA-a1 algorithm we could improve threshold determination.

METHODS: Physically active individuals (n=64, age range 20-50) performed an incremental cycle ergometer cardiopulmonary exercise test (CPET) with inter-beat interval (RR) measurements. Kubios VT estimation algorithm (VT-algorithm) is based on instantaneous values or heart rate (HR) in relation to individual HR reserve, respiratory rate (RF), and fractal behavior of HRV measured by DFA-a1. HR reserve was obtained by subtracting a fixed 60 bpm resting HR from the maximal HR achieved during the CPET. The RF was derived from beat-to-beat RR data. DFA-a1 and Kubios VT-algorithm were used to evaluate HR and oxygen uptake (VO2) on ventilatory thresholds (VT1 and VT2). The true VTs were evaluated from the CPET by an exercise physiology specialist.

RESULTS: On average the VO2 at the true, DFA-a1, and VT-algorithm derived ventilatory thresholds were 1.74, 2.00 and 1.89 l/min (VT1) and 2.40, 2.41 and 2.40 l/min (VT2), respectively. Correspondingly, average HRs at the true, DFA-a1, and VT-algorithm thresholds were 141, 151 and 142 bpm (VT1) and 169, 168 and 170 bpm (VT2), respectively. When compared to the true thresholds, the error (bias ± standard deviation of error) of the DFA-a1 thresholds were -0.26±0.41 l/min or -10±16 bpm at VT1 and 0.00±0.34 l/min or 1±10 bpm at VT2, whereas the error of the VT-algorithm were -0.15±0.28 l/min or -1±11 bpm at VT1 and 0.01±0.20 l/min or -1±7 bpm at VT2.

CONCLUSION: HRV based VT determination algorithms provide an accurate estimation of ventilatory thresholds to get an insight into training zones, internal loading, and metabolic transitions during exercise without laboratory equipment. The Kubios VT-algorithm, which considers instantaneous HR and RF in addition to DFA-a1, provided higher accuracy for VO2 and HR values for both VT1 and VT2. Our findings suggest that inclusion of instantaneous HR and RF values in the VT estimation minimizes the limitations of the DFA-a1, which include instability of the estimate and possible need to individually adjust the DFA-a1 threshold values based on training status. However, using Kubios VT-algorithm is currently limited only to post-session evaluation and does not give insights to evaluation of systemic internal loading during exercise.

COMPARISON OF GAME VARIABLES IN THE MAIN EUROPEAN RINK HOCKEY LEAGUES

ARBOIX-ALIÓ, J.1,2,3, TRABAL, G.4, AGUILERA-CASTELLS, J.1, MIRÓ, A.1, FORT-VANMEERHAEGHE, A.1,2,5, BUSCÀ, B.1
1FPCEE BLANQUERNA RAMON LLULL UNIVERSITY , 2FCS BLANQUERNA RAMON LLULL UNIVERSITY ,3FC BARCELONA, SPORT PERFORMANCE AREA . 4DEPARTMENT OF SPORTS S

INTRODUCTION: Performance analysis appears to be widely accepted by players, coaches and sports scientists as useful feedback in the coaching process to achieve better results (Liu et al., 2016). Rink hockey, also known as roller hockey or hardball hockey, is not an exception, and, lately, the number of studies about this sport has grown considerably (Arboix-Alió et al., 2023). However, although it has been studied in other sports, there are few data regarding the comparison of game variables according to the main European rink hockey leagues. Therefore, the aim of this study was to compare the rink hockey game variables in the three top national championships of Spain, Portugal and Italy.

METHODS: A sample of 1,665 matches corresponding to the Spanish League: OK Liga (n = 654), Portuguese League: Primeira Divisao (n = 497), and Italian League: Serie A1 (n = 514) played between the 2018-2019 and 2020-2021 seasons was analyzed. Comparisons were made using an analysis of the variance (ANOVA) followed by Bonferronis post hoc multiple comparison tests. Additionally, the t-Student test was used to compare each variable according to match location.

RESULTS: Results showed that OK Liga was the championship with the fewest goals per game and Serie A1 was the championship with higher goals ($p = 0.001$, $\eta p2 = 0.217$). In Primeira Divisao there were more individual set-pieces (penalties and free direct hits), team fouls and cards, and a higher percentage of individual set-pieces' goals with respect to total goals. In the three championships, the performance variables associated with the victory (total goals, goals from individual set-pieces, team fouls and cards received) were favorable to home teams.

CONCLUSION: The analysis of the match variables can provide valuable information to help coaches and practitioners to better understand the rink hockey game dynamics. Additionally, these findings could help staff teams to prepare training sessions based on the specificity of a particular competition or simulate different scenarios.

PHYSICAL QUALITIES AND THEIR RELATIONSHIP TO MATCH PERFORMANCE IN FEMALE YOUTH BASKETBALL PLAYERS.

THEOS, A., NILSSON, R., LINDBERG, A.S., HANGASJÄRVI, W.

UMEÅ UNIVERSITY

INTRODUCTION: Basketball is a physically demanding sport known for intermittent high intensity efforts in a combination of movements like jumping, sprinting, repeated accelerations, and decelerations in different directions (1). The concept of evaluating and predicting future match performance is central to planning and prescribing individualized training programs (2).

Purpose

The purpose of the present study was to identify the physiological variables that are of significance for basketball players' performance capacity during basketball games.

METHODS: Thirty-six female basketball players (age: 17.2 ± 0.9 years; body height: 1.80 ± 0.06 m and body weight: 72.5 ± 5.9 kg) were tested according to a test battery called Fysprofilen (https://fysprofilen.se/sv/default.aspx). Physical tests were conducted at the end of the precompetitive phase. Match performance was assessed by analyzing the four initial games of the regular season and by calculating the effectivity score for each player. Data were analyzed with the use of Principal Component Analysis (PCA) and Partial Least Squares Projection to Latent Structures (PLS).

RESULTS: No significant relationships were observed between physical qualities and basketball match performance. Goodness of fit (R2Y) explained 29% of the variance in match performance. Goodness of prediction, judged via cross-validation, (Q2Y= 0.12) indicated that physical characteristics and physical test results had poor predictive ability on future performance in female youth basketball players.

CONCLUSION: Performance on the basketball court is dependent on physical, technical, tactical, and psychological factors (3,4). The model's poor predictive ability highlights the importance of treating players' physical qualities cautiously especially when it comes to predicting match performance.

NEURAL CORRELATES OF SPORT-SPECIFIC SPATIAL ANTICIPATION: A SYSTEMATIC REVIEW FOR FUTURE APPLICATION OF NEUROPHYSIOLOGICAL METHODS WITH ENHANCED ECOLOGICAL VALIDITY

ASAMOAH, J.

UNIVERSITY OF HAMBURG, INSTITUTE OF HUMAN MOVEMENT SCIENCE

INTRODUCTION: In sports, the anticipation of actions is essential and correlates with sports performance (Nadin, 2015). Experts outstanding ability to anticipate is based on long-term motor training that influences the human brain (Makris, 2014). To date, the neural correlates that explain the underlying processes contributing to successful anticipation in sports reveal inconsistencies (Smith, 2016). Therefore, this systematic review aims to examine the feasibility of quantifying sport-specific spatial anticipation (SSSA) via different neurophysiological methods, to elaborate on specific markers and brain areas reflecting anticipation processes, and to develop methodological adaptations regarding future research and analysis.

METHODS: A literature search was performed in PubMed/MEDLINE, Web of Science, and PsycINFO published until December 2021. Included were neurophysiological studies quantifying the neural activity of expert athletes and control participants during a video-based SSSA task recorded from the first-person perspective. Quality evaluation was assessed using the quality assessment tool provided by the National Institutes of Health.

RESULTS: The review includes ten studies involving 370 participants. Average methodological quality is rated as fair. Selected methodological approaches comprise transcranial magnetic stimulation (TMS), functional magnetic resonance imaging (fMRI), and electroencephalography (EEG) in five different sports. All studies reveal expertise-related neural alterations during SSSA associated with the action observation network (AON) and adaptational performance monitoring processes. However, results vary in significance, causing some methods to be more appropriate for quantifying SSSA than others. In addition, there are deviations between experimental task demands and the requirements of natural environments.

CONCLUSION: This review indicates expertise-related neural alterations during SSSA extend beyond brain regions of the AON and are best quantified via fMRI and EEG. However, due to the restrictions on subjects' mobility during neurophysiological assessments along with simplified motor responses, it is questionable whether these approaches can reflect real-world scenarios (Mann et al., 2013). Based on included studies and recent research in exercise neuroscience (Chang et

al., 2022), methodological considerations for future research are proposed, including the integration of mobile EEG and time-frequency analysis for quantifying SSSA.

AIX MARSEILLE UNIV, CNRS, ISM, MARSEILLE, FRANCE <1> / UNIV GUSTAVE EIFFEL, COSYS-PICS-L, F-77454 MARNE-LA-VALLÉE, FRANCE <2> / UNIV RENNES, INRIA, M2S - EA 7470, RENNES, FRANCE <3>

INTRODUCTION: The 4x100 m relay is a very demanding sport as performance depends on the ability of athletes to run at the highest possible speed of course, but also and above all to pass the baton at a high speed in a constrained space. The coordination between runners is one of the main determinants of performance and requires highly developed anticipation skills in athletes. Indeed, success presupposes for the receiver to pick-up information early on their running partner to be able to initiate their race at the right time. In this context, the go-mark's placement on the ground is supposed to help receivers to initiate their run at the right time (i.e., when the partner passes over of the go-mark). The ambition of the present study is twofold. The first one is to better understand the perceptual-motor mechanisms allowing athletes to successfully perform this highly constrained synchronization task. The second one is to analyze the way expertise shapes the implemented mechanisms.

METHODS: The participants were equipped with a virtual reality headset to be immersed in a virtual stadium at the receiver's position. Three groups were formed according to their level of expertise: beginner, intermediate (regional level) and expert (national/international level). They were instructed to initiate their race when the avatar of their partner, who could arrive in a straight line or in a bend, passed over the go-mark. They performed 3 blocks of 10 trials (5 trials per condition). Their perceptual-motor strategies have been characterized according to several levels of analysis: the timing error, the temporal sequence of remarkable events (athletes preparatory movement initiation, end of taking information on the avatar, initiation of the race...) and the information sampling strategies employed.

RESULTS: The results revealed that the strategies implemented depended on the level of expertise: the timing error was lower for experts and performance was more stable. Interestingly, the time sequence of the remarkable events was more efficient for the experts, reflecting the importance of the movement preceding the initiation of the race in the process of anticipation. In the same way, the analysis of the eye tracking data also revealed specific strategies for taking information according to the level of expertise, with experts spending more time scrutinizing the most information-rich areas.

CONCLUSION: Taken together, these results provide a first insight regarding the effect of expertise on athletes anticipatory behavior during the initiation of the race while approaching the partner. Even if new studies are necessary to provide more information about the involved mechanisms, our study already underlines the close links between perception and action in the anticipation process of experts and the extreme sophistication of the implemented mechanisms.

PERFORMANCE EVALUATION OF THE 2022 FIFA WORLD CUP TEAMS USING THE MEASURE OF SPATIAL ENTROPY OF SUCCESSFUL PASSES

XIONG, X., CUI, Y., DENG, K.

BEIJING SPORT UNIVERSITY, BEIJING 100084

INTRODUCTION: In recent years, network science has received increasing attention from the research community to analyze players' performance in team sports. Most studies have focused on analyzing the passing network using various measures of network centrality while ignoring the spatial distribution of passes. The concept of spatial entropy is defined as a measure of the distribution of different elements within a grid area, and it is a direct measure of the level of complexity or disorder of spatial structure. The aim of this study is to evaluate passing performance of players from different positions at the 2022 FIFA World Cup through the measure of spatial entropy.

METHODS: First, the event data of all 64 matches during the 2022 FIFA World Cup provided by Opta are processed to extract the spatial coordinates of 55887 successful passes. Next, the average spatial entropy of successful pass coordinates is calculated separately for goalkeepers, defenders, midfielders, and forwards. Here, we calculate the spatial entropy by dividing the average nearest neighbor distance by the expected average nearest neighbor distance. The average nearest neighbor distance is the average of the distances of all successful passing points on the pitch and other successful passing points that are closest to each other. The expected average nearest neighbor distance is equal to half of the square root of the area of the pitch divided by the number of successful passes.

RESULTS: The average values of spatial entropy of successful pass coordinates are 0.32, 0.77, 0.79 and 0.78 for goalkeepers, defenders, midfielders and forwards respectively. Among all teams, Senegal presents the highest spatial entropy of 0.73 per game and Spain has the lowest value of 0.52. Serbian goalkeepers show the highest average spatial entropy of

0.56, and Saudi Arabia has the highest value of 1.10 for defenders. Brazilian midfielders own the highest average spatial entropy of 0.95; while Japan, which upsets Spain and eliminates Germany, has the highest average spatial entropy of 1.16 for its forwards.

CONCLUSION: The novel findings of this study are that, in the 2022 FIFA World Cup, (I)the goalkeeper passes have the least value of spatial entropy, which is consistent with the finding of a previous study on 2017-2018 La Liga; (II) the defender, midfielder and forward passes have similar values of spatial entropy, mainly because they are all highly involved in the games and have greater randomness in their range of movement on the pitch; and (III) the Spain team has the least average value of spatial entropy of successful passes among all teams, which may be related to the fact that they have the highest number of passes per game. In the following study, we will focus on the effect of spatial entropy of players' pass coordinates on other match behaviors and even the outcomes of games.

PERFORMANCE PROFILES & PEAK AGE OF ADOLESCENT TRIPLE JUMP CONTESTANTS AT YOUTH OLYMPIC GAMES

NIESSEN, M., ROST, M., HARTMANN, U.

UNIVERSITY LEIPZIG - FACULTY OF SPORT SCIENCE

INTRODUCTION: A decade ago the summer edition of the world-spanning under 18 yrs of age (u18) competition, the Youth Olympic Games (YOG) were introduced. In recent years there is a rising scientific interest regarding the nonlinear and highly variable developmental trajectory of performance in adolescent athletes due to the individual biological adaptations as a result of growth, maturation, training load & strain, and aging. Aim is to quantify age of peak performance (APP) and improvements over the preceding years of athletic career (AC) in former YOG athletics contestants in the complex movement and physically demanding triple jump (TJ) according to athlete performance level, sex, and age group.

METHODS: Data were extracted from a renowned database (www.worldathletics.org) through 10/2021. Competition results of 29 female TJw & 31 male TJm qualifiers & medallists at YOG (2010, 2014) and their performance profiles of legally achieved outdoor season bests were empirically analysed. Comparisons of selected age groups & peers, AC duration and last performance, personal best (PB) and APP as well as participation & success at further champs were made.

RESULTS: Contestants achieved YOG results of 85.7±3.0% (TJw) & 86.9±4.1% (TJm) relative to world's u18 best; meanwhile PB developed to 84.1±3.6% (TJw: 12.32-14.35m) & 86.8±5.1% (TJm: 13.97-17.18m) relative to actual world record. APP of YOG competitors is sig. lower (Kruskal-Wallis r=0.50-1.04) compared to peers & all-time best athletes ($X2(4) = 81.65$ (TJw) & 40.04 (TJm), $p \leq 0.001$)), but not sig. different between sex. The average annual improvements were +1.5-6.3% in u18 followed by an increase rate levelling off at -2.0% to +2.0% in juniors (u20 & u23) to seniors (= mostly performance plateau or decline). The attrition rate until 2021 was 68% (22 TJw & 19 TJm). Of the remaining 32%, only 4 athletes achieved medal success in world junior champs, 5 athletes were contestants in senior world champs & Olympic Games so far.

CONCLUSION: Accompanying the accumulation of adolescent competitions one observes a clear shift of APP to younger age (80-86% in u20) as well as shorter AC in YOG TJ contestants and therefore a need of a deeper knowledge on possibilities/limits of adaptation & training in adolescent TJ athletes. Jump performance in elite TJ is determined by the balance among velocity, force and movement technique which requires patience to continually adapt. Derived findings should provide further approaches on long-term, more holistic development pathways and strategic training planning (less is more; quality prior quantity) with enough attention on the biological domain (e.g. load & recovery, adaptation time, and enhanced vulnerability to injury/illness during biological maturation). Identification & documentation of qualitative factors (nature & nurture) should strengthen a viable, flexible, healthy & sustainable pathway from adolescent to senior TJ success.

TEXT NETWORK ANALYSIS USING RESEARCH KEYWORDS IN FOOTBALL ARTICLES BETWEEN 1948 AND 2022

KIM, J.

MIDDLESEX UNIVERSITY

Text network analysis using research keywords in football articles between 1948 and 2022

Jongwon Kim1, Miyoung Lee2, Chunghyeon Na2, Minah Park2 & Yohan Kim2

1London Sport Institute, Faculty of Science & Technology, Middlesex University, London, NW4 4BT, UK

2Department of Sports Sciences, Kookmin University, Seoul, Korea

INTRODUCTION: Football is the sports enjoyed and loved by the world's largest population and has become a culture beyond sports. There have been many peoples efforts in various fields before football developed. Among them, many researchers in the academic field have conducted various research for the development of football for a long time. This study aimed to identify research topics in football papers and analyze changes of research trends by periods.

METHODS: The used research was collected from 'Web of Science' and a total of 36,256 football articles between 1948 and 2022 were analyzed. The used keywords went through refining process such as using only nouns, synonym, thesaurus, independent word, etc. for network analysis. Cyrams Netminer 4.0 software was used for the network analysis. Centrality analysis was conducted by extracting only words corresponding to the top 2% of the research main topics, and degree centrality and eigenvector centrality were calculated.

RESULTS: The most frequently mentioned research keywords were 'injury', 'performance', 'club' and 'training'. The keyword 'performance' showed the highest degree centrality(0.294) and 'world' and 'cup' showed the highest eigenvector centrality. The 7 clusters were formed regardless of ranking from centrality analysis(modularity=0.662) and each cluster could be

understood as 'performance', 'analysis', 'injury', 'training', 'research sample', 'experiment' and 'exercise' respectively. As of 2010, the keyword with the highest degree centrality value changed from 'injury'(prior to 2000 and 2000s) to 'performance'(2010s and 2020s). Meanwhile, the keyword with the highest eigenvector degree value changed from 'injury'(prior to 2000) and 'world'(2000s) to 'cup'(2010s and 2020s).

CONCLUSION: The number of published football papers rapidly increased every year. The majorities of football research papers were physical injury related to knees, ankles, ligaments and experimental from university in the past, whilst recently many papers related to applied football field such as performance, analysis, clubs and World Cup have been published. This paper is meaningful in that it could be a basic data by grasping the trends of all football articles published over the last 75 years.

This study was supported by National Research Foundation of Korea [NRF-2021R1A2C2013651].

PACING PATTERNS IN THE LAST DECADE OF WORLD ROWING CHAMPS AND OLYMPIC GAMES

GARCÍA-GONZÁLEZ, P., JAENES, J.C., ALARCÓN, D., ARENILLA, M.J., ORTÍZ-VELASCO, S., WILCZYNSKA, D., GENE-SANAHUJA, P.

UNIVERSITY PABLO DE OLAVIDE, UNIVERSITY OF GDANSK.

INTRODUCTION: Pacing strategies in rowing are the varied strategies which rowers use to distribute their energy and efforts throughout 2000 meters. The Olympic distance lasting between 5'30"-7'30" (Boillet, 2022). Rowing competitions are 6-line elimination races with boats navigating backwards so an early lead allows the leader to monitor the progress of opponents (Astridge 2022). Given this particularity the most common rowing pacing patterns is parabolic (Muehlbauer, 2011) described as reversed Jshaped (Mentzoni, 2021). Taking this into consideration we examinate the last decade of rowing to identify the common pacing and tactics as an important info for coaches and rowers.

METHODS: Rowing times of each 500m sector of the 6 Finalist boats (1-6th) of each modality were registered from World Rowing Championships (WR) (2010-2022) and Olympic Games (2012-2020).

RESULTS: Mean rowing times at finals for single sculls were (men (M): 1:40,16; 1:43,84; 1:44,15; 1:42,32 & women (W) 1:51,24; 1:54,58, 1:55,30, 1:55,04) for doubles scull (M: 1:32,7; 1:35,6; 1;35,9; 1:34,1 & W 1:42,4; 1:45,5; 1:45,8; 1:44,5), lightweight double scull (M: 1:35,4; 1:38,1; 1:39,0; 1:37,2 & W: 1:45,8; 1:49,0; 1;48,6; 1:46,5), pairs (M: 1:35,9; 1:39,8; 1:40,0; 1:38,9 & W: 1:45,9; 1:49,8; 1:49,7; 1:48,3) fours (M: 1:29,0, 1:31,9, 1:32,6, 1:30,4 & W: 1:37,1, 1:41,2, 1:42,1, 1:39,3) quads (M 1:26,4, 1:28,6, 1:29,1, 1:27,4 W 1:36,1, 1:39,3, 1:39,7, 1:38,0) & eights (M 1:21,4, 1:24,0, 1:24,6, 1:22,4 W 1:30,2 1:32,8, 1:33,4, 1:31,7).

CONCLUSION: Results shown that the most common pacing strategy for each modality at the WR & Olympic Finals was the J-shaped as mentioned before, being the first 500m of the race the fastest one, and the last 500m the second. Central sectors (2n and 3rd 500m) showed similar times having the ability to maintain this speed during the whole race will produce a more even rowing times as happened in Tokyo 2021 (Kleshnev, 2021).

TACTICAL ANALYSIS IN OLYMPIC WRESTLING: A MARKOV CHAIN APPROACH

MOUSSA, I., DRIDER, A., VITEL, V., SCHORTGEN, A., LEROY, P., SAULIERE, G., GOYALLON, T., FRUCHARD, B., VAZEILLES, P., REVERET, L., TOUSSAINT, J.

IRMES - INSEP - UNIVERSITÉ DE PARIS-CITÉ, INRIA - LJK - LOKI - ZENITH, FÉDERATION FRANCAISE DE LUTTE

INTRODUCTION: In sport, the concept of tactics has been defined by several authors as the actions taken by players to adapt to dynamically changing match situations. The delicate competitive balance between two athletes is broken as soon as the former scores a point. This change in the status of the fight inevitably leads to changes in the tactics, style of play and psychological state of the athletes [1]. Therefore, the objective of the study was to develop a tactical model of wrestling matches in order to determine the probability of the outcome as a function of a given score, the time remaining before the end of the match and the associated co-variables throughout a match.

METHODS: The score, time, weight class, round of competition and wrestling style were automatically annotated from 5280 bouts from the international wrestling circuit. In order to determine the probability of evolution and outcome of the fight, a multi-state Markov model was calculated. The transition intensities were calculated from the Nelson-Aalen estimator. The evolution probabilities of the fight were calculated at each moment of the fight thanks to the Aalen-Johansen estimator.

RESULTS: The model developed makes it possible to understand the mechanisms of score transitions during a fight. It also allow to estimate outcome of fight according to the current score. All the probabilities of score changes and combat outcomes were calculated for each possible score difference and grouped into a matrix. Taking the example of a 4-point gap, regardless of the style of wrestling, this advantage lead the fight towards victory (40%). And this tend to be accentuated if this gap occurs late in the fight (90% in the last minute).

CONCLUSION: This work presented a Markov chain approach for better understand the tactical evolution of a wrestling match. Although the results are promising, we see opportunities for several improvements, though the majority can only be implemented with a more detailed dataset. In the near future, we will be able to add the techniques associated with each point scored as well as the area on the combat surface. The current model will be able to evolve towards a semi-Markovian model inhomogeneous in time [2], taking into account the time spent in a state, and parametric by testing several laws a priori.

PERFORMANCE ESTIMATION BASED ON BIOMETRIC PARAMETERS

BARLIER, K.

INSEP

INTRODUCTION: Estimating individual sporting potential is a decision aid for staff and federations, especially in rowing. One way to estimate the performance is to estimate the relationship between age and performance. Several equations were designed to model this relationship. Dan H. Moore [1] proposed in 1975 the Moore's equation and more recently G. Berthelot [2] and al. published in 2019 an integrative modeling approach to the age-performance relationship (IMAP), but these approaches use only age to estimate performance. We aim to include biometric parameters like weight in the age-performance relationship in rowing to improve the accuracy of the estimation of athletic potential.

METHODS: The results and weight of French athletes aged 14 to 68 years in 2000-meters ergometric tests from 2002 to 2023 for men and women were used. The best performance by age for men and women was modeled using least squares method with the Moore's equation with an added coefficient specific to the weight representing its impact on performance. The adjusted R-squared of the Moore's equation and its weight-aware version were compared in order to determine whether or not the addition of weight in performance estimation is relevant.

RESULTS: For men, the adjusted R-squared is 0.9024 for the Moore's equation considering the weight against 0.8942 for the Moore's equation. The estimated peak age is 23.7 years for the weight adjusted equation against 23 years. For women, the Moore's equation taking into account the weight has an adjusted R-squared of 0.7221 against 0.7220. 19.30 years is the estimated peak age for the Moore's equation considering the weight against 20.32 years for the other one.

CONCLUSION: For men, adding weight to the Moore's equation increases the adjusted R-squared. For the women, the adjusted R-squared of both equations are similar to each other. The addition of weight reduced the uncertainty in the estimation of men ergometric test results.

Training and Testing

THE EFFECTS OF SHORT-TERM HIGH-INTENSITY INTERVAL TRAINING VS. GENERAL INTERVAL TRAINING IN RUGBY PLAYERS

LIU, C.M.

CHANG JUNG CHRISTIAN UNIVERSITY

INTRODUCTION: High-intensity interval training (HIIT) is one of the training methods which designed to optimize the athletic performance through variety exercise type with high exercise intensity, less recovery time (interval), and several bouts. It has been found varying HIIT doses were effective, but there is no indication of the different effects between the short term HIIT and general interval training. The purpose of this study was to investigate the different effects of short-term HIIT and general interval training on speed, power, agility, and endurance of rugby players.

METHODS: Thirty-two trained male college rugby players (age: 20.66 ± 1.63 years; height: 174.69 ± 5.41 cm; body mass: 79.41 ± 13.15 kg) participated in this study. Written informed consent was obtained from all the subjects before the experiment begin. The subjects were randomly divided into the HIIT group (HG, n=18) and general interval training group (GG, n=14), respectively. The HG took twice a week of high-intensity interval training for 3 weeks and the GG took the general interval training as the original schedule. The Yo-Yo IR2 test, counter-movement jump, 30 m sprint and T test of subjects were measured before (pretest) and after (post test) training, and after the tapering phase which will be the fourth week from the begin of training (retest). Two-way mixed-design ANOVA and LSD post-hoc procedures was used in this study. Significance was set at $P < .05$.

RESULTS: According to the analysis results of speed, there is no difference both in main effects [group: $F(1, 30) = 1.430$, $p = .241$, ES = .048; time: $F(1, 49) = 1.263$, $p = .267$, ES = .042)] and interaction effects [$F(1, 49) = 2.617$, $p = .112$, ES = .087]. We found similar result in power, there is no difference both in main effects [group: $F(1, 30) = .508$, $p = .481$, ES = .017; time: $F(2, 60) = .844$, $p = .435$, ES = .028)] and interaction effects [$F(2, 60) = .786$, $p = .460$, ES = .026]. The results of agility showed that significant difference were observed in time factor ($F(2, 60) = 52.563$, $p < .001$, ES = .653). Post-hoc test revealed the results of post test (10.38 ± 0.54 s) is better than retest (10.68 ± 0.59 sec), and retest is better than pretest (11.39 ± 0.58 sec). Significant effect was found in the interaction of results in endurance [$F(1, 44) = 6.198$, $p = .017$, ES = .207], and the simple

interaction effect showed the results of pretest (1595.56 ± 250.32 m) and retest (1687.78 ± 323.88 m) are both better than post test (1492.22 ± 218.35 m) in HG.

CONCLUSION: we conclude that there is no significant difference in short term training effects between HIIT with general interval training. Moreover, both two types of short term interval training can only maintain the exercise ability in this study. While HIIT is adopted as a training session, the training-induced fatigue should be considered. However, the advantages of HIIT in time saving and high intensity, which could be the option of tapering strategy.

COMPARASION OF PHYSIOLOGY CHARACTERISTICS OF DIFFERENCE POSITION IN ELITE MALE HANDBALL PLAYERS

XIAOBIN, W.

BEIJING SPORT UNIVERSITY

INTRODUCTION: Handball players have several field positions, but the physical abilities of players in different positions may vary and therefore need to be treated differently.

METHODS: 25 elite male handball players (age:22.6±3.7, height: 191.3±6.4cm, weight: 90.9±13.2kg) participated in the study, tested twelve physiological and physical fitness indexes of the players, and compared the differences between different position(goalkeeper, pivot, back and wing) by ANOVA with Bonferroni post-hoc test

RESULTS: There were no difference with height, weight, vertical jump height, 30m sprint, YoYo test, pull-up, 60°·s-1 isokinetic muscle strength test in different position ($p > 0.05$). There were group differences in the 1RM squat and bench press ($p < 0.05$).

CONCLUSION: No difference in height, weight, speed, endurance, explosive power, slow isometric muscle strength between position handball players and there is a difference between the maximum strength of deep squat and bench press. Practitioners can use the result as a reference for training, but should also be aware of the small sample size in this study.

A NOVEL FORMULA USING ENERGY CONTRIBUTIONS TO CALCULATE PURE MAXIMUM RATE OF LACTATE PRODUCTION (PNLA.MAX) DURING AN ALL-OUT ANAEROBIC CYCLING TEST

KIM, Y.

CHA UNIVERSITY

INTRODUCTION: The aim of this study was to compare previous calculating formulas of maximal lactate produced rate (□La.max) and a novel formula of pure □La.max (P□La.max) during a 15-s maximal sprint cycling test (MSCT) and to analyse their correlations.

METHODS: Thirty male national-level track cyclists participated in this study (n = 30). They performed a 15-s MSCT in which anaerobic power output (peak watt; Wpeak and mean watt; Wmean), peak and mean oxygen uptakes (V̇O2peak and V̇O2mean), and maximal blood lactate concentrations (Lamax) were measured. These variables were utilised for different calculations of □La.max and three energy contributions (phosphagen contribution; WPCr, glycolytic contribution; WGly, and oxidative contribution; WOxi). P□La.max calculation considered ΔLa−, timespan until Wpeak (tPCr−peak), and contributed timespan of the oxidative system (tOxi). Other □La.max values without tOxi were calculated using decreased time by 3.5% from Wpeak (tPCr −3.5%) and tPCr−peak.

RESULTS: Absolute (kJ) and relative (%) WPCr indicated higher levels compared to WGly and WOxi. Values of WGly in kJ and % were significantly higher than WOxi ($p < 0.0001$, respectively). The value of □La.max (tPCr −3.5%) was significantly higher than P□La.max and □La.max (tPCr−peak) (0.97 ± 0.18, 0.88 ± 0.13, and 0.85 ± 0.12, respectively; $p < 0.0001$) while □La.max (tPCr−peak) was lower than P□La.max ($p < 0.0001$, respectively). A very high association between P□La.max and □La.max (tPCr−peak) was observed ($r = 0.99$; $R2 = 0.98$). This was higher than the relationship between P□La.max and □La.max (tPCr −3.5%) ($r = 0.87$; $R2 = 0.77$). □La.max (tPCr−peak), P□La.max, and □La.max (tPCr −3.5%) correlated with absolute Wmean and WGly (vs. Wmean: r = 0.48, 0.45, and 0.43; vs. WGly: r = 0.73, 0.70, and 0.61, respectively).

CONCLUSION: P□La.max as a novel calculation of □La.max provides more detailed insights into interindividual differences in energy and glycolytic demands than □La.max (tPCr−peak) and □La.max (tPCr −3.5%). In particular, because WOxi and WPCr can differ remarkably between elite cyclists, implementing those values in P□La.max can therefore establish more optimized individual responses for elite track cyclists.

RELIABILITY OF A NOVEL INDOOR GPS TECHNOLOGY DURING A BASKETBALL EXERCISE SIMULATION TEST

HAMLIN, M.J.1, SMITH, H.K.1, SPRIGGS, N.1, COSKUN, B.2, BIRD, S.P.3, ELLIOT, C.A.1, OLSEN, P.4

1.LINCOLN UNIVERSITY, 2.ERCIYES UNIVERSITY, 3.UNIVERSITY OF SOUTHERN QUEENSLAND, 4.ARA INSTITUTE OF CANTERBURY

INTRODUCTION: Exercise tests used to assess acute and chronic athletic performance need to closely simulate the movement characteristics of players during the actual game or match. Such tests also need to have adequate reliability to ensure changes in performance can be appropriately identified. Therefore, the aim of this study was to investigate the measurement reliability of movement characteristics during a simulated basketball exercise simulation test using novel indoor GPS technology (VX Sport, Omni, Wellington New Zealand).

METHODS: Eighteen regional or national representative basketball athletes (13 males; 20.4 ± 1.3 yr, 185.8 ± 27.5 cm, 87.7 ± 8.0 kg and 5 females; 20.4 ± 1.5 yr, 175.5 ± 7.5 cm, 75.2 ± 6.0 kg mean ± SD) performed two trials (7-8 days apart) of

the basketball exercise simulation test (BEST) on a FIBA-sized basketball court with VXSport Omni devices inserted into custom-made pockets located between thoracic vertebrae T1-T4 in the back of the VXSport Smartvests. Initially, each player completed a standardised movement sequence on an outside field to allow the VXSport unit to calibrate for the players gait cycles and movement patterns before moving inside to the basketball court. Measures taken included total distance and relative distance covered during the test, maximal speed, total number of sprints, total number of jumps, total number of accelerations/decelerations as well as high-intensity accelerations/decelerations (> 3m/s2) and average heart rate. The test-retest reliability was determined by using the typical (standard) error, coefficient of variation (CV) and intraclass correlation coefficient (ICC).

RESULTS: All movement parameters showed reasonably high between-trial ICCs ranging from 0.77 to 0.98. Total distance covered during the test, total number of sprints, total number of jumps, total number of accelerations/decelerations and average heart rate all exhibited low CVs (≤5%), while relative distance, maximal speed, and total number of sprints over 15 km/h had slightly higher CVs (5.8, 7.0, 7.2%). Total number of high-intensity accelerations and decelerations had high CVs (17.8 and 15.6% respectively).

CONCLUSION: The novel finding of this study was that the VXSport Omni unit showed adequate reliability for most movement characteristics measured indoors during an on-court basketball simulation test. This suggests that using GPS units with added micro-technology (accelerometers, gyroscopes, and inertia sensor) can reliably measure most simple movement characteristics in basketball players on indoor courts where satellite coverage is unavailable.

HEART RATE VARIABILITY AND ITS ASSOCIATION WITH TRAINING AND MATCH LOAD IN FEMALE SOCCER PLAYERS

PARPA, K., PALUDO, C.A., MICHAELIDES, M.

UCLAN UNIVERSITY OF CYPRUS

INTRODUCTION: Identifying fatigue and overtraining would be helpful for coaches and athletes as the training load could be modified accordingly. It is, therefore, imperative to have reliable and valid indicators of players' adaptation to training and competitive load. There are several scientifically validated tools currently available for this purpose. Accordingly, the measurement of resting or post-exercise HR variability (HRV) has been suggested to indicate both positive and negative adaptations to training and it can be indicative of the physiological stress and fatigue levels during and after training or matches. Hence, we conducted this pilot study to (i) analyse changes in HRV as indicated by the root mean square of successive differences (rMSSD) during four microcycles of competition and (ii) observe the relationship of HRV with training and match load.

METHODS: Data from nine female soccer players (age 21±6.18 years, height 164.33±5.52 cm, weight 53.79±6.40 kg) was analysed for this study. Resting HRV (rMSSD in ms) was measured daily upon waking using the validated HRV4Training app, while the training load was acquired after each training and match. The session RPE method was used for quantifying training load, which involves multiplying the athlete's RPE (on a 1–10 scale) by the duration of the session (in minutes). The Spearman rank test (rho) was used to assess the relationship of HRV with training and match load measures.

RESULTS: No significant changes in HRV were identified between the four microcycles of competition. In addition, results indicated significant moderate associations in HRV between MD (match day) and MD-3 (three days before match) (r =0.41) as well as MD and MD-4 (four days before match) (r =0.44). HRV of MD-1 and MD-2 were also significantly correlated (r = 0.62). Lastly, the HRV of MD-4 was significantly correlated with MD-3 (r =0.55). Regarding the training load, MD-3 and MD-4 were significantly positively associated (r =0.51), while significant negative associations were indicated between the training load of MD and MD-2 (r =-0.34), MD-1 and MD-2 (r =-0.61) as well as MD-2 and MD-5 (r =-0.76). Lastly, no significant associations were indicated between HRV and training load despite the aforementioned associations.

CONCLUSION: The results indicate that HRV is sensitive to changes in stress or fatigue, but in general, athletes should be considering HRV in relative terms and not as an outcome. Therefore, the goal should be to maintain a stable HRV and look at relative changes over time so that they can balance stressors, regardless of the absolute values of HRV. Conclusively, evaluating HRV during training and match days can aid in better planning of the training load as well as avoiding negative chronic responses, but the interpretation of the HRV should be done with caution especially considering the great variability of rMSSD values that are obtained through the apps and wearables.

A COMPARISON OF OVERHAND AND SIDE-HAND THROW TECHNIQUES IN HANDBALL THROW: EXPLORING THE EFFECT OF PHYSICAL CONSTITUTION AND STRENGTH ON THROWING PERFORMANCE

MAEDA, K.1, KATO, T.2, MIZUSHIMA, J.3, MATSUKI, Y.4

1KYOTO UNIVERSITY OF ADVANCED SCIENCE; 2SHONAN INSTITUTE OF TECHNOLOGY;3 TOYO UNIVERSITY; 4TENRI UNIVERSITY

Introduction

The overhand throw is widely used to assess the throwing ability in handball throw, which is part of a physical fitness test in Japan. However, individuals with limited physical constitution or strength may struggle to perform the proper kinematic chain known as the "whip-like motion" properly and grip the ball, leading to reduced overhand throwing distance. This underscores the limitations of assessing throwing ability solely through the overhand throw. This study explores the side-hand throw as an alternative throwing technique and classifies throwers based on their performance using both techniques. Additionally, comparisons will be made between groups in terms of physical constitution and strength.

Methods

Thirty-nine college students participated in this study. Each participant performed two trials of handball throws using both side-hand and overhand throwing techniques, and the best results were used for analysis. The order of the techniques was randomized. Physical constitution and strength were measured using following variables: height, weight, arm span, shoe size, hand length, hand width, arm length, leg length, grip strength, and standing long jump. Participants were classified using cluster analysis based on the ratio of side-hand to overhand throw performance. An unpaired t-test was used to compare the measurement variables, and Cohen's d was calculated. The significance level was set at $p < 0.05$.

Results

Two groups of throwers were identified: one group had significantly lower overhand throw records compared to side-hand throw (SHT), and the other group showed little difference in their throwing records between the two techniques (OHT). The OHT group had significantly higher records for both overhand throw and weight compared to the SHT group. Although there were no significant differences between the groups, the effect sizes for grip strength of both hands were approximately medium (right: $d = 0.47$, left: $d = 0.55$).

Discussion

The results of this study suggest that individuals who struggle with overhand throw can still achieve some distance with side-hand throw. Although only weight showed significant differences, it is an indicator of muscle strength and the effect sizes for grip strength of both hands, a measure of muscle strength, were approximately medium. Previous research has found a relationship between muscle strength and ball speed in baseball pitching (1). These studies suggest muscle strength affects the overhand throw performance. In side-hand throw, participants can throw the ball without using "whip-like motion" and gripping the ball, making the motion simpler than overhand throw and less reliant on physical attributes. These findings indicate that individuals may benefit from a throwing technique that takes into account their physical constitution and strength.

PHYSICAL FITNESS COMPARISON BETWEEN PROFESSIONAL SOCCER PLAYERS AND U17 ELITE YOUTH

MICHAELIDES, M.

UCLAN CYPRUS

INTRODUCTION: According to the literature, the success rate of a youth footballer, already at the highest youth level, becoming a professional soccer player is minimal. However, general athleticism is undeniably a major factor in a successful transition to senior soccer. Therefore, comparing these youth athletes athleticism to those already at the highest standards would provide an inside into the fitness parameters needed.

METHODS: Fifty-two professional male football players (pro) (age =27.37 ± 5.57 years) and forty-four youth players (age =16.20 ± 0.80 years) performed a series of laboratory tests to assess anthropometry, lower body strength, cardiovascular endurance, lactate curve profiling and leaping ability.

RESULTS: Independent t-tests demonstrated that the pros were significantly taller 179.77 ± 6.72 cm and heavier 77.11± 6.54 kg than the youth 175.97 ± 5.84cm and 66.98 ± 6.19 kg, respectively. The 7-site skinfold method demonstrated no significant difference in body fat percentage (BF%) (10.5±3.28 pro vs 9.83±3.01 youth). The remaining sites were not significantly different. Pros demonstrated greater leaping ability on both the squat jump (39.62±3.83 vs 33.68±4.73cm) and the countermovement jump (42.52±3.84 vs 36.86±4.73cm). The quadriceps and hamstrings strength measured on the isokinetic device at a speed of 60 degrees /sec demonstrated that both muscle groups were significantly higher in pros. The pro group ran significantly longer on the incremental running test (18.08±1.83 vs 17.19±1.86 min). Mixed design ANOVA was used to evaluate the aerobic fitness characteristics within the pro and youth groups and between them at each of the increments. The Greenhouse-Geisser analysis demonstrated that the was a significant effect of within-group lactate values ($F(5, 125) = 723.3$, $p<0.001$, $\eta2=0.92$) and a significant interaction of playing standards ($F(5, 125) = 3.30$, $p<0.05$, $\eta2=0.05$). The pairwise comparison demonstrated that after the first running increment, the youth experienced significantly greater production of lactates in all the remaining increments. Similarly the VO2 values had a significant within group VO2 values ($F(5, 125) = 722.59$, $p<0.001$, $\eta2=0.91$) and a significant interaction of playing standards ($F(5, 125) = 3.23$, $p<0.05$, $\eta2=0.04$). The pairwise comparison demonstrated that the youth experienced significantly greater VO2 values in all the remaining increments. Thus, the VO2 max of the youth was significantly higher, 61.12±5.57 ml/kg/min, than the pros, 55.32±6.76 ml/kg/min.

CONCLUSION: The findings of this study demonstrated the superiority of pro footballers compared to youth U17 in all laboratory fitness parameters. The results indicated that cardiovascular fitness depended mainly on lactate kinetics rather than the VO2 max when comparing the two groups. Furthermore, the most notable difference is lower body strength. Practitioners could use the results in developing targeted programs that would enhance the chances of a successful transition to senior soccer.

ACUTE PHYSIOLOGICAL RESPONSES TO HYPEROXIC HIGH-INTENSITY INTERVAL EXERCISE IN HORSES

MUKAI, K., EBISUDA, Y., SUGIYAMA, F., YOSHIDA, T., MIYATA, H.

EQUINE RESEARCH INSTITUTE, JAPAN RACING ASSOCIATION

INTRODUCTION: High-intensity interval training in hyperoxia has been proposed to enhance exercise performance and aerobic capacity, but its potential efficacy and mechanism are unclear. Therefore, the aim of this study was to determine the effect of breathing hyperoxic gas during high-intensity interval exercise and moderate-intensity continuous exercise in horses.

METHODS: In a randomized crossover study design, seven trained Thoroughbred horses performed four distance-matched treadmill exercise protocols: 1) moderate-intensity continuous exercise in normoxia (FIO2 = 0.21, 6 min at 70%VO2max; N-MICT), 2) high-intensity interval exercise in normoxia (FIO2 = 0.21, 6 × 30 s at 100%VO2max with 30 s recovery; N-HIIT), 3) moderate-intensity continuous exercise in hyperoxia (FIO2 = 0.30, 6 min at 70%VO2max; H-MICT), and 4) high-intensity interval exercise in hyperoxia (FIO2 = 0.30, 6 × 30 s at 100%VO2max with 30 s recovery; H-HIIT). Arterial blood samples were collected during exercise to measure blood gases and plasma lactate concentration. Heart rate during exercise was also recorded. Data are expressed as mean ± SE, and effect of the protocol was analyzed using mixed models ($P < 0.05$).

RESULTS: At the end of exercise, arterial O2 saturation (SaO2) in H-MICT (95.6 ± 0.1%), H-HIIT (95.1 ± 0.2%) and N-MICT (92.4 ± 0.7%) was significantly higher than that in N-HIIT (86.5 ± 1.6%) ($P < 0.0001$). Arterial O2 partial pressure (PaO2) in H-MICT (158.2 ± 1.6 Torr) and H-HIIT (155.1 ± 2.9 Torr) was significantly higher than that in N-MICT (95.1 ± 1.9 Torr) and N-HIIT (89.3 ± 1.3 Torr) ($P < 0.0001$). Heart rate and plasma lactate concentration in N-HIIT (216 ± 3 bpm, 23.6 ± 2.6 mmol/l, respectively) and H-HIIT (214 ± 2 bpm, 19.5 ± 2.6 mmol/l) were significantly higher than those in N-MICT (198 ± 4 bpm, 9.5 ± 2.1 mmol/l) and H-MICT (202 ± 4 bpm, 12.0 ± 2.5 mmol/l) (heart rate, $P = 0.0009$; lactate, $P = 0.0003$). Arterial pH in N-HIIT (7.183 ± 0.032) and H-HIIT (7.195 ± 0.031) was significantly lower than that in N-MICT (7.354 ± 0.021) and H-MICT (7.299 ± 0.031) ($P = 0.0002$).

CONCLUSION: Heart rate, plasma lactate concentration, and arterial pH were not affected by inspired O2 concentration, while SaO2 and PaO2 were maintained even in high-intensity interval exercise when breathing hyperoxic gas. These results suggest that hyperoxic high-intensity interval exercise can enhance O2 delivery to skeletal muscle and can lead to additional stimulus to mitochondrial oxidative capacity.

MULTIFACTORIAL INDIVIDUALISED PROGRAMME FOR HAMSTRING MUSCLE INJURY RISK REDUCTION IN PROFESSIONAL FOOTBALL: A PROSPECTIVE COHORT STUDY

LAHTI, J., EDOUARD, P., MORIN, J.B., FLERES, L., AHTIAINEN, J., MENDIGUCHIA, J.

ARCADA UNIVERSITY OF APPLIED SCIENCES

INTRODUCTION: The aim of this prospective cohort intervention study was to test whether an innovative hamstring injury risk reduction program could further reduce the risk of hamstring muscle injuries (HMI) in professional football settings with ongoing risk reduction efforts.

METHODS: HMI and player exposure were registered prospectively during the two seasons (2019 & 2021) in 5 Finnish premier football league teams. The 2019 season was used as a control (n = 90), while the intervention was conducted in the 2021 season (n = 87). Questionnaires for the coaching staff were also used to better understand the differences between the 2019 and 2021 seasons in terms of HMI risk reduction strategies. Cox regression hazard ratio (HR) was used as the primary analysis to compare seasons, which was adjusted for age, team, team position, body mass, height, and history of HMI. Secondary analysis included adjusting for program compliance.

RESULTS: The seasons were similar in nature, including non-significant differences in match exposure, age, and previous HMI. A total of 20 index HMI were registered during the control 2019 season (average injury per team: 4.8, range: 4-5, injury burden: 15.1) and 16 index HMI during the intervention season (average injury per team: 3.2, range: 1-6, injury burden: 14.5). Average compliance of the intervention program was 50% (CI95%: 38-62). Cox regression analysis showed a non-significant trend toward increased risk of hamstring injuries during the intervention season (HR: 1.35, CI95: 0.68 – 2.66, $p = 0.39$). However, when controlling for total compliance, there was a non-significant trend toward the intervention season reducing the risk of injury (HR: 0.52, CI95%: 0.05 – 5.33, $p = 0.58$). Furthermore, players showing reductions in maximal theoretical horizontal force or knee flexor force between pre-season and mid-season screening measurements had a significantly higher risk of sustaining an HMI later in the season (Risk Ratio: 5.6 – 12.1, $p < 0.05$).

CONCLUSION: The innovative multifactorial and individualized injury risk program was not successful in further reducing HMI risk in a professional football setting with ongoing risk reduction protocols. The program remained feasible as it didn't increase risk, while future research should explore whether increased compliance in a multifactorial and individualized approach can improve the HMI risk outcome.

FATIGUE IN A SHUTTLE REPEATED SPRINT-RUNNING TEST IN MALE AND FEMALE STUDENTS IN A SCHOOL SETTING: A COMPARISON BETWEEN CALCULATION METHODS

TSOUKOS, A., BOGDANIS, G.C.

UNIVERSITY OF ATHENS

INTRODUCTION: It has been shown that 62% of high school students seem to prefer mainly team sports during physical education classes [1]. Repeated sprint ability (RSA) is an important determinant of performance in team sports, and is readily assessed by the shuttle repeated sprint running test [2, 3]. Fatigue in this test may be assessed by different methods, e.g., by calculating the fatigue index (FI), the percent sprint decrement (Sdec) or the slope of performance decrement over the six sprints [4,5]. The aim of the present study was to examine the relationships between FI, Sdec and slope during a shuttle repeated sprint-running test in male and female students in a school setting.

METHODS: Twenty-six adolescent students performed six 30 m sprints with a change in direction of 180o at 15 m, indoors on a non-slippery court. Performance time of each sprint was measured by a timing gate which was set at the start (which was also the end of each sprint). The following methods of fatigue calculation were used: (a) Fatigue index (FI%)=((fastest time – slowest time) x fastest time -1) ·x 100 , (b) percent sprint decrement (Sdec%) = 1 – (Total time x (6 x minimum time)-1) and (c) (slope of the individual performance time decrement over the six sprints using linear regression x fastest time -1)x100. Significance was set at $P<0.05$.

RESULTS: The two-way ANOVA (sex x sprint repetition) showed a significant main effect for sprint repetitions during the shuttle repeated sprint running test ($p<0.01$). Tukey's post hoc tests indicated that performance time in both male and female students significantly increased as sprints progressed (1st vs. 3rd till 6th, 2nd vs. 4th till 6th, 3rd vs. 5th and 6th, 4th vs. 6th). Also, males had significantly faster times than females ($p<0.01$) at every corresponding sprint. The correlation coefficient of the linear regression used to calculate the slope of performance decrement was $r = 0.90 \pm 0.08$. All fatigue indices were similar for males and females (FI%: -11.5% ± 5.0% and -15.1% ± 4.3%, p=0.07; Sdec%: -5.6% ± 2.2% and -7.3% ± 2.2%, p=0.08; slope: 2.1 ± 1.0 and 2.9 ± 1% per sprint, p=0.059). Slope was strongly correlated with fatigue index and Sdec in males (FI: r = -0.97 and Sdec: r = -0.89; $p<0.05$) and females (FI: r = -0.96 and Sdec: r = -0.86; $p<0.05$).

CONCLUSION: The slope of individual sprint time curve was strongly correlated with the FI and Sdec in both males and females and could be used as an alternative index to determine the level of the RSA of individuals.

EVALUATING HANDBALL THROWING USING OBSERVATIONAL STANDARDS FOR SOFTBALL THROWING

KATO, T.1, MURAKAMI, K.2, MAEDA, K.3, MIZUSHIMA, J.4

1SHONAN INSTITUTE OF TECHNOLOGY, 2ODAWARA JUNIOR COLLEGE, 3KYOTO UNIVERSITY OF ADVANCE SCIENCES, 4TOYO UNIVERSITY

INTRODUCTION: Overhand throws are a crucial skill in various sports, and observational standards have been established to evaluate the movements. In Japan, overhand throws in either softball or handball are evaluated, however, only observational standards for softball throws exist. The aim of this study was to determine the feasibility of evaluating handball throws using the observational standards for softball throws.

METHODS: Forty male collegiate students participated and performed overhand throws with a handball. The throws were recorded by two high speed cameras at 120 fps, placed on the right side and backward against the throwing direction. The video was repeatedly observed and evaluated based on the observational standards of softball throwing four movements (step length, backswing action, throwing arm kinetic chain, and free arm leading movement) on a three-point scale (3: excellent, 2: fair, 1: poor) by two evaluators [1]. Pearsons product-rate correlation coefficient was used to determine the relationship between the handball throw record and the total evaluation score. Multiple regression analysis, using the stepwise method, was performed with the handball throwing record as the dependent variable and the evaluation results of each movement as independent variables to determine the impact of each movement.

RESULTS: A significant positive correlation was found between the handball throw record and total score of the four movements ($r = 0.75$, $p < 0.01$). The results of multiple regression analysis showed that the throwing arm kinetic chain ($\beta = 0.44$, $p < 0.01$) and free arm leading movement ($\beta = 0.56$, $p < 0.01$) had a significant impact on the record ($R^2 = 0.70$, $p < 0.01$), while step length and backswing action were excluded.

CONCLUSION: The findings indicate that the throwing arm kinetic chain and free arm leading movement are valid standards for evaluating handball throwing by observation, similarly to softball throwing [2]. However, step length and backswing action may not be significant factors in handball throwing. In softball throwing, stepping with the foot initiates the transfer of weight and kinetic energy, while backswing action prepares the throw [2]. The handball, with its larger diameter and mass compared to softball, may have resulted in some participants prioritizing their grip on the ball given their hand size and grip strength, causing a deviation from stepping or backswing compared to softball throwing. Neverthe-

less, the effective use of kinematic chain and free arm leading motion allowed for successful handball throws. Therefore, it can be concluded that the critical preparatory movements in handball throwing differ from those in softball throwing, as determined by observational evaluation.

THE EFFECTS OF DARK CHOCOLATE SUPPLEMENTATION ON RATE OF PERCEIVED EXERTION AND FATIGUE INDEX DURING ANAEROBIC SPRINT TEST

BALASEKARAN, G., FOONG, K.M.S., NG, Y.C.

NANYANG TECHNOLOGICAL UNIVERSITY

INTRODUCTION: Studies have revealed that diet rich in flavanols have positive effects on cardiovascular health. Dark chocolate (DC) contains high amounts of flavanols due to high levels of epicatechin present that promotes availability and activity of nitric oxide (Patel, Brouncer & Spendiff, 2015). The increase in nitric oxide has shown to decrease oxygen cost during exercise and thus improving cardiovascular health (Engler & Engler, 2004). To investigate the effects of DC on anaerobic performance and OMNI rate of perceived exertion (RPE) in running-based anaerobic sprint test (RAST).

METHODS: Ten healthy participants (age: 23.8 ± 1.21 years; height: 1.74 ± 5.78 m; weight: 73.91 ± 9.18 kg; body fat percentage: 19.18 ± 6.17 %; lean muscle mass: 77.95 ± 6.16 %) volunteered for this study. Their anthropometric measurements were recorded, and body composition measured via dual-energy X-ray absorptiometry (DEXA) machine. Participants were randomly assigned to DC trial and white chocolate trial (WC); and consumed 300ml each of DC milk and plain milk mixed with 5-7 WC flavor drops respectively. They completed other trial (DC or WC) after a 7-day wash-out period. The RAST was conducted, and participants had to perform six 35m sprints with 10s passive recovery between each sprint. Timings gates were used to measure the time taken. RPE was recorded after 2nd, 4th and 6th sprint stages and Fatigue Index (FI) were recorded at the end of each RAST test.

RESULTS: Significant differences was indicated for both trials for 4th stage RPE ($t(9) = -2.54$, $p = 0.03$, $r = 0.64$, DC: 5.4 ± 1.3 vs. WC: 6.5 ± 1.2)); FI in 1st RAST ($t(9) = -2.73$, $p = 0.02$, $r = 0.01$, DC: 34.40 ±8.71 vs. WC: 39.60 ± 2.89)). Positive significant correlations were revealed between trials for FI in 1st RAST: (DC: 34.40 ± 8.71 vs. WC: 39.60 ± 9.14, $p = 0.02$, $r = 0.67$); FI in 2nd RAST: (DC: 35.61 ± 9.14 vs. WC: 40.58 ± 11.92, $p = 0.03$, $r = 0.69$). Results revealed negative significant correlation within trial for DC FI and 4th stage RPE for 1st RAST (DC FI: 34.40 ± 8.71 vs. DC RPE: 5.40 ± 1.35, $p = 0.04$, $r = -0.65$); positive significant correlation between WC FI 2nd RAST and WC 2nd RAST 2nd stage RPE (WC FI 2nd RAST: 40.58 ± 11.92 vs. WC 2nd RAST 2nd stage RPE: 5.30 ± 0.67, $p = 0.02$, $r = 0.71$).

CONCLUSION: Results indicate that pre-consumption of DC before exercise significantly may have reduced FI and RPE during anaerobic exercise for certain stages during the RAST. Furthermore, athletes and sports enthusiasts may consider consuming DC as a safe ergogenic aid to help improve anaerobic performance. RPE may be used to regulate intensity for anaerobic performance. Further studies need to be conducted to ascertain similar results.

EFFECTS OF ENDURANCE TRAINING ON ATHLETIC RECORDS AND ANAEROBIC POWER PRODUCTION CAPACITY IN JAPANESE LONG-DISTANCE RUNNERS.

MIYAZAKI, D.1, TANAKA, S.2, KUMAGAWA, D.2, OKADA, M.2

1, KOKUSHIKAN UNIVERSITY SPORTS PROMOTION CENTER ; 2, KOKUSHIKAN UNIVERSITY

INTRODUCTION: Previous studies have reported the importance of improving aerobic capacity in improving the athletic records of long-distance athletes [1]. Recently, the athletic record is affected by the running speed in the last spurt. For this reason, not only aerobic capacity but also anaerobic capacity is considered important factor for long-distance runners. Changes in maximal anaerobic power and middle power and their effects on athletic records have not been examined by endurance training throughout one year. Therefore, the purpose of this study was to examine the change of athletic record and anaerobic power generation capacity throughout the year in Japanese long-distance runners.

METHODS: The subjects were 18 male collegiate long-distance runners (age: 19.6±1.1yrs, Height: 170.0±4.7cm, Weight: 56.0±4.8kg). In this study, the athletic records in 5,000m, 10,000m and 20km were researched throughout season1 and season2(one year after season 1). The maximal anaerobic power (MAP), middle power (MP) and middle power to peak power ratio (MP/PP ratio) in each season as an anaerobic power generation capacity were measured by cycling ergometer (Power max VII), respectively. The change ratio of measurement parameters was calculated in all subjects. Subjects were classified by athletic record based by 10,000m athletic record faster (AG) and slower (BG) than 30:30 in season 1.

RESULTS: As a results, the athletic record of 5,000m was improved both AG and BG. In 10,000m, BG only observed improve the athletic record. However, improve the athletic record of AG and BG were not observed in 20km. The change ratio of athletic record in BG (5,000m: 2.2±1.7%, 10,000m: 1.5±0.8%, 20km: 2.5±3.8%) was showed high value than that of AG (5,000m: 1.1±1.7%, 10,000m: 0.3±1.3%, 20km: 1.4±3.0%). MAP and MP were not improved in both groups. In addition, MP/PP ratio in season2 was showed significantly higher than that of season1 in BG. The change ratio of MP/PP ratio was observed significantly higher BG (MAP: -6.2±9.2%, MP: -4.7±7.5%, MP/PP ratio: 4.5±3.3%) than AG (MAP: -1.5±5.2%, MP: 2.9±9.4%, MP/PP ratio: 1.1±6.5%).

CONCLUSION: In this study, it was cleared that endurance training in long-distance runners fails to produce high value for MAP and MP as in previous study [2]. However, MP/PP ratio in BG was improved by endurance training throughout one year. From these results, it might be considered that improve the MP/PP ratio reflect to improve the athletic record for long-distance runners who have not yet reached a high level.

EFFECTS OF DRY-LAND STRENGTH TRAINING SESSION ON SWIMMING PERFORMANCE THE FOLLOWING DAY

TOUBEKIS, A.2,3, TSOLTOS, A.1,2, ARSONIADIS, G.2, TSOLAKIS, C.1,2,3, CHATZIGIANNAKIS, A.4, SIMEONIDIS, T.1, KOULOUVARIS, P.1

1SPORTS EXCELLENCE, 1ST ORTHOPEDICS DEPARTMENT, SCHOOL OF HEALTH SCIENCES, NATIONAL AND KAPODISTRIAN UNIVERSITY OF ATHENS, ATHENS, GREECE; 2NATIONAL AND KAPODISTRIAN UNIVERSITY OF ATHENS, DIVISION OF

INTRODUCTION: Strength endurance (SE) or maximum strength (MS) training may affect subsequent in-water performance of competitive swimmers. Any effect on performance may be dependent on the time available for recovery. The aim of the study was to examine the effect of dry-land SE and MS training sessions on the following day swimming performance.

METHODS: Eight national level competitive swimmers (age 18.6 ± 2.9 years) performed in a random order: i) SE (2x15-20 repetitions, 50% of 1-repetition maximum), ii) MS training (2x5 repetitions, 85% of 1-repetition maximum), iii) a control condition (CON: no dry-land training) in an afternoon session (18:00 – 18:40 p.m.). Each dry-land session was followed by 90 minutes of in-water swimming training (19:00 – 20:30 p.m.). Upper body and lower body muscles performance was evaluated via a 3 kg medicine ball throw and countermovement jump (CMJ), free countermovement jump (FCMJ) and squat jump (SJ), before and after each dry-land training session and 12 hours later in the next morning, before a 100-m front crawl performance test at 8:30 a.m. Performance time, arm-stroke rate (SR), arm-stroke length (SL) were measured in the 100-m test. Blood lactate concentration (BL) was measured at the start and the end of the 100-m test and heart rate (HR) and rating of perceived exertion (RPE) were measured at the end of the test.

RESULTS: Performance time and biomechanical variables (SR, SL) as well as physiological response (BL, HR) in the 100-m test were no different between conditions (time, MS: 64.70 ± 7.35, SE: 63.81 ± 7.29, CON: 64.52 ± 7.71 s, p=0.57). CMJ was higher in SE compared to MS, and SJ was higher in SE compared to CON condition ($p<0.05$). FCMJ was no different between conditions. Jump height in all types of jumps was not changed before and after dry-land sessions and before the 100-m test in all conditions ($p>0.05$). Medicine ball throw was lower in MS compared to CON before the 100-m test (MS: 4.44 ± 1.11 vs. CON: 4.66 ± 1.21 m, p=0.01).

CONCLUSION: Performance time and biomechanical variables in a 100-m test, are not affected by dry-land maximum strength or strength endurance training performed 12 hours earlier. Upper but not lower body explosive power may be affected by dry-land MS training completed 12 hours earlier without affecting swimming performance. Swimmers may apply dry-land SE or MS training 12 hours prior to 100-m swimming race without any negative effect on performance.

EFFECTS OF REDUCED CONCURRENT TRAINING FREQUENCY ON MUSCLE HYPERTROPHY, MUSCLE STRENGTH AND AEROBIC POWER

TERZIS, G., MPAMPOULIS, T., METHENITIS, S., STASINAKI, A., ZARAS, N., PASCHALIS, V., BOGDANIS, G.

NATIONAL AND KAPODISTRIAN UNIVERSITY OF ATHENS

INTRODUCTION: Systematic resistance training combined with high intensity interval bicycling (i.e. concurrent training) results in muscle mass and strength increases together with increases in aerobic power, especially in unaccustomed individuals [1]. However, many trainees need to reduce their training frequency for certain periods of time due to injuries or other personal/professional reasons. Yet, little is known about the effect of reduced concurrent training frequency in protecting the already achieved adaptations with concurrent training [2]. Aim of the study was to compare the effects of concurrent training once per week or once per two weeks, on muscle mass, strength and aerobic power in young females, implemented after 12 weeks of systematic concurrent training.

METHODS: Fourteen young active females (height 1.69±0.06m, body mass 61.1±6kg), unaccustomed to resistance training and intense bicycling, underwent 12 weeks of leg press training [4 sets x 6-8 reps at 80-85% maximum strength (1-RM)], followed by 10 x 1-min high intensity bicycling at 90-100% maximum heart rate, twice per week [1]. Participants were then equally assigned into 2 groups: group G7 continued to train once per week, while group G14 continued to train once every two weeks, for another 12 weeks with the same training intensity and volume used at the last session of the systematic concurrent training period. Leg press 1-RM, quadriceps cross sectional area (qCSA, via ultrasonography) and maximum aerobic power were measured at the initiation of the project (T1), at the end of 12 weeks systematic concurrent training (T2), and after 12 weeks of reduced training frequency (T3). Repeated measures ANOVA with Tuckey post-hoc test was used to explore differences between interventions at $p<0.05$ statistical significance.

RESULTS: The initial training intervention (T1-T2) increased leg press 1-RM and qCSA by 29.9±11.3%, and 12.2±5.5%, $p<0.01$, respectively. Leg press 1-RM was not decreased between T2-T3 for the G7 (-1.1±1.7%, $P>0.05$), but it was reduced for the G14 (-4.3±3.4%, $p<0.05$). Yet, G14 group had higher leg press strength at T3 compared to T1 ($p<0.05$). Quadriceps CSA decreased similarly for both groups between T2-T3 (G7: -5.9±3.8%; G14: -4.7±2.5%, $p<0.01$), yet it remained higher than the initial qCSA at T1 for both groups ($p<0.05$). Aerobic power was increased by 20.6±10.7% ($p<0.01$), between T1-T2, while it remained unchanged for G7 ($p>0.05$), and it was decreased for G14 (-4.7±2.5%, $p<0.01$), between T2-T3.

CONCLUSION: These results suggest that performance improvements achieved with systematic concurrent training may be partly preserved for up to 12 weeks by performing at least one training session every two weeks. For this to occur training intensity and volume should be the same as the one used at the last training session of the systematic training period.

A STUDY OF PHYSICAL FITNESS TEST ITEMS FOR EFFECTIVE USE IN SOCCER COACHING - FOCUSING ON PHYSICAL FITNESS TESTS INCLUDING REACTION COMPONENTS

FUKUSHI, N., SUDA, Y.

KEIO UNIVERSITY

INTRODUCTION: Although the use of scientifically-based methods for sports training and practice is actively promoted, the most familiar and simple scientific approach to instruction is to quantify the physical strength and ability of the athlete via physical fitness tests. However, it is difficult to clearly define and quantify competitive skill in a soccer competition, and determining the most appropriate test for physical strength can be challenging. According to a questionnaire survey of Japanese university soccer teams, approximately half of the teams did not undergo physical fitness tests (Fukushi et al., 2015). The purpose of this study was to identify and propose physical fitness tests that can be utilized in instructional settings in soccer competitions. We conducted physical fitness tests on a university soccer team and compared the results between two groups of players: those who participated in official matches and those who did not. The association between the physical fitness test results and competitive performance was analyzed, with particular focus on a physical fitness test that includes a reaction component.

METHODS: Subjects were 67 male collegiate soccer players (19.7 ± 1.06 years old). The physical fitness test items were 50-m running (10, 20, 30, 40m transit time), Arrowhead agility test (AAT), Pro agility test (PAT), Reactive Pro agility test (RPAT), 10m x 5 shuttle-run, bounding, standing broad jump, and Yo-Yo intermittent recovery test level 2 (YYIR2). Each test was performed in accordance with the references (Japan Football Association, 2005; Bangsbo and Mohr, 2015; Ministry of Education, Culture, Sports, Science and Technology, 1999; Ariga et al., 2016). For the RAPT, subjects begin running in the direction of alternately lit LEDs placed to the right and left sides of the finish line; time measurement begins when the LED is lit. Unpaired t-tests were used for statistical analysis. Statistical significance was determined as p values less than 5%.

RESULTS: Comparisons between the two groups revealed significant differences ($p<0.05$) in six events: 50-m running (30,40,50m transit time), AAT, RPAT, 10m x 5 shuttle-run, bounding, and YYIR2.

CONCLUSION: Physical fitness elements necessary for soccer players include "sprinting ability" and "agility" (Bangsbo and Mohr, 2015). The 50-m run results in our study revealed no significant differences in the transit time at shorter distances such as at 10 m and 20 m. In addition, no significant differences were found in the PAT for the 20 m total distances. However, significant differences were found in the RPAT results. This suggests that the cognitive functions that contribute to running ability, the ability to respond to sensory information, and the ability to control the body instantly may be expressed differently depending on the levels of competition. Therefore, coaches and recruiters may discover more competitive soccer players by conducting fitness tests that include a reaction component, such as the RPAT.

EFFECT OF CARBON FIBER PLATE EQUIPPED RUNNING SHOES ON LACTATE METABOLISM DURING INCREMENTAL RUNNING TEST

SUZUKI, Y.

TOKYO KEIZAI UNIVERSITY

INTRODUCTION: The purpose of this study was to examine the changes in physiological load in hypoxic environment caused by differences in shoes with and without carbon fiber plates in an elite Japanese distance runner.

METHODS: The Carbon Plated Shoes: Nike-ZoomX Vaporfly Next% 2 (VFN), and the non-carbonated shoes: Nike-ZoomX Pegasus Turbo 2 (PT2) were tested in an elite male distance runner on a 10-step x 3-min incremental running test under normobaric hypoxia (FiO_2=14.4%).

RESULTS: The longest 30-min incremental running test could not be completed in either shoe condition, with a duration of 26 min in PT2 and 28 min 30 sec in VFN. Running speeds at blood lactate concentrations (La) of 2 mmol/L and 4 mmol/L were 242 m/min and 280 m/min, respectively, for PT2 compared to 285 m/min and 308 m/min, respectively, for VFN. The highest value of La occurred at stage 9, when exhaustion was reached in both conditions, at 15.2 mmol/L for PT2 compared to 12.5 mmol/L for VFN. In addition, lower heart rate and higher arterial oxygen saturation were observed in the VFN condition compared to the PT2 condition at the same stage.

CONCLUSION: These results suggest that changes in running shoes with and without carbon fiber plates may alter energy metabolism in the glycolytic system, and therefore, continuous assessment of aerobic capacity by running should be performed using the same running shoes.

MAXIMUM VELOCITY SPRINT TRAINING: A CASE STUDY INVESTIGATING ECCENTRIC HAMSTRING STRENGTH, FASCICLE LENGTH AND FORCE, VELOCITY, AND POWER PROFILING IN SEMI-PROFESSIONAL AUSTRALIAN FOOTBALL.

FREEMAN, B., TALPEY, S., JAMES, L., OPAR, D., YOUNG, W.

FEDERATION UNIVERSITY AUSTRALIA & THE UNIVERSITY OF NOTRE DAME AUSTRALIA

INTRODUCTION: Sprint training is viewed as important for hamstring strain injury (HSI) prevention in Australian Rules Football (AF). Eccentric hamstring strength and biceps femoris long head (BFLH) fascicle length are modifiable risk factors for HSI. Maximum velocity sprint training has been viewed as less important than acceleration training for AF. Analysis of the influence of maximum velocity sprinting on force production and work completed shows a significant increase between 80% and 100% of maximum velocity. Therefore, maximum velocity training may provide a conditioning stimulus to the hamstrings that is not replicated in other training methods.

METHODS: One Victorian Football League athlete (age = 19, height = 1.79, mass = 69.4kg) completed pre- and post-testing consisting of a 40-metre sprint, which was also analysed utilising the MySprint application. The 40-metre sprint included a 0-10-metre split to measure acceleration, and a 30-40-metre split to measure maximum speed. This was followed by an eccentric hamstring strength assessment, and an ultrasound scan of the hamstrings. The athlete then completed six weeks of maximum velocity sprint training that aligned with best practice recommendations (weekly volume = 130-210m). In these sessions, a gradual acceleration was utilised to achieve a higher maximum velocity. This consisted of two sessions per week, separated by a minimum 48 hours. A weekly ultrasound was completed 24 hours after the last session of the week. Ethical approval along with informed consent was obtained prior to the commencement of this investigation.

RESULTS: Fascicle length increased by 1.31cm. Acceleration and maximum velocity qualities improved (0.05s and 0.15s, respectively). Eccentric hamstring strength displayed no change (pre = 343N, post = 337N), however, muscle symmetry improved (pre = 21%, post = 11%). The force-velocity-power profile displayed improved peak power (pre = 17.83 w/kg, post = 19.05 w/kg).

CONCLUSION: The volume of sprint training was suitable to improve sprint performance and increase fascicle length in this athlete. The average eccentric hamstring strength remained unchanged, however, this may be because the training load was insufficient to elicit a positive adaptation. Despite completing targeted maximum velocity training, a small increase was observed in acceleration qualities. This is encouraging from a performance perspective. Similarly, the improved Force-Velocity-Power profile is evidence of the potential benefits that results from a maximal sprint, where key determinants of success, such as peak power, peak force, and the ratio of forces can all improve with exposure to a relatively low volume of training. The improvements in fascicle length over a short intervention are further rationale to include maximum speed sprinting as a part of a multifactorial approach to physical preparation and injury prevention. Findings indicate maximum speed sprint training was likely effective in improving sprint performance and muscle architecture.

VALIDITY OF USING PERCEIVED EXERTION TO ASSESS MUSCLE FATIGUE DURING BENCH PRESS EXERCISE

HANYE, Z.1, DASOM, S.2, JUNICHI, O.1

WASEDA UNIVERSITY

INTRODUCTION: Muscle fatigue can be perceived as subjective feelings such as fatigue and tiredness [1,2]. The rating of perceived exertion (RPE) is an exercise intensity estimator that combines numbers and verbal [3]. The interdependence between physiological and perceptual responses during exercises indicate that the RPE may be a valid method of assessing muscle fatigue. Velocity loss has been recommended as muscle fatigue indicator for explosive resistance exercises [4], however, the validity might not be justifiable when exercise is performed under non-explosive manner. Therefore, this study's aims are as follows: (1) to examine the validity of using RPE to assess muscle fatigue quantified by new surface electromyography (sEMG) techniques, and (2) to compare the validity of using velocity loss as a fatigue indicator during non-explosive bench press (BP) exercise.

METHODS: Fifteen male athletes underwent different fatigue levels of BP consisting of 30% (L), 60% (M), and 90% (H) volume at 65% of one-repetition maximum. The sEMG signal (Kissei-Com Tech, Japan), RPE, and velocity (Fitronic, Slovenia) were measured throughout trials. Muscle fatigue was quantified by spectral fatigue index (SFI) using sEMG signal [5]. Velocity loss was calculated as the percentage loss in velocity of each condition. RPE was assessed using Borg's CR-10 scale. One-way ANOVA followed by Bonferroni post-hoc test was used to compare between conditions. The relationship between variables was examined using Spearman's correlation analysis. Significance was set at $p < 0.05$.

RESULTS: Significant difference in overall-RPE was observed between L (3.06 ± 1.28), M (5.67 ± 1.35) and H (7.27±1.75) conditions ($p < 0.001$). With regards to average velocity loss, significant difference was observed in L vs. H ($p < 0.001$) and M vs. H ($p < 0.05$) comparisons (L: 12.80 ± 7.82%, M: 20.44 ± 9.91%, H: 28.14 ± 7.22%). Similar results were observed in average SFI (L: 1.08 ± 0.05, M: 1.17 ± 0.08, H: 1.32 ± 0.11, L vs. H: $p < 0.001$, M vs. H: $p < 0.05$). Significant relationship was confirmed in both SFI-RPE ($r = 0.681$, $p < 0.001$) and SFI-velocity loss ($r = 0.510$, $p < 0.001$).

CONCLUSION: The current study has demonstrated that overall-RPE, average velocity loss, and average SFI change correspondingly, indicating that both velocity loss and RPE are effective for assessing overall muscle fatigue levels of non-explosive BP. Further, significant RPE-SFI and velocity loss-SFI correlations were observed, indicating that both RPE and velocity loss changes within the increase of muscle fatigue levels. However, regarding the easy-to-use characteristics of RPE, it could be concluded that RPE is more suitable for muscle fatigue assessment when performing non-explosive BP.

Consequently, both RPE and velocity loss are useful for muscle fatigue assessment, however, RPE is easier to be applicated when performing non-explosive BP exercise.

THE USE OF ARMS IN WRESTLING KUMITE

ITO, S., KANOSUE, K., NAGASHIMA, K., MATSUMOTO, R., ITEYA, M.

FUKUOKA UNIVERSITY

INTRODUCTION: The purpose of wrestling is to take down the opponent. Leg attack is the most important technique to this end and obtain scores (1). The set up is an efficient way to improve the leg attack success rate (2). The situation in which wrestlers push or pull the opponent to execute the set up and leg attacks is defined as kumite. In kumite, wrestlers use arms to gain control over the opponent to break their balance. A wrestler's stance is usually putting one leg about one foot in front of the other. The hand closest to the opponent is called close hand (CH) and the hand furthest is called far hand (FH). Little is known of the role of each arm in kumite, although coaches and athletes would understand its importance. The purpose of this study is to clarify arm use in kumite to improve wrestlers' performance.

METHODS: We conducted a survey using a questionnaire (Google form) and collected responses from 110 collegiate wrestlers. Survey items covered how wrestlers use their CH and LH in kumite by selection and explanation. From the answer options, participants chose from "pull", "push", "stop", and "relax". Additionally, wrestlers responded regarding their competition level. The chi-square test was incorporated to investigate the relationship between arm use and competition level, as well as the opinions related to their CH and LH.

RESULTS: There was no significant association between wrestlers arm use and competition level in CH ($p = 0.321$) and FH ($p = 0.090$). As for each hand placement, pushing is considered important in CH and pulling is important in FH ($p < 0.001$). In explanations regarding CH, there were varied responses such as sensing the opponents movement, measuring the distance to the opponent, and touching the opponent. Explanations concerned with FH, most were related to the pulling movement.

CONCLUSION: This study revealed athletes focus on pulling the opponent with the FH, while pushing the opponent and feeling the opponent's move and response with the CH. Before executing the leg attack, wrestlers try to cause the opponent to lose balance. The most effective, fundamental movement is to push the opponent with the CH. In this case, the opponent usually try to push back because they lose one point if they go outside the mat circle. The attacker can break the opponent's balance by pulling their opponent as they push back. Thus, by sensing the opponents movement and pushing back with the CH, they decide when to pull or relax in response to their opponent. Therefore, it is essential wrestlers and coaches understand the role of each arm when practicing the set up and overall movement in kumite.

DIAGNOSTICS OF LOWER EXTREMITY EXPLOSIVE MUSCULAR STRENGTH ON RUNNING SINGLE-LEG VERTICAL JUMP WITH DIFFERENT APPROACH DISTANCES

CHANG, Y.H., HSU, T.M., HUANG, B.X., NAI, H.F., LIN, J.Z.

NATIONAL TAIWAN UNIVERSITY OF SPORT

INTRODUCTION: Vertical jumping is one of the key forms of movement required to achieve success in athletic performance [1]. Taking the long jump action as an example, the jump process involves maintaining horizontal and vertical speed to produce the most vertical lift and achieve the maximum distance [2]. Although the running single-leg jump (RSJ) is also an explosive jumping method, the action is similar to the high jump or long jump in the starting movement. However, the RSJ actions have received less attention in terms of the explosive muscular strength of the lower extremities [3]. Therefore, the aim in this study was to compare the characteristics of the explosive muscular strength of the lower extremities on the single-leg vertical jump. We observed what distance of jumping helps athletes jumping performance, providing a reference for future training or jumping applications.

METHODS: We recruited eight general athletes. The running distance is set to 1, 3, and 5 m outward from the force plate boundary. For this experiment, we used the dominant foot as the starting test foot to randomly collect data from three successful movements for each distance. The test required the participants to run to the force plate, and then use their maximum strength to perform a vertical jump with one foot, followed by a double foot landing. We used one Kistler force plate to record the ground reaction force data after touchdown to define the instant of landing. The data analysis was mainly based on the IRFD, RFD, RSI, SSI, vertical stiffness and impulse from the moment of landing to the jumping phase. We used repeated measures one-way ANOVA.

RESULTS: We compared the explosive muscular strength of the lower extremities during a running single-leg vertical jump with different approach distances. The results of repeated measures one-way ANOVA showed that the SSI with the 1 m approach run was significantly higher than with 3 (P=.001) and 5 m (P=.003) approaches. The RFD (P=.009) and RSI with the 5 m (P=.006) approach were significantly higher than with the 1 m approach.

CONCLUSION: We performed diagnostics of the lower extremities explosive muscular strength during running single-leg vertical jump with different approach run distances. RSI is used to assess an athletes ability to convert centrifugal to centripetal force during the jumping process. It can also be used to examine the strengths and weaknesses of an athletes

ability to shorten the cycle during movement. The result of this study shows that the 5 m horizontal distance helped increase the muscle efficiency of the SSC and increase jumping performance. Our findings show that the approach run distance influences jump performance [4]. We also found that different approach run distances influence the explosive muscular strength of the lower extremities. These findings can be used to help improve athletic performance.

THE IMPACT OF BALANCE AND MINDFULNESS TRAINING ON YOUNG BIATHLETES SHOOTING EFFICIENCY

SLOMKA, K.J., WALACH-BISTA, Z.

INSTITUTE OF SPORT SCIENCES, ACADEMY OF PHYSICAL EDUCATION IN KATOWICE

INTRODUCTION: The purpose of the study was to evaluate the effectiveness of two alternative methods for improving the shooting performance of biathletes. The first relies on motor skills and stresses body balance. Not only does effective postural balance reduce the risk of body imbalance, falls, and associated injuries, but it also enhances motor performance in a variety of sports. The second method is based on the concept of mindfulness and emphasizes psychological competence. Mindfulness is a way of paying attention that involves putting your attention on the present moment and accepting it without judging it. Recent research shows that parts of mindfulness are linked to better shooting performance in competitions. This is because mindfulness and refocusing make you more aware of your surroundings.

METHODS: The 6-week balance training and 6-week Mindfulness Sports Performance Enhancement (MSPE) programs were designed to improve youth biathletes shooting performance. In this study, 16 youth biathletes served as the experimental group, whereas 10 youth biathletes served as the control group. Both categories were covered by National Sports Championship Schools. The tests included functional balance tests, balance tests on force platforms, dry shooting tests with the Scatt shooting system, and a number of psychological inventories and assessments. Also, the quality of the aiming was tested with a video tracking system and laser feedback experiments. After the biathletes did a short, hard workout on a ski ergometer, their performance was also measured after they were tired. The experimental group was separated into a Stability (n=8) group and a Mindfulness (n=8) group, and after the initial measures, they completed different training programs concurrently with their daily practice.

RESULTS: Significant associations existed between posturographic parameters and shooting performance. There were also substantial correlations between shooting ability and the results of tests and questionnaires measuring mindfulness. After the training, the importance of these dependencies was emphasized even more than before. The trials after effort implemented in the experiment did not appreciably alter these characteristics. We were only able to identify a positive trend in the direction of balance and mindfulness improving, but these changes did not reach the level of statistical significance required to be considered significant.

CONCLUSION: The most significant and potentially advantageous result of the research is that it lends support to the theory that maintaining ones physical equilibrium and being mindful of ones surroundings can significantly improve ones shooting accuracy. Our findings should be replicated in subsequent research using the same procedures, but with athletes who are more skilled and with a larger number of participants overall. It is likely that the studys results would be more evident if the training program had been implemented at the beginning of the planning phase.

DOES BIOELECTRICAL IMPEDANCE-BASED BODY COMPOSITION RELATE TO LOWER LIMB ISOMETRIC STRENGTH AND POWER INDEXES IN ALPINE SKIERS?

BERTOZZI, F.1, TENDERINI, D.2, CAMUNCOLI, F.1, SIMONI, G.1, GALLI, M.1, TARABINI, M.1

1 POLITECNICO DI MILANO; 2 SCI CLUB LECCO ASD

INTRODUCTION: Alpine skiing performance depends on several physical factors beyond technical ones, including lower limb strength and power [1]. These features may be, in turn, influenced by intrinsic athletes characteristics, such as body composition [2]. Therefore, this study aimed to assess the relationship between bioelectrical impedance-based body composition and selected lower limb power and strength measures in alpine skiers.

METHODS: Nineteen young alpine skiers (7F / 12 M, age: 17 ± 1 years, BMI: 23 ± 1.6 kg/m2) underwent a foot-to-hand bioelectrical impedance vector analysis (BIVA; BIA 101 BIVA PRO, Akern) body composition assessment, obtaining phase angle (PA) and computing fat mass percentage (%FM) using a validated athletic specific equation [3]. After a warm-up, they completed two countermovement jump (CMJ) trials, and from the highest one, jump height (JH) and jump peak power (JP) were computed [4]. Finally, maximal isometric strength was assessed in both limbs (ForceFrame, Vald), and then summated to obtain the total standing hip flexion (Hflex) and extension (Hext), and lying (with 45° knee angle) hip abduction (Habd) and adduction (Hadd) strength.

After checking outliers and data normality, pairwise Pearson correlation tested the relationship (r coefficient was computed) between body composition and lower limb strength and power-related variables, with α=0.05.

RESULTS: %FM showed significant (p from 0.001 to 0.039) negative correlations with large magnitudes with all power and strength variables (r from -0.58 to -0.70), except for Hext, which revealed a moderate correlation (r=-0.48). Similarly, PA exhibited significant (p from 0.005 to 0.026) positive large correlations with all variables (r from -0.52 to -0.64), except for Hext (p=0.061).

CONCLUSION: Raw (PA) and advanced (%FM) BIVA-based measures showed a significant relationship with the selected lower limb strength and power indexes (JH and JP). In particular, lower percentages of fat mass and higher PA are related

to greater hip isometric strength and jump-related power production. Therefore, our results indicate that body composition assessment should be implemented in alpine ski racers development screening process, as it may influence key physical performance indicators.

VALIDITY AND REPEATABILITY OF WALKING TEST IN POLAR PACER GPS WATCH

OIKARINEN, S.1, TORNBERG, J.2, LUOMALA, M.3, LAUKKANEN, R.1,3

UNIVERSITY OF OULU, OULU DEACONESS INSTITUTE FOUNDATION, POLAR ELECTRO OY

INTRODUCTION: Polar introduced a walking test in Pacer-series in April 2022. This Polar Walking Test (PWT) estimates maximal aerobic power (VO2max ml/kg/min) based on a 15-minute fast walk, subject´s demographics (age, height, weight) and distance walked and heart rate during the test. The test is built on the basis on 2-km UKK Walk test, established in 1991. Walking test is targeted to healthy adults who do not participate in competitive sports. In this pre-validation study PWT was validated scientifically against reference measure of VO2max. Repeatability was evaluated based on two repeated tests.

METHODS: Altogether 24 volunteers (13 women and 11 men, mean age 44 and 41 years, mean BMI 25 and 26 kg/m2, mean VO2max 40 and 45 ml/kg/min (range 28-49, 35-52), mean maximal heart rate (HRmax) 183 bpm for both, respectively) participated into study. First, they all did a laboratory test in a maximal walk-run treadmill protocol with breath-by-breath VO2 measurements. After this they performed two walking tests within 2-week period with Pacer guidance on a self-selected route. Firstly, user settings were given to watch. The test started with warm-up and during the test appropriate walking speed was guided using HR, which should exceed 65% of HRmax. As a result, Pacer calculated distance, speed, test HR, VO2max -value and corresponding Fitness level.

RESULTS: The mean walking distances in the first and second test were 1750 and 1780 meters and the mean heart rates 124 and 128 bpm. Predicted VO2max -values were 38 and 39 ml/kg/min in the first and second tests. The mean absolute errors and standard deviations between the laboratory and walk test VO2max were 5.9 (4.8) and 5.8 (4.8) ml/kg/min and absolute %-errors (SD) 13.6 (9.9) and 13.4 (10.4) % in the first and second test. Comparing the first and second test the mean absolute error between the tests in maximal aerobic values were 2.3 (1.4) ml/kg/min and correlation 0.95. There was no difference in two repeated tests in VO2max estimations. However, more (83% in the second test vs 75 % in the first test) subjects were able to reach target HR during the second test resulting to faster walk and longer walking distance. In addition, more subjects (29% in the second and 21% in a first test) had a same Fitness level in the second test.

CONCLUSION: This pre-validation study indicates rather good validity and a small learning effect in Polar Walking Test in Pacer watch, although 9/24 (38%) of the subjects were highly fit and not the ideal target group to the PWT. In UKK Walk Test validation studies the standard errors of estimates to lab VO2max have varied between 3.3 - 5.1 ml/kg/min. Based on pre-validation it can be concluded that a training test and/or at least a supervised Polar Walking Test should be carried out when PWT is used in a scientific study, as recommended in original UKK walking test. For Polar customers Walking test provides a rather good self- test alternative to assess and follow changes in aerobic fitness.

CLASSIFICATION OF SPORTS BASED ON COACHES PERSPECTIVE ON ENVIRONMENTAL, INDIVIDUAL AND TASK REQUIREMENTS: A MACHINE LEARNING SPORTS PROFILE ANALYSIS.

TEUNISSEN, J., FABER, I., DEBOCK, J., VERSTOCKT, S., LENOIR, M., PION, J.

HAN UNIVERSITY OF APPLIED SCIENCES

INTRODUCTION: Well-designed talent programs with a focus on talent identification, orientation, development, and transfer may support the engagement of young individuals in sports and the pursuit of elite performance. To facilitate these processes, a systematic analysis of task, environmental and individual characteristics for each sport is much needed. This study analysed whether unique profiles per sport could be established based upon generic characteristics.

METHODS: By means of a validated survey 1247 qualified coaches from 34 different sports ranked 18 different characteristics on importance to their sports (0-10; not important at all - very important). To discriminate the responses per sport, 1) a Linear Discriminant Analysis (LDA) was carried out, 2) a Machine learning method - Uniform Manifold Approximation and Projection (UMAP) with Catboost classifier - was performed to refine the linear process of classification. Cross-validation was carried out by means of the leave-one-out method. To test the performance of the Catboost classifier-algorithm a Confusion matrix was generated.

RESULTS: Cross-validated LDA showed that 70.2% of the coaches were correctly classified to their sport. Applying the UMAP/Catboost technique increased the accuracy to 75.1%. The Confusion matrix showed the correctly predicted responses per sport ranged from 18.2% (sailing) - 98.2% (soccer). Conclusions: With varying precision, the algorithm was able to classify the different sports by importance of its characteristics.

CONCLUSION: This method enables coaches to construct unique sport profiles for the optimisation of talent identification, orientation, transfer, and development programs by searching for similarities and differences between sports.

ACUTE EFFECTS OF TISSUE FLOSSING VERSUS NEUROMUSCULAR ELECTRICAL STIMULATION OF THE QUADRICEPS FEMORIS MUSCLE ON IMPROVING VERTICAL JUMP PERFORMANCE

TEO, F., MUKHERJEE, S.

NANYANG TECHNOLOGICAL UNIVERSITY

INTRODUCTION: Vertical jump (VJ) is an explosive action and a significant component of sports such as basketball [1], and can be an important determinant of match-winning actions [2]. Current training methods of improving VJ performance, such as resistance [3] or plyometric training [4], are effective but require investment of a significant amount of time. Tissue flossing (TF) and neuromuscular electrical stimulation (NMES) are methods purported to improve functional performance. However, research on their effects of an acute bout on the quadriceps femoris (QF) and VJ performance is lacking. This study compared the acute effects of a bout of either TF or NMES on the QF to improve VJ performance.

METHODS: 20 male basketball players (age 23.45±2.13 y) participated in a randomized crossover study. Participants were subjected to an acute bout of either TF or NMES on two separate sessions, with a washout period of at least 24 hours. For TF, the floss band was applied on the QF of each leg and range-of-motion exercises were performed, with the band removed after two minutes to allow reperfusion of blood to the muscle tissue. For NMES, electrodes were placed on the vastus medialis and lateralis, with stimulation intensity increased to the maximal tolerable levels to achieve the strongest muscle contractions. Countermovement jump (CMJ) height was chosen as the VJ measure and recorded as the pre-test and post-test measure. Three CMJs were performed at 1 min intervals, with the best trial used for data analysis.

RESULTS: Mean CMJ measure differed significantly between conditions, $F(2, 36)=46.83$, $p<.001$, $np2=.722$. Mean CMJ increased from baseline (67.90±6.38 cm) to post-TF (69.71±6.50 cm) by 1.81cm but decreased by 1.13cm post-NMES (66.77±6.43 cm). Post hoc analysis with a Bonferroni adjustment revealed significant differences in CMJ post-TF ($p<.001$) and post-NMES ($p=.003$). For TF, no adverse effects on CMJ were reported, but for NMES, 12 participants showed decreased CMJ and only 2 had increased CMJ performance.

CONCLUSION: The results of this study suggested that TF is a valid intervention for acute VJ performance improvement. Our results were comparable to those of traditional resistance training programs ranging from 6 to 15 weeks [5]. In line with current literature, NMES should be combined with other training methods for potential gains. Comparing the two, TF demonstrated more promising results for acute improvement in VJ. It is likely that there were too many contractions in the NMES protocol, which led to fatigue of the fast twitch muscles and poorer VJ performance. Future studies should investigate the time course effects of these interventions and the optimal NMES parameters to achieve a potentiation effect.

EFFECTS OF PAST EXERCISE EXPERIENCE ON COORDINATION ABILITY AND MEASURING TIME OF GRIP STRENGTH

HAYASHI, Y.1, WAKATABE, S.1, MURAYAMA, T.2, NAKANO, T.3, SAKAI, T.4, OYAMA, Y.5, KAMEOKA, M.2

1 HOSEI UNIVERSITY; 2 NIIGATA UNIVERSITY; 3 CHUKYO UNIVERSITY; 4 NAGOYA GAKUIN UNIVERSITY; 5 TOIN UNIVERSITY OF YOKOHAMA

INTRODUCTION: Previous studies on the coordination ability in grip strength were based on the magnitude of the difference between the target value set based on the maximum value and the grip strength exerted with that value considered as an index [1]. However, no study has taken into account the time required to measure this ability. Therefore, in this study, we measured the difference in the grip strength relative to a target submaximal value and the time needed to measure the grip strength. We also examined the relationship between these values, as well as exercise experience and exercise habits of the subjects.

METHODS: A total of 155 healthy male and female university students (mean age, 18.5 ± 0.8 years) were enrolled. We measured the error in the isometric grip strength measurement for the target value corresponding to 30%, 50%, and 70% of the voluntary maximal grip strength (0.1 kg), and the time (0.1 sec) required for the measurement. The grip strength was measured using the specially altered grip dynamometer, which recorded the grip strength by pressing the switch as fixed and together and measured the time from the start of measurement to pressing the switch. Furthermore, we investigated past exercise experiences retrospectively for all subjects using questionnaires. The subjects were administered a questionnaire about their exercise experience, participation in exercise events, number of exercise sessions per week (day/week), implementation time per session (hours), and exercise intensity (5-Point Likert Scale) for every 6 school-age categories based on the educational stage in Japan. A multilevel model of hypothesized relationships among error in grip strength exhibited for the target value (Grasp error), time of measurement (measuring time), grasp error relative to the measuring time (error time), and questionnaire responses was tested.

RESULTS: Grasp error as a dependent variable had a significant relationship with exercise volume in the pre-school ($P <.01$) and lower grade of elementary school age-groups ($P =.02$). Moreover, exercise volume of pre-school ($P =.04$) and junior high school groups ($P <.01$) had a significant relationship with measuring time as a dependent variable. Error time as a dependent variable showed a significant relationship ($P =.02$) with only the current exercise volume (university student), and the error time increased with decreasing current exercise volume.

CONCLUSION: The results of this study suggest that the simple grading ability of adolescents to grasp exercise may increase by practicing exercise with certain intensity and frequency above a certain intensity. Moreover, current exercise volume was not related with the grading ability to grasp or the time required for measurement.

THE RELATIONSHIP BETWEEN RATE-DEPENDENT METRICS IN THE ISOMERIC SQUAT AND ISOMETRIC MID-THIGH PULL

GENEAU, M.

LA TROBE UNIVERSITY

INTRODUCTION: Isometric strength assessments have become a popular means of assessing maximal and rate-dependent strength in athletes. The most common tests of multi-joint isomeric strength include the isometric squat and the isometric mid-thigh pull (IMTP). To date, only a single study has evaluated whether there is a difference between the measures of rate-dependent metrics between these two conditions [1]. It is important to also understand the associations between these metrics to determine if the tests assess similar or different qualities. Thus, the purpose of this study was to assess the association between peak and rate-dependent metrics of the isometric squat and IMTP in semi-professional athletes. We hypothesised that there would be strong associations between the peak and rate-dependent metrics between tests.

METHODS: Twenty-six male (BM=79.5±8.9 kg) and 27 female (BM=65.7±8.3 kg) athletes from an elite junior Australian rules football (17-19 years of age) league performed trials of the isometric squat and IMTP with instructions to push/pull as fast and as hard as possible. Seven metrics were derived from each test: net peak force [N], net force at 100ms, 150ms, and 200ms [N], and net force/net peak force at 100ms, 150ms, and 200ms [%]. The trial with the highest peak force was used for analysis.

RESULTS: There were weak correlations between the metrics of the two isometric tasks (r = 0.22-0.42).

CONCLUSION: The present study determined that there were weak associations between rate-dependent metrics of the IMTP and isometric squat. These findings suggest that the two tests may measure different qualities in junior-level athletes. It is recommended that practitioners approach the interpretation of values across isometric tests independently, as they may contain unique information.

HIGH-CONCENTRATION ARTIFICIAL CARBONATED SPRING LOWER LEGS BATH AFFECTS MUSCLE TISSUE ELASTICITY AND MUSCLE STRENGTH

NORIYUKI, Y.1, YU, K.2, TOMOYA, H.5, FUMIKO, T.3, YUKINORI, S.4, TADASHI, W.5

1 JAPANESE RED CROSS HOKKAIDO COLLEGE OF NURSING, 2 SENSHU UNIV., 3 HOSHI UNIV., 4 WAKAYAMA PROFESSIONAL UNIV. OF REHABILITATION, 5 KOKUSHIKAN UNIV.

INTRODUCTION: Facilitation of the blood supply and oxygen consumption in the muscle by a local immersion of the extremities into high-concentration carbon dioxide water (CO2-water, CO2≥1000ppm) suggests an improvement in muscle performance and flexibility (Yamamoto, 2007). In the present study, we investigated whether the lower legs bath into artificially made high-concentration CO2-water (CO2≥1000 ppm) influences muscle tissue elasticity and muscle strength.

METHODS: The healthy male college students (n=6, 19-24yrs, 170.4±4.7cm, 63.8±9.1kg) participated in this study. The subjects were randomly divided into the tap-water group and the CO2-water group, and a crossover test was conducted. The subjects immersed their lower legs up to below the knee into tap-water or CO2-water at 35 °C for 10 minutes. Subjective thermal sensation (TS) during the lower leg bath were recorded by every two minutes. The medial head of gastrocnemius muscle (MG) dominant muscle hardness was evaluated using ultrasound real-time tissue elastography and maximum isometric plantar flexion and dorsiflexion strength at pre and post lower legs bathing. The strain ratio (SR) between the MG and the subcutaneous adipose tissue of the calf was calculated. In addition, the rate of force development (RFD) was also measured. We compared the variables after the tap water bath and after the CO2 water bath using a paired Students t-test. The significance level was set at $p < 0.05$.

RESULTS: TS in the CO2-water was significantly higher than in the tap-water (tap-water vs. CO2-water at 10 minutes in the bath, -0.50±0.55 vs. 1.17±0.41, $p<0.001$). After the lower leg bath, in the CO2-water compared with the tap-water, SR significantly increased (3.26±1.52 vs. 7.82±3.91, $p<0.05$). Ankle joint peak strength and RFD (0-200ms) were not significantly difference between pre and after tap-water bathing. However, mean right ankle dorsiflexion strength increased significantly more CO2-water than tap-water (14.4±10.0 Nm vs. 15.8±7.3 Nm, $p<0.05$).

CONCLUSION: We reported previously that the muscle blood flow in the immersed part was larger in CO2-water than tap-water of the same temperature. In addition to a local effect of CO2, suppression of muscular sympathetic activity may also contribute to the increase in local blood flow. The facilitation of muscle tissue elasticity shown in this study might be caused by the increased muscle blood flow. The present results suggested that the high-concentration artificial CO2-water lower leg bath improves the muscle elasticity of the immersion part. No significant change in RFD was observed with the lower leg bath. However, muscle strength tended to improve slightly. It was suggested that CO2-water bathing might contribute to muscle strength improvement.

GENDER DIFFERENCES IN POWER PRODUCED DURING JUMPS IN NON-ATHLETES AND ATHLETES

ZEMKA, F.1, KOTYROVÁ ŠTEFÁNIKOVÁ, G.2,3, KYSELOVICOVÁ, O.2, LEHNERT, M.1, ZEMKOVÁ, E.2,3

1: PALACKÝ UNIVERSITY IN OLOMOUC, CZECH REPUBLIC, 2: COMENIUS UNIVERSITY IN BRATISLAVA, SLOVAKIA, 3: UNIVERSITY OF SS. CYRIL AND METHODIUS IN TRNAVA, SLOVAKIA

INTRODUCTION: Although various tests of explosive strength have been incorporated into physical fitness test batteries for children and adults (e.g., standing long jump, squat jump, countermovement jump, drop jump, jumping sideways, triple hop, single-leg hop, maximal and submaximal hopping), data providing information on age-related changes in test variables in female and male competitive athletes are still lacking. This study investigates gender differences in power produced during jumps in non-athletes and athletes during adolescence.

METHODS: A group of 352 female and male non-athletes aged 6-23 years (~20 in each age category), recruited from schools and universities, was supplemented by 59 competitive aerobic dancers, ballroom dancers, gymnasts, and rock & roll dancers aged 12-18 years. They performed a test of 10-s maximal jumps with hands fixed on their hips. Subjects were instructed to minimize ground contact time and to maximize jump height. Two trials with a 2-min rest period were performed while the better of them was analysed. A FiTRO Jumper consisting of a contact switch mat, which measures contact and flight times during jumps, was used to calculate the power in the concentric phase of take off normalized to body weight.

RESULTS: The power in the concentric phase of take-off was significantly higher in male than female non-athletes from the age of 13 years. While the power increased year on year in males, females reached a plateau from 13 to 17.5 years, and then only slightly increased up to age 23. However, compared to non-athletes, power gradually increased with increasing age in both male and female athletes. There were significant between-gender differences during adolescence, with higher power in favor of males, at 13y (7.6%, p=0.043), 14y (9.2%, p=0.021), 15y (11.5%, p=0.006), 16y (13.5%, p=0.001), 17y (15.2%, p=0.001), and 18+y (16.3%, p=0.001).

CONCLUSION: The power produced during 10-s maximal jumps increased from childhood to adulthood in male non-athletes and athletes. However, its values have reached a plateau during adolescence in female non-athletes, whilst in athletes they increased during this period. These differences in adolescent females may be ascribed to their different amount of muscle mass contributing to power production during jumps. Genetic predispositions (larger proportion of fast-twitch fibers) and adaptation to jumping or hopping exercises in gymnastic and dance sports might have also contributed to greater power in female athletes than non-athletes. Taking these gender differences into account, normative data are needed to classify jump performance in adolescent athletes.

SELECTED ANTHROPOMETRIC AND PHYSICAL PERFORMANCE PARAMETERS RELATED TO THROWING PERFORMANCE IN YOUTH MALE SHOT PUT ATHLETES

ZHAO, Y., ZHAO, K.

CHINA INSTITUTE OF SPORT SCIENCE

INTRODUCTION: Anthropometric and physical performance Variables including body mass, height, strength and power are considered crucial parameters in shot put. The purpose of this study was to investigate the characteristics of selected anthropometric and physical performance parameters in throwers for the Fitness assessment and Talent identification.

METHODS: 55 youth elite male shot put athletes (aged 16.15±1.09) from China participated in a total of sixteen Anthropometric and physical performance tests viz Body mass, height, Body mass index, Sit and Reach Flexibility, 30m sprint, 60m sprint, Standing long jump, Standing triple jump, Hexagon Agility Test, Balance cushion One leg stand, The Plank Fitness Test, Pull-Up Test, 2000m rowing ergometer; To avoid the effects of technique, we chose 5kg Overhead Medicine Ball Throw (forwards), 5kg Medicine Ball Throw(backwards) and Standing shot put test(5kg) to assess the throwing ability of athletes. The correlation analysis was made between throwing ability tests and other tests.

RESULTS: 5kg Overhead Medicine Ball Throw (forwards) was correlated with Sit and Reach Flexibility(r=0.688,p=0.000), 30m sprint(r=-0.370,p=0.005), 60m sprint(r=-0.623,p=0.000), 2000m rowing ergometer(r=-0.413,p=0.002), Pull-Up Test(r=0.702,p=0.000), The Plank Fitness Test(r=0.764,p=0.000), Balance cushion One leg stand(r=0.656,p=0.000), Standing long jump(r=0.290,p=0.032) and Standing triple jump(r=0.477,p=0.000). 5kg Medicine Ball Throw(backwards) was correlated with Sit and Reach Flexibility(r=0.704,p=0.000), 60m sprint(r=-0.619,p=0.000), 2000m rowing ergometer(r=-0.373,p=0.005), Pull-Up Test(r=0.722,p=0.000), The Plank Fitness Test(r=0.723,p=0.000), Balance cushion One leg stand(r=0.570,p=0.000) and Standing long jump(r=0.462,p=0.000). Standing shot put test(5kg) was correlated with Sit and Reach Flexibility(r=0.637,p=0.000), 60m sprint(r=0.639,p=0.000), 2000m rowing ergometer(r=-0.373,p=0.005), Pull-Up Test(r=0.755,p=0.000), The Plank Fitness Test(r=0.656,p=0.000), Balance cushion One leg stand(r=0.568,p=0.000), Hexagon Agility Test(r=-0.280,p=0.038) and Standing long jump(r=0.448,p=0.001).

CONCLUSION: The test results show that flexibility, strength, speed, agility, aerobic ability are significantly related to the throwing ability of young shot put athletes. There is no correlation between height, weight, BMI and throwing ability These

findings provide information for coaches that young shot putters need to develop their overall physical ability to promote their speciality. Project 22-23 Supported by the Fundamental Research Funds for the China Institute of Sport Science.

LONGITUDINAL MONITORING OF THE FUNCTIONING ON HORSEBACK OF YOUNG PROFESSIONAL RIDERS IN VOCATIONAL TRAINING

PYCIK, E., LE NAVENEC, C., BIAU, S.

INSTITUT FRANÇAIS DU CHEVAL ET DE LEQUITATION

INTRODUCTION: Horseback riding is a dyad sport. To perform, the rider-horse synergy must be effective since each of the athletes influences the functioning of the other. For his part, the rider must acquire a good functioning i.e. a straight and stable trunk [1,2], fixed wrists and head [2,3] and independence of aids. Acquiring this expertise requires time, technical work and good physical condition. The objective of this study is to follow the evolution of the functioning on horseback of a group of 10 riders in their first year of vocational training.

METHODS: Today, rider's kinematics and kinetics can be easily assessed [4]. Here, 10 professional riders in the first year of vocational training at the IFCE were measured (2 men and 8 women; age=19±0.5 years; weight=57±9 kg; height=167.5±10 cm; handedness: 9 right-handed and 1 left-handed). Riders were equipped with 2 inertial units (Shimmer) on the upper back (sternum) and lower back (L3). Flexion-extension and right-left inclination were calculated. Rein tension and the forces normal to the floor of the stirrups were measured using force sensors (IFCE-CAIPS, 5). Riders performed a standardized sequence of gaits (walk, rising trot, sitting trot and 3-point canter) during 4 sessions: September (T1), December (T2), March (T3) and June (T4). 5 riders change the horse during the year. In parallel with the technical teaching, the riders benefited from general physical preparation (3x45min/week). Differences in functioning between sessions over the entire sequence on horseback was assessed with Friedman test ($p<0.5$).

RESULTS: Stirrups: the average right stirrup forces decrease ($p=0.019$; T1: 2.3±0.7 N/kg; T4: 1.7±0.2 N/kg) while there is no difference in left stirrup forces over the year (T4: 1.7±0.3 N/kg). Reins: no difference in rein tension is observed. Upper back: the standard deviation of the flexion-extension angles decreases ($p=0.0004$; T1: 8.8±1.4°, T4: 6.0±0.9°). The standard deviation of the inclination angles decreases ($p=1.3e-05$; T1: 4.9±0.7°; T4: 3.1±0.5°). Lower back: the standard deviation of the flexion-extension decreases ($p=0.001$; T1: 8.8±1.1°; T4: 6.6±0.9°). Mean inclination decreases ($p=5.3e-05$; T1: -2.1±2.6°; T4: 0.5±1.9°) as the standard deviation ($p=0.0003$; T1: 5.3±1.2°; T4: 3.5±0.4°).

CONCLUSION: Stirrup forces can be a strong expression of the rider's laterality, which symmetrise with technical teaching and physical preparation. Rein tension are not specific to the rider but also depend on the horse and on environmental factors [6]. Regarding the back, better stability is observed in the antero-posterior and lateral axes, acquired thanks to technical teaching and physical preparation. In any case, the acquisition of a good functioning on horseback is a long-term objective which is envisaged as a team (rider, coach and physical trainer) and which depends on technical, physical and environmental factors.

BODY COMPOSITION MONITORING OF YOUNG PROFESSIONAL RIDERS IN VOCATIONAL TRAINING

BIAU, S., LE NAVENEC, C., PYCIK, E.

INSTITUT FRANÇAIS DU CHEVAL ET DE LÉQUITATION

INTRODUCTION: The body composition phenotype of an athlete is the result of the interaction between genotype, sport requirements, diet and training program. The variability of the literature values concerning the rider is high, due to a highly variable physiological answer depending on the discipline and to the technology/method used to carry out the measurements. The first objective of the study was to characterize the phenotype of the professional rider at the beginning of his career by a bio-impedancemetry technique. The characterization of this population will constitute a reference. The secondary objective was to study the evolution of body composition and bone density during their first year of training.

METHODS: A group of 10 riders in their first year of vocational training were monitored for body composition and bone density every 6 weeks from October (start of training) to May (first-year exam). The group consisted of 8 girls and 2 boys, reflecting the population of members of this mixed sport. The average age of the group was 19±0.5 years and the minimum level of competition was amateur.The impedance was evaluated by a Z-Metrix® multifrenquency impedancemeter (BioparHom Company, France). The weight (W), fat Mass (FM, %w), muscular mass (MM, %w) and bone mineral content (BMC, kg) were evaluated. Descriptive statistics were calculated at each test and variables were compared between the 7 tests for everyone (Friedman test, $p<0.05$).

RESULTS: The mean height was 167.5±10 cm and the mean weight was 57±9 kg. These values are consistent with the population described in the literature [1]. At the end of the training program, FM was 15±6%W and MM was 37±5%W. The FM value is much lower than the % found in the literature (23.5 - 28.6%). Their activity and the measurement method may explain these differences. The estimated BMC values (2.8±00.3 % MNG or 1.4±0.3 kg) are hardly comparable to the literature data. The equations used are specific to the measurement method [2]. The dispersion at t1 and t7 reflects a stability of body composition and bone mineral content, although there are significant variations per individual that could have been explained by a period of examination, with Covid etc.

1.Douglas (2012) 2.Moreno (2015)

CONCLUSION: This study has shown the feasibility and interest of monitoring the body composition by bio-impedancemetry of professional riders in training, a population which despite their intensive sports activity, are still insufficiently monitored.

A STUDY ON THE IMPACT OF ADDING THREE MAJOR BALLS ON PHYSICAL EDUCATION TEACHING IN JUNIOR MIDDLE SCHOOLS IN WUHAN UNDER THE CONTEXT OF PHYSICAL EDUCATION SECONDARY EXAMINATION REFORM

LI, Y.N., LIU, L.H.

CHINA UNIVERSITY OF GEOSCIENCES, WUHAN

INTRODUCTION: The reform of the Physical Education Secondary Examination is not only relevant to the development of students, but also marks the future direction of physical education in schools. The incorporation of the three major balls in the physical education examination not only enables students to develop their physical fitness more comprehensively, but also has the important significance of enhancing the popularity of the three major balls in China, and laying the foundation for the future reserve talents of the three major balls in China.

METHODS: This paper analyses and discusses the current situation of physical education in Wuhan after the reform of physical education secondary examination through questionnaire, literature review, and mathematical statistics. The impact of the reform on the participants, teaching objectives, teaching contents, and teaching methods of physical education will be discussed.

RESULTS: (1) The reform has broadened students'choices, changed the traditional physical education learning mode which focuses only on practicing physical fitness, and increased students'motivation to learn physical education.

(2) Although the reform has put greater pressure on PE teachers, there is an increased emphasis on the work of PE teachers, and social status of PE teachers has improved.

(3) The reform has placed higher demands on PE teachers and school sports venues and equipment. Thus, the resources for teachers of the three major balls in schools are generally uneven, and the lack of football teachers is particularly serious.

(4) The teaching content and method for the three major balls lack variety, and there is a phenomenon of exam-oriented practice of what is tested.

CONCLUSION: (1) Education department should continue the implementation of the three major balls in schools, improve the setting of items and scores for the examination, explore the teaching situation and feedback, promote the construction of selective physical education class system, and ensure the smooth connection of physical education from primary school to junior high school.

(2) Middle schools should strengthen the training of PE teachers and management of three major balls. The recruitment of qualified professionals from universities and outstanding teachers can ensure the balanced development of three major balls. To address the problem of venue and equipment limitations, middle schools can increase funding or arrange for staggered training.

(3) PE teachers themselves should constantly strengthen their professional knowledge and skills, teaching abilities, and their awareness of lifelong learning. Three major balls'teaching should not be limited only to exam content, the teaching content should be optimized, and teaching methods should be innovated.

CAN I SWIM AND TALK COMFORTABLY?

FUSCO, A.1, DE MAIO, M.1, PAPALE, O.1, DI ROCCO, F.1, DI FAZIO, M.1, FESTINO, E.1, FOSTER, C.2, CORTIS, C.1

1 UNIVERSITY OF CASSINO AND LAZIO MERIDIONALE; 2 UNIVERSITY OF WISCONSIN-LA CROSSE

INTRODUCTION: Subjective methods to measure exercise intensity, such as the Talk Test (TT), have been shown to be practical alternatives of prescribing exercise in healthy individuals and athletes. Despite the TT is widely used in several sport such as cycling and running, no study has yet investigated its conceptual validity in swimming. Therefore, this study aimed to describe the variability of the land and water-based version of the TT.

METHODS: One elite male breaststroker swimmer (age: 24 years; height: 184 cm; weight: 84 kg) participated in the study. Three incremental treadmill running talk test (RTT) and 3 incremental swimming talk test (STT) sessions were performed. RTT consisted of 3-min warm-up with a slope of 1% (fixed for the test), with subsequent speed increase of 1 km/h every 2-min. For the STT, individual target times for each incremental bout were calculated based on the seasonal competitive personal best. STT consisted of 200m incremental bouts with the first bout set at 30s greater than the personal best, whereas all successive bouts' target time were set at 5s less than the previous bout. During each testing session, subject was required to rate his perceived exertion (RPE) on a 0-10 scale. At the end of each stage/bout the subject was also required to recite the Olympic Oath. Immediately after reciting the speech, subject was asked if he "Could speak comfortably" with three possible answers: "Yes", "Not sure" or "No". The last "Yes" answer was coded as last positive (LP), the first "Not sure" as equivocal (EQ) and the first "No" as negative (NEG). RPE values were then associated with LP, EQ and NEG stage for each TT. Tests were stopped if volitional fatigue was reached or "No" was given as answer. The two-standard deviation (SD) band method was used to describe the variability of the LP, EQ and NEG answers between the land- and water-based version of the tests, by using the RTT values as baseline mean and SD.

RESULTS: Significant differences were found between RPE RTT and STT LP values with at least 2 STT sessions (2nd STT: 4.5 AU; 3rd STT: 5.5 AU) over 2 SD of the baseline RTT (LP: 4.2 AU). Trivial significant differences were found for the EQ values,

with all STT sessions (1st and 2nd STT: 5.5 AU; 3rd STT: 6.5 AU) higher than the RTT SD upper limit of 5.4 AU. No significant difference was observed for the NEG, with only one STT session higher than the upper band of the RTT 2 SD (STT NEG: 8.0 AU > RTT 2 SD upper band: 7.5 AU).

CONCLUSION: TT protocol might be applied in swimming for measuring exercise intensity, especially at higher intensities such as the ones above the ventilatory and respiratory compensation thresholds. The higher STT RPE values found might be related to the test specificity, and therefore further studies should evaluate larger and specific samples with different characteristics in order to select the best procedure to adopt in this particular environment.

AN INNOVATIVE BASKETBALL JUMP SHOT PERFORMANCE TEST

BUNGMARK, W., BOONSOM, N.

SILPAKORN UNIVERSITY

INTRODUCTION: The purpose of this study was to validate An Innovative Basketball Jump Shot Performance Test.

METHODS: The subjects were ten university level male basketball players (aged 18 to 25). Each subject completed two trials of An Innovative Basketball Jump Shot Performance Test. Each week the test was consisting of 15 shot attempts from middle distances on 3 different court locations (4.60 m. away from the basket). Each shot attempt was follow operations and scored. The operations were 1) Step forward the usual 2-step and get the ball out of training assistant hands and jumping with both feet facing the left side towards the basket 2) Dribble the ball once and catch the ball and jump backwards until face approached the basket, landing on the ground with both feet 3) Jump and Shooting. The scoring criteria are as follows: 3 points is the basketball go through the basket no hit on the loop or a backboard, 2 points is basketball hit on the loop or a backboard before go through the basket, 1 point is basketball hit on the loop or a backboard but do not down through the basket and 0 points is basketball no hit on the loop or a backboard and do not down through the basket.

RESULTS: There was a high correlation between 2 trials basketball jump shot scored (intraclass correlation coefficient (ICC) = 0.86, $P < 0.001$).

CONCLUSION: An Innovative Basketball Jump Shot Performance Test appears to be high valid in predicting and scoring jump shot performance.

BILATERAL VARIABILITY IN Q-ANGLE AND LOWER-LIMB PERFORMANCE AMONG DIVISION I BLACK BASKETBALL PLAYERS: SEX DIFFERENCES

EGRET, C.1, PAPADAKIS, Z.1, STAMATIS, A.2, BOOLANI, A.3

<1> BARRY UNIVERSITY, <2> UNIVERSITY OF LOUISVILLE, <3> CLARKSON UNIVERSITY

INTRODUCTION: Female basketball players show a higher prevalence of knee injuries compared to males [1, 2]. Increased quadriceps angle (Q-angle) is positively related to knee injuries due to decreased quadriceps strength [3, 4]. Quadriceps' functional performance can be measured via jumping tests [5, 6]. Bilateral variability is an injury predictor due to compensation [7, 8]. Even though Q-angle has been examined worldwide, its bilateral variability is less studied, especially on Black basketballers [9, 10]. The purpose of the study was to examine bilateral variability and the relationship of Q-angle to jumping performance among division I Black basketball players.

METHODS: A licensed Physical Therapist (PT) performed a goniometric Q-angle measurement on fifteen players (Male = 9, Age = 21.2 ± 1.1; Female = 6, Age = 19.5 ± 0.8) and an evaluation of lower-limb performance (via a vertical jump [VJ] and a standing broad jump [SBJ]) according to standard procedures. Paired t-test and independent t-test were performed to determine bilateral variability in Q-angle by sex, while Pearson's r correlation was used to determine the relationship between Q-angle and lower-limb performance. Statistical analyses were performed using Jamovi (v. 2.3.3.0) at $p < .05$.

RESULTS: The average Q-angle for the sample was 9.5 ± 2.3 and 9.3 ± 1.8, for the left and right limbs, respectively. Q-angles were higher for females compared to males (11.8 ± 1.2 vs. 8.0 ± 1.4 and 10.8 ± 1.3 vs. 8.2 ± 1.3 for left and right limbs, respectively). No significant differences were observed between the left and right limbs in males ($t8 = -1.0$, $p = 0.35$), while females' left Q-angle was significantly different from the right Q-angle ($t5 = 2.7$, $p = 0.04$). Significant differences between sex were observed in both left and right Q-angles ($t13 = 5.5$, $p < 0.001$, and $t13 = 3.8$, $p = 0.002$, respectively). The left Q-angle was negatively correlated to VJ ($r = -0.7$, $p = 0.002$) and SBJ ($r = -0.7$, $p = 0.004$), while the right Q-angle was only negatively correlated to SBJ ($r = -0.6$, $p = 0.02$). Only males showed a significant correlation between Q-angles for the left and right limbs ($r = -0.9$, $p = 0.002$).

CONCLUSION: Our quadriceps strength findings provide indirect evidence of the greater risk for knee injuries in Black female basketball players: a) less strength than males and b) variability in-between legs. Investigation of bilateral variability in one-leg strength assessments may add value in terms of knee injury when screening this demographic.

DETERMINATION OF THE ANAEROBIC THRESHOLD FOR RUNNING FROM CENTER OF MASS VERTICAL DISPLACEMENT

SENTIJA, D., MARSIC, T.
FACULTY OF KINESIOLOGY, UNIVERSITY OF ZAGREB

INTRODUCTION: During incremental treadmill running neuromuscular and metabolic changes, which determine the anaerobic threshold, are associated with changes of specific kinematic parameters. The main objectives of this research were to investigate: 1) the relationship between the amplitude of vertical displacement of the center of mass for lower extremities and pelvis (CMa) and running speed during incremental running, and the possible presence of a nonlinear trend change, or threshold, for CMa (CMTh) with increasing running speed; 2) the relationship between the ventilatory anaerobic threshold (ATh, respiratory compensation point) and the CMTh.

METHODS: Twenty-three PE students were subjected to an all-out incremental treadmill test, with measurement of gas exchange (VO2, VCO2) and kinematic parameters. Independent evaluators defined the ATh (modified V-slope method) and CMTh thresholds. The APAS system (Ariel Dynamics, USA) with surface markers was used to measure the CMa, and the Quark b2 (Cosmed, IT) system for spiroergometry data. Student's t-test, correlation coefficient (r), and limits of agreement (LoA) were used to compare the ATh and CMTh thresholds obtained in the graded exercise test.

RESULTS: In 19 subjects CMTh was determined as the point of stagnation or decrease of the vertical displacement in the sagittal plane of the CM with increasing running speed. In the remaining 4 subjects a shift in the CMa trend was seen at the running speed corresponding to ATh. A strong relationship between ATh and CMTh ($r = 0.83$, $p < 0.01$) was determined. The average values of ATh and CMTh did not differ significantly, although a trend towards somewhat higher values for CMTh was present (LoA = 0.2 ± 2.5 km/h).

CONCLUSION: We conclude that, during graded treadmill running, there is close coupling between trend changes of center of mass vertical displacement and changes in gas exchange parameters that determine the anaerobic (second ventilatory) threshold. The results of the study give the opportunity for development of a new method for anaerobic threshold determination by center of mass measurement during graded treadmill running.

EFFECTS OF NON-DOMINANT SIDE STRENGTH TRAINING ON ATHLETIC PERFORMANCE OF MODERN PENTATHLON ATHLETES

WANG, J.H., QIU, J., TAN, C.H., CAO, G.H., CAO, Z.R., ZHANG, B., DONG, H.Y.
SHANGHAI RESEARCH INSTITUTE OF SPORTS SCIENCE

INTRODUCTION: This study evaluates the changes in the strength of both sides of the lower limbs after stage training through unilateral lower limb resistance strength training intervention with the same load and different movement modes. It explores the impact of non-dominant side strength changes on the related sports performance of modern pentathlon athletes.

METHODS: Fourteen athletes from the Shanghai modern pentathlon training team were selected as subjects for this study. The experimental intervention group was identified based on isokinetic strength test results. The experimental intervention involved seven participants in the experimental intervention group and seven participants in the experimental control group. The control group utilized bilateral load balance training for strength training, while the experimental group used unilateral strength training with both single and bilateral movement modes, maintaining a one-to-one correspondence, and the training load remained consistent. The training was conducted three times a week for a duration of 12 weeks.

RESULTS: (1) Non-dominant knee flexor and extensor strength, non-dominant ankle dorsiflexor strength were significantly correlated with CMJ, SJ, lower extremity relative maximum strength, 2 sets of 14m kendo round trip, 100 m swimming, laser run. (2) After training intervention, the strength of knee flexor and extensor muscle on the non-dominant side and dorsiflexor muscle on the non-dominant side of ankle joint in the experimental group were significantly increased, and the difference between the two sides was significantly decreased ($P < 0.01$), and the Y balance in the experimental group was significantly improved. (3) The maximum power and average power of anaerobic power in the experimental group were significantly increased in 30s, and CMJ, SJ, reaction force, 1RM squat, relative 1RM squat, 30 m run, 3000 m run in the experimental group were significantly increased. The performance indexes of 2 sets of 14m Kendo round trip, 100 m swimming, 200 m swimming and laser running were significantly improved in the experimental group.

CONCLUSION: Our findings suggest that (1) The strength of the non-dominant lower limb may significantly impact the Y balance, sports injury, anaerobic work, speed, strength, and specific sports performance indexes of modern pentathlon athletes. (2) Unilateral body strength training, utilizing both single and bilateral movement modes, can effectively improve the flexion and extension strength of the non-dominant knee joint and the plantar dorsiflexion strength of the ankle joint in modern pentathlon athletes. (3) The improvement in flexor and extensor muscle strength of the knee joint on the non-dominant side, along with dorsiflexor muscle strength of the ankle joint on the non-dominant side, can effectively promote

the development of special strength, speed, anaerobic endurance, aerobic endurance quality, and specific sports performance of modern pentathlon athletes.

THIGH MUSCLE ACTIVITIES DURING BOTH- AND ONE-LEG STAND-UP TESTS FROM DIFFERENT SEAT HEIGHTS

OSAWA, T.

JAPAN WOMENS COLLEGE OF PHYSICAL EDUCATION

INTRODUCTION: Both- and one-leg stand-up tests are simple and relatively safe, and are used for evaluating lower limb strength and balance, especially in older persons. The scores were reported to have a linear relationship with the weight bearing index of maximal knee extension isometric strength. However, few studies have investigated thigh muscle activities during stand-up tests. The purpose of this study was to examine thigh muscle activities, assessed using electromyographic (EMG) analyses, during both- and one-leg stand-up tests from seats of different height.

METHODS: Thirteen active young females (age: 21 ± 1 years, height: 159.2 ± 7.1 cm, weight: 52.8 ± 7.1 kg, BMI: 20.8 ± 2.3 kg/m2) participated in this study. Their body composition was measured using bio-impedance analysis, and the thickness of their muscles and fat in the middle of the anterior thigh was assessed using ultrasound B-mode imaging. Their maximal knee extension isometric strength was measured using a strain gage. Seven types of stand-up tests were performed randomly: both-leg stand-up tests from seats 40-, 30-, 20-, and 10-cm high (BL40, BL30, BL20, and BL10, respectively), and one-leg (right side) stand-up tests from seats 40, 30, and 20-cm high (OL40, OL30, and OL20, respectively). During the tests, the EMG activities of the vastus lateralis (VL), rectus femoris (RF), and vastus medialis (VM) of the right thigh were continuously measured. The root mean squares of the EMG values were calculated and normalized to OL20 (i.e., the EMG value during OL20 is 1.00).

RESULTS: There was significant interaction between the three muscles ($p < 0.05$). The mean EMG values in the VL and VM, but not in RF, increased gradually in the following order: BL40, BL30, BL20, BL10, OL40, OL30, and OL20. The EMG values during OL40 were significantly higher than those during BL10 in the VL ($p < 0.001$) and VM ($p < 0.001$). However, those in the RF were not significantly different between BL10 (0.531 ± 0.124) and OL40 (0.507 ± 0.144). The EMG value in the RF was significantly different between OL30 (0.783 ± 0.129) and OL20 (1.000 ± 0.000) ($p < 0.001$), although those in the VL and VM were similar between the two tests (N.S.).

CONCLUSION: These results suggest that, although the scores of stand-up tests were reported to be linearly related to the lower limb strength per body weight, the changes in muscle activity during the tests are different between the thigh muscles, and none of the muscle activities increased linearly from BL40 to OL20.

RELATIONSHIP BETWEEN UNILATERAL JUMP AND DIFFERENT COD ASYMMETRIES IN ACTIVE YOUNG ADULTS

BUSCÀ, B.1, RODRÍGUEZ, J.1, ARBOIX-ALIÓ, J.1,2, AGUILERA-CASTELLS, J.1, MIRÓ, A.1, FORT-VANMEERHAEGHE, A.1,2, HUERTAS, P.1

1 PSYCHOLOGY, EDUCATION AND SPORT SCIENCES FACULTY OF BLANQUERNA - URL; 2 FACULTY OF HEALTH SCIENCES BLANQUERNA - URL

INTRODUCTION: The repeated execution unilateral jumps and COD actions involve large neuromuscular loads which may lead to asymmetries between limbs (Bishop et al, 2019) and, consequently, to an injury risk. The magnitude and direction of these asymmetries during change of direction (COD) actions have rarely favoured the same direction in sport population (Bishop et al., 2017). Moreover, the relationship between the performance and the asymmetries in different COD angles are not clear (Dos'Santos et al., 2018). Therefore, the main aim of the present study was to evaluate the neuromuscular asymmetries between the lower extremities in active and healthy students during the execution of different changes of direction (180º, 135º and 45º) and unilateral jumps, as well as to determine their directionality according to the behaviour of each extremity in each test.

METHODS: The sample (n = 22, age = 23 ± 1.40 years) of the present study performed two performance tests, the bilateral jump with countermovement (CMJ) and the 10m sprint, and several unilateral tests such as the unilateral jump with countermovement (SLCJ) and three types of changes of direction (COD: 180º, 135º and 45º). To identify differences between limbs, the magnitude of differences between HPL and LPL were assessed with paired sample t-tests. Kappa test (k) were used to establish the directionality of ASI scores and a correlation analysis of all variables was conducted.

RESULTS: Results showed significant differences between the established legs as HPL and LPL in all unilateral tests observed ($p < 0.001$). The Kappa coefficients determined a poor consistency in the directionality of the asymmetries, thus indicating that these rarely favored the same extremity in the respective tasks (kappa = -0.30 to 0.24). The calculated COD deficit values reported a higher magnitude of the asymmetries compared to the one obtained from the total COD times. However, both the magnitude and the directionality in question also differed depending on the change of direction. At the same time, no significant correlation was observed between performance testing and unilateral testing.

CONCLUSION: The present study highlight the lack of consistency towards the magnitude and directionality of the asymmetries, thus highlighting the fluctuation of their behavior depending on the task evaluated. The fact that no direct relationship was found between performance and asymmetries suggests that each motor skill observed should be specifically assessed and trained.

DEVELOPMENT AND VALIDATION OF A NEW ANTHROPOMETRIC PREDICTIVE EQUATION FOR ESTIMATING FAT MASS IN ELITE MALE SOCCER PLAYERS

BONGIOVANNI, T.1,2, CAMPA, F.3, ROSSI, A.4, CERULLO, G.3, CASOLO, A.3, MARTERA, G.5, TRECROCI, A.6, MORO, T.3, PAOLI, A.3

1 DEPARTMENT OF BIOMEDICAL AND NEUROMOTOR SCIENCES, UNIVERSITY OF BOLOGNA, BOLOGNA, ITALY 2 DEPARTMENT OF PERFORMANCE, PALERMO FOOTBALL CLUB, PALERMO 3 DEPARTMENT OF BIOMEDICAL SCIENCES, UNIVERSITY OF

INTRODUCTION: This study aimed i) to develop and validate an anthropometric soccer-specific equation for predicting FM using dual energy X-ray absorptiometry (DXA) as a reference method; ii) to assess the performance of existing soccer-specific predictive equations.

METHODS: Eighty male soccer players (age 24.4 years, BMI 23.7 kg/m2) participating in the first Italian league underwent anthropometric measurements and DXA scan during the in-season period. the participants were divided into development and validation groups. The validation group returned for a second assessment three months later and was included in an analysis of longitudinal validity.

RESULTS: The best developed model was: FM (kg)= -9.905 + (sum of triceps, iliac crest, abdominal, and front thigh skinfolds (mm) × 0.175) + (thigh circumference (cm) × 0.258) - (ethnicity × 1.577) - (age (years) × 0.068), R2=0.73, standard error of estimation (SEE)=1.01 kg, where ethnicity is 1 for black and 0 for white. Cross-sectional validation showed r2 values ranging from 0.71 to 0.72 with SEE equal to 0.80 kg and 0.86 kg for the baseline and the second assessments, respectively. Concordance correlation coefficients (CCC) were 0.84 at baseline and 0.86 at the second visit. The agreement analysis showed no mean bias at any time (p>0.05) and lower 95% limits of agreement (LoA) ranging from -1.5 kg to 1.8 kg. Longitudinal validation demonstrated a high accuracy at both group (r2= 0.80, SEE= 0.37 kg, CCC= 0.90) and individual (mean bias= 0.04 kg, 95%LoA= -0.7 kg to 0.8 kg, r= 0.117) levels.

CONCLUSION: The FM estimated from existing predictive equation differed from DXA for all the cross-sectional and longitudinal assessments, showing less accuracy compared to the new equation. This study presents a new soccer-specific predictive equation based on four skinfolds and a circumference, allowing for a valid and sport-specific assessment of FM across the competitive season.

TRAINING CHARACTERISTICS AND RACE-RELATIVE INTENSITY DISTRIBUTION OF ELITE TEAM PURSUIT CYCLISTS

STADNYK, A., STANLEY, J., DECKER, T., SLATTERY, K.

UNIVERSITY OF TECHNOLOGY SYDNEY

INTRODUCTION: The training process involves the systematic planning and execution of exercises to develop athletic qualities and performance. Team pursuit track cyclists require highly developed aerobic, anaerobic, and neuromuscular capacities to repeatedly and extensively produce the required power output to execute the race strategy. This study aimed to profile the general training characteristics of an elite team pursuit cycling squad relative to their own world-record performance power and torque demands.

METHODS: Training data of five male track endurance cyclists (mean ± SD age 21.9 ± 3.52 y; 4.4 ± 0.16 W.kg-1 @ LT2; 6.2 ± 0.28 W.kg-1 @ VO2peak; peak oxygen uptake 68.7 ± 2.99 mL.kg.min-1) were analysed across a 36-week preparation period. Training intensity distribution for power and torque were calculated with reference to the athletes' subsequent world-record performance (3:49.804 min:sec.ms) demands for the 4-km team pursuit (i.e., WR Lead [wheel 1], WR Average [wheel 1-4], WR Follow [wheel 2-4], along with variations in weekly total training volume by activity type, and training gear and pace evolution.

RESULTS: Across 436 ± 16 sessions during the 36-week period, athletes completed 543 ± 37 hours of training activities (e.g., track, road, ergometer, gym), with 11246 ± 1140 km total distance cycled. Seventy percent of on-bike training was performed at low-intensity power output (below LT1), with 7.7% performed at high intensities (above LT2). Torque demands for WR Lead, Average, and Follow were 55, 45, and 39 Nm, respectively. Athletes accumulated 4.4% of on-bike load above WR Lead torque requirements (55 Nm), with a further 4.7% above WR Average (45 Nm) and 5.6% above WR Follow (39 Nm).

CONCLUSION: These data provide valuable insight to the training characteristics of a recent world-record team pursuit squad. The development of anaerobic and neuromuscular capacities was a major component of these athletes' training, which differs from previous descriptive studies of elite team pursuit cyclists. The findings also present novel quantification of race pace-relative intensity distribution for team pursuit power and torque demands, which may have relevance to coaches and practitioners in training prescription. General intensity distribution observed was not dissimilar to those reported in other endurance sports, although there was limited shift toward a polarised distribution in the competition taper.

THE HIGH INTENSITY INTERVAL TRAINING AND VIGOROUS-INTENSITY CONTINUOUS TRAINING PROTOCOLS DURING CYCLEBOXING - PRELIMINARY STUDY FOR MONITORING TRAINING LOAD AND PHYSIOLOGICAL RESPONSES

KUO, W.H., HSU, W.C., LIN, Y.J.

NATIONAL TAIWAN UNIVERSITY OF SCIENCE AND TECHNOLOGY

INTRODUCTION: Optimal exercise prescription for the effect in high intensity interval training (HIIT) during cycling has been well documented (Buchheit and Laursen 2013, Martland, Mondelli et al. 2020) and those in vigorous-intensity continuous training (VCT) during cycling has also been reported (Gerber, Brand et al. 2014). Cycleboxer is a sports equipment which allow boxing and cycling simultaneously. However, as a new option for strengthening, cardiopulmonary fitness and conditioning, there is no study which adopted specific exercise protocol such as the HIIT and VCT to investigate the training loads and the immediate physiological responses while performing Cycleboxing. Therefore, current study aimed to investigate the relationships between various kinds of external and internal loads with the oxygen consumption.

METHODS: Participants were recruited to perform Cycleboxing with two different prescriptions, namely the HIIT and VCT. The HIIT prescriptions included 2 min exercise and 1 min resting intervals for 6 sets and the VCT prescriptions included first 25 minutes vigorous intensity and last 10 minutes vigorous-to-high intensity for a total of 35 minutes. During cycleboxing, the participants wore Polar H10 heart rate belt (Büttelborn, GER) on the chest, breathing mask, non-invasive Muscle Oxygen Monitors(MOXY, Fortiori Design LLC, Hutchinson, MN, USA) on the upper limb (biceps humerus) and lower limb (vastus lateralis), the inertial sensor on the upper arm, forearm and thigh. External load and internal training loads such as heart rate, oxygen uptake, SmO2, EMG, blood lactic acid, power, and RPE were monitored during training.

RESULTS: The multiple linear regression model of HIIT showed better coefficient of determination (R2=0.964), with SmO2_VL being the best followed by the Power as predictors for VO2, compared with the determination (R2=0.332), with SmO2_VL being the best followed by the SmO2Bl_diff and by Power as predictors for VO2.

CONCLUSION: Compared with the SmO2 measured in VCT prescriptions, SmO2 measured in HIIT showed better coefficient of determination, suggesting a better explanatory were reached in shorter interval training than in longer endurance training. And this predicting capacity was related to local body parts, gender, and athletic level.

ACUTE EFFECTS OF JAW CLENCHING WHILE WEARING A CUSTOMIZED BITE-ALIGNING MOUTHGUARD ON MUSCLE ACTIVITY AND FORCE PRODUCTION DURING MAXIMAL UPPER BODY ISOMETRIC STRENGTH

MIRÓ, A.

UNIVERSITAT RAMON LLULL

INTRODUCTION: Beyond the preventive role of wearing bite-aligning mouthguards (MG), recent research has investigated its neuromuscular effects and the possible benefits in different parameters such as muscular strength, power or muscle activation (Allen et al., 2018; Ebben et al., 2008; Schulze & Busse, 2019). The reason for these positive effects may be associated to the phenomenon called concurrent activation potentiation (CAP). This raising mechanism may be promoted by a remote voluntary contraction (RVC) of the mandible muscles (Ebben et al., 2008). It has been reported that the use of these devices promote a better temporomandibular repositioning and a more powerful occlusion, which may magnify the effects of the RVC (Maurer et al., 2018). Thus the aim of the present study is to investigate the effects of jaw clenching while wearing a customized MG on masticatory and prime movers muscle activation as well as on force production during maximal upper body isometric tests.

METHODS: Twelve highly trained rink-hockey athletes participated in the study. A randomized, repeated measures within study design was carried out to compare the acute effects of three experimental conditions: jaw clenching while wearing MG (MG), jaw clenching without MG (JAW) and non-jaw clenching (NON-JAW). Conditions were randomly distributed to avoid the influence of fatigue and the test learning effects. Participants performed three different isometric force tests following the next order: handgrip test (HG), bench press (BP) test and biceps curl (BC).

RESULTS: Statistical analyses revealed a significant higher force production ($p < 0.05$) in all tests for MG conditions with respect to NON-JAW. When comparing JAW and NON-JAW conditions an increased peak force was found in handgrip ($p = 0.045$) and bench press ($p = 0.018$) but not in biceps curl ($p = 0.562$). When comparing MG and JAW conditions, no differences were observed in any force output. In terms of muscle activity, significant differences were found in the agonist muscles of the handgrip test for MG with respect to NON-JAW ($p = 0.031$ - 0.046), whereas no differences were observed when comparing MG and JAW conditions.

CONCLUSION: The present study demonstrated that jaw clenching, with and without MG, is a good strategy to increase the upper body isometric strength compared to NON-JAW condition. A higher isometric force production was observed in all tests for MG with respect to NON-JAW conditions. When comparing JAW and NON-JAW conditions, this improvement was only observed in two of the three tests. The non-significant differences found in force production neither in muscle

activity between JAW and MG conditions, speculated that these ergogenic effects might be attributed to the jaw clenching, even though the use or non-use of MG.

INFLUENCE OF SEVERE COLD METEOROLOGICAL CONDITIONS ON HUMAN CORE TEMPERATURE DURING MARATHON EXERCISE

JI, T., WANG, K.

SHANGHAI JIAO TONG UNIVERSITY

INTRODUCTION: As an extreme sport, marathon is conducted outdoors under a variety of meteorological conditions. It is significantly affected by meteorological conditions, which brings higher sports risks. Marathon participation in extreme severe cold environment may lead to hypothermia and impair life and health, but over the past years there are few quantitative studies on the relationship between meteorological conditions and human hypothermia in marathon exercise. The study was aimed at quantitatively investigate the influence of severe cold meteorological conditions on the time of hypothermia in marathon.

METHODS: From the perspective of heat transfer and according to the characteristics of human body in marathon exercise, this study established the algorithm of internal heat transfer of human body and the heat transfer process between human body and the surrounding environment, and iterated, simulated and calculated the hypothermia process of human body in marathon exercise under the condition of low temperature and cold weather.

RESULTS: In marathon exercise, when there was only low temperature weather, hypothermia never happened when the ambient temperature exceeded -2°C.When low temperature and rainfall weather existed at the same time, assuming that the ambient temperature was 4°Cand the rain temperature was 0°C, the time of fatal hypothermia was about 18-45min when the rainfall was in the range of 0.5-1.75mm/h. Assuming that the ambient temperature was 4°Cand the rainfall was 1.25mm/h, the time of fatal hypothermia was about 20-40min when the rain temperature was in the range of 0-3°C. When low temperature, rainfall and strong wind weather existed at the same time, assuming that the ambient temperature was 4°C, the rain temperature was 0°Cand the rainfall was 1.25mm/h, the ambient wind speed varies in the range of 1-15 m/s, the time for fatal hypothermia of human body is about 20min.

CONCLUSION: Rainfall is the most important meteorological factor affecting hypothermia during marathon, then low temperature takes the second place and strong wind takes the third place. In the future outdoor marathon, special attention should be paid to the prevention of the risk of hypothermia when low temperature, rainfall and strong wind occur at the same time.

EXTERNAL LOAD ANALYSIS IN DIFFERENT FOOTBALL PITCH DIMENSIONS

FERNANDO, S., MARTIM, R., PEDRO, F., TIAGO, S., VÍCTOR, H., MARTÍN, G., CÁTIA, F., MÁRIO, E.

POLYTECHNIC INSTITUTE OF SETÚBAL - SCHOOL OF EDUCATION

INTRODUCTION: Monitoring training loads is essential for more effective training planning and operationalization, allowing the coach to know the training exercises effects (1). It is important for a relevant monitoring of the training load, that the variables to be analyzed consider the specific football game characteristics (2). The game of football is characterized by complexity (3), in which players develop synergies at different times of the game, in which high intensity strengths are relevant to determine the results of the game (4). In this sense, knowledge about training tasks that promote optimal stimulation according to the football players age is fundamental to football coaches (5). The aim of this study was to comparatively analyze the variable external load distance traveled (m) and the distance in high-speed running - HSR (>21 km), high acceleration - Hac (>3m/s2) and high deceleration - Hdec (>-3m/s2), manipulating the pitch size in GK+10x10+GK games.

METHODS: Considering the official football playing area, the analyzed games were performed on 1/2 pitch, 3/4 pitch and the total pitch size. The study included 20 young U-17 players (age: 16.1±0.76 yrs; heigh: 1.73±0.03 m; weigh: 61.81±3.54 kg). The data were collected using WIMU devices that were placed on the back of the trunk with vests specific for this purpose. Data analysis was performed through descriptive statistics, and the comparison between games was made using Anova One-Way. Effect size (ES) was also calculated using Eta-square ($\eta p2$).

RESULTS: The results showed that there are statistically significant differences ($p<0.001$) in the HSR variable between the 1/2 (14.98±14.34 m), 3/4 (27.64±19.27 m) and total pitch size (74.00±62.68 m). It has been observed that pitch size manipulation has an ES on the HSR (ES=0.31). Regarding the variables distance covered, no significant differences ($p>0.05$) were found between Hac and Hdec in the three games analyzed, (ES<0.06).

CONCLUSION: The used game formats are not promoters of differences in distance and distance covered in Hac and Hdec. It is also clear that for players to register HSR values it is necessary that the pitch size is greater than 3/4 official football pitch dimensions.

CROSSOVER EFFECT OF STATIC STETCHING TRAINING ON ANKLE DORSIFLEXION IN ADOLESCENT FEMALE ATHLETES

DONTI, O.1, PANIDI, I.1, GASPARI, V.1, KONRAD, A.2, TERZIS, G.1, DONTI, A.1, BOGDANIS, G.C.1

1NATIONAL AND KAPODISTRIAN UNIVERSITY OF ATHENS, GREECE; 2UNIVERSITY OF GRAZ, AUSTRIA

INTRODUCTION: The mechanisms underlying stretch-induced joint range of motion (ROM) increases have been attributed to peripheral (muscle and tendon) and central (neural) components. Whereas several studies documented that central neural factors affect the stretched muscle groups, there is some evidence that static stretching also increases ROM in the contralateral non-stretched muscles (1). Thus, the aim of this study was to examine the crossover effect of static stretching training on ankle dorsiflexion in adolescent athletes.

METHODS: Twenty-one adolescent female volleyball athletes (age: 13.5 ± 1.4 years, height: 159.8 ± 7.0, body mass: 53.7 ± 7.6 kg) participated in this study. Static stretching of the plantar flexors of one leg (STR) was performed five times per week for 12 weeks in addition to volleyball training, while the contralateral leg served as control (CON). Total duration of stretching per session increased from 540 s to (week 1) to 900 s (week 12). At baseline, week 3, 6, 9, 12 and after 3 weeks of detraining, ankle angle was measured at rest and at maximum dorsiflexion using video analysis with the athletes performing wall calf stretching.

RESULTS: Resting ankle angle did not differ between legs at baseline ($p = 1.000$). Ankle dorsiflexion of the STR leg increased from baseline by 12% (week 6) to 20.1% (week 12) ($p < 0.001$) and this improvement was maintained during detraining ($p = 1.000$). Similarly, ankle dorsiflexion of the CON leg increased from baseline by 6% (week 9) to 11% (week 12) ($p < 0.001$) and was maintained during detraining ($p = 1.000$). Between legs difference in ankle angle was 28% at week 3 ($p = 0.019$) and increased to 55% at week 12 ($p <0 .001$), while it was maintained during detraining ($p < 0.001$).

CONCLUSION: Ankle dorsiflexion angle increased in both legs with a larger increase in the STR than the CON. Contralateral increases in ROM after stretching training may be attributed to central neural adaptations (2), similar to cross-education effects reported in strength training studies (3). The larger increase observed in the STR compared to CON may indicate the contribution of morphological changes of the plantar flexors to ROM increases.

THE EFFECT OF INTERMITTENT PALM COOLING ON AEROBIC ENDURANCE PERFORMANCE FOR DIVISION II FOOTBALL PLAYERS – PILOT STUDY

SALAH, A., BUNK-ANDERSEN, P., ANDERSEN, J.C., REDONDO, G., MILLER, A., TAMULEVICIUS, N.

UNIVERSITY OF TAMPA

INTRODUCTION: Three surfaces of the human body are known to possess high thermo-sensitivity, the face, the bottom of the feet, and the palms (1). Each site comprises glabrous skin and is known to significantly aid in releasing metabolic heat through vasodilation (2). Recent evidence suggests that controlled palm cooling may have an ergogenic effect on performance (2). This study aimed to investigate the effect of intermittent palm cooling on football-specific aerobic endurance test (Yo-Yo IRT1).

METHODS: Fifteen male collegiate football players (age 21 ± 2.4) volunteered to participate in the study. The study was conducted over two separate training sessions (S1, S2) using a cross-over approach with subjects randomly assigned to either the cooling [C] or non-cooling [NC] condition for S1 and crossing over for S2. For S1 and S2, we recorded temperature (˚C), humidity (%), and barometric pressure (mmHg); (S1: 19˚ C, 52.2 %, 766.8 mmHg and S2: 25.4˚ C, 57.7%, 761.7 mmHg). The test consisted of repeated 2 x 20-m shuttle runs back and forth between a starting point, turning point and finish line. The running speed was controlled by timed audio feedback. A 10-second active recovery break between bouts was provided, where the subjects walked 2 x 5 meters and then returned to the starting line. During recovery, the players in the C condition submerged each hand into a separate cooler with water kept at 8˚ - 15˚ C while the NC condition did the recovery walk. The water temperature was monitored using the Physitemp BAT-12 Microprobe Thermometer. Descriptive and inferential statistics were calculated for Yo-Yo IRT1 performance using Jamovi 2.3.16. To determine if the cooling intervention impacted Yo-Yo IRT1 performance, a paired t-test was used with an alpha of ($p \leq 0.05$.)

RESULTS: The overall distance across conditions on the Yo-Yo IRT1 was 1733 ± 237m. The average distance for the Yo-Yo IRT1 for the C condition was 1712 ± 223.8m and the NC condition was 1754.7 ± 255.6m. The paired t-test analyses between the C and NC conditions identified a mean difference of -42.7m (95% CI -159.72m to 74.39m) which was not statistically significant $p=0.447$).

CONCLUSION: To our knowledge, this is the first investigation into the effect of palm cooling on endurance performance of football players. The overall distance is comparable to that seen in male amateur football players (3). With respect to the impact of palm cooling on Yo-Yo IRT1 performance, we observed no effect on football-specific aerobic endurance. This may be due to session variations in temperature and humidity which could mediate the effects of intermittent cooling. It is also possible the magnitude and/or duration of cooling was insufficient to have an effect. Future assessment of the ergogenic effects of intermittent cooling is warranted and should account for these issues.

MAXIMIZING PHYSICAL PERFORMANCE WITH STRENGTH TRAINING DURING THE COMPETITIVE SEASON FOR ICE HOCKEY PLAYERS: FAVORABLE EFFECTS OF 40% VELOCITY LOSS

BJØRNSEN, T., REMME, S., NYQUIST, N., HAUKALI, E., TVEITEVOLL, Å., VÅRVIK, F.T.

UNIVERSITY OF AGDER

INTRODUCTION: Recent studies have explored the impact of velocity-based strength training (VBST) on athletes and have indicated that applying velocity losses of 10-20% can result in neuromuscular adaptations while minimizing neuromuscular fatigue (1). However, during the in-season period, athletes typically engage in a greater volume of high-velocity, power-based movements as part of their sport-specific training regime. This raises the question of whether a different, more fatiguing training stimulus would be advantageous. To the best of our knowledge, the effects of VBST during the competitive season have not yet been investigated. The aim of this study was therefore to compare the effect of 20% vs. 40% velocity loss protocols during the back squat exercise in semi-professional ice hockey players during the in-season period.

METHODS: A total of 24 ice hockey players were randomly assigned to either a 20% velocity loss (VL20: 8 male and 4 female, 17.1±1.5 yrs, 176.6±10.4 cm, 77.8±14.7 kg) or a 40% velocity loss group (VL40: 7 male and 5 female, 16.9±0.9 yrs, 173.3±10.3 cm, 70.0±11.4 kg). Participants underwent a biweekly VBST program with three sets of back squats per session during their competitive season, for a duration of 5 weeks (female team) or 8 weeks (male team). Physical performance, including 1-repetition maximum [1RM] back squat, leg press maximal strength and -power, 30-m on and off ice sprint, and countermovement jump (CMJ), as well as muscle thickness of vastus lateralis (ultrasonography) were assessed at pre- and post-intervention periods.

RESULTS: The VL40 group performed an average of 11±2, 10±2 and 9±2 repetitions in sets 1-3 per session of back squat, compared to 8±2, 7±2, and 7±2 repetitions in VL20 (all $p<0.01$).

The VL40 group showed significantly greater improvements in leg press maximal strength (2.2±5.7% vs. -4.1±4.4% for VL20, $p<0.001$) and -power (2.6±5.3% vs. -1.5±4.3% for VL20, $p=0.05$) than the VL20 group. No other significant group differences were observed, but both VL40 and VL20 protocols led to increases in back squat 1RM (11.1±7.9% and 6.3±6.0%, respectively) and muscle thickness (3.6±3.7% for VL40 and 2.0±1.8% for VL20, both $p<0.001$). Only the VL40 group exhibited a significant improvement in CMJ compared to baseline (2.8±3.0%, $p=0.046$), whereas the VL20 group did not show a significant change (0.1±4.7%, $p=0.688$).

CONCLUSION: Both VBST protocols proved effective in preserving or enhancing muscle size, -strength, and -power among semi-professional ice hockey players during the competitive season. Nonetheless, our results suggest that the 40% velocity loss protocol may be more favorable for achieving strength and power gains than the 20% protocol in-season. Further studies are needed to explore in-season velocity loss protocols that employ equal training volume, to discern whether the results are attributed to velocity loss per se or training volume.

EFFECT OF TIME-OF-DAY AND TWO TYPES OF PARTIAL SLEEP DEPRIVATION ON FEMALE SOCCER PLAYERS' SPECIFIC PERFORMANCE

HUO, Q.W.1,2, VAN CUTSEM, J.2,3, ROELANDS, B.2, PATTYN, N.2,3, MAO, L.J.1

1SHANGHAI UNIVERSITY OF SPORT; 2VRIJE UNIVERSITEIT BRUSSEL; 3ROYAL MILITARY ACADEMY

INTRODUCTION: In general, the sleep of athletes is not optimal (e.g., habitual short sleep (<7 hours/night) and poor sleep quality [1]). Many critical athletic performance factors have been found to be negatively impacted by sleep deprivation [2]. However, athletes' sleep and performance is sex-linked [3], and, in reality, athletes encounter much more situations in which they are only partially sleep deprived. Therefore, this study aimed to investigate the effect of time-of-day and two types of partial sleep deprivation (PSD) on female soccer players' performance.

METHODS: 18 active female collegiate soccer players (19.3 ± 1.6 yrs, 165 ± 6 cm, 58 ± 7 kg, healthy sleepers, no extreme chronotypes) performed three sessions of soccer-specific performance tests. Following the baseline session, players were separated into two PSD groups; 9 participants were deprived of ~3.5h sleep in the beginning (PSDB) of the night, while the sleep of the other 9 participants was similarly deprived, but at the end of the night (PSDE). Subsequently, two other performance sessions were conducted in the morning and afternoon following on the PSD. Outcome measurements include specific fitness tests [countermovement jump (CMJ), 30-m sprint (30-m), T-test and YoYo IRTL 1(YOYO)] and skill tests [Loughborough Soccer Shooting and Passing Test (LSST and LSPT)]. Data were analyzed using a mixed ANOVA analysis in SPSS. Significance was set at $p < 0.05$.

RESULTS: A significant main effect of time was found in CMJ ($p<0.001$), T-test ($p=0.035$) and YOYO ($p<0.001$). These performances all significantly declined in the morning and afternoon following on PSD. A significant interaction effect was present in 30-m ($p=0.035$). In PSDB, 30-m performance was slower in the morning than baseline ($p=0.04$) and the afternoon ($p=0.02$). However, in the PSDE group, there were no differences across time. All aspects of LSPT [i.e., Original ($p=0.014$), Penalty ($p=0.005$) and Performance ($p=0.002$)] significantly deteriorated due to sleep deprivation, independently from

PSD-group. Regarding LSST performance, Sequence time (p=0.001) and Null shots (p=0.045) were impaired in time. In addition, Speed of shots was faster in PSDE than in PSDB, showing a main effect of group (p=0.032).

CONCLUSION: Female soccer players' upper body power, agility and aerobic endurance were negatively affected by PSD in the morning and afternoon following on the PSD, independently from the type of PSD. Passing skill and shooting performance were impaired by PSD and time-of-day. The findings of this study have practical implications for coaches to optimize performance in situations of PSD.

DEVELOPMENT OF NEW REACTION AGILITY TEST IN TENNIS

POJSKIC, H., STJERNA, T., SEKULIC, D.
LINNAEUS UNIVERSITY

INTRODUCTION: Tennis is an intermittent physically demanding sport with many high-intensity acceleration, and deceleration actions with four directional changes in an average point, where a player runs an average of 3 m per shot [1]. Players have to react rapidly to the opponent's shots and efficiently change their position in all directions to reach and return the ball [2]. Therefore, successful performance in tennis requires well-developed change-of-direction speed (CODS) and reaction agility (RAG) that is dependent on perceptual and decision-making skills [1,2]. However, there is an evident lack of tennis-specific agility tests. Recently, tennis-specific RAG test was developed, but it enabled only testing in two directions, left (L) and right (R), without sprinting forward (F) [3]. Thus, the aim of this study was to examine the reliability and validity of newly developed tennis-specific test (T-RAG) with three movement options (L, R and F).

METHODS: The study included 18 regional-level, male and female youth tennis players (age: 14.5 ± 1.5 years; body height: 1.69 ± 0.08m; body mass: 57.8 ± 10,9kg). Variables included pre-planned T-CODS, and three protocols of non-planned T-RAG (e.g. F, L, R, F). For the T-RAG test, the participants had to execute "split step" across the infrared (IR) line, which initiates the timing and lit one of the three LEDs placed inside the cones (L, F, R). Then players had to assess which cone was lit, run towards it, hit the hanging ball with the racquet. The ball was placed at the specially constructed stand 1.2m above the respective cone and 4m distant from the starting line. Afterwards they sprinted back across the IR line. For the T-CODS, the participants did the test in pre-planned regime (e.g. L, F, R, L). Each test was performed three times.

RESULTS: Both the relative and absolute reliability were good for the T-CODS (ICC = 0.80; CV = 5.8%) and T-RAG (ICC = 0.92 to 0.94; CV = 6.7 – 7.0%). The T-CODS and T-RAG shared 52–66% of the common variance.

CONCLUSION: This study confirmed the high reliability of the three-directional tennis-specific tests of RAG and CODS in youth players which is in line with previous studies [2,3]. However, T-RAG showed better relative reliability compared to T-CODS, which can be explained by larger between-participants variability in T-RAG than in the T-CODS. When the variability is high, it is easier to maintain consistently the ranking order in test-retest measurements [4]. The percentage of shared common variance between T-RAG and T-CODS was higher than in the previous studies, which can be attributed to the lower playing level of participants who could lack movement proficiency when rapidly changing direction in response to external stimuli compared to their older counterparts. The tennis coaches should be aware that the development of RAG, perceptual and decision making abilities is warranted in youth players.

SEX-SPECIFIC DIFFERENCES IN EXERCISE INDUCED MODULATION OF CARDIAC AUTONOMIC ACTIVITY IN PATIENTS WITH MAJOR DEPRESSION

HOOS, O.1, OBERMEIER, L.1, VOGT, J.1, KAUFMANN, S.1, KITTEL-SCHNEIDER, S.2
1 JULIUS-MAXIMILIANS-UNIVERSITY WURZBURG, 2 UNIVERSITY HOSPITAL WURZBURG

INTRODUCTION: As both depressive symptoms and cardiac autonomic regulation are influenced by sex [1], the aim of this pilot study was to evaluate possible exercise related, sex-specific differences in cardiac autonomic activity (HRV) and perceived exertion (RPE) in female (FDP) and male (MDP) patients with major depression during a moderate intensity 2km walking test (2kmWT).

METHODS: n=10 female (FDP; age: 30±15yrs, BMI: 24.3±6.1kg/m2) and n=10 male (MDP; age: 31±10yrs, BMI: 24.2±2.6kg/m2) patients with moderate to severe major depression (QUIDS: MDP: 15.2±7.1 vs. FDP: 18.2±4.3; p=0.27, d=0.51) performed a 2kmWT (Walking index: WI in a.u.), while data on walking speed (WS in km/h) and rating of perceived exertion (RPE) were assessed every 400m. In addition, heart rate (HR in bpm) and linear (SDNN in ms, RMSSD in ms) and non-linear (DFAa1) indices of 5min-HRV were analyzed before (REST), during the last 5min of 2kmWT (EXE) and after 5min of recovery (REC).

RESULTS: Both sexes showed similar, rather low values of WI (MDP: 78.3±24.8a.u. vs. FDP: 79.8±13.3a.u., p=0.87, d=-0.08) and comparable HR (MDP: 149±18bpm vs. FDP: 154±30bpm, p=0.67, d=0.19) and RPE (MDP: 12.6±2.3 vs. FDP: 13.2±2.5, p=0.58, d=0.25) at the end of 2kmWT, while FDP reached lower WS (MDP: 7.4±0.7km/h vs. FDP: 6.7±0.9km/h, p=0.07, d=-0.87). For both sexes the linear HRV indices SDNN (MDP: 27.8±12.3ms vs. FDP: 25.7±13.6ms, p=0.72, d=-0.17) and RMSSD (MDP: 16.4±8.8ms vs. FDP: 17.1±9.0ms, p=0.85, d=0.08) were similar during REST, strongly diminished during EXE (SDNN: MDP: 3.3±2.1ms vs. FDP: 3.2±1.4ms, p=0.86, d=-0.07; RMSSD: MDP: 2.9±1.6ms vs. FDP: 3.7±1.9ms, p=0.36, d=0.42) and showed a comparable vagal reactivation in REC (SDNN: MDP: 16.6±11.9ms vs. FDP: 13.0±6.8ms, p=0.41, d=-0.38; RMSSD: MDP: 8.4±6.0ms vs. FDP: 7.6±5.0ms, p=0.75, d=-0.19). In contrast, non-linear DFAa1 was lower in FDP compared to MDP during REST (MDP: 1.49±0.12 vs. FDP: 1.36±0.17, p=0.07, d=-0.86) and EXE conditions (MDP: 0.99±0.43 vs. FDP: 0.69±0.21,

p=0.07, d=-0.88), while both sexes regained a similar recovery level during REC (MDP: 1.57±0.28 vs. FDP: 1.55±0.22, p=0.82, d=-0.10).

CONCLUSION: In depressed patients the general exercise induced autonomic perturbation shows a similar pattern of vagal suppression and reactivation in both sexes. In contrast, correlation properties of DFAa1 reveal subtle sex-specific differences in complex regulation during rest and exercise. This may point towards a more severe exercise induced organismic stress [2] in female patients. Whether this effect might influence exercise perception and should be considered in sex-specific exercise prescription in major depression remains to be further elucidated.

PHYSICAL PERFORMANCE IN PARALYMPIC WHEELCHAIR RUGBY ATHLETES FROM CUNDINAMARCA-COLOMBIA.

DIOGO, B.

UNIVERSIDAD DE CUNDINAMARCA

INTRODUCTION: In wheelchair rugby, players use an offensive or defensive wheelchair depending on their position on the field and their level of disability. The performance of wheelchair rugby players is related to several paramenters, degree of disability, physical ability, time of experience, type of wheelchair, which are related to sport performance. The objective of this study is to analyze the physical performance of wheelchair rugby athletes from Cundinamarca-Colombia.

METHODS: Eleven people belonging to the wheelchair rugby league of Cundinamarca-Colombia were tested for physical and technical performance, ball handling, blocking performance, 20-meter speed, long-distance passing, Illinois agility test, 40-meter test, up and backs.

RESULTS: Age 37.4 (10.2), Peak speeds of the first 2 pushes (acceleration phase) were significantly higher with the defensive wheelchair than with the offensive wheelchair ($p < 0.05$ and $p < 0.03$). Mean and peak sprint velocity were significantly greater ($p < 0.04$ and $p < 0.06$, respectively) with the defensive wheelchair. In ball handling 8.36 (3.07) sec, blocking performance 29.67 (7.16) effective.

CONCLUSION: The performance was lower with the offensive wheelchair than with the defensive one, suggesting the frequent finding that the higher performance of defensive players compared to offensive ones, the technical variables are aperfecioamento elements for a development with more effective in the matches potentiating better performance for wheelchair rugby.

COMPARISON BETWEEN SPATIOTEMPORAL STRIDE CHARACTERISTICS DURING RAMP VERSUS STEADY STATE RUNNING TESTS

GUYOT, V., MORALES-ARTACHO, A.J., RABITA, G.

FRENCH INSTITUTE OF SPORT , PARIS

INTRODUCTION: Ramp incremental (RI) tests have two major benefits over step tests (ST): their shorter duration (especially at high intensity) and the possibility of assessing metabolic demand over a wide range of speeds as long as the delay to reach a steady state is considered (1, 2). On the other hand, being able to measure the running spatiotemporal characteristics in parallel to the metabolic responses remains an interesting and more complete approach. However, on a treadmill, the spatiotemporal parameters of the stride can evolve over a constant load (3). This case-study aims to compare spatiotemporal stride characteristics at the end of metabolic steady-state steps (ST) versus during the RI at the same speed.

METHODS: An elite runner (10 km run time: 29'05, VO2 max: 80.4 mL.min-1.kg -1) performed a treadmill test (1% gradient) consisting of two stages: 6 min at 15 km.h-1 (moderate intensity domain) and 10 min at 18.5 km.h-1 (heavy). After a 5-min active and 5-min passive recovery, a ramp test (4 minutes at 9 km.h-1 and then + 0.1 km.h-1 / 6 seconds) was performed. Flight time (FT), contact time (CT), stride length (SL) and frequency (SF) were collected throughout the test using an optical measurement system (OptoJump). Vertical (KV) and leg stiffness (KL) as well as duty factor (DF) were determined as proposed by Morin et al. (4). These metrics were compared between the last two minutes during steps [ST], and at the same speed during ramp incremental test [RI] (6 seconds) at 15 and 18.5 km.h-1.

RESULTS: At 15 km/h, CT (ST: 221.4 ± 4.4, RI: 216.3 ± 4.7 ms) and DF (ST: 64.1 ± 1.43, RI: 61.8 ± 1.27%) were superior in the step condition. FT (ST: 124.1 ± 6.4, RI: 133.7 ± 5.0 ms), KV (ST: 19.6 ± 1.1, RI: 21.1 ± 1.2 Kn.m-1) and KL (ST: 7.09 ± 0.4, RI: 7.69 ± 0.5 Kn.m-1) were superior during the ramp incremental condition. On the other hand, SL (ST: 1.44 ± 0.03, RI: 1.45 ± 0.02 m) and SF (ST: 2.90 ± 0.05, RI: 2.86 ± 0.03 Hz), were very similar between the two modalities. For all variables, the relative difference between RI and ST was greatly reduced at 18.5 km.h-1 compared to 15 km.h-1.

CONCLUSION: Spatiotemporal stride characteristics transiently measured during ramp incremental test are closer to those adopted during a steady-state run at 18.5 km.h-1 than at 15 km.h-1 for this elite runner. At 15 km.h-1, the athlete was more aerial and presented higher stiffness values in RI than in ST. These differences were lower at 18.5 km.h-1. The transition from moderate to heavy intensity domain may contributes to these observations, reducing the athletes ability to run at the same speed using varied stride patterns. Furthermore, the ability of a ramp test to translate mechanical characteristics over a wide range of speeds appears relevant to be evaluated in a larger population.

VARIATION IN ENERGY COST IN SWIMMING : HOW MUCH IS USED ACCORDING TO THE STROKE FREQUENCY VARIATION

LETOCART, A.J, LEPRETE, P.M., GUIMARD, A.3, MARIUTTE, T., REGAEIG, M., GUIGNARD, B.1, SEIFERT, L.1

1UNIV ROUEN NORMANDIE, CETAPS UR 3832, F-76000 ROUEN,FRANCE; 2UFR-STAPS, APERE, UNIVERSITÉ DE PICARDIE JULES VERNE,AMEINS, FRANCE,FRANCE;3 STAPS, UNIVERSITÉ SORBONNE PARIS NORD, BOBIGNY, FRANCE.

INTRODUCTION: The successful performer is able to adapt his/her behavior to dynamically shifting environments that characterize sport competition. Regarding motor coordination in cyclic locomotion tasks and particularly in swimming, speed and movement frequency appeared as key constraints[1]. Moreover, competition analysis showed that stroke frequency can really vary within and between laps[2]. This study aimed to examine swimmers' energy cost (C) of locomotion in front crawl when facing different task constraint such as stroke frequency.

METHODS: 17 swimmers (14 men (age 19.8 ± 1.4yrs) and 3 women (age 19.7 ± 1.2yrs) performed as fast as possible a 6x50m front crawl with the first trial with the spontaneous stroke rate (SSR) over 50 m. The second 50 m was performed with an audible metronome to impose SSR. The third to sixth 50 m were randomly performed with the audible metronome set to -6, -3, +3 and +6 cycles/min in comparison to SSR. The energy cost of locomotion was assessed by measuring oxygen consumption and blood lactate. Rating of Perceived Exertion (RPE) was obtained after each trial. For the statistical analysis, multiple logistic regression was used to evaluate if C and success in trial with variation of stroke frequency (identical time and respect of imposed SSR) were associated.

RESULTS: Success in trial with variation of stroke frequency revealed that the C (OR = 1.15, $p < 0.05$) was a significant predictor. Further, RPE was not a statistically significant factor.

CONCLUSION: In this present study, swimmers showed a modification of energy cost in order to satisfy the task demand. When manipulating swimming stroke frequency with dominance for speed, different metabolic pathways could emerge, confirming that this parameter act as a main constraint of the energy system.

TEST – RETEST RELIABILITY OF A 3-MINUTE ALL-OUT 15-METER SHUTTLE RUNNING TEST

TILLIN, N.

UNIVERSITY OF ROEHAMPTON

INTRODUCTION: Critical running speed (CS) is the fastest sustainable speed whilst D' is a finite distance above CS, and these parameters can predict performance and inform training (1). A 3-min all-out running test can determine CS and D' (1). Studies have developed 3-min all-out shuttle running tests involving changes of direction (COD) for relevance to team sport players. However, these tests were: not suitable for simultaneously testing a team of players (2), or did not use COD frequencies similar to those expected in team sport (3), or did not convert CS and D' to critical metabolic power (CPmet) and W' to account for accelerations that occur with COD. Further, no studies have assessed test – retest reliability of their 3-min all-out tests. This study assessed the reliability of a 3-min all-out shuttle running test suitable for simultaneously testing a whole team of players, with a COD frequency (COD every 15 m) similar to team-sport activity, and considered speed and metabolic power metrics.

METHODS: 11 English Premier League Academy soccer players (Age 13.6 ± 0.5 years) performed a 3-min all-out shuttle-run test on 3 separate occasions, with consecutive sessions separated by a week. All participants completed the test together. The 3-min all-out test involved running back and forth between two parallel lines set 15 m apart. Running speeds and distances were measured via a GPS unit (STATSports Viper) sampling at 10 Hz. Metabolic power and work were determined from running speed and acceleration using the equations of de Prampero (4). CS and CPmet were average speed and metabolic power in the last 30 s. D' and W' were the areas below the speed-time and work-time curves above CS and CPmet respectively. Between test coefficient of variation (CV) and bi-variate correlation coefficients were determined.

RESULTS: CVs between test 1 and 2 were 6% (CS), 17% (D'), 10% (CPmet), and 17% (W'). Between tests 2 and 3, CVs improved and were 4% (CS), 11% (D'), 8% (CPmet), and 8% (W'). Bivariate correlation coefficients between test 1 and 2 were weak-moderate (0.38-0.52) for all variables. Correlation coefficients improved between test 2 and 3 (0.4-0.61).

CONCLUSION: This 3-min all-out test provided acceptably low CVs in CS, D', CPmet, and D' between test 2 and 3, but not between 1 and 2, suggesting coaches should familiarise their athletes with the test at least once to ensure reliable measurements. Whilst correlation coefficients were higher between test 2 and 3 than test 1 and 2, they remained weak-moderate for all variables, which may be due to low between-participant variability in the variables recorded. This test can

be reliably completed by a whole team of players simultaneously, and utilises COD frequencies that are similar to team sport activity.

IS MAXIMAL POWER IMPAIRMENT AT THE END OF SEVERE-INTENSITY CYCLING EXERCISE DEPENDENT ON THE INTENSITY OF THE TRIAL?

ROUSSEAU Q., MORALES-ARTACHO A.J., RABITA G.

FRENCH INSTITUTE OF SPORT

INTRODUCTION: In cycling, force-velocity and power-velocity profiling (i.e. maximal force [Fmax], power [Pmax] and velocity [Vmax]) is commonly used to assess the maximal lower limbs capabilities during sprinting (1). These variables have been shown to evolve after completing different fatiguing tasks, like repeated sprint efforts (2) or road race cycling (3). How these parameters evolve when assessed immediately after completing different constant-load cycling exercises (CLCE) to failure in the severe-intensity domain and aiming at depleting the same amount of work above critical power (i.e., [W']) , is unknown. The aim of this study is to investigate how the magnitude of severe CLCE performed to failure influences Fmax, Pmax and Vmax measured at the end of these bouts.

METHODS: One male trained triathlete (age, 29 yr; height, 186 cm; body mass, 67 kg; VO2peak: 73.9 ml.min.-1.kg -1) was tested on 5 occasions on a cycle ergometer, with 48h-rest between the visits. The first visit consisted of a ramp-incremental test to failure (25 W.min-1) achieved at peak power output (POpeak). The next four visits implied performing CLCE to failure into the severe-intensity domain. Immediately after failure, a 5-second all-out sprint was performed. Seven cycle-averaged couples of force and velocity values were obtained for each of the four sprints and effective torque- and power-pedal rate relationships were fitted using linear and quadratic regression models to determine Fmax, Pmax and Vmax indexes.

RESULTS: The participant achieved a POpeak of 405 W. The durations of the severe CLCE were 169, 311, 529 and 767 s. The model that produces the smallest combined SEE of critical power ([CP]) and W' gives the following estimates of these parameters: 314W (SEE: 0,9%) and 15,5 kJ (SEE: 5,3%) respectively. Coefficients of determination of the four linear and quadratic relationships were high ($R^2 \approx 0,95$-$0,99$ and $R^2 \approx 0,86$-$0,98$). Fmax, Pmax and Vmax values ranged between 165-172 N·m, 679-812 W and 155-188 rpm, respectively. Vmax and Pmax linearly decreased ($r^2 = 0,99$ and $0,94$) with the increase of the magnitude of the severe CLCE performed to failure (expressed in W) whereas no relationship exists with Fmax.

CONCLUSION: Maximal power impairment at the end of severe CLCE performed to failure seems to be related to the magnitude of the intensity maintained to failure, rather than the quantity of W' depleted. Moreover, this impairment appears to be due to the decrease of Vmax rather than Fmax. Force-velocity and power-velocity profiling could be relevant to use at the end of fatiguing tasks. Nonetheless, future studies need to be done to confirm these findings with a larger population.
