What is already known about this topic? Prevalence of food sensitization (FS) varies considerably across Europe, and is reported to be on the rise. Environmental influences are likely, but studies investigating currently conceived environmental predictors for FS are lacking.

What does this article add to our knowledge? This is the first study evaluating the main postulated environmental risk factors for FS, using a standardized approach in both children and adults across Europe. Mutually adjusted associations between primarily early-life exposures and FS are revealed.

How does this study impact current management guidelines? Dog ownership appears to protect against childhood FS, but other environmental factors appear to have (more) limited impact on the prevalence of FS in European children and adults.

BACKGROUND: The geographical variation and temporal increase in the prevalence of food sensitization (FS) suggest environmental influences.

Abbreviations used FA- Food allergy FS- Food sensitization IS- Inhalant sensitization OR- Odds ratio

METHODS: Data on childhood and adult environmental exposures (including, among others, sibship size, day care, pets, farm environment, and smoking), infant diet (including breastfeeding and timing of introduction to infant formula and solids), and demographic characteristics were collected from 2196 school-age children and 2185 adults completing an extensive questionnaire and blood sampling in the cross-sectional pan-European EuroPrevall project. Multivariable logistic regression was applied to determine associations between the predictor variables and sensitization to foods commonly implicated in food allergy (specific IgE $\geq 0.35 \text{ kU}_A/\text{L}$). Secondary outcomes were inhalant sensitization and primary (non-cross-reactive) FS. **RESULTS:** Dog ownership in early childhood was inversely associated with childhood FS (odds ratio, 0.65; 95% CI, 0.48-0.90), as was higher gestational age at delivery (odds ratio, 0.93 [95% CI, 0.87-0.99] per week increase in age). Lower age and male sex were associated with a higher prevalence of adult FS (odds ratio, 0.97 [95% CI, 0.96-0.98] per year increase in age, and 1.39 [95% CI, 1.12-1.71] for male sex). No statistically significant associations were found between other evaluated environmental determinants and childhood or adult FS, nor between infant diet and childhood FS, although early introduction of solids did show a trend toward prevention of FS. CONCLUSIONS: Dog ownership seems to protect against childhood FS, but independent effects of other currently conceived environmental and infant dietary determinants on FS in childhood or adulthood could not be confirmed. © 2020 The Authors. INTRODUCTION

Prevalence estimates of IgE sensitization to foods range from 11% to 29% in 7- to 10-year-old children and from 7% to 24% in adults across various European countries.^{1,2} Several studies indicate that the prevalence of food sensitization (FS) in children and adults is rising.³⁻⁷ The geographical variation in the prevalence of FS in children and adults of comparable genetic background, and the proposed increase in FS prevalence over time, suggest an effect of environmental factors.⁸

Although FS does not invariably lead to food allergy (FA), it is a prerequisite, and an objective end point that can feasibly be obtained for multiple foods in a large group of participants. Studies investigating environmental predictors for FS are scarce. Some previous studies report a protective effect of certain environmental determinants on FS in children, such as younger maternal age at delivery,⁹ higher number of previous pregnancies,¹⁰ exposure to a farm environment,^{10,11} or having childhood

pets (dogs or cats).¹¹ Determinants related to infant diet also may be relevant. Vitamin D insufficiency and late introduction of solid foods, for example, have been associated with an increased likelihood of FS.¹²⁻¹⁴ In adults, a link between the use of antacids and increased FS has been proposed.¹⁵ Most studies in adults, however, tend to focus on inhalant sensitization (IS) or other atopic diseases as outcomes.^{16,17} As part of the European Community Respiratory Health Survey, Svanes et al performed extensive analyses on the effect of a multitude of childhood environmental determinants on adult sensitization to inhalant allergens, and found a protective effect of increasing family size, bedroom sharing, and the presence of a dog in the childhood home.¹⁷ Studies on this scale, which include multiple suggested risk factors and allow for mutual adjustment, are not yet available for the outcome FS or FA. Such studies are key to helping us understand differences in prevalence and time trends between and within populations.⁸

This gap in knowledge led to the current study, in which the primary aim was to investigate how environmental, dietary, and demographic determinants are associated with sensitization to foods that are commonly consumed across Europe and frequently implicated in FA. The focus was on early-life events and exposures, and the outcome was assessed in both children and adults, using data collected from all across Europe in a standardized manner during the European Union-funded EuroPrevall project. Secondary outcomes included IS and primary (non-cross-reactive) FS, to determine whether there are differences between predictors for FS and IS, the latter of which was the focus of previous studies in adult populations.¹⁷

METHODS

Study design, setting, and subjects

A full description of the methodology of the EuroPrevall study, a cross-sectional cohort study with a case-control design nested within, is available elsewhere.¹⁸ In the current study, we included randomly sampled children (7-10 years) and adults (20-54 years) from the general population of Athens (Greece), Lodz (Poland), Madrid (Spain), Reykjavik (Iceland), Utrecht (The Netherlands), Zurich (Switzerland), and Vilnius (Lithuania), who completed phase I (a short screening questionnaire) and phase II (a detailed questionnaire, and blood sampling for detection of IgE against 24 common food allergens [termed priority foods] and 6 common inhalant allergens [as summarized in Online Repository Methods on data collection in this article's Online Repository at www.jaci-inpractice.org]). All phase I participants who reported symptoms to 1 or more of the 24 priority foods (cases) and a random sample of phase I participants who reported no symptoms to these foods (controls) were invited for phase II. All data were collected between 2007 and 2009 for children, with a median time interval of 5 months between phase I and II; and between 2006 and 2009 for adults, with a median time interval of 8 months. The local ethical committees of all participating centers gave approval for this study, and informed consent was obtained from all participants.

Data collection

The primary outcome, FS, was defined as positive serology (specific IgE $\geq 0.35 \text{ kU}_A/\text{L}$) to at least 1 of the 24 selected foods. IS was considered present if a subject was sensitized to at least 1 of the 6 selected inhalant allergens. Primary FS, defined as sensitization occurring through true plant- or animal-derived food allergens, rather than through pollen inhalant allergens cross-reacting

Downloaded for Anonymous User (n/a) at Vilnius University from ClinicalKey.com by Elsevier on April 27, 2021. For personal use only. No other uses without permission. Copyright ©2021. Elsevier Inc. All rights reserved.

with plant food allergens, was determined using an allergen microarray assay (see Figure E1 in this article's Online Repository at www.jaci-inpractice.org). The overlap between the various outcome variables is depicted in Figure E2 in this article's Online Repository at www.jaci-inpractice.org.

Information on determinants was extracted from answers to the EuroPrevall phase II questionnaire (see Figures E3 and E4 in this article's Online Repository at www.jaci-inpractice.org). In addition to the childhood environmental factors that were investigated for both adults and children, infant dietary factors were taken into account for children, and adult environmental factors for adults. Childhood environmental determinants were investigated for exposure before the age of 2 years for children and before the age of 5 years for adults. To give a complete overview, demographic factors were also assessed. More details on data collection are available in this article's Online Repository at www.jaci-inpractice.org.

Data analysis

As an initial exploration, differences between subjects with and without FS were examined using the χ^2 test for categorical variables and the 2-sample t test for continuous variables. Univariable logistic regression was performed to assess crude associations between each individual determinant and FS (crude odds ratios [ORs]). Multivariable logistic regression including all determinants was then applied to obtain the independent contribution of the determinants to FS (adjusted ORs). Details on missing data are available from Table E1 in this article's Online Repository at www.jaci-inpractice.org. To ensure optimal power in the multivariable analysis and potentially reduce bias, multiple imputation was performed using fully conditional specification (20 imputations, 20 iterations), for which all variables in Table E1 were included as covariates. Because it is known that the prevalence of FS is variable between countries,^{1,2} all analyses were controlled for center by adding center as a categorical covariate in the model. To better understand the independent contribution of the various determinants, a stepwise approach to model building was chosen. In model I, multivariable analysis was performed with only demographic factors. In model II, childhood environmental determinants were added. In model III, infant dietary determinants were added for children, and adult environmental determinants for adults.

To observe how the association between the determinants and FS changed on adding comorbidity with overlapping pathophysiological mechanisms, we performed additional analyses. First comorbid atopy (asthma, allergic rhinitis, or atopic dermatitis, or at least 1 of these 3 diseases in first-degree relatives, or parental FA [for the pediatric population]), and then coexisting IgE sensitization to inhalant allergens, was incorporated into model III.

To evaluate whether predictors for FS differ from predictors for IS and primary FS, and enable comparison with earlier studies regarding factors associated with sensitization, we also fitted model III for these outcomes.

Analyses were conducted with SPSS version 25 (IBM Corporation, Armonk, NY). *P* values less than .05 were considered statistically significant.

RESULTS

Of the 2326 children and 2256 adults completing the phase II questionnaire, the 2196 children and 2185 adults with available food serology were evaluated in this study. There were no differences in age or sex between those subjects who did and who did not complete phase II. In subjects who did complete phase II, subjects with available serology appeared somewhat more

likely to report symptoms to (priority foods) and were more likely to be male, than subjects with missing serology results, but no other remarkable differences were observed in demographic characteristics or allergic comorbidities (see Table E2 in this article's Online Repository at www.jaci-inpractice.org).

Respectively 494 children and 441 adults were sensitized to at least 1 of the priority foods. The median age of the children was 8.9 years in both those with and without FS, and respectively 50.8% and 49.6% were males (Table I). The food-sensitized adults had a median age of 35.3 years and 49.0% were males, whereas the nonsensitized adults had a median age of 39.2 years and 41.1% were males (Table II). Data on all determinants were complete in 76.5% of the children and 82.2% of the adults; in the rest, missing values on 1 or more of the determinants were estimated by multiple imputation.

Children: Crude associations between demographic, childhood environmental, and infant dietary determinants and FS

Table I presents the results of univariable analyses in children. No significant associations between demographic factors, age, sex, and parental level of education and FS in childhood were found. Lower gestational age, lower birth weight, and shorter length at birth tended to increase the likelihood of FS (Table I). Comorbid atopy, parental FA, and IS also showed strong positive associations with FS.

Many childhood environmental factors demonstrated significant inverse associations with FS, specifically having more siblings, having older siblings, day care attendance before the age of 2 years, and having a pet dog before the age of 2 years.

Regarding dietary determinants, breast-feeding for longer than 6 months was inversely associated with FS, compared with breast-feeding for less than 6 months. Breast-feeding was not necessarily exclusive. Use of infant formula, which could be either a replacement of or complementary to breast-feeding, was positively associated with FS, especially hypoallergenic infant formula. In subjects who received infant formula, a trend was suggested where the younger infant formula was introduced, the less likely FS became. A similar trend was observed for solid food introduction.

Independent predictors of FS in children

In multivariable analyses, gestational age was the only demographic determinant that remained significantly associated with FS in childhood (Table III). The longer the pregnancy, the lower the chance of FS in the child (OR, 0.93 [95% CI, 0.87-0.99] per week of pregnancy duration). Of the childhood environmental determinants, having a pet dog before the age of 2 years was still significantly inversely associated after multivariable adjustment (OR, 0.65 [95% CI, 0.48-0.90]). Of the infant dietary determinants, use of hypoallergenic infant formula maintained a positive association with childhood FS (OR, 1.51 [95% CI, 1.06-2.15]).

Adjustment for comorbid atopy did not result in relevant changes to the associations obtained in model III (see Table E3 in this article's Online Repository at www.jaci-inpractice.org). Subsequent correction for coexisting IS resulted in male sex becoming significantly inversely associated with FS (OR, 0.64 [95% CI, 0.49-0.84]) and attenuated the associations between having a pet dog before the age of 2 years and use of hypoallergenic infant formula and FS in childhood, suggesting that

reverse causality explains part of the observed associations (Table E3). The association between pet dog and FS remained significant.

Adults: Crude associations between demographic, childhood, and adult environmental determinants and FS

Table II presents the results of univariable analyses in adults. Of the demographic factors, younger age and male sex were significantly positively associated with FS, as were comorbid atopy and IS.

Analyses of childhood environmental determinants in adults showed a significant inverse association between having more siblings, sharing a bedroom with other or older children before the age of 5 years, and growing up on a farm before the age of 5 years and FS in adulthood (Table II). In contrast to the findings in children, day care attendance before the age of 5 years was shown to significantly increase the likelihood of adult FS.

Of the adult environmental determinants, ever having had a food-related occupation was associated with a lower risk of FS.

Independent predictors of FS in adults

Only the demographic factors age and sex remained significantly associated with adult FS after multivariable adjustment (Table III), yielding an OR of 0.97 (95% CI, 0.96-0.98) per year increase in age and an OR of 1.39 (95% CI, 1.12-1.71) for male sex. Multivariable analyses revealed no significant associations between childhood or adult environmental determinants and FS in adults.

Addition of comorbid atopy and subsequently IS to the model did not notably change any of the observed associations (Table E3).

Secondary outcomes: Independent predictors of sensitization to inhalant allergens and primary food allergens

Table E4 in this article's Online Repository at www.jaciinpractice.org facilitates comparison of predictors for FS, as discussed above, with predictors of the secondary outcomes, IS and primary FS.

In children, the results pertaining to IS were generally similar to those related to FS. Noticeable exceptions were that bedroom sharing with other children before the age of 2 years and growing up in a farm environment showed stronger inverse associations with IS, the former of which reached statistical significance. Also, although sex was not associated with FS, male sex was significantly positively associated with IS. Regarding primary FS, no particular differences in predictors were found compared with overall FS.

In adults, it was noteworthy that where there were no significant associations between the childhood environmental determinants and FS in adulthood, there was a significant inverse association between growing up in a farm environment or with a pet cat before the age of 5 years and IS. Furthermore, increasing maternal age was significantly associated with a higher risk of IS. Adjustment for comorbid atopy attenuated the protective effect of cat ownership, but not that of farm or maternal age, which suggests some reverse causality in the association between cat ownership and IS.

Regarding the outcome primary FS, bedroom sharing with older children before the age of 5 years was found to be inversely associated, and smoking in adulthood significantly increased the likelihood of primary FS in adults.

DISCUSSION Summary of findings

Until now, no study existed in which the main postulated environmental and infant dietary risk factors for FA were evaluated collectively in multivariable analysis, especially not all over

Europe for both children and adults. The data from the Euro-Prevall project made this possible. In our study, having a pet dog before the age of 2 years was the only statistically significantly predictive early-life exposure, and it was found to be strongly associated with a decreased risk of FS in childhood. Higher gestational age at birth was also significantly inversely associated with childhood FS. No childhood or adult environmental determinants were significantly associated with FS in adulthood, but demographic characteristics lower age and male sex did make adult FS more likely.

Early-life exposures: Environmental determinants

The finding that having a pet dog in early childhood was inversely associated with FS consolidates existing evidence that dog ownership protects against childhood FA.¹⁹⁻²¹ The protective effect is thought to be the result of exposure to diverse environmental microbiota.²¹ Similarly to the adjusted OR of 0.65 (95% CI, 0.48-0.90) in the current study, Koplin et al²² reported an adjusted OR of 0.6 (95% CI, 0.3-0.8) for the association between dog ownership and challenge-proven egg, peanut, and sesame allergy in Australian infants participating in the HealthNuts study; and Von Hertzen et al¹¹ found an adjusted OR of 0.57 (95% CI, 0.35-0.95) for the association between having a dog before the age of 1 year and food and inhalant sensitization in Finnish schoolchildren aged 7 to 16 years. More recent findings from Europe by Marrs et al²¹ demonstrate an even stronger relationship, with an adjusted OR of 0.1 (95% CI, 0.01-0.71) between dog ownership before 3 months and challenge-confirmed FA to cow's milk, egg white, cod, peanut, sesame, and wheat in infants aged 1 to 3 years from the United Kingdom and Wales.²¹ Perhaps the association is stronger depending on how young the subject is at exposure, or depending on how old the subject is when the outcome is measured. Our finding that having a pet dog in childhood was not as strongly inversely associated with FS in adulthood as with FS in childhood, might be explained by the fact that the exposure to dog before the age of 5 years instead of 2 years was examined in adults. Or maybe the protective effect does not last until adulthood. Alternatively, one should consider the fact that the adults stemmed from an environmentally different childhood era than the children in this study, which could mean that predictors for the current adults differ from those for the current children when reaching adulthood.

Previous literature suggests that environmental factors other than having a pet dog in childhood also influence the likelihood of FA.²³⁻²⁶ Two environmental determinants that are relatively consistently suggested to protect against FA in children are an increasing number of siblings, especially older siblings,²³⁻²⁶ and rural or farm lifestyle.^{23,27,28} In our study, these determinants also exhibited an inverse association with FS in univariable analysis, both for children and for adults. However, the suggested protective effects were attenuated and lost statistical significance in multivariable analysis. Although the current study was not specifically powered to detect associations (of minimal relevant size) for all predictors studied, nor was it designed to assess causal associations, our study is unique in that it included both childhood environmental exposures and infant dietary determinants in multivariable analysis for prediction of childhood FS, which may influence the observed associations in comparison with earlier studies where a more limited set of predictive factors was evaluated. Furthermore, because the outcome FA is often (partly) defined by a measure of subjective interpretation, subjects self-reporting symptoms may be more likely to report risk factors associated with FA than subjects without symptoms, thus possibly inflating associations. Our objective outcome, FS, may have mitigated these associations.

Nonetheless, several studies also report a significant protective effect of early-life farm exposure on IgE sensitization, in both children^{11,29} and adults.^{17,30} All these studies, however, focused on IS. In our study, early-life farm exposure, but also bedroom sharing in childhood for example, was more strongly inversely associated with IS than with FS in both children and adults, to the point of reaching statistical significance. Even larger differences were observed when comparing IS to primary FS. It is possible that predictors for FS and IS differ (in effect size), despite shared pathophysiological mechanisms.

Early-life exposures: Infant diet

Regarding infant diet, none of the dietary determinants evaluated in our study significantly predicted FS in childhood, except for the use of hypoallergenic infant formula. Findings from models with further adjustment for comorbid atopy and IS, where the association between the use of hypoallergenic infant formula and FS lost statistical significance, suggest that reverse causality may play a role here. In other words, food-sensitized infants may be more likely to receive hypoallergenic infant formula rather than the other way around.

Literature is inconsistent on whether breast-feeding is protective against allergy, neutral, or allergy-promoting.³¹ In accordance with our findings, most systematic reviews of literature conclude that there appears to be no significant association between breast-feeding ever versus never, or breast-feeding duration, and FA.^{23,32,33} Interestingly, Hong et al³¹ found that breast-feeding significantly increased or decreased the odds of FS in childhood depending on genotype, implying that individual genes may decide whether breast-feeding promotes or protects against FS.³¹

No significant trend was found for timing of introduction of infant formula or solid foods and likelihood of FS in childhood in multivariable analyses, but effect direction did suggest that earlier introduction of solid foods may protect against FS. Introduction before 4 months would appear to be associated with the least likely FS, as was also concluded in a recent systematic review and meta-analyses by Burgess et al.³⁴

Demographic characteristics

Demographic factors were taken into account for complete adjustment, and as expected, some were relevant predictors of FS in our data. Interestingly, higher gestational age at delivery was found to be inversely related to FS in childhood. Available literature on the relationship between gestational age and the outcome FS is scarce, and previously showed no significant relationship.³⁵ For the outcome FA, some results are contradictory in that they reveal a positive association between preterm birth and FA,^{19,36} whereas others again report no significant relationship.^{37,38} Several studies suggest that immune system homeostasis, gut barrier function, and diversity in gut microbiota are essential for normal tolerance development.^{39,40} Because these features are underdeveloped in preterm infants, this may make FS more likely. Another possibility is that there is confounding through cesarean section, on which we had no data. Systematic reviews have concluded that cesarean section, which is more common in preterm births, is positively associated with both FS and FA, mostly based on the theory that babies born through cesarean section are deprived of first colonization of the gut with maternal vaginal bacteria.^{39,41}

In adults, FS significantly decreased with age in our study. Our data on primary FS in children suggest the same effect direction for children, but the association probably did not reach statistical significance due to the small age range in included children (7-10 years). Similar trends were found in cross-sectional studies in American, Italian, and German children and adults.⁴²⁻⁴⁴ These trends may be the result of increasing prevalence of FS over time, as suggested by some studies,^{3,6,7} which would lead to a higher prevalence of sensitization in the younger age groups.

Male sex was positively associated with FS in adults. The latter finding appears to contradict the predominating thought that women are at a higher risk of FA than men.^{23,26,32,45} However, with regard to FS, available studies also found that adult males are more likely to be food sensitized than adult females.^{42,44} Because many studies investigate the outcome FA rather than FS, outcome measures are mainly based on patient history. Because women are more likely than men to report symptoms to foods,^{44,46,47} this may explain the discrepancy.

Strengths and limitations

Overall, this study is unique in that data on determinants were analyzed for the outcomes FS, IS, and primary FS, in both children and adults, after assessing IgE sensitization to 24 foods. A limitation is the retrospective data collection on childhood determinants, which means that some recall bias is likely, especially in adults. Also, causal inference was limited, because we had no information on when sensitization developed in relation to the exposure variables. We did attempt to take the possibility of reverse causality into account, assessing the change in associations after adjusting for comorbid atopy. The standardized approach of this multicenter study all across Europe is a major strength, allowing valid comparisons. The broad inclusion from the general population and the use of multiple imputation for sporadically missing data on determinants yielded a large study population in which we could evaluate most currently conceived environmental, infant dietary, and demographic risk factors.

CONCLUSIONS

Our findings consolidate existing evidence that dog ownership in early childhood protects against FS in later childhood. Other postulated environmental and infant dietary risk factors for FA appear to have (more) limited impact on childhood or adult FS after mutual adjustment, though preventative tendencies were observed for certain early-life exposures, including early introduction of solid foods. Demographic factors also appear relevant, in that gestational age affects the likelihood of childhood FS, and age and sex the likelihood of adult FS.

ONLINE REPOSITORY

METHODS

Questionnaires

The EuroPrevall phase I screening questionnaire was a selfadministered 1-page document, designed to detect subjects with and without food-related reactions. The phase II questionnaire was an extensive interviewer-administered questionnaire on symptoms and potential risk factors for FA (Figures E2 and E3).

Determinants

Data on evaluated childhood environmental determinants were obtained from the phase II questionnaire, and consisted of maternal age at the birth of subject, number of siblings, number of older siblings, bedroom sharing with any sibling and with older siblings, day care attendance, dog or cat ownership, growing up on a farm, growing up in the inner-city, and having serious respiratory infections. In children, antibiotic use before the age of 2 years, use of reflux medication in the previous 6 months, maternal smoking during pregnancy, and maternal and paternal smoking since the birth of the subject (at least 1 cigar(ette) per day) were also investigated. Regarding infant diet, duration of breast-feeding, age of start of infant formula, type of infant formula (cow's milk, soy milk, hypoallergenic), age of introduction of solid foods, and vitamin D supplementation before the age of 2 years were assessed. For adults, environmental determinants later in life were food-related occupation (ever worked in the growing, production, processing, or distribution of food), smoking (ever for longer than 1 year), and frequency of use of indigestion medication (antacids, H2-antagonists, or proton pump inhibitors).

Demographic factors, consisting of age, sex, and (parental) level of education for all subjects, and gestational age at birth, birth length, and weight for children, were also evaluated.

Food and inhalant allergens

Specific IgE testing was performed in phase II for 24 foods, which are often implicated in FA or frequently consumed across Europe. These foods were hen's egg, cow's milk, fish, shrimp, peanut, hazelnut, walnut, peach, apple, kiwi, melon, banana, tomato, celery, carrot, corn, lentils, soy, wheat, buckwheat, sesame seed, mustard seed, sunflower seed, and poppy seed. They were termed *priority* foods. IgE testing was also performed for 6 common inhalant allergens: birch, mugwort, grass, and parietaria pollen, house-dust mite, and cat.

IgE testing

All serum samples were analyzed in a single laboratory in the Academic Medical Center, Amsterdam, The Netherlands, using commercially available ImmunoCAP tests (Phadia, *currently ThermoFisher Scientific*, Uppsala, Sweden). All sera that tested positive for at least 1 of the priority foods in phase II, and a random sample of nonsensitized controls, were further tested for specific food allergens using an allergen microarray assay.^{E1-E3}

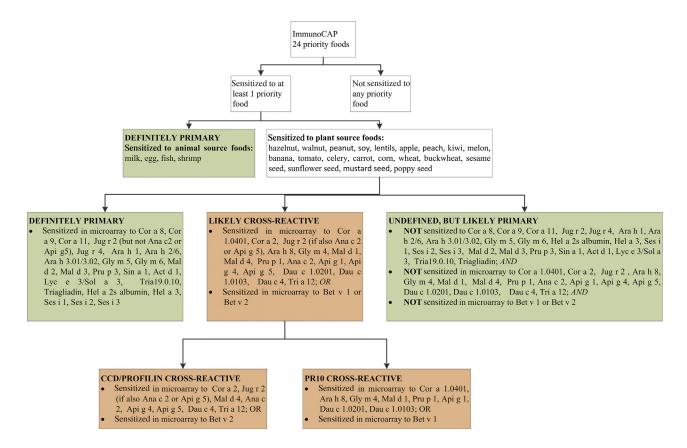

FIGURE E1. Classification of FS into primary sensitization and cross-reactive sensitization. Subjects were classified into 1 *or more* of the boxes depending on their sensitization patterns (ie, subjects could have both primary and cross-reactive sensitization). This is a simplified classification, designed for exploratory purposes, and subjects with cross-reactive sensitization through food rather than pollen, or with cross-reactive sensitization to tropomyosins (eg, shrimp through house-dust mite), have been classified as primary sensitization. However, aforementioned cross-reactivity patterns are much less common than pollen-related cross-reactivity, and are expected to have only limited influence on the prevalence of primary FS. In the prediction modeling of the outcome primary sensitization, the negative outcome comprised no sensitization, or cross-reactive sensitization only. *CCD*, cross-reactive carbohydrate determinants; *PR-10*, pathogenesis-related protein family 10 proteins. Green: Primary sensitization (= definite, or undefined but likely primary sensitization). Orange: Cross-reactive sensitization.

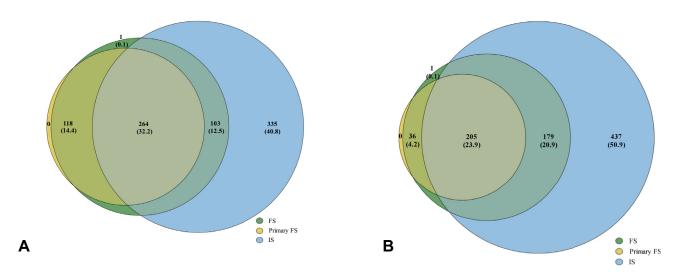

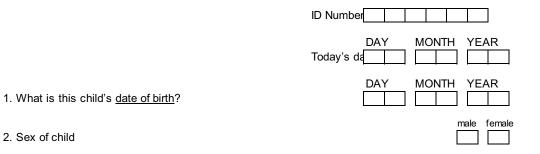

FIGURE E2. Relationship between FS, primary FS, and IS in (A) children and (B) adults. The numbers (%) represent individual subjects included in the study with the particular (combination of) outcome(s). Only subjects with complete data on FS, primary FS, and IS were included in these diagrams.

Child Case-Control Questionnaire

FOOD ALLERGY

2. Sex of child

3. Has this child ever had an illness or problem caused by eating any of the following foods? Say whether or not this child avoids them because they make him/her ill, and approximately how often this child eats the following foods:

ASTHMA AND ALLERGIES

6. Have you had wheezing or whistling in your chest at any time in the last *12 months*?

IF 'NO' GO TO QUESTION 7, IF 'YES':

6.1 Have you been at all breathless when the wheezing noise was present?

6.2. Have you had this wheezing or whistling when you did *not* have a cold?

7. Have you ever had asthma?

IF 'NO' GO TO QUESTION 8, IF 'YES':

7.1 Was this confirmed by a doctor?

7.2 How old were you when you had your first attack of asthma?

7.3 How old were you when you had your most recent attack of asthma?

7.4. Which months of the year do you usually have attacks of asthma?

7.4.1 January / February
7.4.2 March / April
7.4.3 May / June
7.4.4 July / August
7.4.5 September / October
7.4.6 November / December

7.5 Have you ever been admitted to hospital with an attack of asthma?

7.6 Have you had an attack of asthma in the last **12 months?** *IF NO GO TO Q8, IF YES*

7.6.1 How many attacks of asthma have you had in the last 12 months?

7.6.2 How many attacks of asthma have you had in the last 3 months?

7.7 How many times have you been woken up because of your asthma in the last 3 months?

Every night or almost every night More than once a week, but not most nights At least twice a month, but not more than once a week Less than twice a month Not at all

7.8 How often have you had trouble with your breathing because of your asthma in the last **3** *months*?

HDM, House-dust mite; NA, not available.

Bold indicates statistical significance (P < .05). Analyses were adjusted for center. P values for continuous variables (age, gestational age, birth weight, birth length, and maternal age) were based on the 2-sample t test, and those for categorical variables on the χ^2 test.

Reference categories: "number of (older) siblings" = 0; "indigestion medication" = no or $<1 \times /y$; "breast-feeding duration" = never; "age start infant formula" = never; "age introduction solid food = 0-4 mo. "This model was adjusted for comorbid atopy (asthma, allergic rhinitis, or atopic dermatitis in subject or first-degree family member).

†This model was adjusted for comorbid atopy and IS (specific IgE against birch, grass, mugwort, parietaria, HDM, or cat). All P values for continuous variables (age, gestational age, birth weight, birth length, and maternal age) were based on

the 2-sample *t* test, and those for categorical variables on the χ^2 test.

‡For children: high level of education of parents. §Before the age of 2 y.

Before the age of 2 y.

NA, Not available.

Bold indicates statistical significance (P < .05). Analyses were adjusted for center. P values for continuous variables (age, gestational age, birth weight, birth length, and maternal age) were based on the 2-sample t test, and those for categorical variables on the χ^2 test.

Reference categories: "number of (older) siblings" = 0; "indigestion medication" = no or $<1 \times /y$; "breast-feeding duration" = never; "age start infant formula" = never; "age introduction solid food = 0.4 mo. *For children: high level of education of parents.

†Before the age of 2 y.

‡Before the age of 5 y.
